### Synonyms

Oral Crohn's disease; Melkersson-Rosenthal syndrome; Cheilitis granulomatosa; OFG

## Definition and Characteristics

OFG is a rare chronic inflammatory disease affecting the orofacial region presenting most commonly with lip swelling but also affecting many intra-oral sites [1]. Although used as an umbrella term the majority of cases occur as a separate entity but a small proportion may present in association with systemic disease. The most common association is with gut Crohn's disease but rarely sarcoidosis and tuberculosis may present in this way. Melkersson-Rosenthal syndrome (MRS) and cheilitis granulomatosa (CG), regarded as an oligo-symptomatic form of MRS, is also grouped under the term OFG. Histological hallmarks consist of non-caseating epithelioid granulomas (often deep seated), lymphoedema of the corium and dilated lymphatics. Approximately 60% of OFG cases without any apparent systemic disease also have intestinal involvement in the form of minor macroscopic and microscopic signs such as aphthous ulceration, erythema and histological granulomatosis [2]. The significance of the intestinal findings is not clear as the majority do not develop gut disease with long term follow up.

## Prevalence

The true prevalence is not known as no reliable epidemiological data exist. However, true OFG occurs in less than 1% of patients with Crohn's disease. Likewise it has been estimated that the incidence of CG is 0.08% in the general population [3]. Presentation is most commonly in the second or third decade of life. Gender incidence is approximately equal but some small studies report a slight female predominance. There does not appear to be an ethnic difference although most case reports are white Caucasians.

## Genes

No clear genetic link exists but associations have been demonstrated with specific HLA genotypes, A2, A11, B7 and DR2/3/4. Recent evidence also demonstrated in a small cohort of patients with OFG with or without gut CD no CARD 15 association (unpublished data, Nunes et al.).

## Molecular and Systemic Pathophysiology

The etiology remains unknown but the associations with Crohn's disease and atopic diseases such as hay fever suggest that the pathogenesis involves an interaction between genetic and environmental trigger factors. Dietary antigens in particular cinnamon and benzoate have also been closely linked to OFG. The main pathological feature is the presence of non-caseating epithelioid granulomas on the background of a chronic inflammatory cell infiltrate. Lymphoedema and dilated lymphatics are also commonly seen and related to the persistence of lip swelling. Immunologically the inflammatory infiltrate suggest a T-cell driven disease with a Th1 environment similar to Crohn's disease. A restricted T-cell receptor(TCR) V-β gene expression by lesional lymphocytes has also been demonstrated with an identical unique V-D-J junctional sequence seen in more than 20% of the V-β 6 TCR transcripts, suggesting a local antigen driving V-β 6 T-cell clonal expansion within the lesional lymphocytes only. More recent evidence also implicates B-cells in the pathogenesis and may provide a link between the specific recognition of dietary antigens such as benzoate and the associated inflammatory response [4].

## Diagnostics Principles

OFG is predominantly a clinical diagnosis. The most common presentation consists of acute or sub-acute lip swelling of varying degrees eventually leading to chronically enlarged lips (Fig. 1).

Vertical lip fissures with angular cheilitis are also commonly seen. Intra-oral features include aphthous type ulceration, buccal cobblestoning, mucosal tags and deep painful sulcal ulceration. Facial swelling is variable and in many cases restricted to only the lips but may involve larger areas such as the cheeks, lower halve of the face, nose and peri-orbital tissue. VIIth cranial nerve involvement of lower motor neurone type together with lip swelling and a fissured tongue are regarded as hallmarks of the Melkersson Rosenthal syndrome. The diagnosis is usually confirmed with a biopsy from an affected site, commonly the lip. The main diagnostic feature is the presence of non-caseating epithelioid granulomas.

**Orofacial Granulomatosis. Figure 1** Predominant upper lip swelling with erythema of the upper lip tissue in a patient with orofacial granulomatosis. When a lip biopsy is performed of the affected site it typically reveals a chronic inflammatory cell infiltrate with non-caseating epithelioid granulomas, lymphoedema of the corium and dilated lymphatics.

### Therapeutic Principles

Treatment of OFG remains a challenge as the management is based largely on small non-randomized studies and anecdotal experience. The initial management includes a detailed oral and systemic examination to exclude systemic disease. This includes a detailed biochemical and hematological work-up and in selected cases endoscopic examination. The aims of therapy are to induce and maintain remission and may be divided into topical, dietary, systemic and surgical therapy. Topical therapy is particularly useful for those patients without gut involvement. Good responses (as high as 58%) with prolonged periods of remission (up to 19 months) has been reported with topical/intra lesional steroids. Overall, long term use of steroids is not recommended as the response is short lived and not without unacceptable side effects. Topical tacrolimus and mesalazine have also been used with success. Dietary exclusion using a cinnamon and benzoate free diet has proved of particular benefit in recent years with up to 70% response and is used as first line treatment in some institutions [5]. Systemic therapy is used for resistant cases and those with concurrent gut disease. The approach resembles that used in Crohn's disease and includes corticosteroids, thiopurines, methotrexate and biological therapy such as infliximab. Thalidomide has also been used with some success but toxicity largely restricts its use. Surgery, primarily lip reduction, is reserved for those who have failed medical treatment and have chronic disfiguring fibrotic lip enlargement.

### Synonyms

OHDS; Orthostatic hypotensive disorder; Hyperbradykininism; OMIM 143850

### Definition and Characteristics

Familial orthostatic hypotensive disorder is a rare disorder characterized by light-headedness, syncope, palpitations and blue-purple ankle discoloration after standing. This is accompanied by a marked decrease in systolic blood pressure, an increase in diastolic pressure, and tachycardia, all of which resolve when supine [1,2].

### Prevalence

Rare disease.

### Genes

Gene has not been identified; Gene map locus18q; Inheritance autosomal dominant [2].

### Molecular and Systemic Pathophysiology

In the original report plasma bradykinin levels was high although this has not been consistently noted. The molecular pathophysiology may become clear once the genetic defect is identified.

### Diagnostic Principles

Orthostatic hypotension inherited in an autosomal dominant fashion with facial erythema and ankle discoloration

on standing are the typical clinical features. Plasma concentrations of bradykinin are generally elevated.

### Therapeutic Principles

Clinical improvement in a few cases has occurred with fluodrocortisone or cyproheptadine.

## Osteoarthritis: Developmental Dysplasia of the Hip

Donatella Granchi, Nicola Baldini
Laboratorio di Fisiopatologia degli Impianti Ortopedici, Istituto Ortopedico Rizzoli, Bologna, Italy

### Synonyms

Congenital dysplasia of the hip; Congenital dislocation of hip; DDH

### Definition and Characteristics

Developmental Dysplasia of the Hip (DDH) is the preferred term to describe the condition in which the femoral head has an abnormal relationship with the acetabulum. It ranges from the simple unstable neonatal hip due to a slight capsular laxity, without loss of contact of the head with the acetabulum, through moderate lateral displacement of the femoral head, up to complete dislocation of the femoral head from the acetabulum. Because many of these findings may not be present at birth, the term "developmental" more accurately reflects the biologic features than does the term congenital.

### Prevalence

DDH is one of the most common skeletal congenital anomalies, its frequency changing according to geographic and ethnic differences. Among the most developed countries, an incidence of 1.5–20 cases of DDH per 1,000 births can be assumed. DDH can occur as an isolated anomaly or associated with syndromes with chromosomal abnormalities, such as trisomy 18. Moreover, it is an occasional feature in other inherited diseases, e.g. Marfan syndrome, Ehler-Danlos syndrome and Beukes familial hip dysplasia.

### Genes

Genes responsible for DDH are at present unknown.

### Molecular and Systemic Pathophysiology

DDH is a multifactorial polygenic disorder, which shows a familial aggregation and is likely to result from the interaction of genetic and environmental factors [1]. Family history, breech presentation, oligohydramnios and other skeletal malformations represent the most relevant associated risk factors. Carter and Wilkinson have hypothesized that two different genetic systems are responsible for the etiology of DDH: the former, polygenic, related to dysplasia of the acetabulum; the latter, probably dominant, controlling the capsule around the hip joint. According to this hypothesis Wynne-Davies have suggested that hip dysplasia can be classified in two etiologic groups: (i) acetabular dysplasia, inherited through a polygenic system and responsible for most cases with a delayed diagnosis, (ii) joint laxity, responsible for most neonatal cases, revealing a genetic predisposition in which the action of environmental factors appears to be important. A segregation analysis performed in a large sample of pedigrees collected through probands affected by nonsyndromic DDH supports the model proposed by Wynne-Davies, and provides evidence that at least two genetic factors are involved in the etiology of acetabular dysplasia. Even if the genetic substrate of the disease is evident, definition of the molecular basis of hip dysplasia has not been clarified. Candidate genes

suspected of being involved in DDH could be the same considered for osteoarthritis, where cartilage and bone may be altered [2]. Polymorphisms of the alpha 1 chain of Type II collagen, the most abundant structural protein of cartilage, and the vitamin D receptor have been associated with osteoarthritis secondary to DDH [3].

## Diagnostic Principles

The key tools for the diagnosis of DDH are the clinical and the ultrasonographic screening [4]. The clinical examination is based on the Ortolani-Barlow maneuver; the other significant signs of a congenital hip disorders are the observation of a leg length discrepancy, the limitation of normal abduction of the hip, and the asymmetry of posterior thigh or gluteal folds. Ultrasonographic diagnosis is performed by static morphologic testing and by dynamic assessment of stability of the femoral head in the acetabulum. Although ultrasound represents an effective method for the early diagnosis of DDH, its cost-effectiveness is heavily debated, because of the potential overtreatment of infants with non-pathologic hip joint immaturity, and the possible occurrence of the disease after ultrasound examination.

## Therapeutic Principles

The application of devices for the abduction positioning for several weeks to months, has been routinely recommended "as soon as possible" in newborns with DDH. If the treatment is delayed, the possibility of correction without surgical intervention is reduced proportionally. Despite the concerted screening programs and the high rates of resolution, the natural history of DDH indicates that about 30% of patients still experience the sequelae of dysplasia or dislocation of the hip in adulthood, that is severe osteoarthritis requiring total hip replacement.

# Osteoarthritis: Erosive Interphalangeal Arthritis

George E. Ehrlich
University of Pennsylvania School of Medicine, Philadelphia, PA, USA

## Definition and Characteristics

A particularly aggressive inflammatory arthritis occurring predominantly in the finger joints of women of menopausal age with a strong familial history and a possible genetic component.

## Prevalence

Seen chiefly in white women, often of Northern European origin, and rare in blacks and Asians.

## Genes

A possible association with HLA-B18 haplotype and α1-antitrypsin phenotype [1] and possibly other chromosomal regions.

## Molecular and Systemic Pathophysiology

The release of pro-inflammatory cytokines and enzymes in an array of interphalangeal joints (IP), including not only proximal and distal IP but also the base of the thumb (rhizarthrosis) and even some metacarpophalangeal joints and to a lesser extent the joints of the feet and the large joints of the lower extremities, results in destructive erosions and consequent attempts at healing, producing limited motion at the affected joints and large osteophytes at the joint margins [2].

## Diagnostic Principles

The characteristic onset, predominantly in women of middle age with a strong family history of similar lesions, with bumpy enlargements of interphalangeal joints which are painful and often red at inception, heralds this form of osteoarthritis. In susceptible women, it may begin earlier if surgical menopause occurs, and in men, much later in life. Roentgenographic evidence confirms the clinical impression. The lesions are remarkably symmetrical, which also distinguishes them from the usual presentations of osteoarthritis. Elevation of acute phase reactants is modest, but a disproportionate number of women later develop rheumatoid arthritis [3]; whether erosive OA can be considered a prodromal phase has not yet been determined.

## Therapeutic Principles

No cures are known, but better symptomatic relief results from nonsteroidal anti-inflammatory drugs (NSAIDs) than from simple analgesics [4]. Moist heat (paraffin baths) and nylon and spandex stretch gloves worn overnight also help.

Pharmacologic therapy is available: NSAIDs such as ibuprofen, diclofenac, celecoxib, rofecoxib, etc. Experimental use of etanercept and IL-1 antagonists, not yet proven or approved by regulatory agencies.

Other treatments available include physical measures cited above; surgery in severe cases.

# Osteoarthritis: Slipped Epiphysis

Matthew B. Dobbs
Department of Orthopedic Surgery, Washington University School of Medicine, Saint Louis, MO, USA

## Synonyms

Slipped capital femoral epiphysis; SCFE

## Definition and Characteristics

Slipped capital femoral epiphysis is characterized by a displacement of the femoral neck from the capital femoral epiphysis through the physeal plate [1]. This condition occurs in adolescence and frequently is associated with degenerative joint disease of the hip during middle life.

## Prevalence

The annual incidence of SCFE has been reported to average 2 per 100,000 in the general population. The incidence has been reported as low as 0.2 per 100,000 in the eastern half of Japan and as high as 10.08 per 100,000 in certain regions of the United States [2].

## Genes

Though no gene has yet been identified for this disorder, many cases have a reported autosomal dominant inheritance pattern with incomplete penetrance. In this population there is an approximate 7.1% risk of SCFE to a second family member.

## Molecular and Systemic Pathophysiology

The true etiology of SCFE remains unknown. It is unlikely that it is the result of a single factor, but rather is more likely secondary to multiple factors, resulting in a weakened physeal plate that is loaded with a higher than normal shear stress, resulting in a failure of the proximal femoral physeal plate. Local trauma to the proximal femur is one possible etiologic factor reported in as many as 26% of patients. Mechanical factors affecting the proximal femoral physis have also been proposed. Obesity, a decrease in normal femoral anteversion, or a more oblique orientation of the physeal plate during adolescence, have all been shown to be associated with physeal plate fatigue. Inflammatory factors that weaken the physeal plate may play a role in the etiology as evidenced by the almost universal association of synovitis of the hip with SCFE. Endocrine imbalance is known to change physeal plate physiology, and must therefore be considered as a possible etiologic factor in SCFE. An association between endocrine function and SCFE is suggested by the majority of slips occurring during the adolescent growth phase. In addition, growth hormone therapy is known to be associated with the development of SCFE [2].

## Diagnostic Principles

Patients with SCFE usually present with complaints of pain in the affected hip or groin, a change in hip range of motion, and a gait abnormality. A patient can present with pain perceived in the medial thigh and knee region of the affected limb. This phenomenon represents referred pain along the sensory distribution of the obturator and femoral nerves, and commonly is seen in association with hip pathology. If not recognized as referred pain, it can lead to a significantly delayed or even missed diagnosis.

## Therapeutic Principles

The treatment of SCFE is designed to improve on the natural history of the untreated condition. The goals of treatment include the prevention of further slipping by stabilizing the physis and thereby reducing the incidence and onset of osteoarthrosis at the affected hip, and the avoidance of iatrogenically induced osteonecrosis of the femoral head and chondrolysis [2].

**Osteoarthritis: Slipped Epiphysis. Figure 1** Radiographs of the left hip of a 14-year-old boy who had immediate severe hip pain following acute trauma, without prior hip symptoms. The radiograph on the left was made at presentation. Those in the middle and on the right were made during a 1-year follow-up period and show the rapid development of avascular necrosis and severe degenerative changes.

# Osteochondritis

Yasuaki Nakagawa
Department of Orthopedic Surgery, Faculty of Medicine, Kyoto University, Kyoto, Japan

## Synonyms

Osteochondritis dissecans; OCD

## Definition and Characteristics

Osteochondritis dissecans (OCD) is an acquired, potentially reversible idiopathic lesion of subchondral bone resulting in delamination and sequestration with or without articular cartilage involvement and instability. This condition is mainly shown in knee, humeral capitellum, and talus.

## Prevalence

Although the exact prevalence of OCD is unknown, prevalence between 15 and 29 per 100,000 has been reported. Gender differences have also been highlighted among male patients in a ratio of 5:3. The incidence has influenced recently by growing participation in competitive sports by children at younger ages across both genders [1]. As a result, the mean age of OCD onset seems to be lesser, along with an increased prevalence among girls.

## Genes

Although there were some reports that a genetic predisposition to OCD was postulated, at present, the common form of OCD is thought not to be familial.

## Molecular and Systemic Pathophysiology

Although several causes of this condition have been postulated, including inflammation, genetics, ischemia, ossification, and repetitive trauma, there remains insufficient evidence to conclusively support any of these causes at present.

It has been suggested that repetitive trauma may induce a stress reaction resulting in a stress fracture within the underlying subchondral bone. If repetitive loading persists and exceeds the ability of the subchondral bone to heal, the necrosis of the fragment may occur and lead to fragment dissection, separation, and nonunion. The relationship between adult and juvenile forms of OCD also remains unclear. In some cases, the condition develops in childhood, and the lesion either fails to heal or only becomes clinically apparent after closure of the physis [2]. Adult OCD lesions have a greater propensity for instability and typically follow a clinical course that is progressive and unremitting. In comparison, juvenile OCD lesions with an intact articular surface have a potential for healing through cessation of repetitive impact loading. Both adult and juvenile OCD lesions that do not heal have the potential

for later sequel, including premature degenerative joint disease. Humeral capitellar OCD is typically found in baseball players in their early teens. A main causal factor of this disease is considered to be repetitive compression and shear forces to the immature capitellum during throwing.

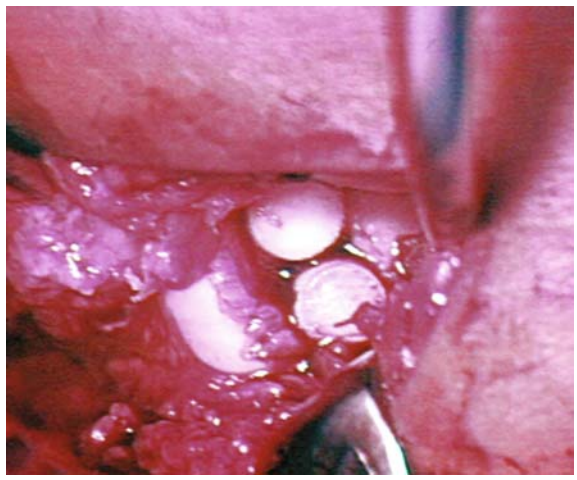
## Diagnostic Principles

In clinical presentation, the majority of juvenile OCD cases involve stable lesions that ultimately heal without long-term consequence. Presentation is generally nonspecific and includes poorly localized knee pain that is exacerbated by exercise, particularly when climbing hills or stairs. In contrast, adult OCD lesions are typically unstable and follow an insidious and unremitting course. The presence of swelling and stiffness and mechanical symptoms such as locking or catching are common in adult OCD and indicate unstable, loose fragments. Incongruity of the joint surface, due to sloughing of loose bodies and subsequent poor healing, predisposes the patient to early onset degenerative joint disease. Unstable lesions are distinguishable by the presence of mechanical symptoms, knee effusion, and often crepitus and pain motion. In the knee, bilateral involvement is reported in up to 25% of cases [1]. Therefore, examination of both knees is important. However, if bilateral disease is present, the lesions are typically asymmetrical in terms of size and symptoms.

Radiological imaging is essential in characterizing the OCD lesion, predicting prognosis after nonoperative management and assessing the ultimate status of the lesion. An ideal imaging algorithm would assist the surgeon in distinguishing cases that would benefit from surgical intervention from those that have a high chance of healing with nonoperative management. Magnetic resonance imaging is now a routine part of the diagnostic evaluation of OCD. It can accurately estimate the lesion size as well as the status of cartilage and subchondral bone. De Smet found that a high signal line behind the fragment was most predictive and was found in 72% of unstable lesions [3]. They found the high signal line was the most common sign in patients who failed nonoperative treatment. The use of technetium bone scans to assess the healing potential of OCD lesions is well documented.

## Therapeutic Principles

Because the natural history of stable OCD lesions is generally favorable in a child with open physes, there is widespread agreement that initial nonoperative management is indicated. Operative treatment should be considered in skeletally immature patients with detached or unstable lesions and in those approaching physeal closure whose lesions have been unresponsive to nonoperative management. In contrast, the majority of adult OCD lesions are unstable and the clinical course more deleterious, necessitating early, aggressive surgical intervention. The goal of treatment for OCD is to prevent the occurrence of osteoarthritis and to allow patients to return to their previous level of sporting activities. To achieve the treatment goal, resurfacing the osteochondral defects with hyaline cartilage should be considered. However, because of the limited potential for self-repair of the articular cartilage, no surgical procedure for cartilage repair has successfully regenerated long-lasting hyaline cartilage tissue to replace cartilaginous lesions. Autologous osteochondral graft (mosaicplasty) is a new technique to provide hyaline cartilage repair for articular defects. The mosaicplasty for OCD lesions is recently performed in knee [4], elbow [5], and ankle joints. This operative procedure gave good clinical outcome in short term, but long-term results are unknown.



**Osteochondritis. Figure 1** Two osteochondral plugs (6 mm in diameter) were implanted in the humeral capitellum for right humeral capitellar osteochondritis dissecans.

# Osteogenesis Imperfecta

James Hyland
Department of Pathology, Center for Gene Therapy, Tulane University Health Sciences Center, New Orleans, LA, USA

### Synonyms

Brittle bone disease

### Definition and Characteristics

Almost exclusively an autosomal dominant disorder characterized by variable bone fragility and deformities, blue sclera, hearing loss and dentinogenesis imperfecta.

### Prevalence

The combined prevalence of the four generally accepted Osteogenesis imperfecta (OI) types is greater than 1 per 10,000.

### Genes

COL1A1, COL1A2.

### Molecular and Systemic Pathophysiology

OI is caused by defects in either of the two genes, COL1A1 or COL1A2, encoding type I collagen [1]. Type I collagen is a trimeric molecule composed of two α1(I) chains and one α2(I) chain. It is a major component of bone, skin and tendon. Type I collagen contains a long triple helical domain composed of Gly-X-Y repeats. Triple helical formation and structural integrity is dependent on this repeat structure.

There are four generally accepted OI types ([2], Table 1).

OI type I is the mild variant. Patients have increased bone fragility, blue sclera and display variable numbers of fractures. Stature is normal or near normal as fractures heal without deformity. The majority of OI type I cases are caused by COL1A1 haploinsufficiency. OI type II is the perinatal lethal variant. Infants suffer from severe bone fragility, short bowed extremities, soft calvariums, beaded ribs, and dark sclera. About 60% die within 24 h of birth. Triple helical domain glycine substitutions in either the α(1) or α(2) chains are frequent. Splice site mutations deletions, insertions and stop codon mutation have also been defined. OI type III is the progressively deforming variant. Fractures may occur in utero. Bones are undermineralized at birth. Fractures heal with deformity and distal cystic structures disrupt growth plates. Short stature is inevitable. Kyphoscolosis results in cardiopulmonary

**Osteogenesis Imperfecta. Table 1** Osteogenesis imperfecta

| Type | Genes | Observed mutations | Clinical information |
|---|---|---|---|
| Mild | *COL1A1* *COL1A2* (rare) | Null and splicing mutations, glycine substitutions Splicing mutations and glycine substitutions | Normal/near normal stature, few to numerous fractures, no deformity, blue sclera |
| Perinatal lethal | *COL1A1* *COL1A2* | Glycine and other substitutions, splicing mutations with exon skipping, small in frame insertions/deletions, frame shifts | Fragile deformed extremities, small thorax and soft calvarium |
| Progressive deforming | *COL1A1* *COL1A2* | Glycine substitutions, splicing mutations, rare out frame deletions | Short stature, fragile bones with angular deformities, foreshortened survival |
| Mild | *COL1A1* *COL1A2* | Glycine substitutions, splicing mutations resulting in insertions/deletions, and exon skipping | Mild to moderate short stature and deformities. Possible in utero fractures |

insufficiency. Dentinogenesis imperfecta is common. COL1A1 and COL1A2 mutations include glycine substitutions and splice site mutations. Additional COL1A2 mutations include glycine deletions. OI type IV is the mildly deforming variant. The patients are usually short, with mild to moderate skeletal deformities, may have suffered fractures in utero or during birth and often have dentinogenesis imperfecta. Scoliosis or kyphoscolisos may compromise respiratory function. Certain glycine substitutions and exon skipping mutations have been defined in both the COL1A1 and COL1A2 genes. Some in-frame insertions and deletions occur.

### Diagnostic Principles

Phenotypic characteristics and family history are used to determine the clinical type. Protein studies and COL1A1 and COL1A2 gene analysis are utilized to confirm diagnosis and determine mutations. Gene analysis is also used for prenatal diagnosis and has proved useful in discriminating between OI type I and suspected abuse cases.

### Therapeutic Principles

Options for treatment remain limited. Bisphosphonate infusion is being assessed and has shown some indication as being beneficial. A small group of severely affected children treated with stem cell transplantation have displayed confirmed improvement [3].

## Osteomalacia (Hypophosphathemic Rickets)

Roland Staud
University of Florida, Gainesville, FL, USA

### Synonyms

X-linked hypophosphatemic rickets; HYP; Autosomal dominant hypophosphatemic rickets; ADHR; Tumor induced osteomalacia; TIO

### Definition and Characteristics

X-linked dominant loss-of-function mutations in the gene PHEX or autosomal dominant gain-of-function mutation in the gene FGF23 result in bone deformities in children and osteomalacia in adults.

## Prevalence

The prevalence of this disorder in the general population is very low (0.005–0.01%).

## Genes

*X-linked hypophosphatemic rickets (HYP)*: PHEX exhibits homology to a family of endopeptidase genes, members of which are involved in the degradation or activation of a variety of peptide hormones. This gene is composed of multiple exons which span at least five cosmids. Intragenic non-overlapping deletions from four different families and three mutations (two splice sites and one frameshift) have been detected in HYP patients, which suggests that the PEX gene is involved in the HYP disorder of FGF23 coding for the thiazide-sensitive cotransporter $NaCl^-$, localized on chromosome 16q13. Autosomal dominant hypophosphatemic rickets (ADHR) has been associated with gain-of-function mutations in FGF23, the gene coding for FGF23. These gain-of-function mutations affect the conserved proteolytic cleavage site in FGF23 ($arginine_{176}$-X-X-$arginine_{179}$), rendering the mutated FGF23 resistant to processing at this site. Consequently, the full-length FGF23, which has been shown to inhibit renal phosphate reabsorption, is allowed to persist. Of note, autosomal recessive loss-of-function mutations in FGF23 have been associated with familial tumoral calcinosis, the "mirror" disease of ADHR. They cause increased proteolysis of FGF23, leading to hyperphosphatemia and often severe ectopic calcifications. The genetic cause underlying hereditary hypophosphatemic rickets with hypercalciuria (HHRH) has not been identified, but is thought to be a defect in a renal sodium-phosphate co-transporter other than NPT2 or in a protein regulating NPT2 expression or activity. Tumor-induced osteomalacia also known as oncogenic osteomalacia or oncogenic hypophosphatemic osteomalacia, tumor-induced osteomalacia (TIO) is associated with oversecretion of FGF23 and/or the matrix extracellular phosphoglycoprotein (MEPE) from tumors that are mostly benign and of mesenchymal origin. The greatly increased concentrations of FGF23 and/or MEPE are believed to exceed the body's mechanisms for proteolytic degradation of FGF23 and/or prevention of the proteolytic release of the acidic serine-aspartate-rich MEPE-associated motif (ASARM) peptide from MEPE, respectively (Fig. 1).

## Molecular and Systemic Pathophysiology

FGF23 is considered to represent the humoral factor ("phosphatonin") responsible for mediating renal phosphate wasting in HYP [1]. Full-length, but not processed FGF23 has been shown to inhibit renal phosphate reabsorption. Loss-of-function mutations in PHEX have been associated with a decrease in the proteolytic degradation of full-length FGF23. The effects of PHEX mutations on FGF23 must be indirect, because FGF23 does not appear to be the substrate of PHEX-encoded endopeptidase. Loss-of-function mutations in PHEX have also been found to increase the proteolytic release of carboxy-terminal peptides from MEPE. Such ASARM peptides seem to inhibit bone mineralization and thus represent candidates for the proposed "minhibin [2]."

## Diagnostic Principles

Diagnosis of hypophosphatemic rickets is based on detection of low serum phosphate, normal serum calcium, inappropriately normal serum 1,25-dihydroxy vitamin $D_3$, elevated serum alkaline phosphatase, normal to low serum parathyroid hormone, and a low tubular reabsorption rate of phosphate and radiological demonstration of rachitic bone deformities. Rachitic deformities are often most apparent at the end of the long bones in the legs, manifesting as flared metaphyses with frayed borders, but may be difficult to detect in infants. In addition, hypophosphatemia may be easily missed in infants, since the reference range for serum phosphate is age dependent.

In sporadic cases of hypophosphatemic rickets or osteomalacia in older children or adults, an exhaustive search should be conducted for tumors causing hypophosphatemia. However, these tumors are often small and difficult to locate.

Genetic testing for loss-of-function mutations in PHEX or gain-of-function mutations in FGF23 can allow diagnosis of HYP and ADHR based on a single

blood draw at any age [3,4]. Thus, genetic testing can simplify diagnosis of hypophosphatemic rickets in infants and help to discriminate HYP and ADHR from TIO in older children and adults.

## Therapeutic Principles

Treatment of HYP and ADHR is based on supplementation with oral phosphate and 1,25-dihydroxy vitamin $D_3$ (calcitriol). Because unopposed phosphate therapy can lead to secondary hyperparathyroidism, which aggravates renal phosphate wasting, calcitriol is usually added to the treatment regimen. Since calcitriol therapy frequently results in mild to moderate hypercalciuria, nephrocalcinosis is often observed during treatment of HYP or ADHR. Because oral phosphate and calcitriol treatment cannot completely normalize skeletal development of affected young children, therapy needs to be initiated in early infancy. Growth hormone therapy has been used successfully in prepubertal children with HYP, but has been shown to only moderately increase adult height.

Rajiv Kumar
Department of Internal Medicine, Mayo Clinic and Foundation, Rochester, MN, USA

## Synonyms

Oncogenic osteomalacia

## Definition and Characteristics

An acquired syndrome due to the presence of a tumor that elaborates humoral factors, which induce renal phosphate wasting, hypophosphatemia and osteomalacia. Removal of the tumor is associated with a cure of the syndrome. Patients typically have osteomalacia or rickets, hypophosphatemia, hyperphosphaturia (a low TmP/GFR), and inappropriately low or normal serum 1α, 25-dihydroxyvitamin D concentrations. In patients with this syndrome, serum calcium concentrations are normal as are concentration of parathyroid hormone and parathyroid hormone-related peptide.

## Prevalence

Oncogenic osteomalacia occurs generally in adults with highly vascular tumors.

## Genes

The mechanisms underlying oncogenic osteomalacia are related to the genetic defects X-linked hypophosphatemic rickets (XLH) and autosomal-dominant hypophosphatemic rickets (ADHR). XLH is due to inactivating mutations of the endopeptidase gene, PHEX (*p*hosphate-regulating gene with *h*omologies to *e*ndopeptidases located on the *X*-chromosome) [2] whereas ADHR is due activating mutations of the FGF23 gene [4]. FGF23 as been shown to be a substrate for PHEX and it is possible that PHEX mutations fail to degrade endogenously produced FGF23 [3].

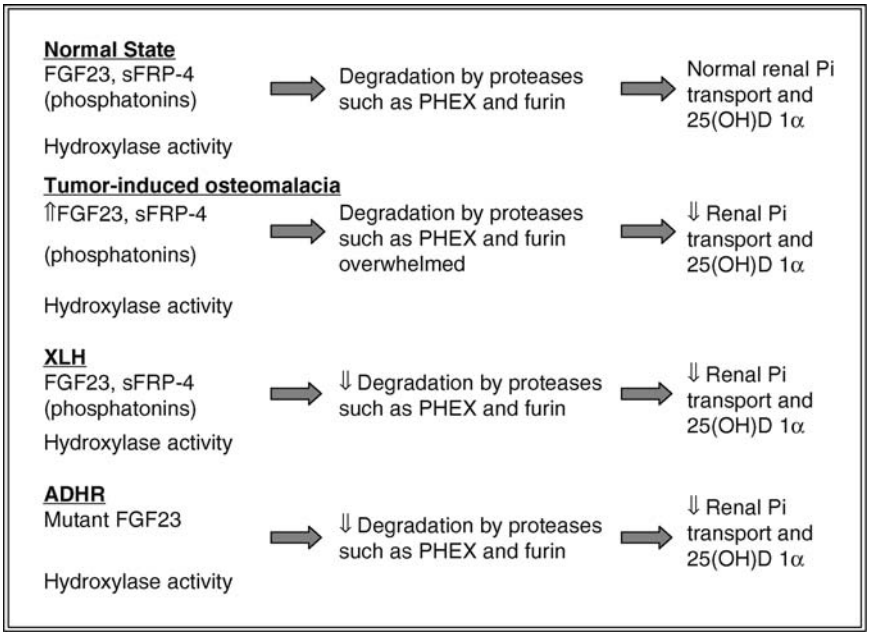
## Molecular and Systemic Pathophysiology

The syndrome is due to the elaboration of circulating factors known as "phosphatonins" that are elaborated by the tumors [1,2]. Two tumor-derived factors have been identified as playing a causal role, namely, fibroblast growth factor 23 (FGF23) and secreted frizzled related protein 4 (sFRP-4) [3]. Both these agents induce phosphaturia and hypophosphatemia.

X-linked hypophosphatemic rickets (XLH) and autosomal-dominant hypophosphatemic rickets (ADHR) lead to virtually the same clinical phenotype. The pathophysiology of the two syndromes and osteomalacia is shown schematically in Fig. 1 below.

## Diagnostic Principles

The condition is diagnosed by the presence of myalgias and muscle weakness in an otherwise normal subject. Radiological and chemical analyses reveal osteomalacia or rickets, hypophosphatemia, hyperphosphaturia (a low TmP/GFR), inappropriately low or normal serum 1α ,25-dihydroxyvitamin D concentrations, normal serum calcium concentrations, and normal parathyroid hormone and parathyroid hormone-related peptide



**Osteomalacia, Tumor-induced. Figure 1**

concentrations. The tumors are often small and difficult to detect although technetium scanning, whole body NMR and CT scanning may be needed. Measurement of serum FGF23 concentrations may also be of help [5].

### Therapeutic Principles

The offending tumor should be surgically removed. If the tumor cannot be detected or removed, treatment with oral phosphate supplements (1–2 g per day) and 1α ,25-dihydroxyvitamin $D_3$ (1–2 μg/day) should be instituted.

### Definition and Characteristics

A subclinical condition involving deterioration of bone mass and microarchitecture as part of a continuum

with osteoporosis. Risk increases with age, female sex, low body weight, lifestyle factors such as smoking, conditions of increased metabolism such as hyperthyroidism, and exposure to drugs such as corticosteroids. The World Health Organization defines osteopenia as bone mineral density (BMD) at one or more sites 1–2.49 standard deviations below that of a healthy white female reference group (T-score –1 to –2.49) [1].

## Prevalence

Approximately 33.6 million U.S. adults were osteopenic in 2002, with 47.5 million affected by 2020. Women are almost twice as likely to be osteopenic, secondary to lower peak bone mass and postmenopausal estrogen deficiency [2]. In women, risk of fracture increases as much as twofold with each 1-point drop in T-score [1]. Although osteopenia carries a lower fracture risk than osteoporosis, the larger osteopenic population accounts for a greater number of fractures.

## Genes

Likely multiple genetic determinants of bone quality, although balance disorders and lifestyle factors may contribute more to fractures in the elderly. Candidate genes include those coding for estrogen receptors alpha and beta, androgen receptor, vitamin D receptor, and enzymes involved in synthesis of estrone, estradiol, and collagen type 1 alpha [3].

## Molecular and Systemic Pathophysiology

Normal bone density and microarchitecture depend on coupled activity of osteoblasts and osteoclasts in the basic multicellular unit (BMU). Osteoclasts resorb bone, followed by deposition of organic matrix and minerals by osteoblasts. Continuous remodeling of cortical and trabecular bone involves complex interactions between osteoclasts, osteoblasts, and numerous hormones, cytokines, and growth factors. Development of osteopenia is multifactorial, but ultimately occurs because osteoclast activity predominates [4].

Estrogen receptor alpha is expressed in the BMU. Estrogen inhibits osteoclasts by blocking production of bone-resorbing cytokines. Estrogen deficiency increases remodeling by prolonging the lifespan of osteoclasts, promoting deeper resorption cavities [4].

Binding of vitamin D to its receptor promotes calcium and phosphate absorption in the intestine and kidney. Vitamin D triggers secretion of parathyroid hormone, stimulating osteoclastic resorption to maintain serum calcium [4].

## Diagnostic Principles

Dual-energy X-ray absorptiometry (DEXA) to measure BMD. Low density at the hip or spine predicts fracture at these sites [1].

## Therapeutic Principles

The therapeutic goal is to inhibit bone resorption and promote bone formation. Smoking cessation, weight-bearing exercise, and adequate calcium and vitamin D intake are recommended universally [1]. Pharmacotherapy is controversial, but may be indicated in osteopenic patients with additional risk factors for fracture, if benefits outweigh risks. Available therapies were studied mainly in postmenopausal women with osteoporosis or prior fracture and target bone resorption.

Postmenopausal estrogen replacement reduces fracture risk, but increases risk for venous thromboembolism. Some preparations are associated with increased risk of invasive breast cancer and cardiovascular disease. Raloxifene, a selective estrogen-response modifier, reduces risk of vertebral fractures and invasive breast cancer, but increases risk for venous thromboembolism and fatal stroke. Testosterone replacement decreases risk in hypogonadal males.

Bisphosphonates inhibit osteoclasts and incorporate into bone matrix. Limited data suggest possible reduction of vertebral fracture in osteopenia [5]. Risks include esophageal ulceration and jaw osteonecrosis necrosis. Calcitonin inhibits osteoclasts, but is less effective.

## Synonyms

Marble bone disease; Albers Schönberg Disease

## Definition and Characteristics

Autosomal dominant and autosomal recessive osteoclast disorders leading to generalized sclerosis of the

skeleton and, because of brittleness of bone, increased risk of pathological fracture. The disease is clinically and genetically heterogeneous with currently seven causative genes known and others expected and under investigation. The most severe cases are the autosomal recessive forms.

## Prevalence

Very rare; incidence for autosomal dominant type II disease is estimated at 5.5:100,000 (with 20–40% of cases being asymptomatic) [1] and only three families have been reported for type I disease. The incidence of dominant osteopetrosis in Denmark, however, is higher and has been estimated at 1:20,000. The incidence of the recessive disease is estimated at 1:200,000, but the many different forms of the disease complicate this estimate. For recessive disease, the highest incidences are in Costa Rica and in Middle Eastern populations of Arabic decent.

## Genes

Autosomal dominant osteopetrosis type II (ADO II), the original Albers Schönberg disease, is caused by mutations in the gene CLCN7 on chromosome 16p13.3. Autosomal dominant osteopetrosis type I, ADO I, is caused by mutations in the gene LRP5 on chromosome 11q12–13 and may be re-classified as primarily an osteoblast disorder and not an osteopetrosis. Autosomal recessive osteopetrosis is heterogeneous in itself and caused by mutations in the gene CA2 on chromosome 8q22, CLCN7 on chromosome 16p13.3, TCIRG1 on chromosome 11q13.4–13.5, OSTM1 on chromosome 6q21, PLEKHM1 on chromosome 17q21.31, and RANKL (TNFSF11) on chromosome 13q14, the latter giving rise to osteoclast-poor osteopetrosis. Further genes involved in this osteoclast-poor subset of cases are currently under investigation.

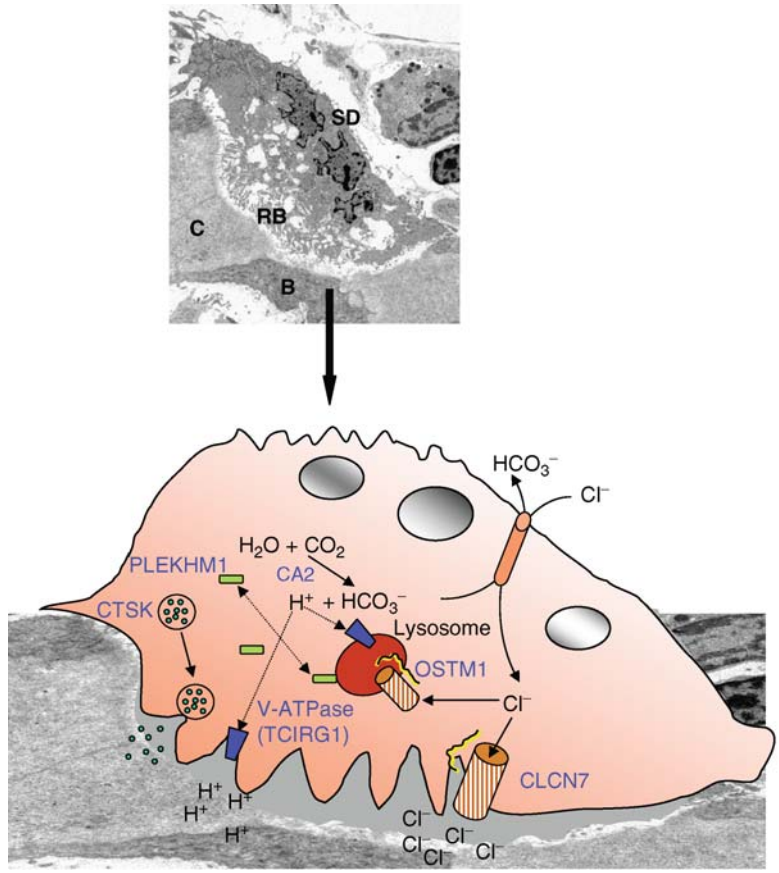
## Molecular and Systemic Pathophysiology

Osteoclasts resorb bone by producing and secreting acid and proteolytic enzymes. Osteopetrosis is generally caused by problems in the production or secretion of acid, whereas failure to produce/secrete proteolytic enzymes (especially Cathepsin K) leads to the disease Pycnodysostosis (see elsewhere). Cases of osteopetrosis in which osteoclasts do not form have also been described, but the genes responsible for those forms are yet to be identified. Generation and secretion of acid by osteoclasts involves initially the production of protons the first step in which is catalyzed by the enzyme carbonic anhydrase type II, encoded by CA2. This is followed by their secretion via the proton pump, the vacuolar ATPase, which, in osteoclasts, contains a cell-specific subunit, a3, coded for by the gene TCIRG1. Proton secretion is linked to secretion of chloride ions to ensure electroneutrality. The chloride channel linked to the vacuolar ATPase in osteoclasts is a member of the CLC family of chloride channels, the protein CLC-7, coded for by CLCN7. Localization of CLC-7 to the appropriate vacuolar membranes (lysosomes in particular) requires association with Ostm1, whereas aspects of vacuolar fusion and transport appears to involve the protein Plekhm-1. The fine details of these protein associations and their precise and unique roles in osteoclasts are as yet unclear. Loss of function mutations in any single one of these genes can cause osteoclast dysfunction leading to osteopetrosis as summarized in Fig. 1.

In all cases animal mutants with loss of function mutations in the equivalent genes have also shown an osteopetrotic phenotype and in many cases the genes in the human disease were identified after careful analysis of the rodent mutants. The bone disease caused by mutations in CA2 is generally of intermediate severity, but is associated with renal acidosis and mental retardation as the gene has important roles in those tissues also. Recessive osteopetrosis caused by mutations in CLC-7 is associated with retinal degeneration and neuronal lysosomal storage disease, indicating an important non-redundant role for the CLC-7 chloride channel in those tissues [2]. ADO II is caused by different mutations in CLCN7 and is thought to act via a dominant-negative mechanism. It is likely that the mutations responsible, which are all in highly conserved regions of the CLC family of chloride channels, are interfering with association of the protein into dimers, the functional unit in which these channels operate. Osteopetrosis caused by mutations in OSTM1 is extremely rare and the mouse form (grey-lethal) is very severe. It is therefore hypothesized this type of osteopetrosis may lead to prenatal, or early perinatal death. The functional reason for this extreme severity is not fully understood as yet, but seems likely to be related to severe central nervous system involvement. Mutations in TCIRG1 lead to the most frequent type of autosomal recessive osteopetrosis. Since the a3 subunit of the proton pump, for which this gene codes, is exclusively expressed in osteoclasts, no defects are found in other cell types expressing vacuolar ATPases, as other isoforms take over its role. The recently discovered form of osteopetrosis caused by mutation in PLEKHM1 leads to a clinical phenotype with intermediate severity [3] and as yet, no defects in cells other than osteoclasts have been found.

## Diagnostic Principles

*Dominant disease*: Increased bone density on X-ray, often discovered following pathological fracture. In ADO II X ray can reveal typical end-plate thickening in the vertebrae (“rugger-jersey spine”), iliac wings (“bone-in bone”) and in the base of the skull. In ADOI



**Osteopetrosis. Figure 1** The *top panel* shows a transmission electron micrograph of an osteoclast. Osteoclasts resorb bone by secreting cathepsin K and $H^+$ into the resorption lacunae underneath their ruffled border (RB). Together these dissolve the mineral and organic component of bone (B) and cartilage (C) matrix. Dissolved bone matrix is taken up, transcytosed through the cell and secreted in an apical secretory domain (SD). Genes involved in production and secretion of protons are indicated in blue in the *bottom* diagram. The enzyme carbonic anhydrase (encoded by *CA2*) is involved in production of protons, whereas the by-product the bicarbonate ion is exchanged for a chloride ion by the chloride-bicarbonate exchanger. The proton is secreted in to the resorption lacuna by a proton pump (V-ATPase) with an osteoclast-specific subunit a3 (encoded by *TCIRG1*). Secretion of each proton is accompanied by secretion of a chloride ion via a channel encoded by *CLCN7*. The same occurs on the membrane of lysosomal structures inside the cell to acidify their lumen. The Ostm1 protein acts as a subunit of the chloride channel and both are colocalized on the ruffled border and the membrane of acid vesicles inside the osteoclast. The protein Plekhm1 localizes transiently to the outer membrane of vesicular structures, including those with low pH, and is likely to play a role in vesicular transport. Loss of function mutations in any of these genes/proteins can be a cause of osteopetrosis. Loss of function mutations in Cathepsin K (encoded by *CTSK*) lead to pycnodysostosis. Loss of RANKL leads to absence of osteoclasts and to osteoclast-poor osteopetrosis. From Helfrich et al. The pathogenesis of osteoclast diseases: some knowns, but still many unknowns. IBMS BoneKEy. 2007 February; 4(2):61–77. Used with permission.

the increase in bone density is most pronounced at the cranial vault and no increase in fracture rate is seen.

*Recessive disease*: Increased bone density on X-ray. In young infant nearly complete absence of medullary spaces and club-shaped appearance of metaphysis due to lack of bone modeling. Other clinical features are visual and hearing impairment (due to narrowing of foramina, or as primary disease caused by CLCN7 mutations), hydrocephalus, seizures, failure to thrive, anemia and related hepatosplenomegaly and recurrent infections.

## Therapeutic Principles

*Dominant disease*: Symptomatic treatment. Cranial nerve compression may need to be alleviated. Patients often suffer repeated pathological fractures and orthopedic

surgery may be required. However, because of the unusual brittleness, combined with the hardness of the bone, this should be undertaken with great care.

*Recessive disease*: Osteopetrosis can have a rapidly fatal outcome if not treated. Bone marrow transplantation (BMT) is the only option for permanent cure in most cases where the disease is osteoclast-autonomous. In the cases where osteoclast formation is affected (osteoclast-poor disease) genetic analysis is important. Cases caused by mutations in RANKL do not benefit from BMT, whereas osteoclast-autonomous forms of osteoclast-poor disease do [5]. Osteopetrosis caused by mutations in CA2 can be treated by $HCO_3^-$ supplementation and the bone disease, but not the renal disease, corrected by BMT. Although the bone disease caused by recessive mutations in CLC-7 will benefit from BMT, it is important to recognize that the retinal degeneration and the neurological storage disease and neurodegeneration is unlikely to be corrected by BMT. In the severe cases in which the disease is caused by mutations in OSTM1, BMT is also unlikely to offer clinical benefit, because of the severe central nervous system involvement. In osteopetrosis dentition may develop late and tooth eruption may be impaired. Orthodontic intervention is difficult as the alveolar bone tends to fracture during extractions, does not heal properly and osteomyelitis often results. Specialist advice should be sought and antibiotic treatment started before orthodontic intervention.

Sequence analysis of the causative genes so far identified in osteopetrosis has allowed a molecular approach to dissect the heterogeneity of this disease, which seems to be characterized, at first glance, by the same clinical features. Prenatal diagnosis is now available for all these forms, and the identification of the molecular defects in the affected foetus allows early bone marrow transplantion. Moreover, experiments in a murine model of osteopetrosis (oc/oc) carrying a deletion in TCIRG1 have shown that in utero bone marrow transplantation can cure not only the hematopoietic defects, but can also avoid the onset of neurological signs [5].

# Osteopoikilosis

Jan Hellemans, Geert Mortier
Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium

## Synonyms

Osteopathia condensans disseminata; Related diseases: Buschke-Ollendorff syndrome and melorheostosis

## Definition and Characteristics

Osteopoikilosis is a rare and benign skeletal dysplasia with autosomal dominant inheritance. The term "osteopoikilosis" means literally "spotted bones" and refers to the multiple, small and round spots of increased bone density [1] that can be detected on radiographs (Fig. 1, left). In the Buschke-Ollendorff syndrome (BOS) these benign and asymptomatic bone lesions are associated with connective tissue nevi in the skin. These lesions can present as either widely disseminated small papules (Fig. 1, middle) or as larger plaques (Fig. 1, right). Osteopoikilosis and the Buschke-Ollendorff syndrome can occur together in the same family. In rare cases melorheostosis patients have been found in BOS families.

## Prevalence

The estimated prevalence is 1:20,000.

## Genes

A genome wide linkage analysis in families with osteopoikilosis, the Buschke-Ollendorff syndrome and melorheostosis allowed the identification of LEMD3 (LEM-domain containing 3, previously known as MAN1) as the causal gene [2]. Heterozygous loss-of-function mutations in the LEMD3 gene can cause osteopoikilosis or the Buschke-Ollendorff syndrome. Inactivating germline mutations in the LEMD3 gene have also been reported in a few melorheostosis patients that belong to a BOS family. However, in the vast majority of sporadic patients with isolated melorheostosis, no germline LEMD3 mutations have been identified. Therefore, the precise role of LEMD3 in the pathogenesis of isolated and sporadic melorheostosis is poorly understood. A contiguous gene deletion syndrome encompassing the LEMD3 gene has also been identified in patients with osteopoikilosis, mental retardation and short stature [3].

## Molecular and Systemic Pathophysiology

The LEMD3 gene encodes a protein with a molecular mass of about 100 kDa composed of a nucleoplasmic

**Osteopoikilosis. Figure 1** (a) Proximal part of the humerus with multiple hyperostotic spots, characteristic for osteopoikilosis. b–c) Connective tissue nevi in a patient with BOS. (b) Widely disseminated, multiple, skin-colored to yellow, small papules (few mm in diameter). (c) Localized, asymmetrically distributed, larger lesion (*yellow plaque*). a→left, b→middle, c→right.

N-terminal domain, a first transmembrane segment, a luminal loop, a second transmembrane segment and a nucleoplasmic C-terminal domain. The N-terminal domain contains the highly conserved LEM domain, binds to lamin A, lamin B1 and the barrier-to-autointegration factor (BAF), and is required for the localization of LEMD3 in the inner nuclear membrane. The C-terminus is also highly conserved and binds several regulators of gene expression, including the SMADs.

In humans, the C-terminal RNA-recognition motif interacts with the MH2 domain of both BMP-specific and TGFβ-specific receptor activated SMAD proteins (R-SMADs). LEMD3 does not affect the expression or stability of R-SMADs, but reduces the amount of phosphorylated SMADs. It also regulates the number of R-SMADs that form heterodimers with SMAD4 and translocate to the nucleus to regulate gene expression [4].

Hence, loss-of-function mutations in the LEMD3 gene will result in an overactivation of TGFβ, BMP and activin-responsive promoters. The importance of BMP and TGFβ pathways in the regulation of bone density has been demonstrated in other skeletal dysplasias. In Camurati-Engelmann disease and sclerosteosis increased bone density is caused by respectively TGFB1 mutations leading to increased TGFβ signaling and by loss of function mutations in SOST leading to decreased inhibition of BMP signaling.

## Diagnostic Principles

Osteopoikilosis is a benign condition, usually found by chance when radiographs are taken for other purposes. The diagnosis of osteopoikilosis mainly relies on a careful radiographic evaluation. Small (1×1 mm to 12×16 mm) and round to oval hyperostotic lesions can be found in different parts of the skeleton, but are most common in the epimetaphyseal regions of the long tubular bones. The axial skeleton (skull, ribs and vertebrae) is rarely affected. The number of hyperostotic spots can vary from a few to many lesions involving nearly all bones [1]. The lesions can be scarce at a young age and therefore be missed early on in life. In BOS patients, the typical hyperostotic spots can be accompanied by connective tissue nevi that appear as either numerous, widely disseminated, skin-colored to yellow small papules or as more localized and asymmetrically distributed larger lesions known as yellow plaques.

## Therapeutic Principles

Osteopoikilosis is a benign and asymptomatic disorder that does not require any treatment.

# Osteoporosis Pseudoglioma Syndrome

Minrong Ai, Matthew L. Warman
Department of Genetics and Center for Human Genetics, Case School of Medicine, Cleveland, OH, USA

## Synonyms

Osteogenesis imperfecta ocular form; OPPG and OPS

## Definition and Characteristics

The osteoporosis pseudoglioma syndrome (OPPG or OPS) [MIM 259770] is an autosomal recessive disorder. It is characterized by congenital or infancy-onset visual loss and by skeletal fragility which is often recognized during childhood. Cognitive impairment was also reported in ~25% patients with OPPG.

## Prevalence

OPPG is a rare disorder with an estimated incidence of approximately 0.5–1 per 1,000,000. The heterozygous carrier frequency is approximately 1 in 500–700.

## Genes

OPPG is caused by loss-of-function mutations in the low-density lipoprotein related protein 5 (LRP5) gene [1].

Interestingly, seven missense mutations in LRP5 have been identified in individuals with autosomal dominant high bone mass (HBM) diseases [MIM 601884, MIM 607636 and MIM 607634]. Mutations in LRP5 have also been associated with familial exudative vitreoretinopothy (FEVR) [MIM 133780 and MIM 601813].

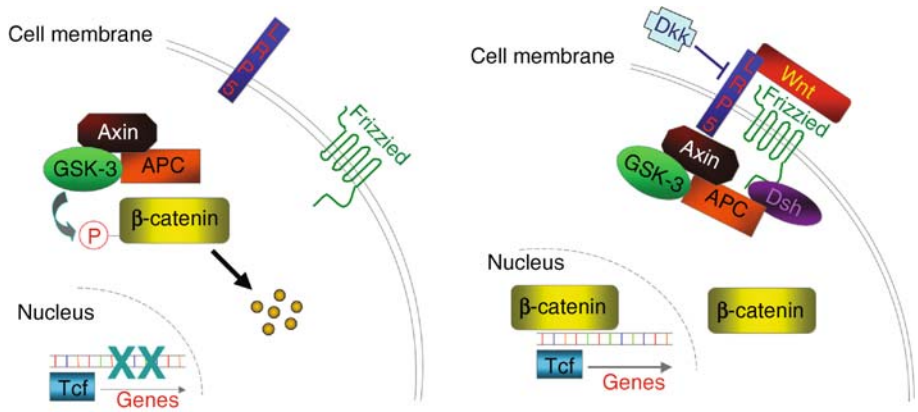
## Molecular and Systemic Pathophysiology

LRP5 is a cell surface receptor that belongs to the LDL receptor superfamily. One function of LRP5 is to bind Wnt ligands and transduce the canonical Wnt signal into cells, resulting in Wnt-dependent gene transcription (Fig. 1) [1,2].

Mutations identified in patients with OPPG abolish the receptor's ability to transduce Wnt signal [3]. LRP5 is expressed in many tissues, including bone. The Wnt pathway appears necessary for mesenchymal precursor cells to differentiate into osteoblasts. It is generally believed that loss of LRP5 results in reduced Wnt signaling in osteoblasts and subsequent decrease in osteoblast number and/or function.

Bone biopsies from patients with OPPG have less trabeculae and thinner cortices, but have otherwise normal appearing osteoblasts, osteoclasts, osteocytes and bone matrix. Serum markers of bone and calcium homeostasis are normal. Obligate carriers of OPPG allele (persons that are heterozygous for deleterious LRP5 mutations) also have significantly reduced bone mineral density compared to age and gender matched controls.

The majority of patients with OPPG are blind by early childhood, a consequence of persistence of the hyaloid blood vessels in the vitreous space and/or incomplete vascularization of retina. A glioma-like mass behind the lens is usually visible. LRP5 and the Wnt signaling are required for the macrophage-mediated clearance of the hyaloid blood vessels.



**Osteoporosis Pseudoglioma Syndrome. Figure 1** The canonical Wnt signaling pathway. In cells not exposed to Wnt ligands (*left panel*), β-catenin is phosphorylated through interactions with Axin, APC, and the protein kinase GSK-3. Subsequently, β-catenin undergoes proteosome-mediated degradation. When Wnt ligands bind to the Frizzled and the LRP5/6 receptors at cell surface (*right panel*), these receptors transduce the signal into cells via Disheveled (Dsh) and Axin. As a consequence, the degradation of β-catenin is inhibited, and this protein accumulates in the cytoplasm and nucleus. β-catenin then interacts with TCF in nucleus to regulate transcription of target genes. DKK proteins are a family of secreted inhibitors that bind to LRP5/6 and antagonize the canonical Wnt signaling.

## Diagnostic Principles

The diagnosis should be considered in persons who have: (i) bilateral eye involvement including vitreoretinal dysplasia, phthisis bulbi, persistent hyperplasia of the primary vitreous (PHPV), congenital retinal folds, or exudative retinopathy, and (ii) skeletal fragility, accompanied by fractures and severe radiological osteoporosis with bone mineral density more than three standard deviations below the mean. Other features previously described in patients with OPPG including mental retardation, ligamentous laxity, isolated cataract, retinal coloboma and Peter's anomaly are variable among patients and therefore, should not be the standard for diagnosis.

DNA sequencing of the LRP5 gene should be carried out as the genetic basis of diagnosis. However, absence of an identifiable mutation in LRP5 does not exclude the possibility of OPPG, since mutations may be missed during DNA sequencing of this 23-exon gene [3].

## Therapeutic Principles

Currently, no treatment is available for OPPG. However, there has been one report showing that intravenous bisphosphonate treatment resulted in significant improvement of lumbar spine bone mineral density and prevention of future skeletal fractures in three children (ages 9–11 years) with OPPG [4]. In addition, oral administration of lithium chloride (LiCl) significantly increased the bone mineral density in mice lacking the *Lrp5* gene [5]. Lithium can activate the canonical Wnt signaling downstream of LRP5 and therefore may be useful in treating patients with OPPG. The effect of Lithium in patients with OPPG has not yet been tested. To date, there is no treatment or prevention for the ocular abnormalities in OPPG. Because there is no risk of malignant transformation of the glioma-like mass in the eyes, enucleation should not be performed.

## Synonyms

AOM

## Definition and Characteristics

Acute otitis media (AOM) is an inflammation of the middle ear that presents with a rapid onset of signs and

symptoms, such as pain, fever, irritability, anorexia or vomiting.

Otoscopic findings of inflammation in AOM may include decreased mobility of the tympanic membrane, which has a bulging contour that can be recognized because the visibility of the ossicular landmark is impaired by a yellow or red (or both) colored exudate and bullae.

## Prevalence

Otitis media occurs most frequently in children. In fact, it ranks second to the common cold as the most common health problem in preschool children. Fifty percent of children have had at least one episode by one year of age. Between one and three years, 35% will have had repeated episodes. For school children, an estimated five million school days are missed every year due to otitis media.

## Molecular and Systemic Pathophysiology

Acute otitis media results from infection by viruses or bacteria, often as a complication of the common cold or of allergies. Acute otitis media is more common in children than in adults. Symptoms and treatment are similar in adults and older children.

The most common bacterial pathogens in acute otitis media are *Strep. pneumonia* and *Haemophilus influenza*, the pathogens most frequently associated with sinusitis and pneumonia. Additional bacterial pathogens include *Moraxella catarrhalis, Strep. pyogenes, Staph. aureus*, gram-negative enteric bacteria and anaerobes. The nature of the relation between viral and bacterial infection is controversial. Since viruses have been identified as the sole ineffective agent in only 6% of the middle ear aspirates obtained from children with AOM, viruses may promote bacterial superinfection by impairing Eustachian tube function and other host defenses, such as respiratory epithelial cell barrier.

*Complications:*

1. Mastoiditis with consecutive risk of sinus thrombosis, epidural abscess, meningitis
2. Facial paralysis
3. Labyrinthitis
4. Chronic otitis media
5. Adhesive otitis media commonly referred to as glue ear

## Diagnostic Principles

1. Otolaryngological examination
2. Pure tone audiometry
3. In case of complications, imaging of the laterobasis e.g., Schüller, CT

## Therapeutic Principles

Antimicrobial therapy is one of the cornerstones in the management of AOM but some studies have suggested that its routine use is not indicated [2]. Because the majority of cases of AOM resolve spontaneously [1], it might appear that antimicrobial therapy is not necessary. Nonetheless, in the pre-antibiotic era, complications of AOM such as mastoiditis were far more common than they are today; this difference may be due to the current routine use of antibiotics. A recent meta-analysis of 5,400 children with AOM indicated that antimicrobial therapy enhanced the "primary control" by 13.7% despite a spontaneous recovery in 81% of cases [1]. Because it is probably not possible to determine a priori which cases of AOM will result in suppurative complications, it is likewise not possible to determine which cases require antimicrobial therapy and which will resolve spontaneously. Therefore, it appears prudent to consider all cases of AOM as candidates for antimicrobial therapy in order to minimize the likelihood of complications. Some experts recommend watchful waiting for 48–72 h before initiating antibiotic therapy. This approach may be feasible in children over two years of age if good follow up can be assured; therefore, decisions about whether to withhold antibiotic therapy initially must be made on a patient by patient basis.

Despite theoretical concerns about the diminishing usefulness of amoxicillin, it continues to be as effective as any other oral antimicrobial agent for childhood AOM. In fact, it works as well as extended spectrum, penicillinase resistant oral agents for otitis media caused by either penicillin susceptible or resistant bacteria. Most comparative trials of antimicrobial therapy in AOM have failed to demonstrate a difference in effectiveness between amoxicillin and any other agent. Furthermore, the newer, broader spectrum, penicillinase stable antimicrobial agents are substantially more expensive than amoxicillin. Their use may be associated with relatively high rates of side effects and may increase the pressure for selection of multiply antibiotic resistant strains of bacteria. Therefore, because of its excellent "track record" (for infections due to penicillin susceptible and resistant bacteria), low cost, safety and acceptability to patients, amoxicillin remains the drug of choice for uncomplicated AOM.

# Otitis Media with/without Effusion

►Middle Ear Disease, Chronic

# Otosclerosis

Markus Pfister, Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Definition and Characteristics

Otosclerosis is a disease of bone that is unique to the otic capsule. It may cause a conductive hearing loss, a mixed conductive-sensorineural hearing loss or occasionally a purely sensorineural hearing loss. In 1860, Toynbee first described the condition causing a hearing loss by fixation of the stapes. Politzer in 1894 referred to the fixation of the stapes as otosclerosis, whereas Siebenmann revealed on microscopic examination that the lesion seemed to begin as spongification of the bone and termed the process otospongiosis [2].

## Prevalence

Clinical otosclerosis (OMIM 166800) has a reported prevalence of 0.2–1% among white adults, making it the single most common cause of hearing impairment in this population. Mean age of onset is in the third decade and 90% of affected persons are under 50 years of age at the time of diagnosis.

## Molecular and Systemic Pathophysiology

See [1,2]. Clinically, otosclerosis patients are seen with progressive hearing loss. If the otospongiotic process primarily involves the stapes, the hearing loss is conductive. The most common area for stapedial fixation is the anterior crura. The process may progress to involve the entire footplate or may continue anteriorly toward the cochlea, causing a sensorineural hearing loss. There have been many genes and proteins identified that, when mutated, may lead to these lesions. Also there is mounting evidence that measles virus is present within the otosclerotic foci, implicating an infectious etiology (this has also been noted in Paget's disease). Families with autosomal dominantly inherited otosclerosis have been described, but in most patients the etiology of the disease is unknown. So far, five gene loci have been detected [3]. Clinical otosclerosis is rare in blacks, Asians and Native Americans.

## Diagnostic Principles

1. Otolaryngological examination
2. Pure tone audiometry, immittance audiometry battery consisting of tympanometry, static compliance and acoustic reflex testing
3. In case of hereditary hearing loss a high resolution CT can be performed to rule out other malformations of the middle and inner ear

## Therapeutic Principles

*Conservative*: In case of a rapid deterioration of the inner ear, sodium fluoride can be administered [1]. However, clinical studies showing clear benefit are not available and sodium fluoride has considerable side effects. Alternatively hearing aids may be used in combined as well as sensorineural hearing loss. If the patient has a significant sensorineural component to the hearing loss, a hearing aid may be required even after successful stapedectomy [1].

*Surgery*: Patients with a combined hearing loss of more than 20 dB and a loss of discrimination in speech audiometry of more than 30% and less than 70% can be offered a surgical procedure called stapedectomy or stapedotomy. The chance of losing all hearing in the operated ear is less than 1%.

# Otospondylomegaepiphyseal Dysplasia

►Stickler Syndrome

# Ototoxicity

Stefan K. Plontke, Hans-Peter Zenner
Department of Otorhinolaryngology - Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Synonyms

Vestibular and auditory toxicity; Toxic hearing loss

## Definition and Characteristics

Ototoxicity is the ability of drugs or chemical agents to cause temporary or permanent inner ear dysfunction with symptoms of cochlear damage (i.e., hearing loss and tinnitus) or symptoms of injury to the vestibular apparatus (e.g., dizziness and vertigo).

Many substances may cause ototoxicity: aminiglycoside antibiotics (e.g., gentamicin, streptomycin, kanamycin, tobramycin, amikacin, netilmicin), antineoplastic agents (e.g., cisplatin, carboplatin), salicylates, loop diuretics (e.g., furosemide, bumetanide, ethacrynic acid), quinine and related drugs, erythromycin and related macrolide antibiotics, vancomycin, organic solvents (e.g., toluene, styrene, xylene, *n*-Hexane, ethylbenzene, fuels, perchlorethylene, carbon disulfide), asphyxiants (carbon monoxide, hydrogen cyanide), metals (lead, mercury), and pesticides/herbicides (paraquat, organophosphates).

## Prevalence

Incidence of aminoglycoside cochlear toxicity is estimated to be up to 33% and vestibular toxicity is approximately 15% [1,2]. The prevalence of aminoglycoside ototoxicity is highest in developing countries because there, these drugs are often the only affordable antibiotics.

## Genes

Mice lacking Na/2Cl/K transporter SLC12A2 – the primary target for loop diuretics in the inner ear – are deaf. Mice overexpressing superoxid dismutase show protection from aminoglycoside ototoxicity [1,2].

## Molecular and Systemic Pathophysiology

Aminoglycosides exert their damaging effect via a cellular redox-imbalance triggering apoptotic or necrotic cell death. Aminoglycosides can form active, ototoxic metabolites by combining with iron. These iron complexes promote the iron-catalyzed production of reactive oxygen species (ROS) from unsaturated fatty acids as electron donors [2]. ROS reacts with phospholipids in the cell membrane, DNA, and proteins. Aminoglycoside ototoxicity routinely manifests itself after a time interval following the initiation of treatment. It mainly affects cochlear out hair cells (starting with hair cells of the basal turn) or vestibular hair cells or both, although different aminoglycosides affect the hearing and balance organs to different degrees. Cisplatin also increases the formation of ROS and reactive nitrogens species (RNS). In association with cisplatin-induced ototoxicity, members of the intrinsic antioxidant defense system of the inner ear – Glutathione and its related antioxidant enzymes, glutathione peroxidase, glutathione reductase, catalase and superoxide dismutase – are reduced [1]. ROS react with plasma membranes leading to the formation of membrane lipid peroxidation products such as the highly reactive substance 4-hydroxynonenal which can lead to cellular damage and cell death. Outer hair cells appear most susceptible to cisplatin especially in the basal turn (high frequency region). The primary target of loop diuretics is the stria vascularis, especially the Na/2Cl/K transporter (SLC12A2), leading to a reduction in the endocochlear potential and an elevation of hearing threshold in electrophysiological measures. The reversible action of salicylates with hearing threshold elevation and tinnitus is strongly related to the serum and thus perilymph levels. The mechanism of action is assumed to be a reduction in cochlear blood flow and changes in the stiffness of the lateral wall of the outer hair cells.

There appears to be a enhancement of the ototoxic effect if an additional noise exposure is present with a reduced thresholds for damage to the inner ear for either of the substances (►Noise-induced hearing loss).

## Diagnostic Principles

Standard audiological and vestibular test batteries indicate the loss of function within the respective organs. A deterioration of pure tone threshold usually starts in the high frequency region and can be detected with high-frequency audiometry, which, however, is clinically not used on a routine basis. Damage to outer hair cells may be objectively detected by the deterioration of otoacoustic emissions (especially input/output functions), while loss of function in the vestibular system may be detected by a reduced caloric response. For many of the above substances diagnostics of cochleo-vestibular injury is complicated by the additional neurotoxicity, since damage to the central nervous system may interact with peripheral cochleo-vestibular tests.

## Therapeutic Principles

After permanent damage to the cochleo-vestibular apparatus has occurred, therapeutic options are sparse. There is a strong dose-effect relationship for most of

the ototoxic drugs which results in the recommendation of drug serum level monitoring and control of work place concentrations for ototoxic chemicals to avoid inner ear damage. Antioxidants can protect from aminogylcoside-induced hearing loss in animals without compromising their antibacterial efficacy [1,2]. A recent randomized, placebo-controlled clinical trial demonstrated evidence for the protective effect of acetyl salicylate in significantly reducing the risk of gentamicin-induced hearing loss [3].

## Pachyonychia Congenita

Markus Braun-Falco
Department of Dermatology, University of Freiburg, Freiburg, Germany

### Synonyms

Pachyonychia congenita type I (PC-I) Jadassohn-Lewandowsky (MIM 167200); PC-II Jackson-Lawler (MIM 167210)

### Definition and Characteristics

Group of four autosomal dominant inherited ectodermal dysplasias, with hypertrophic nail dystrophy (pachyonychia) as the constant main feature [1]. In addition, type I reveals palmoplantar hyperkeratosis, follicular hyperkeratosis, and oral leukoplakia; type II multiple pilosebaceous cysts, palmoplantar blisters, hyperhidrosis, and neonatal teeth; and type III and type IV ear–nose and throat abnormalities and mental retardation.

### Prevalence

Overall very rare; distribution among different PC-types: PC-1 > 50%; PC-2 ≈ 25%; PC-3 and PC-4 < 25%.

### Genes

PC-1: Keratin (K) 6a and K16; PC-2: K6b and K17.

### Molecular and Systemic Pathophysiology

Keratin intermediate filaments belong to the cytoskeletal system within the cytoplasm of epithelial cells. They consist of type I and II proteins, which assemble into 10-nm intermediate filaments. The central coiled-coil α-helical rod domain of each keratin contains highly Hconserved sequences at both ends, termed helix boundary motifs known to be involved in the filament assembly. The helix boundary motifs represent mutational high spots for keratin disorders. Any substitution or deletion within the rod domain is expected to cause distortion of the α-helix structure, and thus lead to instability of the heteropolymeric intermediated filaments. In PC, the majority of mutations are confined to the helix boundary motifs of either K6a and K16 in PC-1 or K6b and K17 in PC-2 [2,3].

### Diagnostic Principles

If clinically suspicious for PC, mutational analysis should focus on exons 1 and 6 in K16 and K17, and exons 1 and 7 in K6.

### Therapeutic Principles

Treatment options are purely symptomatic. Nail care is compulsory. The hyperkeratotic nail plates have been milled down regularly. A last option would be nail extraction followed by destruction of the nail matrix. For skin and mucosa changes, oral retinoids were occasionally beneficial. Gene therapy is not jet available.

# Paget's Disease of Bone

Henry J. Mankin
Orthopedic Surgery, Massachusetts General Hospital, Boston, MA, USA

### Synonyms

Osteitis deformans

### Definition and Characteristics

Paget's disease of bone is a mysterious entity with no readily identifiable cause and an array of different presentations. Although suggestions of viral and genetic possible causes have been made, there is still no clear definition as to the origin of the disease [1,2]. The first description of Paget's disease was by Sir Samuel Wilks in 1869, who reported a case of 60-year-old man who died and at autopsy, was found to have enlarged and very thick bones [3]. Sir James Paget became intrigued by the syndrome and in 1877 described 11 cases of the same disease and named it "osteitis deformans." In 1888, Jonathan Hutchinson changed the name of osteitis deformans to "Paget's Disease of Bone."

### Prevalence

The disorder is common and its frequency range is approximately 3% of the population over the age of 50, many of whom are asymptomatic. There is a strong difference in ethnic frequency with Caucasians and particularly persons of English, Australian or New Zealand origin being much more likely to have the disease than native-Americans, Eskimos, Africans, Indians or Orientals.

### Genes

The causes of Paget's disease of bone have always been obscure. Because the disease appeared to occur in patients mostly after the age of 50, genetic causes initially seemed unacceptable and the etiology related to parvomyxovirus infection was proposed but could not be confirmed. The racial and ethnic distribution seemed to strongly support the occurrence of the disease in patients of British origin and the relative rarity of the presentation in persons from Sweden, the Netherlands, Africa, India, Japan and China supported this view. Gene studies have recently disclosed modifications of tseqestosome 1 gene (also known as p 62); modifications in the RANKL, RANK and OPG systems with alterations in Bcl-2, an apoptotic suppressor; or finding of alterations in chromosome 9p13.3–p12 or 18g21.1–q22 or 6p21.3 [4].

### Molecular and Systemic Pathophysiology

In patients with Paget's disease bone is both synthesized and destroyed equally at extremely rapid rates. Because of this rapid turnover, the affected bone becomes markedly enlarged with very thick cortices, coarse but purposeful trabeculae and irregular lytic areas in some parts of the bone. Bowing of the affected bone is common (Fig. 1).

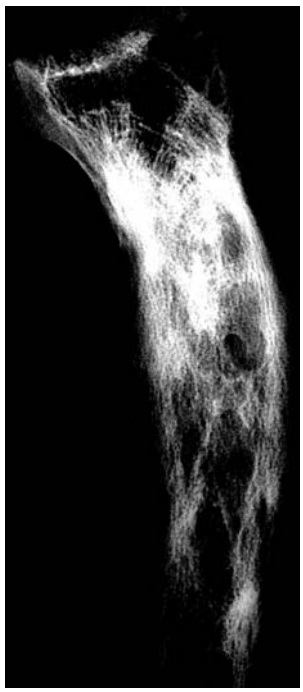
Because of the marked increment in synthetic activity, the bone scan is almost always intensely positive over the site and the serum alkaline phosphatase and the hydroxyproline peptides become markedly increased. Histologically in active sites, one sees an extraordinary vascularity and an enormous collection of osteoblasts making irregular columns of mature bone, which are simultaneously being destroyed by an equal number of osteoclasts (Fig. 2).

With time the bone becomes less active in terms of turnover and develops cement lines separating the segments of bone.

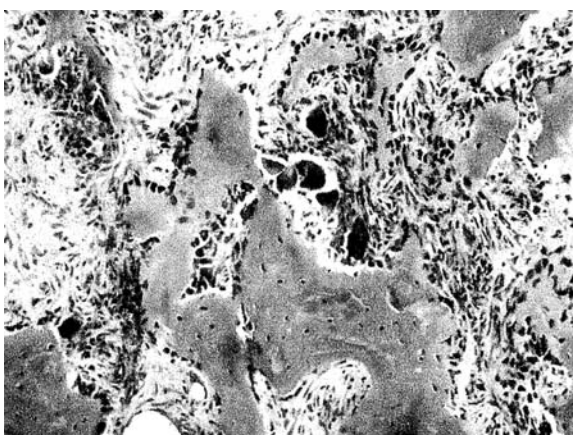
### Diagnostic Principles

The findings that distinguish Paget's disease from almost all other disorders are four in number: the bone is larger in width (and often in length) than normal; the cortices are wider than normal; the trabeculae in the medullary cavity are coarse but purposeful; and the medullary bone often contains sometimes large lytic areas.

In addition there are several changes that are sometimes present. These include: the "advancing wedge" of the disease; "stress lines" on the convex side of the bone; changes in the skull structure ("osteoporosis



**Paget's Disease of Bone. Figure 1** Classic radiographic appearance of a femur of a patient with severe Pagetoid bone changes. Note the bowing, the increased bone width, the thickening of cortices, the coarse but purposeful trabeculae and the lytic areas.



**Paget's Disease of Bone. Figure 2** Histologic picture of the bone from a patient with severe Paget's disease. Note the increased vascularity and the irregular structure of the bone. Numerous osteoblasts and osteoclasts are present. (Hematoxylin and eosin × 200).

cicrumscripta cranii") (Fig. 3); large vertebra with coarse trabeculae ("ivory vertebra"); and an enlarged jaw with "floating teeth" on imaging studies.

Many patients with Paget's disease at a single site are asymptomatic and the diagnosis is made on the basis of an imaging study for some other problem. It is often the complications of the disease that produce symptoms. The complications include the following: bone pain over the site of the lesion; bone deformities which may cause severe disability; osteoarthritis in the hip, knee or spine; foraminal encroachment which leads to deafness, blindness or Bell's palsy; pathologic fractures which heal poorly and are difficult to treat surgically; high output left heart cardiac failure; and Paget's sarcoma which occurs in 10% of patients with diffuse disease and is usually fatal.

**Paget's Disease of Bone. Figure 3** X-ray of the skull of a patient with extensive Paget's disease. Note the enlargement of the bone and the marked sclerosis, which is quite irregular in distribution.

## Therapeutic Principles

Until relatively recently there was very little treatment available for patients with Paget's disease. Those patients who have a solitary focus with little or no discomfort or deformity may be watched periodically with serial X-rays, bone scans and assays for serum alkaline phosphatase. Patients who develop osteoarthritis or fractures can be treated by appropriate surgery which is sometimes difficult because of excessive blood loss and problems with getting hardware to work effectively, and high output cardiac disease making anesthesia complicated. The newest systems of treatment for patients with extensive Paget's disease are based on medications that diminish the bone turnover. These include calcitonin and bisphosphonates which act principally by inhibiting osteoclastic activity and causing a "remission" in bone pain, cardiac problems, arthritis difficulty, hearing loss and fracture rate [5].

Sharon L. Wenger
Department of Pathology, West Virginia University, Morgantown, WV, USA

## Synonyms

Tetrasomy 12p mosaicism; Isochromosome 12p [i(12)(p10)] syndrome

## Definition and Characteristics

The additional chromosome consists of two short arms of chromosome 12, resulting in four copies of 12p (Fig. 1).

Individuals with Pallister-Killian syndrome show tissue-limited mosaicism of the isochromosome, rarely seen in cultured peripheral blood lymphocytes, but present in fibroblasts and bone marrow [1]. The i(12p) cell line decreases in fibroblasts with increased age of patient, in vivo, and with serial passaging of fibroblasts, in vitro [2]. This is thought to be due to growth disadvantage of the cells containing the isochromosome. The isochromosome may be lost more quickly in some cells due to greater somatic selection against cells containing the i(12p).

## Prevalence

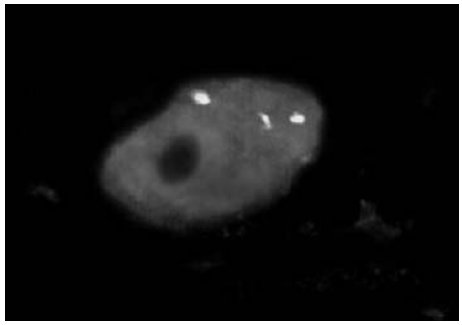
This is a rare sporadic chromosomal abnormality with over 100 cases reported in the literature.

## Molecular and Systemic Pathophysiology

The isochromosome 12p is a mosaic condition with tissue-limited mosaicism. Molecular studies have demonstrated that almost always the isochromosome is maternal in origin, with the majority suggesting second meiosis error [3]. This is supported by increased risk with advanced maternal age [4]. While a variety of methods have been proposed, the majority support a meiotic error

**Pallister-Killian Syndrome. Figure 1** Partial G-banded karyotype showing normal chromosomes 12 (*left* and *center*) and isochromosome 12 (*right*).

P



**Pallister-Killian Syndrome. Figure 2** Alpha-satellite FISH probe for centromere of chromosome 12 showing three signals in an amniocyte nucleus.

of nondisjunction followed by centromere mis-division. FISH probes for the centromere of chromosome 12 show the isochromosome to have a single centromeric signal, suggestive of mis-division of the centromere. Some isochromosomes have been reported to have a smaller signal, which may predispose to mitotic loss. While the zygote contains the isochromosome, the presence of two cell lines indicates a mitotic loss during early fetal development.

A common finding on prenatal ultrasound is a diaphragmatic hernia, the major cause of perinatal death. Characteristics in liveborn infants include hypotonia, profound mental retardation, seizures, hypertelorism, prominent lower lip and cupid-bow shaped upper lip with long philtrum, large ears, macrostomia, prominent forehead, flat nasal bridge, and sparse temporal scalp hair in young patients. Adults have a coarse facial appearance with prominent mandible. Pigmentary streaks of skin can demonstrate hyper/hypo pigmentation, most likely related to the mosaicism [5].

### Diagnostic Principles

Diagnosis is made by cytogenetics with use of a DNA centromeric probe for chromosome 12 by fluorescence in situ hybridization (FISH), which can confirm the isochromosome origin in metaphase and in interphase cells (Fig. 2).

### Therapeutic Principles

If miscarriage did not occur, management after birth is aimed at seizure control and physical and speech therapy.

### Synonyms

Keratosis palmoplantaris diffusa; Epidermolytic palmoplantar keratoderma

### Definition and Characteristics

Autosomal dominant defect in keratin 9 (K9) leading to diffuse, non-transgredient keratoderma of the entire surface of palms and soles with red margins and histologically with or without epidermolytic hyperkeratosis. Additional features are clubbing of nails and knuckle pad-like keratoses.

### Prevalence
The most common palmoplantar keratoderma (PPK) with approximately 1 in 100,000.

### Genes
Keratin 9 (MIM 144200) on chromosome 17q21 (very rarely keratin 1 in mild or atypical variants).

### Molecular and Systemic Pathophysiology
Keratin intermediate filaments belong to the cytoskeletal system within the cytoplasm of epithelial cells. They consist of type I and II proteins, which assembly into 10-nm intermediate filaments. The central coiled-coil α-helical rod domain of each keratin contains highly conserved sequences at both ends, termed helix boundary motifs known to be involved in the filament assembly. The helix boundary motifs represent mutational high spots for keratin disorders.

K9 belongs to the type I keratins. In contrast to other keratins, K9 is exclusively synthesized in suprabasal keratinocytes of palmoplantar skin. K9 pairs with K1. To date, approximately 14 different mutations have been described. The majority of them were missense mutations in the highly conserved coil-A segment within the α-helical rod domain of K9. Most prevalent are mutations at codon 160 or 162 within the helix boundary motifs. The primary structure is characterized by "heptad" substructure $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_m$, which are involved in the formation of heterodimers. Each residue has its specific properties, for instance in the polar interaction with neighboring keratin molecules. Mutations in these segments are thought to have a dominant negative effect on the assembly of keratin intermediate filaments and cause their instability.

### Diagnostic Principles
The clinical picture of diffuse palmoplantar hyperkeratosis with a red margin should lead to mutational analysis within keratin 9.

### Therapeutic Principles
Treatment options are purely symptomatic and focus on the reduction of hyperkeratosis by using urea containing ointments, topical calcipotriol, or mechanic keratolysis by rubbing with pumice stones. Gene therapy is not yet available.

## Definition and Characteristics

Includes cancers of the exocrine pancreas, excluding tumors derived from the pancreatic islets. Pancreatic cancer has an extremely poor prognosis, with mortality rates nearly matching incidence rates [1]. Incidence is rare before age 45, but increases steadily thereafter. The majority of patients have regional or distant spread at diagnosis. Risk factors include cigarette smoking, diabetes mellitus, obesity, and chronic pancreatitis. Multiple hereditary syndromes increase the risk for pancreatic cancer as well, including hereditary chronic pancreatitis, Peutz-Jeghers syndrome, BRCA2, ataxia-telangectasia, and familial atypical multiple-mole melanoma (FAMMM) [1]. Patients with hereditary pancreatic cancer develop pancreatic cancer earlier in life compared to sporadic cases.

## Prevalence

232,241 new cases and 226,949 deaths yearly worldwide [2].

## Genes

Multiple genetic alterations, both germline and somatic, are associated with the development of pancreatic carcinoma (Table 1). The primary oncogenic mutation in pancreatic cancer, found in over 90% of tumors, is a mutation in codon 12 of the K-Ras gene. K-Ras mutations occur more frequently in pancreatic cancer than any other human cancer, and the mutation of K-Ras codon 12 is considered a molecular hallmark of pancreatic cancer. The ErbB-2 proto-oncogene, also known as Her-2/neu, is a receptor of the epidermal growth factor family, and is amplified in approximately 65% of pancreatic carcinomas.

Multiple tumor suppressor genes are inactivated in pancreatic cancer, including the p16 gene, the p53 gene, and the deleted in pancreatic cancer 4 (DPC4) gene, also known as SMAD4. p16 inactivation occurs in 95% of pancreatic cancers, and p53 inactivation occurs in 50–75% of pancreatic cancers. In the pancreas, the loss of p16 and p53 appear to be specific to the development of malignant disease; they are rarely inactivated in chronic pancreatitis or other nonmalignant pancreatic diseases. Loss of DPC4 is relatively specific for pancreatic cancer, although it does occur at low rates in other malignancies. Of note, the combination of K-Ras activation and p16 inactivation occurs almost exclusively in pancreatic cancer, and there is interest in using this combination of genetic mutations as a pancreatic cancer signature. In addition to somatic mutations, there are multiple germline mutations that increase pancreatic cancer risk [3]; these are detailed in Table 1.

**Pancreatic Cancer. Table 1** Common genetic mutations in pancreatic carcinoma

| Somatic mutations | | | |
|---|---|---|---|
| **Mutation** | **Gene type** | **Mutation timing** | **Description** |
| K-Ras | Oncogene | Early | Activating somatic mutation occurs in 90% of pancreatic carcinomas |
| ErbB2 (Her-2/neu) | Oncogene | Early | Amplified in ~65% of pancreatic carcinomas |
| p16 (CDKN2A) | Tumor suppressor | Middle | Somatic inactivation occurs in 95% of pancreatic carcinomas |
| p53 | Tumor suppressor | Late | Somatic inactivation occurs in 50–75% of pancreatic carcinomas |
| DPC4 (SMAD4) | Tumor suppressor | Late | Somatic inactivation occurs in ~55% of pancreatic carcinomas |
| **Germline mutations** | | | |
| **Mutation** | **Gene type** | **Genetic syndrome** | **Lifetime risk** |
| STK11 | Tumor suppressor | Peutz-Jeghers syndrome | 36% |
| p16 (CDKN2A) | Tumor suppressor | Familial atypical multiple mole melanoma syndrome | 19% |
| BRCA2 | Tumor suppressor | Familial breast cancer | 5% |
| ATM | Tumor suppressor | Ataxia-telangectasia | Unknown |
| MLH1, MSH2 | DNA mismatch repair | Hereditary nonpolyposis colon cancer | Unknown |

## Molecular and Systemic Pathophysiology

In general, pancreatic oncogenesis is caused by the accumulation of multiple genetic alterations. Similarly to colorectal cancer, pancreatic cancer progresses in a stepwise manner from normal epithelium to progressive stages of pancreatic intraepithelial neoplasia (PanIN) to neoplastic tissue [4]. PanIN lesions are divided into four categories: PanIN-1A, a flat duct lesion; PanIN-1B, a papillary lesion; PanIN-2, an atypical papillary lesion; and PanIN-3, a severely atypical papillary lesion. In general, the activation of both K-Ras and ErbB-2 occur early in PanIN development (PanIN-1A and PanIN-1B). Inactivation of p16 occurs later in pancreatic neoplastic development, being initially found in PanIN-1B and PanIN-2 lesions. Loss of p53 and DPC4 tend to occur later in pancreatic cancer development, usually appearing initially in PanIN-3 lesions.

## Diagnostic Principles

Due to a lack of specific signs, symptoms or an effective screening test, pancreatic cancer is difficult to diagnose at an early stage; most patients are diagnosed with advanced disease. Presenting symptoms also tend to be nonspecific including abdominal pain that radiates to the back, anorexia, weight loss and obstructive jaundice. Ascites or an abdominal mass may be present on examination. Tumors which present in the head of the pancreas tend to cause jaundice and anorexia, while tumors in the body or tail of the pancreas tend to cause pain.

The initial workup for suspected pancreatic cancer are imaging studies, including ultrasound (transabdominal or endoscopic), CT scan, MRI, or endoscopic retrograde cholangiopancreatography (ERCP). ERCP offers the potential advantage of relieving a biliary obstruction through stent placement. The suspicion of disease must be confirmed by biopsy, which can be done using a needle guided by CT or ultrasound, endoscopic ultrasound (EUS), ERCP, or laparoscopy.

## Therapeutic Principles

Therapy for pancreatic cancer depends on the extent of the disease [5]. About 20% of patients have tumor localized to the pancreas that is resectable, offering the only potential for cure. However, most have recurrence of their disease, with 5-year survival ranges of 10–25%. For this reason adjuvant chemoradiation with 5-fluorouracil or gemcitabine (before or after surgery) followed by adjuvant gemcitabine is recommended. Approximately 40% of patients present with locally advanced disease, indicating either unresectable disease or local lymph node involvement. Optimal treatment for these patients has not been completely defined, but chemoradiation with 5-fluorouracil or gemcitabine is recommended. Median survival for these patients is approximately one year. Finally, approximately 40% of patients present with metastatic disease, primarily to the liver. Treatment with gemcitabine is the standard for metastatic disease; the addition of the EGFR inhibitor erlotinib modestly improves overall survival. Median survival for patients with metastatic disease is approximately 6 months with therapy, and 4 months in the absence of therapy.

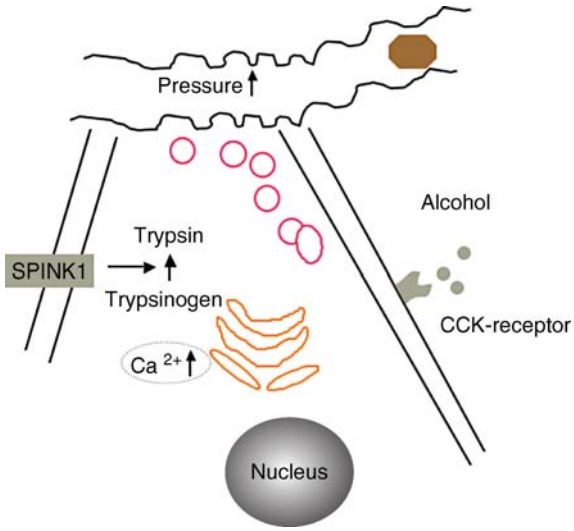
## Definition and Characteristics

Acute pancreatitis (AP) is characterized by a rapid onset of inflammation of the pancreas. The disease is mainly associated with biliary duct obstruction or alcohol consumption. Rare causes of AP include drugs, hypercalcemia, hyperlipidemia, trauma, endoscopic interventions, autoimmune response, infections or genetic predisposition. In up to 25% the cause cannot be determined. In about 80% of the cases inflammation is limited to the pancreatic gland resulting in mild pancreatitis with little mortality. Severe pancreatitis usually includes necrosis of pancreatic tissue with a generalized inflammatory state involving failure of distant organ systems such as kidney, lungs and liver.

## Prevalence

The prevalence in Europe and the USA of acute pancreatitis is constantly increasing and reaches about 24–75 cases per 100,000 adults [1].



**Pancreatitis, Acute. Figure 1** Overview of molecular processes in acute pancreatitis in an schematic acinar cell: Increased mechanical pressure in the biliary duct, alcohol, cholecytokinine (CCK) overstimulation, inhibition of SPINK1 or increase in calcium level lead to intracellular activation of trypsinogen to active trypsin.

## Genes

Genetic alterations have been identified in the context of chronic or recurrent acute pancreatitis, i.e., patients suffering from a hereditary form of pancreatitis express mutations in the cationic trypsinogen gene PRSS1 (e.g., R122H or N29I). Only a subgroup of patients with recurrent idiopathic acute pancreatitis has mutations of the cystic fibrosis gene CFTR.

## Molecular and Systemic Pathophysiology

Most investigators believe that the key factor in AP is the uncontrolled, premature activation of intracellular trypsin from trypsinogen in the acinar cell. This process can be triggered by increased pressure in the biliary or pancreatic duct (i.e., in gallstone disease) or alcohol consumption. In animal models acinar hyperstimulation (i.e., with excessive doses of cholezystokinine, CCK) or the inhibition of the serine protease inhibitor Kazal type 1 (SPINK1) lead to activation of acinar trypsin [2]. Moreover, defense mechanisms such as controlled low intracellular calcium levels, cellular compartmentalization and the autodigestion of trypsin have to be overcome. Together with trypsin, inflammatory mediations such as phospholipase A2 and elastase are activated. These events trigger the release of IL-1, IL-6 and IL-8 mainly from local inflammatory cells. This cascade of events results in local damage such as edema, necrosis, abscess or cyst formation of the pancreas. The process further triggers activation of inflammatory mediators in i.e., the liver causing a generalized inflammatory state with distant organ failure [3].

## Diagnostic Principles

Acute pancreatitis starts with abdominal pain often accompanied by nausea, vomiting and fever. Elevated serum levels of amylase or lipase may support the clinical diagnosis; they rise within a few hours after onset of symptoms. Serum levels of ASAT (>3-fold of normal limit) indicate biliary pancreatitis. Standard diagnostic procedures to rule out biliary pancreatitis include detection of gallstones by ultrasonography or endosonography. The alcoholic form of pancreatitis is likely if alcohol is drunken regularly. To assess the severity of the inflammatory process measurement of the C-reactive protein (CRP) is applied, multi-score-systems (Ranson-Score, Imrie-Score, APACHE II-Score) may be useful to predict clinical outcome. If diagnosis is unclear or complications are suspected computer tomography is performed.

## Therapeutic Principles

Therapeutic principles in AP include supportive therapy, sufficient intravenous fluid administration and adequate pain control. If signs of respiratory

insufficiency, renal failure or metabolic complications are present, intensive care is necessary. Enteric feeding should be administered in the early course of the disease either by a nasogastric or jejunal feeding tube [3]. In case of biliary pancreatitis, endoscopic retrograde cholangiography should be performed within the first 72 h to remove stones from the bile duct. Infection of pancreatic necrosis is a major complication in acute pancreatitis. In the case of infected necrosis, abscess, cholangitis, sepsis or extrapancreatic manifestations intravenous antibiotic therapy should be initiated, the use of prophylactic antibiotic administration is unclear.

# Pancreatitis, Autoimmune

Guido Adler
Department of Internal Medicine I, Ulm University, Ulm, Germany

## Synonyms

Lymphoplasmacytic sclerosing pancreatitis; LPSP; IgG4-related sclerosing disease

## Definition and Characteristics

Autoimmune pancreatitis is a benign chronic disease of the pancreas characterized by lymphoplasmacytic infiltration, diffuse organ enlargement, irregular narrowing of the pancreatic duct and a favourable response to glucocorticoid treatment. The inflammatory process is usually focal and mainly involves the head of the pancreas and the distal bile duct. Intense cellular infiltration is observed around medium-sized and large interlobular ducts [1]. Infiltrating cells are mainly CD8 and CD4 positive T lymphocytes. Periductal fibrosis increases with duration of disease. Inflammatory pseudotumors in the head of the pancreas may represent advanced stages of fibrosing autoimmune pancreatitis. High serum concentrations of the IgG4 subclass of immunoglobulins are closely related to disease activity. Patients with autoimmune pancreatitis often have extrapancreatic diseases like sclerosing cholangitis, retroperitoneal fibrosis, sialadenitis and lymphadenopathy. At the onset of disease patients present with unspecific symptoms like obstructive jaundice, abdominal or back pain, new-onset diabetes, or pancreatic mass. The severity of acute attacks of pancreatitis and the intensity of pain is mild [2].

## Prevalence

The exact occurrence rate of autoimmune pancreatitis is still unknown. Most cases have been published in the Japanese literature. Males (83%) are clearly predominant over females. The published mean age at diagnosis was between 54.7 and 63 years [2].

## Molecular and Systemic Pathophysiology

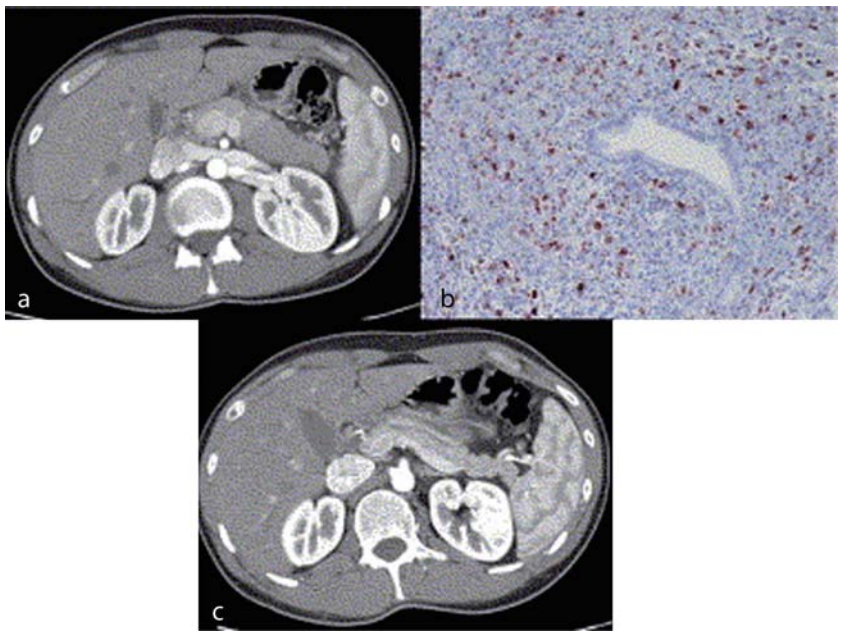
IgG4 plays a major role in the pathogenesis of autoimmune pancreatitis. This concept is supported by the specific rise of serum levels of IgG4, the close association with disease activity and the abundance of IgG4-positive cells infiltrating the pancreas (Fig. 1B).

Recent studies suggested that autoimmune pancreatitis causes several extrapancreatic manifestations (see above) that are characterized by IgG4 cell infiltration. It is suggested that potential antigens within the duct epithelium are the targets of the autoimmune process [3]. The frequent occurrence of antibodies against pancreatic proteins like carboanhydrase, pancreatic secretory trypsin inhibitor and lactoferrin support this concept. Similar to other autoimmune diseases the HLA haplotype DRB1*0405-DQB1*0401 is associated with autoimmune pancreatitis. Only recently an association of polymorphisms of the Fc receptor-like genes (FCRLs) with autoimmune diseases has been demonstrated. FCRL 3 expression on B cells is suggested to increase autoantigen production. In patients with autoimmune pancreatitis the frequency of the FCRL3–110A/A alleles was significantly increased compared with controls [4]. It is now suggested that both the HLA DRB1*0405-DQB1*0401 haplotype and FCRL3–110 alleles are related to susceptibility for autoimmune pancreatitis.

## Diagnostic Principles

At present no unanimously accepted diagnostic scoring system exists. Essential are imaging, serology and in some scoring systems the response to steroid therapy (Table 1).

Typically the pancreas is diffusely enlarged on CT or MR imaging and ultrasonography. On contrast-enhanced CT a low attenuation rim surrounded the pancreas. A focal mass lesion could be detected in



**Pancreatitis, Autoimmune. Figure 1** Morphology of autoimmune pancreatitis. (a) CT scan demonstrating low density lesion in the tail of the pancreas (arrowheads), (b) Pancreatic biopsy shows abundant IgG4-positive cells on immunostaining, (c) Resolution of changes in pancreatic tail after prednisone therapy ([2] with permission).

**Pancreatitis, Autoimmune. Table 1** Diagnostic criteria for autoimmune pancreatitis (from [2])

| Category | Criteria |
|---|---|
| Histology | At least one of the following:<br>1. Periductal lymphoplasmacytic infiltrate with obliterative phlebitis and storiform fibrosis (LPSP)<br>2. Lymphoplasmacytic infiltrate with storiform fibrosis showing abundant (≥10 cells/HPF) IgG4-positive cells |
| Pancreatic imaging | Typical: diffusely enlarged gland with delayed (rim) enhancement; diffusely irregular, attenuated main pancreatic duct |
| | Others[a]: Focal pancreatic mass/enlargement; focal pancreatic duct stricture; pancreatic atrophy; pancreatic calcification; or pancreatitis |
| Serology | Elevated serum IgG4 level (normal, 8–140 mg/dL) |
| Other organ involvement[b] | Hilar/intrahepatic biliary strictures, persisent distal biliary stricture, parotid/lacrimal gland involvement, mediastinal lymphadenopathy, retroperitoneal fibrosis |
| Response to steroid therapy[c] | Resolution/marked improvement of pancreatic/extrapancreatic manifestation with steroid therapy |

[a]With negative work-up for known etiologies for pancreatic disease, especially pancreatic/biliary cancer.
[b]Radiologic evidence of organ involvement can be confirmed by biopsy showing lymphoplasmacytic infiltrate with abundant IgG4-positive cells or its resolution/improvement with steroid therapy.
[c]Resolution/marked improvement of pancreatic/extrapancreatic manifestation with steroid therapy.

few patients only. ERCP images demonstrated focal (90% of patients) or diffuse (10% of patients) narrowing of main pancreatic duct and narrowing of distal bile duct. In patients with autoimmune pancreatitis serum levels of pancreatic enzymes, IgG and IgG4 are increased. In addition several autoantibodies are detected like antinuclear antibody (ANA), anti-lactoferrin antibody (ALF), anti-carbonic anhydrase – II-antibody (ACA-II), rheumatoid factor and only recently antibodies against pancreatic secretory trypsin

inhibitor (PSTI). Serum IgG4 concentrations are closely associated with disease activity and distinguish autoimmune pancreatitis from other pancreatic disorders with a high sensitivity (95%) and specificity (97%). Recently a role for pancreatic biopsy was suggested in diagnosing autoimmune pancreatitis, however, the values and risks of this procedure need further confirmation.

## Therapeutic Principles

While a few patients improve without any treatment, in different series almost every patient responded to glucocorticoid therapy. Without establishment of a detailed treatment schedule, oral prednisolone is initiated at 40 mg/day. After confirmation of the response prednisolone is tapered during a period of 12–16 weeks to a dose of 2.5–5 mg/day. Therapy may be maintained at this dose or discontinued completely. This regimen caused significant improvement in clinical symptoms, negative conversion of detected autoantibodies, normalization of elevated levels of IgG and IgG4, regression of pancreatic enlargement, resolution of pancreatic ductal narrowing and improvement of bile duct stricture. Associated type 2 diabetes may improve after glucocorticoid therapy. In some diagnostic scoring systems response to glucocorticoid therapy is included as a criterium for definite diagnosis. The response within two weeks of therapy could help to differentiate autoimmune pancreatitis from pancreatic cancer.

# Pancreatitis, Chronic

David C. Whitcomb, Dhiraj Yadav
Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh, Pittsburgh, PA, USA

## Definition and Characteristics

Chronic pancreatitis is a syndrome of recurrent and chronic pancreatic inflammation and progressive fibrosis, with eventual loss of exocrine and endocrine function and usually abdominal pain [1]. Anatomic features include inflammatory cell infiltration, fibrosis, loss of acinar and islet cells, dilated ducts, enlarged and inflamed nerve trunks and calcifications. The etiologies of chronic pancreatitis are nearly all complex, requiring combinations of interacting and sequential genetic, environmental and metabolic risk factors for the pathological features to develop. Alcohol abuse and tobacco smoking are major environmental risk factors but are not sufficient to cause chronic pancreatitis alone. Genetic polymorphisms, autoimmune disorders, recurrent and severe acute pancreatitis attacks and duct obstruction are also important risk factors but many cases remain idiopathic.

## Prevalence

Accurate data on the prevalence of chronic pancreatitis is lacking due to poor definition of early chronic pancreatitis and the lack of high quality of abdominal imaging techniques in older studies. Older studies from Europe, the United States and Mexico suggest a prevalence of 10–15 cases per 100,000 people, but more sensitive approaches used recently in Japan suggest a prevalence of 45 per 100,000 in males, and 12.4 per 100,000 in females. Incidence rates vary widely between countries, primarily due to differences in risk factor prevalence and criteria used for case-definition/acquisition. Longitudinal data from Western countries (United States, United Kingdom and Denmark) suggests an increase in incidence over time.

## Genes

Chronic pancreatitis, as a complex inflammatory process, is associated with a variety of genes affecting susceptibility to injury, genes modifying the inflammatory response, and genes associated with other complications of recurrent injury or linked with specific types of environmental factors. The most widely studied susceptibility genes include PRSS1 coding for cationic trypsinogen (the cause of autosomal dominant hereditary pancreatitis [2]), SPINK1 coding for pancreatic secretory trypsin inhibitor (PSTI) [3], and CFTR coding for the cystic fibrosis transmembrane conductance regulator [4].

## Molecular and Systemic Pathophysiology

In most cases chronic pancreatitis is linked to recurrent trypsin-initiated pancreatic injury. Normally, the exocrine pancreas synthesizes digestive enzymes in inactive forms and secretes them into the duodenum during a meal where they are activated by trypsin after enterokinase (a duodenal brush border enzyme) initiates the activation cascade by converting trypsinogen to trypsin. Since trypsin also activates trypsinogen to more trypsin, prematurely activated trypsin within

the pancreas can trigger the digestive enzyme activation cascade leading to pancreatic injury and an inflammatory response. Recurrent injury leads to chronic inflammation and fibrosis – the hallmarks of chronic pancreatitis.

Different pathologic conditions leads to premature activation of trypsinogen inside the acinar cell and inside the pancreatic ducts [5]. Acinar cell protection from trypsin is dependent on low calcium concentrations because they retard trypsinogen activation and facilitate autolysis thru calcium binding sites on the trypsinogen molecule. Mutations in PRSS1 (the trypsinogen gene) effecting calcium-regulated trypsin activity predispose to recurrent acute and chronic pancreatitis. The duct cells protect the pancreas from trypsin by flushing enzymes out of the duct. Secretion is driven by ion secretion through CFTR channels. Mutations in CFTR, or other factors that limit duct drainage, lead to trypsin-related injury of ductal origin. Biallelic severe CFTR mutations affect other organs, including lungs and intestines, causing cystic fibrosis. PSTI, an acute phase protein and specific trypsin inhibitor, is markedly up regulated in inflammation. Mutations in the PSTI gene, SPINK1, are associated with early onset chronic pancreatitis and tropical pancreatitis.

## Diagnostic Principles

Because of the current risk of pancreatic biopsy the diagnosis of chronic pancreatitis is usually inferred from imaging studies demonstrating gland atrophy and distortion, dilation of the duct system, calcifications, pseudocysts or persistent inflammatory masses. Pancreatic insufficiency alone is not diagnostic. Genetic testing is available for the major genes (e.g. PRSS1, SPINK1 and CFTR). Some pancreatitis-associated CFTR mutations do not cause cystic fibrosis, so screening of the entire gene may be indicated.

## Therapeutic Principles

Chronic pancreatitis is a complex process with many complications, so no single therapy will be effective. Gene therapy is not currently available, but advances in cystic fibrosis therapy may benefit the subset of pancreatitis patients with CFTR mutations. The use of vitamins and antioxidants appears to benefit some patients with hereditary pancreatitis. Dietary recommendations are usually for multiple, small, low fat meals. Lost exocrine function is replaced with pancreatic enzyme supplements, with or without gastric acid suppression. Diabetes is managed with diet, pancreatic enzyme supplements, oral hypoglycemic agents and insulin. Early intervention with prevention of organ injury and fibrosis appears to be the best approach to chronic pancreatitis in the future.

# Pancreatitis, Hereditary

Johannes Bode
Department of Gastroenterology, Hepatology and Infectiology, University-Hospital, Heinrich-Heine University Duesseldorf, Duesseldorf, Germany

## Definition and Characteristics

Hereditary pancreatitis is characterized by recurrent episodes of acute pancreatitis or a priori as chronic pancreatitis in several members of one family in the absence of other causes of pancreatitis. Classical hereditary pancreatitis follows an autosomal dominant expression pattern with incomplete penetrance of approximately 80%. The onset of hereditary pancreatitis is bimodal with a first peak of onset at 1–6 years and a second at 18–24 years of age. The median age of onset is 10–13 years. Apart from hereditary pancreatitis, cystic fibrosis is another inherited cause of chronic pancreatitis and mutations within the CFTR gene have been associated with an increased risk for the onset of pancreatitis [1,2].

## Prevalence

The incidence in Western Europe and North America of acute pancreatitis varies from 4.8 to 24.2 per 100.000 and of chronic pancreatitis from 3.5 to 7.7 per 100.000. Less than 2% of all these cases are related to hereditary pancreatitis with cationic trypsinogen or SPINK mutations or to cystic fibrosis with mutations of the CFTR gene [3].

## Genes

The disease gene for the classical hereditary pancreatitis phenotype is located on the long arm of chromosome 7. Among the eight trypsinogen genes identified in the T-cell receptor β-chain locus in 7q35 three generate

functional proteins: the cationic trypsinogen gene, the anionic trypsinogen gene and the mesotrypsinogen gene. Particularly mutations (A16V, D22G, K23R, N29I, R122H and R122C) of the cationic trypsinogen gene significantly correlate with hereditary pancreatitis. Apart from the cationic trypsinogen gene mutations of the SPINK1 gene (M1T and N34S) and the CFTR gene have been associated with an increased risk for the onset of pancreatitis. Of note, many of these mutations have also been detected in patients with idiopathic chronic pancreatitis that has no obvious hereditary basis. Hence, hereditary pancreatitis should be particularly considered if a positive family history for pancreatitis is reported [1,2,4,5].

## Molecular and Systemic Pathophysiology

Auto-digestion of the pancreas by various proteases that are activated in response to ectopic activation of trypsinogen is thought to be an important mechanism in the onset of pancreatitis. Pancreatic enzymes are stored as inactive precursors in pancreatic zymogen granules. Normally activation is strictly controlled in order to prevent premature intra-pancreatic activation and subsequent autodigestion. Triggers which impair these protective mechanisms and lead to activation of trypsinogen and of other downstream zymogens include excessive pancreatic exocrine stimulation, reflux of bile, duodenal fluid, disturbance of pancreatic duct flow, alcohol, and inflammation. Control of premature intra-pancreatic activation in particular of cationic trypsinogen is disturbed in patients with inherited pancreatitis, resulting in a higher susceptibility to respective triggers.

A relationship between mutations of the cationic trypsinogen gene and pancreatitis was initially reported 1996 [1,2,5], whereas the effect of mutations in the pancreatic secretory trypsin inhibitor (also known as serine protease inhibitor Kazal type [SPINK]1) on the onset of pancreatitis was first reported in 2000.

Four mechanisms have been proposed to explain how mutations in the cationic trypsinogen gene can lead to an increase in trypsin activity:

1. Mutation of the cationic trypsinogen protein (R122H and R122C) prevents inactivation of activated trypsin1 by autolysis and results in increased auto-activation.
2. The mutation (N29I) leads to changes of the higher order structure of trypsin, resulting in decreased inactivation by SPINK1 binding, increased stability of trypsin and auto-activation.
3. Increased auto-activation of trypsinogen to trypsin by mutations of the trypsinogen N-terminal peptide (A16V, D22G and K23R) which changes the signal peptide cleavage site of trypsin and increases the susceptibility to trypsin-mediated auto-cleavage.
4. Enhanced transcriptional activation (228delTCC) of the cationic trypsinogen gene and subsequent increased expression of trypsinogen, facilitating its activation.

SPINK1 is a major inhibitor of trypsin in the pancreas. Hence, functional alterations of the SPINK1 gene would result in an imbalance of trypsin activation and its inhibition and may predispose for the development of pancreatitis.

Two mutations of the SPINK1 gene at positions 1 (M1T) and 34 (N34S) have been identified which are correlated with increased susceptibility to develop chronic pancreatitis. The M1T mutation eliminates the SPINK start codon leading to an overall loss of SPINK1 activity. Family members carrying this mutation have pancreatitis as dominant trait, indicating that the absence of one functional SPINK1 allele is sufficient to induce pancreatitis. The importance and the functional implication of the N34S mutant is less clear. The N34S mutation in SPINK1 has been reported in familial pancreatitis and in children with idiopathic chronic pancreatitis, but also in 2% of control populations. However, patients homzygous for the N34S mutant of SPINK have an almost 100% risk (98%; 49/50) to develop pancreatitis, which suggests that this mutations may be a recessive inherited trait.

An increased prevalence of mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene has been reported for patients with idiopathic pancreatitis. CFTR conducts both chloride and bicarbonate, and largely controls pancreatic fluid secretion. Mutations of this gene, together with other genetic and environmental factors, are risk factors for chronic pancreatitis, by altering the ability to clear digestive enzymes from the pancreatic duct.

## Diagnostic Principles

Genetic testing for inherited pancreatitis should be considered in patients with onset of symptoms of idiopathic pancreatitis at a young age (<35 years) and/or a strong family history compatible for hereditary pancreatitis. Prior to and after genetic testing these patients should have genetic counseling. The procedure for the diagnosis of pancreatitis does not differ from that of sporadic acute or chronic pancreatitis. Whereas acute pancreatitis is usually accompanied by an increase of pancreatic enzymes (amylase and lipase) in the blood and typical findings (e.g. edema or necrosis, calcifications, ductal changes) in imaging procedures (abdominal and/or endoscopic ultrasound, CT scan, ERCP, MRCP) the diagnosis of chronic pancreatitis can be challenging since laboratory studies and imaging procedure can be almost normal.

Steatorrhea indicates severe exocrine pancreatic insufficiency and can be diagnosed qualitatively by Sudan

staining of feces, or quantitatively by determination of fecal fat excretion per 24 h on a 100 g fat diet. Moreover, determination of fecal elastase can be helpful for evaluating pancreatic exocrine dysfunction [1,2].

## Therapeutic Principles

The management of hereditary pancreatitis resembels that of sporadic pancreatitis. The disturbances of fluid and electrolyte homeostasis during severe acute pancreatitis usually require surveillance of these patients at intensive care units. Apart from this, stimulation of the pancreas should be avoided. Traditionally this goal has been achieved by total parenteral nutrition, which carries the risk of sepsis and metabolic disturbances. These risks can be handled by enteral feeding, which has been shown to be safe, as effective as total parenteral nutrition, and well tolerated in severe acute pancreatitis. Therefore enteral nutrition by nasojejunal tube or percutaneous jejunostomy has largely replaced total parenteral nutrition in the management of severely catabolic acute pancreatitis. Patients should be closely monitored for development of infectious complications which would require immediate antibiotic treatment. Prophylactic application of a broad spectrum antibiotic should be considered in patients with acute pancreatitis complicated by necrosis. Probably the main complaint of most patients with acute or chronic pancreatitis is pain which requires treatment with analgetics in the acute situation and if due to complications of acute or chronic pancreatitis (e.g. pseudocysts or biliary obstruction) urges for specific endoscopic or surgical interventions. Use of pancreatic enzyme preparations for pain relief is controversial but indispensible upon signs of exocrine insufficiency. Likewise endocrine insufficiency should be considered and adequately treated by monitored substitution of insulin if necessary. Patients with hereditary pancreatitis are especially prone to development of pancreas cancer and require adequate surveillance [1,2].

# Panniculitis

Martin Wabitsch, Klaus-Michael Debatin, Pamela Fischer Posovzsky
Division of Pediatric Endocrinology and Diabetes, University of Ulm, Ulm, Germany

## Synonyms

Acquired lipodystrophy; Localized lipodystrophy; Centrifugal lipodystrophy

## Definition and Characteristics

The lipodystrophy syndromes are rare disorders characterized by the loss of adipose tissue [1]. The loss of fat tissue can have genetic, immune, or infectious/drug-associated causes. Metabolic complications, such as insulin resistance, diabetes mellitus, hypertriglyceridemia, and fatty liver, increase in severity with the extent of fat loss. Lipodystrophies can be divided into two subtypes: familial and acquired. Causative mutations have recently been identified in one form of familial lipodystrophy as well as in one form of acquired lipodystrophy. Several mouse models might help understanding the development of these syndromes.

Panniculitis describes a clinical symptom caused by an inflammation of subcutaneous adipose tissue followed by a loss of adipose tissue. Panniculitis may be a sign of some forms of acquired lipodystrophy. Panniculitis may occur as an autoimmune process associated with other autoimmune phenomena.

Panniculitis may follow subcutaneous injection of drugs, especially insulin and corticosteroids (see Fig. 1).

## Prevalence

*Acquired generalized lipodystrophy (Lawrence-syndrome)*: So far approximately 80 patients have been described.

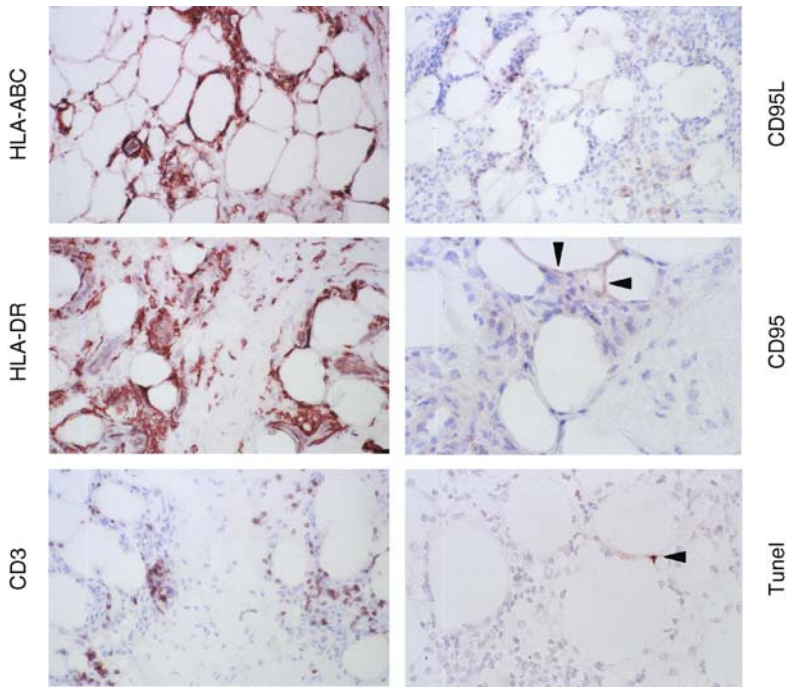
*Acquired partial lipodystrophy (Barraquer-Simons-syndrome)*: so far approximately 250 cases have been described.

## Genes

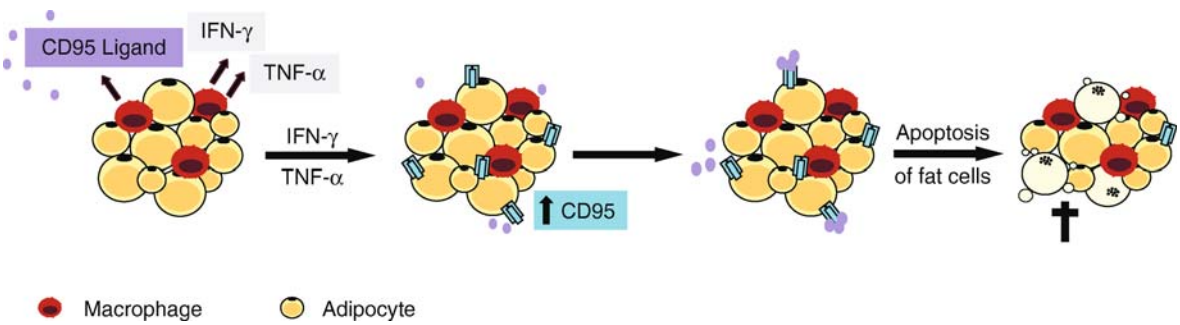
Several genes have been shown to be involved in inherited forms of lipodystrophy (AGPAT2, BSCL2 (Seipin), AKT2, LMNA, PPARG, ZMPSTE24) [2]. However, those forms are not associated with panniculitis.

## Molecular and Systemic Pathophysiology

The pathogenic basis of panniculitis and the mechanism of fat loss have so far been poorly understood.



**Panniculitis. Figure 1** Immunohisthemical examination in a patient with autoimmune lipodystrophy. Immunohistochemical examinations were performed on subcutaneous biopsies of body regions with ongoing fat loss in a patient with autoimmune lipodystrophy. Expression of HLA-ABC and HLA-DR was upregulated and tissue infiltration of CD3+ T cells was detected. While CD95 expression could be localized to lipid-filled adipocytes (*arrows*), expression of CD95L was restricted to cells of the inflammatory infiltrate. TUNEL staining revealed TUNEL-positive events demonstrating apoptosis of adipocytes.



**Panniculitis. Figure 2** Possible molecular mechanisms of fat cell loss in autoimmune lipodystrophy. Affected adipose tissue shows lymphocytic infiltration and accumulation of activated macrophages. Increased secretion of IFN-γ and TNF-α within adipose tissue results in upregulation of CD95 expression in mature lipid-laden adipocytes. CD95 ligand (CD95L) is secreted from the inflammatory infiltrate. Binding of CD95L to ite specific receptor induces apoptosis (as seen here by DNA fragmentation and membrane bledding). This finally leads to loss of adipocytes and development of lipodystrophy.

The association with autoimmune diseases suggests that the pathogenic mechanism may be an expression of autoimmunity. Strong molecule expression of HLA-A, B, C, and HLA-DR in adipocytes underlines an ongoing immunological process. However, the initial cause of HLA-DR upregulation and the presented antigen are not identified. Patients may have elevated circulating levels of inflammatory cytokines INF-γ

(interferon-gamma) and TNF-α (tumor necrosis factor-alpha) as well as sCD95L (soluble CD95 ligand). Histopathology of affected adipose tissue shows lymphocytic infiltration with $CD3^+$, $CD4^+$, and $CD8^+$ T cells, $CD57^+$ natural killer cells, and $CD11c^+$ macrophages. Macrophages contain large lipid droplets suggesting phagocytosis of adipocytes. Loss of adipocytes is mediated by programmed cell death as demonstrated by TUNEL-positive adipocytes. Adipocytes in affected fat tissue are induced to express CD95 by cytokines released by inflammatory cells and thereby become sensitive for apoptosis. CD95 expression in human adipocytes is upregulated by IFN-γ and TNF-α [3]. CD95L is expressed by cells of the inflammatory infiltrate. After binding of CD95L, its receptor caspase-8 and FADD are recruited to CD95 and form the death-inducing signaling complex (DISC).

The onset of acquired generalized lipodystrophy has been heralded in approximately 25% of cases by an episode of subcutaneous inflammatory nodules, termed panniculitis. Initially, these lesions heal, with localized loss of fat at subcutaneous regions, eventually causing generalized lipodystrophy (see Fig. 2).

## Diagnostic Principles

Panniculitis and loss of subcutaneous fat tissue is a clinical diagnosis based on history and clinical examination [2]. Histological examinations as shown above may be added to prove the autoimmune pathogenesis. Circulating serum triglyceride levels indicate the activity of fat cell loss.

## Therapeutic Principles

So far there is no causal therapy. Treatment aims at treating the comorbidities as there are insulin resistance, diabetes mellitus, hypertriglyceridemia, and fatty liver. Recently, subcutaneous recombinant leptin appeared to be safe and effective for improving metabolic complications of severe forms of fat loss. Furthermore, cosmetic problems may be treated by fat tissue transplantation, implantation of silicone and bovine-collagen implants, and liposuction.

The efficacy of corticosteroids or other immunosuppressive drugs to prevent further fat loss has not been studied systematically. Experimental treatment with immune modulating drugs has not been reported to positively influence the course of the disease.

In vitro, human adipocyte apoptosis can be inhibited by activating IGF-1 signaling [4]. Factors interacting with the IGF-I/IGF-IR (Insulin-like growth factor-1/Insulin-like growth factor-1 receptor) circuit would therefore be able to change the sensitivity of human fat cells for entering into apoptosis.

# Panniculitis at α-1 Antitrypsin Deficiency

Akmal Hassan, Mosaad Megahed
Clinic of Dermatology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Suppurative panniculitis

## Definition and Characteristics

A chronic, relapsing ulcerating panniculitis caused by an autosomal recessive genetic disorder characterized by deficient serum levels of α-1 antitrypsin (AAT).

## Prevalence

Panniculitis occurring in AAT-deficient individuals is very rare, and is considered the least common of the well-recognized complications of this genetic disorder. The exact prevalence is, however, unknown.

## Genes

Protease inhibitor (PI) gene coding for AAT, localized on chromosome 14q31.1.

## Molecular and Systemic Pathophysiology

AAT is a 52-kDa glycoprotein protease inhibitor synthesized mainly by hepatocytes. It is an acute phase reactant protein that potently inhibits a broad spectrum of proteases including trypsin, neutrophilic elastase, chemotrypsin, collagenase and plasmin. AAT is encoded by a highly polymorphic gene, with at least 75 allelic variants. The M allele is the most common normal allele, while Z and S alleles are the most common mutant alleles

associated with deficient levels of AAT. Panniculitis associated with AAT deficiency occurs principally in individuals homozygous for the Z allele (PiZZ phenotype) resulting from a point mutation in exon 5 at position 342 of the PI gene, in which glutamine to lysine substitution causes decreased secretion of AAT by hepatocytes. Other reported phenotypes include PiMZ, PiMS, PiSZ and PiSS. In the latter phenotypes the S allele results from a mutation in exon 3 causing the substitution of valine for glutamine at position 264 resulting in the production of an inhibitor with decreased stability. Panniculitis usually follows trauma or infection which initiate an inflammatory cascade. The deficiency of AAT causes an unopposed action of proteases such as elastase and collagenase generated by neutrophils and monocytes resulting in degradation of the dermal and subcutis tissues. Concurrently, AAT deficiency enhances the activation of lymphocytes and phagocytes. Eventually, severe tissue inflammation and necrosis results.

### Diagnostic Principles

AAT deficiency panniculitis is characterized by recurrent tender, erythematous, subcutaneous ulcerating nodules predominantly on the trunk and the proximal extremities. Early lesions resemble cellulites and an oily discharge representing necrotic adipocytes is usually seen. The panniculitis may accompany or precede other common manifestations of AAT deficiency such as emphysema, hepatitis, cirrhosis angioedema and vasculitis. Histopathological features, decreased levels of AAT and detection of mutations in the PI gene confirm the diagnosis.

### Therapeutic Principles

Dapsone, tetracycline, colchicine, hydroxychloroquine, corticosteroid and cyclophosphamide have been reported to be of help. Replacement therapy with AAT human purified enzyme has been used effectively in severe cases.

## Papillon-Lefèvre Syndrome

Tord M. Lundgren
Department of Periodontics, Loma Linda University, Loma Linda, CA, USA

### Synonyms

PLS

## Definition and Characteristics

Papillon-Lefèvre syndrome (PLS) is an autosomal recessive dermatologic/odontogenic disease. Obligate symptoms include severe aggressive periodontitis (Fig. 1b) and palmar plantar hyperkeratosis (PPK) (Fig. 1a,c). Other areas of the skin that are subjected to friction, such as the knees and elbows, are often hyperkeratinized as well. Increased susceptibility to infections, including pyogenic hepatic abscesses, intracranial calcification of falx cerebri (Fig. 1d) and retarded somatic development have also been described.

## Prevalence

There is no recent report regarding prevalence. A publication from 1964 reported an incidence of one to four cases per million people. Consanguinity of the parents was described in one third of those affected.

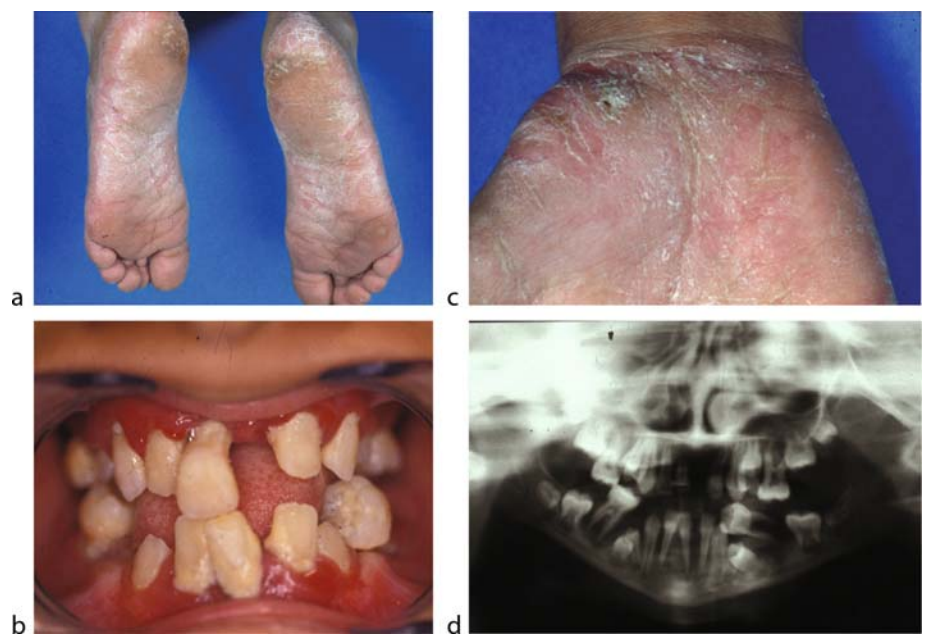
## Molecular and Systemic Pathophysiology

The genetic defect in PLS (Mendelian Inheritance in Man, MIM # 245000) involves mutations in the cathepsin C (CTSC) gene, located at 11q 14.1–q14.3. The CTSC gene encodes a lysosomal cystein protease, dipeptidyl aminopeptidase I (DPPI). DPPI is a high weight (2200 kDa) oligomeric enzyme found in most tissues of the body, including cells of the immune system and also palmar, plantar and gingival epithelial cells. Biochemical analysis has demonstrated almost no cathepsin C activity in leucocytes from patients with PLS.

DPPI is functioning as a coordinator in a variety of immune and inflammatory processes, including cell-mediated cytotoxicity, phagocytic destruction of microorganisms, activation and deactivation of cytokines and other inflammatory mediators. In addition, DPPI is thought to play an important role in protein degradation and proenzyme activation. According to current evidence there are over 46 mutations in the CTSC gene. Mutations of the cathepsin C gene have also been confirmed in patients with Haim-Munk syndrome, a condition with phenotypic expression similar to PLS, as well as in cases of non-syndromic prepubertal periodontitis lacking dermatologic involvement. Recent evidence suggests that PLS patients with confirmed CTSC mutations exhibit functional defects in unstimulated NK-cells. The clinical significance of this NK-cell functional defect remains to be determined.

## Diagnostic Principles

The coincidence of PPK and aggressive periodontitis affects both the primary and the permanent dentition. Diagnosis of the periodontal disease component is based on clinical assessments including gingival sulcular probing depth, attachment loss, bleeding upon probing and alveolar bone loss. There seems to be no correlation between the level of the periodontal involvement and the severity of the skin lesions.



**Papillon-Lefèvre Syndrome. Figure 1** Obligate symptoms of PLS.

Family history may reveal the genetic origin. Detection of mutations in the CTSC gene confirms the diagnosis of this rare disease.

## Therapeutic Principles

Mild to moderate hyperkeratotic skin lesions can be treated with lubricants and topical agents, such as urea cream, lactic acid, or salicylic acid. More severe PPK may, in addition to topical treatment, receive systemic medication with synthetic retinoids.

Early diagnoses together with a comprehensive preventive dental care program seem to be particularly important to prevent development of aggressive periodontitis in this group of patients. An intensive preventive program based on mechanical plaque control along with local and/or systemic antibacterial measures have shown some success in slowing this disease. In cases where the primary dentition is affected by periodontitis, it has been suggested to extract all deciduous teeth prior to eruption of the permanent teeth in order to increase an infection-free edentulous period.

Patients presenting an established periodontitis in the permanent dentition should undergo an intensive mechanical and antimicrobial regimen including extraction of all teeth considered untreatable, non-surgical and/or surgical treatment, often together with local and systemic chemotherapeutics. Compliance with the treatment protocol has shown significant effect in slowing the progression of periodontal disease and decreasing the loss of permanent teeth.

# Paraganglioma

Markus Pfister, Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Synonyms

Glomus tumors

## Definition and Characteristics

Paraganglioma is a rare neoplasm that can be found in the head and neck region and other less common areas. They are usually considered benign. However, in about 3% of cases they are malignant and have the ability to metastasize. Paragangliomas are still sometimes called glomus tumors and chemodectomas, but paraganglioma is the currently accepted and preferred term.

Paragangliomas arise from the glomus cells, which are special chemoreceptors located along blood vessels that have a role in regulating blood pressure and blood flow. The main concentration of glomus cells are found in the carotid body, located in the upper neck at the branching of the common carotid artery and the aortic bodies, located near the aortic arch. The glomus cells are a part of the paraganglion system composed of the extra-adrenal paraganglia of the autonomic nervous system, derived from the embryonic neural crest. Thus, paragangliomas are a type of neuroendocrine tumor and are closely related to pheochromocytomas. Although all paragangliomas contain neurosecretory granules, only about 1–3% have clinical evidence of over-secretion.

Paragangliomas are found predominantly in the abdomen (85%) and the thorax (12%). Only 3% are found in the head and neck region. Most occur as single tumors.

## Prevalence

The prevalence of paragangliomas is approximately 1 to 30,000. About 10 to 50% of all paragangliomas are familial.

## Genes

Familial paragangliomas account for approx. 25% of cases, are often multiple and bilateral and occur at an earlier age. Mutations of the genes SDHD (previously known as PGL1), PGL2 and SDHC (previously PGL3) have been identified as causing familial head and neck paragangliomas. Mutations of SDHB play an important role in familial adrenal pheochromocytoma and extra-adrenal paraganglioma (of abdomen and thorax), although there is considerable overlap in the types of tumors associated with SDHB and SDHD gene mutations.

## Molecular and Systemic Pathophysiology

Paragangliomas are described by their site of origin and are often given special names.

*Carotid Paraganglioma (Carotid Body Tumor)*: This is the most common of the head and neck paragangliomas. It usually presents as a painless neck mass, but larger tumors may cause cranial nerve palsies, usually of the vagus nerve and hypoglossal nerve.

*Glomus Tympanicum and Glomus Jugulare*: Both commonly present as a middle ear mass resulting in tinnitus (in 80%) and hearing loss (in 60%). The cranial nerves of the jugular foramen may be compressed, resulting in swallowing difficulty.

*Vagal Paragangliomas*: These are the least common of the head and neck paragangliomas. They usually present as a painless neck mass, but may result in dysphagia and hoarseness.

*Other Sites*: Rare sites of involvement are the larynx, nasal cavity, paranasal sinuses, thyroid gland and the thoracic inlet.

## Diagnostic Principles

1. Otolaryngological examination
2. Audiometry
3. Imaging: MRT, CT, angiography and embolization

## Therapeutic Principles

*Medical Therapy*: Some cases require no treatment, because they are either small or diagnosed within the sixth or seventh decade of life, can be followed by imaging only and may not need surgical intervention. Medical therapy may be indicated in some cases. Alpha-blockers and beta-blockers are useful for tumors secreting catecholamines. They are usually administered for 2–3 weeks before embolization and/or surgery to avoid potentially lethal blood pressure lability and arrhythmias.

*Surgical Therapy*: Surgery is the treatment of choice for glomus tumors. The surgical approach depends on the localization and extension of the tumor. Intraoperative monitoring including EEGs and somatosensory evoked potentials (SSEPs) are routinely used.

Fisch type A tumors can be excised by a transmeatal or perimeatal approach.

Fisch type B tumors require an extended posterior tympanotomy.

Fisch type C tumors require radical resection via a standard combined transmastoid-infratemporal or transtemporal-infratemporal approach with or without ICA trapping, preceded by external carotid artery embolization or superselective embolization. Intraoperatively, the transverse or sigmoid sinus should be temporarily occluded with EEG monitoring to determine whether vein bypass should be performed for total resection. Surgery leads to therapeutic success in about 90% of patients. Intratumoral injection of cyanoacrylate glue has been proposed to control bleeding.

Large Fisch type D tumors need to be treated with a combined otologic and neurosurgical approach. An infratemporal approach with a skull base resection and a posterior fossa exploration are the most advisable in the attempt to remove the entire tumor. Partial resection of the tumor needs to be followed by radiation and follow-up MRI/CT scanning.

Radiation therapy and radiosurgery may be indicated. Both classic fractionated radiation therapy (40–50 Gy) and stereotactic radiosurgery (e.g. gamma knife surgery) are successful in long-term control of tumor growth and in decrease of catecholamine excretion in functional tumors; however, the short duration of observation after stereotactic radiosurgery does not allow for definite conclusions. Radiation treatment is advised as the sole treatment modality for elderly or infirm patients who are symptomatic, especially those with extensive or growing tumors.

Gross total resection of some extensive tumors may be extremely difficult and may carry unwarranted risk. In such cases, radiotherapy may be indicated to treat residual tumor following subtotal resection.

## Definition and Characteristics

Paraneoplastic syndromes can be defined as a whole of systemic signs and symptoms related to cancer (Table 1).

These signs and symptoms are directly related to substances that the tumor produces or to a host's reaction to the cancer. Paraneoplastic syndromes may appear in the patients during the natural history of the cancer or before the initial diagnosis.

## Prevalence

### Rheumatic Paraneoplastic Syndromes

*Rheumatoid arthritis* is associated with lymphatic malignancies in 80% of cases. Polymyositis and Dermatomyositis are associated with cancer in 15% of cases. Breast and lung cancers are the most frequent malignancy associated. Amyloidosis is associated to cancer in 15% of cases, while *vasculitis* only in 5% (usually in patients with lymphatic malignancy) [1].

### Mucocutaneous Paraneoplastic Syndromes

Some dermatoses are frequently associated to hematological diseases (15–20%) while other mucocutaneous syndromes appear in patients with solid tumors (8–15%).

### Hypertrophic Osteoarthropathy

Prevalence ranges from 1 to 29%.

### Renal Paraneoplastic Syndromes

Renal paraneoplastic syndromes are associated to malignancies in 1–63% of cases, depending to the type of cancer.

*Neurological Paraneoplastic Syndromes (NPS)*: Neurological paraneoplastic syndromes are rather uncommon (1%) [2].

*Systemic Syndromes*: Systemic syndromes are common in neoplastic patients: neoplastic cachexia-anorexia is usually present in advanced cancer patients (45–80% of cases); [3] systemic fever is associated with almost all tumors (frequently to lymphatic disease); metabolic paraneoplastic syndromes are also rather common (more than 60% of cases).

*Hematological Paraneoplastic Syndromes*: The prevalence of anemia is high (50–60%) [4]. Leukocytosis and thrombocytosis are common paraneoplastic syndromes (30–50% of cases) too. Leukopenia and thrombocytopenia not related to chemotherapy are very uncommon.

*Blood Coagulation*: VTE (venous thromboembolism) and pulmonary embolism are frequently associated with cancer. While sub-clinical coagulation activation is encountered in up to 90% of cancer patients, only 4–15% of them develop VTE or pulmonary embolism. About 3–10% of cancer patients develop a DIC.

## Molecular and Systemic Pathophysiology

*Rheumatic Paraneoplastic Syndromes*: Myopathies are characterized by inflammatory reactions within muscles, necrosis, and regeneration of muscle fibers. Amyloidosis is characterized by an extracellular deposit of eosinophil hyaline amorphic substance (amyloid) that leads to a damage of different organs (heart, skin, liver, kidney). Vasculitis is a heterogeneous group of diseases and characterized by blood vessel phlogosis leading to organs' dysfunction. Vascular damage is probably due to an immunologic reaction [1].

*Mucocutaneous Paraneoplastic Syndromes*: Dermatosis can represent an idiopathic condition or can be ssociated with a tumor. The pathogenesis is unknown.

*Hypertrophic Osteoarthropathy*: The osteal alterations in hypertrophic osteoarthropathy start with a light periosteal inflammation and with subsequent apposition of new bone tissue. The connective tissue of fingers and nail beds increases with a typical aspect of "drum stick fingers." At present, there are no conclusive evidences in the etiopathogenesis.

*Renal Paraneoplastic Syndromes*: Chemotherapy, radiotherapy, hypercalcemic and hyperuricemic

nephropathy, cancer infiltration, and paraneoplastic syndromes are all the possible causes of kidney's failure. Common renal paraneoplastic syndromes are those caused by direct glomerular damage: (i) Membranous glomerulonephritis is generally idiopathic and the etiopathogenesis is related to a deposit of immunocomplexes into the glomerulus generally related to tumor antigens production. (ii) In foot process disease the etiopathogenesis is not clear but has been supposed to involve immunological mechanisms.

*Neurological Paraneoplastic Syndromes*: The etiopathogenesis of NPS is unknown; the majority of authors believe in an immunological pathogenesis. A few cancer types produce antigens with a subsequent immune response, which is directed to the nervous system [2].

*Systemic Syndromes*: Paraneoplastic cachexia-anorexia results from excessive anaerobic glycolysis, the main process used by the tumor in order to produce energy. Systemic fever is caused by many cytokines produced by cancer cells. Several endogenous factors are responsible for hyperpyrexia: IL-1, TNF, IL-6, alpha-interferon, and other cytokines [3]. Endocrine paraneoplastic syndromes result from production of proteohormones and glycoproteins by the neoplastic tissue. Metabolic paraneoplastic syndromes include hypercalcemia, which may be related to bone destruction with renal tubular calcium absorption; in other cases, the tumor produces some factors, which stimulate bone absorption. In hypoglycemia, the insulin-like growth factor is responsible for the decline of plasma glucose concentration. Another cause of hypoglycemia is the reduction of food intake. Hyperuricemia is generally related to spontaneous or therapy-induced tumor lysis. Pathogenesis is due to an enhanced nucleotide metabolism, which leads to a subsequent increase of plasma uric acid concentration.

*Hematological Paraneoplastic Syndromes*: Anemia may be due to several causes, including deranged iron metabolism, reduced level of erythropoietin, inadequate erythropoiesis, and antibody production, but its pathogenesis is not clear and may vary in different tumors. Pathogenesis of the remaining hematological paraneoplastic syndromes has not been fully elucidated, yet [4,5].

*Coagulation*: Thrombosis may be caused by alterations in blood viscosity or by the alteration of the factors involved in the coagulative process. DIC can be due to several causes: production of high levels of thromboplastic agents by the tumor, tumoral lysis due to antineoplastic therapies, treatments, such as surgery or trauma.

## Diagnostic Principles

*Rheumatic Paraneoplastic Syndromes*: Polymyositis and dermatomyositis are characterized by inflammation and weakness of proximal muscles in arms and legs and sometimes they are associated with pain. Generally, the first symptom is a progressive weakness of hips and thigh muscles; successively, the face skin rash (helyotropic rash) appears. The diagnosis of cancer can be done either before the first appearance of myositis or also two years thereafter. Typical paraneoplastic amyloidosis symptoms are peripheral neuropathy, orthostatic hypotension, dyshidrosis, and dysperistalsis [1].

*Mucocutaneous Paraneoplastic Syndromes*: Mucocutaneous paraneoplastic syndromes can precede the diagnosis of cancer or appear during or after the tumor diagnosis.

*Hypertrophic Osteoarthropathy*: DC is an anatomic and functional condition of fingers and toes characterized by erythema and tissue leading to thickening of the ungula phalanx and nail convexity. DC and hypertrophic osteoarthropathy are two different aspects of the same disease, and therefore the phenotypes are generally associated. The lesions are generally bilateral and symmetric. Tibia, fibula, radius, ulna are involved at the beginning. Initial phases of disease can be asymptomatic or characterized by an unpleasant feeling of finger pyrosis. Pain and finger function loss appear when the periosteitis increases.

*Renal Paraneoplastic Syndromes*: Membranous glomerulonephritis is characterized by proteinuria, hypertension, and macroscopic hematuria. The natural evolution is variable from the spontaneous remission (25% of cases) to advanced kidney's failure. Foot process disease is characterized by nephrotic syndrome.

*Neurological Paraneoplastic Syndromes*: There are a variety of neurological disorders, which are exclusive or frequently associated to a cancer [2].

*Systemic Syndromes*: Paraneoplastic cachexia-anorexia can be defined as a whole of symptoms (such as nausea–anorexia–weight loss, alteration of hydroelectrolytic equilibrium, increased energy metabolism) that cause a progressive failure of vital functions [3]. Systemic fever can be defined as a body temperature >37.8°C (oral measurement) or >38.4°C (rectal measurement). Diagnosis of endocrine paraneoplastic syndromes can be done on the basis of biological criteria (neoplastic tissue which expresses hormones) or clinical criteria (association between tumor and endocrine syndrome). Most frequent syndromes are caused by an ectopic ACTH production, an HCG production, and an inadequate ADH secretion. Metabolic paraneoplastic syndromes are characterized by an alteration of glucose, lipid, and electrolyte metabolism. The parameters for diagnosis of hypercalcemia are A calcium level >10.5 mEq/l, clinical symptoms (i.e., asthenia, anorexia, itch, polydipsia, and dehydration), organ-related signs, in particular renal signs (polyuria, lithiasis, variable grade of renal failure), gastrointestinal signs (nausea, vomiting, constipation, paralytic ileum), cardiac signs (arrhythmia, bradycardia, P-R elongation), and neuromuscular signs (hyporeflexia, somnolence, obfuscation). The diagnosis of hypoglycemia is clinical and it is based on asthenia, confusion, swelling, and shudder. Hyperuricemia can lead to an acute uratic nephropathy.

*Hematologic Paraneoplastic Syndromes*: In chronic anemia the hemoglobin level is usually not inferior to 9 g/dL. Laboratory examinations show reduced levels of iron and hyper-transferrinemia. Clinical characteristics are fatigue, dyspnoea, tachycardia, and all the other typical signs and symptoms of anemia [4,5]. Leukocytosis is characterized by an increase of leukocytes. Differential diagnosis with chronic myeloid leukemia consists in detecting myeloid blasts in the peripheral smear, with the absence of splenomegaly, thrombocytosis, and Philadelphia chromosome. On the other hand, leukopenia is characterized by a decrease of leukocytes with subsequent susceptibility to infections.

*Coagulation*: VTE may be asymptomatic; in some cases, it can be characterized by edema and pain.

Clinical features of pulmonary embolism are dyspnoea, tachypnoea, pain, and cough. DIC may be characterized by hemorrhage that can be acute or subacute and generally involves the CNS, the gastrointestinal tract, and the urinary tract. Laboratory examination shows low levels of platelets, fibrinogen, pro-thrombin, and coagulation factors, as well as a PT and a PTT extension.

## Therapeutic Principles

In all the cases, the best therapy is represented by the tumor treatment.

Epoetin can be employed in the treatment of anemia [4,5]. Heparin is used in the treatment of thrombosis.

# Parasternal Chondrodynia

►Tietze's Syndrome

# Parathyroid Hormone and Related Peptides

Geoffrey N. Hendy
Departments of Medicine, Physiology and Human Genetics, McGill University; Calcium Research Laboratory; Hormones and Cancer Research Unit, Royal Victoria Hospital, Montreal, QC, Canada

## Definition and Characteristics

Parathyroid hormone (PTH) is essential for the maintenance of calcium homeostasis, and an excess or deficiency can cause severe and potentially fatal illness. PTH is synthesized in the parathyroid glands in the neck, and after secretion, PTH exerts its effects directly on the skeleton and kidneys.

## Prevalence

Primary hyperparathyroidism, 1 in 1,000; secondary (renal) hyperparathyroidism, 1 in 1,000; and hypoparathyroidism, between 1 in 1,000 and 1 in 10,000.

## Genes

PTH is the product of a single-copy gene and in mammals has 84 amino acids. The gene, which encodes a larger precursor molecule of 115 amino acids, preproPTH, is organized into three exons. Exon I encodes the 5′ untranslated region (UTR) of the messenger RNA; exon II encodes the $NH_2$-terminal pre- or signal peptide and part of the short propeptide; and exon III encodes the $Lys^{-2}$-$Arg^{-1}$ of the prohormone cleavage site, the 84 amino acids of the mature hormone, and the 3′-UTR of the mRNA (Fig. 1).

The gene for PTH-related peptide (PTHrP), a widely expressed cytokine, has a similar organization with the same functional domains – the UTR, preprosequence of the precursor peptide, and the prohormone cleavage site and most or all of the mature peptide – being encoded by single exons. For the PTHrP gene, exons encoding alternative 5′ UTRs, carboxyl-terminal peptides, and 3′ UTRs may also be present depending on the species.

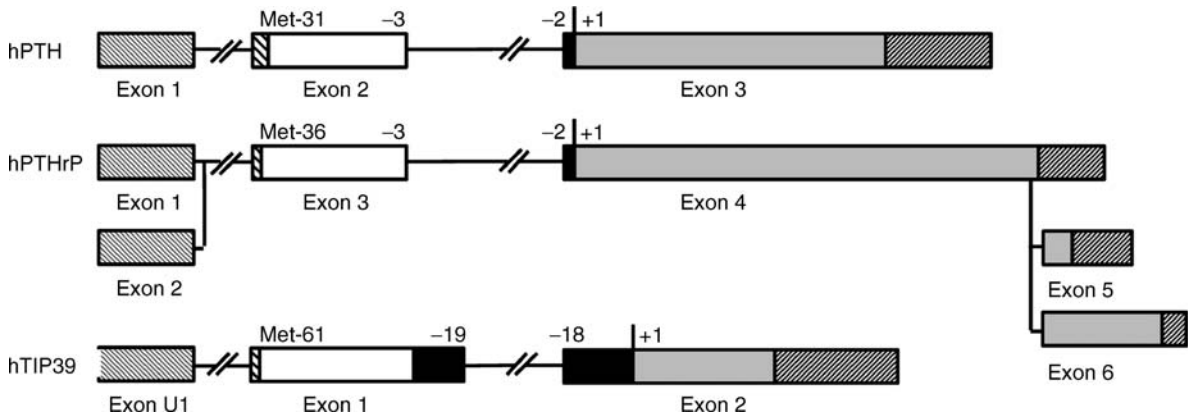
The PTH and PTHrP genes map to chromosome 11p15 and chromosome 12p12.1–11.2, respectively. Because of the similarity in $NH_2$-terminal sequence of their mature peptides, their gene organization, and chromosomal locations, it is likely that the PTH and PTHrP genes evolved from a single ancestral gene.

The gene for the neuromodulator, tuberoinfundibular peptide of 39 residues (TIP39), a more distantly related member of the gene family, resides on chromosome 19q13.33. The TIP39 gene shares organizational features with the PTH and PTHrP genes having one exon encoding the 5′ UTR, one encoding the precursor leader sequence, and one encoding the prohormone cleavage site and the mature peptide.

## Molecular and Systemic Pathophysiology

*Hyperparathyroidism*: Abnormally increased parathyroid gland activity may be primary or secondary. Primary hyperparathyroidism is associated with hyperplasia and neoplasia, the latter predominantly adenomas; parathyroid carcinoma is extremely rare. Parathyroid adenomas are monoclonal, involving molecular genetic derangements, such as loss of the multiple endocrine neoplasia (MEN) type 1 gene on chromosome 11q13, which encodes a tumor suppressor called menin, or overexpression of the cyclin D1 gene on chromosome 11q. Hyperparathyroidism may occur as part of rare familial syndromes including MEN 1, MEN 2A, familial hypocalciuric hypercalcemia (FHH), and neonatal severe hyperparathyroidism (NSHPT). Heterozygous and homozygous inactivating mutations in the parathyroid calcium-sensing receptor (CASR) gene, located on chromosome 3q13.3–21, cause FHH and NSHPT, respectively. Mutations in the CASR gene itself do not contribute to sporadic parathyroid tumorigenesis, although CASR expression is often reduced in parathyroid tumors, Parafibromin, the product of the tumor suppressor gene associated with the hyperparathyroidism-jaw tumor syndrome and some cases of familial isolated hyperparathyroidism, is implicated in sporadic parathyroid carcinoma.

Secondary hyperparathyroidism occurs when extracellular calcium and/or 1,25-dihydroxyvitamin D levels fall



**Parathyroid Hormone and Related Peptides. Figure 1** Comparison of the structural organization of the human PTH, PTHrP, and TIP39 genes. Exons are boxed: from left to right, stippled and hatched boxes denote 5′UTRs, white boxes denote presequences, black boxes denote prosequences, light gray stippled boxes denote mature polypeptide sequences, and dark gray stippled boxes denote 3′UTRs. +1 denotes the beginning of the mature polypeptide. [From Hendy GN (2005) Calcium-regulating hormones. Vitamin D and parathyroid hormone. In: Melmed S, Conn PM (eds) Endocrinology: basic and clinical principles, 2nd edn. Humana Press Inc., Totowa, NJ pp 283–299.]

below normal, as in chronic renal disease or vitamin D deficiency. Tertiary hyperparathyroidism ensues when a parathyroid adenoma arises from the secondary hyperplasia caused by chronic renal failure.

Excess circulating PTH leads to altered function of bone cells, renal tubules, and gastrointestinal (GI) mucosa. This may result in kidney stones and calcium deposits in renal tubules, and decalcification of bone, resulting in bone pain and tenderness and spontaneous fractures. The hypercalcemia may also lead to muscle weakness and GI symptoms.

*Hypoparathyroidism*: The most common cause of hypoparathyroidism, in which the deficiency of PTH secretion results in hypocalcemia and hyperphosphatemia, is surgical excision of, or damage to, the parathyroid glands. Hypoparathyroidism may be due to metabolic disease such as mitochondrial myoneuropathies, inborn error of oxidative fatty acid metabolism or metal storage disorders. Isolated or idiopathic hypoparathyroidism develops as a solitary endocrinopathy: familial forms occur with either autosomal-dominant, autosomal-recessive, or X-linked recessive modes of inheritance. Familial autosomal hypoparathyroidism can be due to inactivating mutations in the PTH gene, activating mutations in the CASR gene, or inactivation of the gene encoding the transcription factor glial cell missing-2. Hypoparathyroidism may also occur as part of a pluriglandular autoimmune disorder (AIRE gene) or as a complex congenital defect, including the DiGeorge (Tbx1 transcription factor and other genes), autosomal-recessive Kenny-Caffey or Sanjad-Sakati (tubulin-specific chaperone E gene), and Barakat or HDR (hypoparathyroidism, nerve deafness, and renal dysplasia) (GATA3 transcription factor gene) syndromes.

## Diagnostic Principles

*Primary Hyperparathyroidism*: Primary hyperparathyroidism must be differentiated from other causes of hypercalcemia such as humoral hypercalcemia of malignancy, vitamin D or vitamin A intoxication, milk-alkali syndrome, granulomatous disorders (especially sarcoidosis), immobilization of patients with a pre-existing high bone turnover state such as adolescence, thyrotoxicosis, Paget's disease and treatment with thiazide diuretics or lithium. PTHrP is the major (although not the only) causative agent in the humoral hypercalcemia of malignancy.

*Hypoparathyroidism*: Acute hypocalcemia can be life threatening and present with seizures, tetany or cardiac arrhythmias.

## Therapeutic Principles

*Hyperparathyroidism*: Criteria for surgery in hyperparathyroidism have been established by a consensus conference and a follow-up workshop of the National Institutes of Health. Candidates for surgery are those having one or more of the following: hypercalcemia >11.6 mg/dL; hypercalciuria >400 mg/day; kidney stones; reduced bone density or age <50 years. Asymptomatic patients who are managed conservatively with twice yearly serum calcium and urinary calcium excretion determinations and annual bone densitometry generally do well since the progression of the disease is usually quite slow.

*Hypoparathyroidism*: Intravenous calcium can alleviate the symptoms of hypocalcemia rapidly although this should be done cautiously to minimize risks associated with this route of administration. With chronic hypocalcemia, oral supplementation with

calcium and vitamin D analogues is usually employed. Careful monitoring of the patient's calcium homeostatic status is necessary as, with under replacement, cataracts and symptoms of numbness and tingling can occur. With over replacement, there is the risk of nephrocalcinosis and nephrolithiasis.

Idiopathic Parkinson syndrome; IPS

## Definition and Characteristics

Parkinson's disease (PD) is a progressive neurodegenerative disorder. The cardinal symptoms of PD include bradykinesia, rigidity, resting tremor and impairment of postural stability. In addition, non-motor symptoms such as depression, dementia, autonomic failure or pain frequently occur in patients with PD. Motor symptoms are linked to the loss of dopaminergic nigro-striatal neurons while the pathogenesis of non-motor symptoms is less clear. Degeneration of nigral dopaminergic neurons is usually accompanied by the formation of cytoplasmic α–synuclein-positive inclusion bodies (Lewy bodies) in the remaining neurons [1,2]. Due to this neuropathological hallmark, PD is classified as a synucleinopathy (together with multiple system atrophy (MSA), dementia with Lewy-bodies (DLB) and others).

## Prevalence

PD is one of the most frequent neurodegenerative disorders and accounts for approximately 80% of all patients with a parkinsonian syndrome. The incidence is approximately 10–20 patients per 100,000. The prevalence is estimated as 0.1–0.3% in the general population with a gender ratio of 1:1.5 (female:male). Age is an important risk factor. Surprisingly, smoking has been associated with a decreased risk to develop PD [3].

## Genes

Several loci and mutations have been identified in familial parkinsonism (Table 1). PARK1 was the first locus which was detected as associated with PD in a large kindred with familial parkinsonism with autosomal-dominant inheritance. Subsequently, various point mutations in the SNCA gene located within this locus were identified. However, not only mutations of this gene but also multiplication (triplication) can induce parkinsonism (which was formerly reported as PARK4 locus). The SNCA gene encodes α-synuclein, a protein which is accumulated in Lewy bodies and is localized on the short arm of chromosome 4 (4q21–23). The clinical presentation is similar to that of the sporadic disorder.

The locus PARK2 (6q25–27) includes a gene encoding for an ubiquitin E3 ligase termed parkin. More than 70 different autosomal-recessive mutations have been identified that account for >25% of patients with parkinsonism and disease onset before age 30. Clinical symptoms also include focal dystonia and diurnal fluctuations.

The locus PARK5 on chromosome 4p is very rarely associated with autosomal-dominant PD, and a mutation of an ubiquitin C-terminal hydrolase gene which is located within this locus was detected in one family with PD.

The PD locus PARK6 on chromosome 1p35–36 relates to mutations of a mitochondrial kinase gene (PINK1). First mutations were identified in patients with early onset autosomal-recessive inheritance. However, heterozygous gene carriers may develop late onset parkinsonism.

**Parkinson's Disease. Table 1** Synopsis of familial (monogenetic) parkinsonian syndromes

| Name of the locus | Locus | Gene, protein | Mode of inheritance | Age at onseta | Comments |
|---|---|---|---|---|---|
| PARK1 [OMIM: 168601] | 4q21–23 | *SNCA*, α-Synuklein | ad | Middle | Lewy bodies (diffuse pattern), fast progression, postural tremor, late onset dementia |
| PARK2 [OMIM: 600116] | 6q25–27 | *Parkin*, Parkin | ar | Juvenile | Unspecific nigral degeneration, rare Lewy boy pathology, slow progression, focal dystonia |
| PARK3 [OMIM: 602404] | 2p13 | – | ad | Late | Lewy bodies (typical pattern in brain stem), dementia |
| PARK4 | | | | | Same gene as PARK1 locus, refer to PARK1 locus |
| PARK5 [OMIM: 191342] | 4p14 | *UCH-L1*, UCH-L1 | | Middle | No neuropathological data, only one family |
| PARK6 [OMIM: 605909] | 1p35–p36 | *PINK1*, PINK1 | ar | Early | No neuropathological data, slow progression, tremor, dystonia |
| PARK7 [OMIM: 606324] | 1p36 | *DJ-1*, DJ-1 | ar | Early | Heterozygous cases with Lewy bodies, slo progression, focal dystonia |
| PARK8 [OMIM: 607060] | 12p11–q13 | *LRRK2*, Dardara (LRRK2) | ad, sporadic | Early | Lewy bodies, tauopathy, levodopa responsive |
| PARK9 [OMIM: 606693] | 1p36 | – | Ar | Early | Spasticity, supranuclear palsy, dementia, also: Kufor-Rakeb-Syndrome |
| PARK10 [OMIM: 606852] | 1p32 | – | | Late | Iceland population study |
| PARK11 [OMIM: 607688] | 2q36–37 | – | | Late | Sibling study |
| Nurr1 [OMIM: 601828] | 2q22–23 | *NR4A2*, Nurr1 | Ad | Late | Lewy bodies (brain stem) |
| Synphilin-1 [OMIM: 603779] | 5q23 | *SNCAIP*, Synphilin-1 | | Late | – |
| NF-M | 8p21 | *NF-M*, NF-M | | Juvenile | Only one family, late-onset dementia |
| Mitochondrium [OMIM: 252010] | | NADH Komplex 1 | Mitochondrial | Late | – |

ad, autosomal-dominant; ar, autosomal-recessive; Nurr1, Nuclear receptor-related 1, UCH-L1, Ubiquitine C-terminal hydrolase L1, NF-M, neurofilament medium, LRRK2, Leucine-rich repeat kinase 2; juvenile onset (mean age at onset <25 years), early onset (mean age at onset 25–45 years), middle onset (mean age at onset 46–60 years), late onset (mean age at onset >60 years).

The frequency of these mutations is not yet clear. Clinical symptoms seem to be similar to those elicited by parkin mutations, although focal dystonia may be less frequent.

PARK7 was mapped to chromosome 1p36. The gene product is an RNA binding protein termed DJ-1, which is activated by oxidative stress. Mutations in this gene are rare and induce early onset and slowly progressive autosomal-recessive parkinsonism.

PARK8 seems to be the locus most relevant to sporadic PD. Many mutations in the respective gene, leucine rich repeat kinase 2 (LRRK2), have been identified in families with autosomal-dominant late onset parkinsonism. Up to 70% of families with late onset parkinsonism may carry mutations in this gene. Due to a limited penetrance also ~2% of patients with sporadic disease carry such mutations. LRRK2 is a so-called ROCO gene with many different functional domains. The most frequent mutation (Gly2019Ser) occurs within a MAP kinase kinase kinase domain. Clinical symptoms are variable with many patients presenting with a typical PD syndrome, but others may present with predominant dementia, dystonia, etc. Also neuropathological findings may vary within the same family from classical Lewy body disease to abnormal Tau pathology.

PD has been associated with genetic polymorphisms of various genes, including genes of the dopamine metabolism, the dopamine transporter gene and the gene encoding for α–synuclein (SNCA gene). However, most of these results were not confirmed by other association studies.

## Molecular and Systemic Pathophysiology

The hallmark of PD is a loss of dopaminergic neurons within the substantia nigra pars compacta with

cytoplasmic inclusions in the remaining cells and a subsequent dopamine deficiency in the striatum. This dopamine deficiency leads to an increased activity of inhibitory output neurons of the basal ganglia loop located in the medial segment of the globus pallidus. Except for familial syndromes, the pathogenesis remains unclear, although there are also patients with parkinsonism following specific infections (von-Economo encephalitis) or intoxications (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MPTP). The latter compound induces mitochondrial dysfunction via blockade of complex I in dopaminergic neurons. Whether this mechanism is also relevant to patients with sporadic disease is still not clear. However, several lines of evidence exist for a pivotal role of reduced mitochondrial activity, increased oxidative stress, and impaired function of the ubiquitin-proteasome system in the pathogenesis of PD. It is in contrast unclear how these mechanisms fit into a global pathogenetic concept.

## Diagnostic Principles

The diagnosis is primarily clinical. Established criteria are based on the cardinal symptoms bradykinesia, resting tremor, rigidity and loss of postural reflexes as well as asymmetry and responsiveness to levodopa [4,5]. Degeneration of dopaminergic neurons in the substantia nigra may be proven by nuclear medicine techniques and ligands that specifically bind to these neurons.

## Therapeutic Principles

At present, dopamine replacement therapy remains the gold standard. Levodopa as a metabolic precursor of dopamine is the most frequently used antiparkinsonian drug. It is very effective and well tolerated, but during long-term treatment several side effects occur including motor fluctuations, dyskineasias and psychiatric symptoms. Dopamine agonists are chemical compounds which directly act on dopamine receptors, while MAO-B inhibitors and COMT-inhibitors block levodopa and/or dopamine catabolism. Amantadine as an inhibitor of glutamate receptors of the NMDA type and displays mild antiparkinsonian effects and additionally some antidyskinetic activity. The use of anticholinergics seems obsolete. Advanced patients can be treated via modulation of the neuronal activity in the subthalamic nucleus using deep brain stimulation.

# Paroxismal Nocturnal Hemoglobinuria

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

## Definition and Characteristics

Acquired hematologic disorder. The mean age at presentation is 30–40 years (range 6–82) and the median survival at diagnosis is 10–15 years. A deficiency of the glycosylphosphatidylinositol (GPI) anchor in red blood cells leads to the absence of several GPI-linked proteins, which makes these cells more sensitive to the lytic effect of complement. Frequent hemolytic episodes and thrombosis in hepatic, other intraabdominal, cerebral, and peripheral veins as well as marrow aplasia are clinical manifestations of the disease. Progression to leukemia or a myelodysplastic syndrome may occur.

## Prevalence

The prevalence is estimated a few cases per million.

## Genes

Phosphorylinositol glycan class A (PIG-A), Xp22.1.

## Molecular and Systemic Pathophysiology

A number of cell surface proteins are missing in PNH. Some of these, CD59 and CD55, protect red blood cells against the hemolytic action of complement. The GPI anchor is essential for a number of proteins to attach to the cell membrane. The observation that all missing proteins in PNH are GPI related implicates that a defect in the complex biosynthesis of GPI must be involved in PNH pathogenesis. The first step in GPI synthesis, the transfer of N-acetylglucosamine to phosphatidylinositol, is defective in PNH patients. The PIG-A gene and

three other genes are involved in this transfer. A number of mutations in the PIG-A gene, which led to partial or complete GPI deficiency, have been observed in PNH patients. In some patients, multiple erythroid clones have been identified. All patients with PNH have mutations of the PIG-A gene in hematopoietic stem cells, but a certain predisposition (which is yet to be identified) is needed for the expansion of PNH cells.

The pathophysiology of thrombosis in PNH is not fully understood, but may involve pro-coagulant platelet microvesicle formation (platelets in PNH lack complement activation regulatory proteins as well), increased prothrombinase activity as well as impaired fibrinolysis (due to deficiency of the GPI-linked urokinase plasminogen activator receptor of monocytes).

### Diagnostic Principles

Lysis of erythrocytes by acidified serum is demonstrated in the Ham test, the classic test that is still a specific and relatively sensitive test. With the use of flow cytometry quantification of specific GPI-anchor binding using fluorescent-labeled inactive toxin aerolysin (FLAER), it is possible to detect small PNH clones.

### Therapeutic Principles

The treatment of anemia is supportive. Iron supplementation, to compensate the iron loss due to hemosiderinuria, and folic acid supplementation are recommended, with red blood cell transfusions only when necessary. Prednisone reduces the rate of hemolysis. Also androgens are effective in reducing anemia. Treatment with an antibody against terminal complement protein C5, eculizumab, reduced intravascular hemolysis, hemoglobinuria, and the need for transfusion in a recent study. Bone marrow transplantation is generally reserved for patients with life-threatening disease.

Paroxysmal dystonic choreoathetosis; PDC; historically: Extrapyramidal epilepsy; Striatal epilepsy; Tonic seizures; Reflex epilepsy; Periodic dystonia

### Definition and Characteristics

Intermittent attacks of involuntary movements, usually dystonia, chorea or ballism, induced by trigger factors including sudden movements (paroxysmal kinesigenic dyskinesia, PKD), prolonged exercise (paroxysmal exercise-induced dyskinesia, PED) or alcohol and coffee (paroxysmal non-kinesigenic dyskinesia, PNKD) or during sleep (nocturnal hypnogenic dyskinesia, PHD) according to the Demirkiran and Jankovic classification [1,2]. Onset of primary forms is usually in childhood.

*PKD*: up to 30–100 very brief (seconds) attacks per day triggered typically by sudden movement or sudden increase in speed, amplitude, force or strength, startle, sound, photo stimulation, vestibular stimulation, hyperventilation or stress. Speech disturbance in 30%. Sometimes aura. Refractory period (20 min).

*PNKD*: attacks (30 min–6 h) induced by alcohol, coffee, coke, tobacco, emotional excitement, hunger, concentration or fatigue several times per week or per year. 1/3 secondary cause.

*PED*: Attacks (2 min–2 h) induced by prolonged or sustained exercise usually affecting the feet (80%).

*PHD*: Intermittent (sometimes complex) attacks (30–60 s) often in clusters during non-REM sleep, particularly stages 2–3, causing sleep fragmentation. Manifestation of nocturnal frontal lobe epilepsy (NFLE).

*Other paroxysmal disorders*: Paroxysmal ataxias (episodic ataxia 1 and 2); tonic spasms in MS; torticollis in infancy; Sandifer's syndrome; paroxysmal superior oblique myokymia; paroxysmal tonic conjugate deviation of the eyes.

## Prevalence

Data limited, overall rare. One report states 92 cases among 12,063 patients (0.76%) seen over 19 years.

## Genes

*PKD*: 70% familial, autosomal dominant. Heterogeneity. Linkage to at least two loci on chromosome 16. A third locus must exist as not all cases link to chromosome 16. Proximity or overlap with infantile convulsions (ICCA syndrome) and rolandic epilepsy, paroxysmal exercise-induced dyskinesia and writer's cramp (RE-PED-WC).

*PNKD*: autosomal dominant. Missense mutation (A7V and A9V) in the myofibrillogenesis regulator gene (MR-1) (2q33–35), associated with the myofibril contractile apparatus. A separate condition "paroxysmal choreoathetosis/spasticity" has been mapped to a region of 2 cM between D1S443 and D1S197 on chromosome 1p.

*PHD*: NFLE (eponym "autosomal dominant nocturnal frontal lobe epilepsy" (ADNFLE)), see chapter on "Idiopathic focal epilepsies."

*PED*: genetic defects not known.

## Molecular and Systemic Pathophysiology

*PNKD*: Mutations cause alteration in the amino-terminal α-helix [3]. There are two isoforms, MR-1S and MR-1L. The MR-1S isoform is ubiquitously expressed in peripheral tissues and the brain and shows diffuse cytoplasmic and nuclear localization. The MR-1L isoform is exclusively expressed in the cell membrane of the brain. Within the mouse brain, mRNA expression (detected by BRP17) was allocated to the substantia nigra, albeit at low levels, apart from other areas (red nucleus, mammillary nucleus, raphe nucleus, interpeduncular nucleus, the periaqueductal grey, forebrain areas (cortex, hippocampus, dentate gyrus and medial and lateral habenula) and ventral regions including the piriform cortex, amygdala and the ventromedial hypothalamic nucleus, cerebellum (granule cells and Purkinje cell layers, particularly in the lateral lobules and the paraflocculus) and the spinal cord) [3]. It has been suggested that the regions involved in motor control (basal ganglia, motor cortex and cerebellum) or rather their dys-function may play an important role in PNKD [3].

There is no published information on human gene function but homology of MR-1L with the hydroxyacylglutathione hydrolase (HAGH), a member of the zinc metallohydrolase enzyme family, was found by gene bioformatic analysis (41% identity) [3]. All zinc-binding residues were conserved. HAGH plays a role in the detoxification pathway of methylglyoxal, a compound present in coffee and alcoholic beverages both of which can induce attacks in patients with PNKD.

*PHD [4]*: see chapter on ►Idiopathic focal epilepsies.

## Diagnostic Principles

Diagnosis depends on a detailed history, family history and clinical characterization of the type of dyskinesias. Secondary causes, i.e. demyelination, vasculopathy, infectious disease (HIV, CMV), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction (diabetes mellitus, hyperthyroidism, hypoparathyroidism, pseudohypoparathyroidism), neoplasm, Chiari malformation, cervical syringomyelia and cerebral palsy must be excluded.

Ictal and interictal EEG and sleep-EEGs usually show normal or transient epileptic discharges. Basal ganglia hyperperfusion occurs contralaterally to the side of attacks (PKD and PNKD) or anterior cingulate gyrus (PHD) on SPECT.

## Therapeutic Principles

*PKD*: Anticonvulsants, carbamazepine as first choice but also levetiracetam, oxcarbazepine, phenytoin, topiramate, barbiturates or acetazolamide.

*PNKD*: Triggering factors should be avoided. The response to antiepileptics is less dramatic than in PKD. Benzodiazepines, sodium valproate, haloperidol, gabapentin or acetazolamide are used.

*PED*: Gabapentin, clonazepam.

*PHD*: Carbamazepine, phenytoin and acetazolamide.

## Patent Ductus Arteriosus

Adriana C. Gittenberger-de Groot, Regina Bökenkamp, Marco C. DeRuiter
Department of Anatomy and Embryology, Leiden University Medical Center, Leiden, The Netherlands

### Synonyms

Persistent ductus arteriosus; PDA

### Definition and Characteristics

Normal ductal closure after birth consists of physiological contraction followed by irreversible anatomical closure. When this closing process is absent or delayed, we talk about patent ductus arteriosus (PDA). If still present in a full-term infant beyond the age of 3 months,

it is referred to as persistent ductus arteriosus. There is no strict use of the terms clinically. The PDA is histologically characterized by the close adherence between the endothelium and a subendothelial elastic lamina. Under pathological circumstances, this is an additional lamina on top of the intimal cushion, whereas in premature infants without cushion formation and delayed closure this is the regular internal elastic lamina [1,2].

## Prevalence

PDA occurs in 13.5% of all heart defects at birth. Data on the prevalence of PDA in full-term infants beyond the age of 3 months are not available. PDA can be found as an isolated anomaly and accompanying various congenital cardiac malformations.

## Genes

PDA in full-term infants is believed to be multifactorial. Familial recurrence and syndromic forms have been reported. Autosomal-recessive PDA could be linked to chromosome 12q24 [3]. In the autosomal-dominant trait of Char syndrome, the TFAP2B gene has been mapped to the critical region 6p12–21, encoding a neural crest-related transcription factor [4]. In a strain of beagles, PDA is a dominant inherited anomaly with histopathological abnormalities of the elastin deposition similar to the human PDA cases. Mutations in the human MYH11 (myosin heavy chain) genes are demonstrated to cause thoracic aortic aneurysms and/or aortic dissection (TAAD) and PDA [5].

## Molecular and Systemic Pathophysiology

The PDA is a vascular shunt between the systemic circulation and the pulmonary circulation. The pathophysiological consequences of these malformations vary with the size of the ductus and additional cardiac anomalies. In small- to moderate-sized isolated PDA (Fig. 1a), the continuous left-to-right shunt leads to volume overload of the left side of the heart. The pulmonary vascular bed is not damaged by this restrictive ductus, and pulmonary pressure remains low. In large PDA (Fig. 1b) with low pulmonary vascular resistance, pulmonary congestion and medically untractable heart failure can develop.

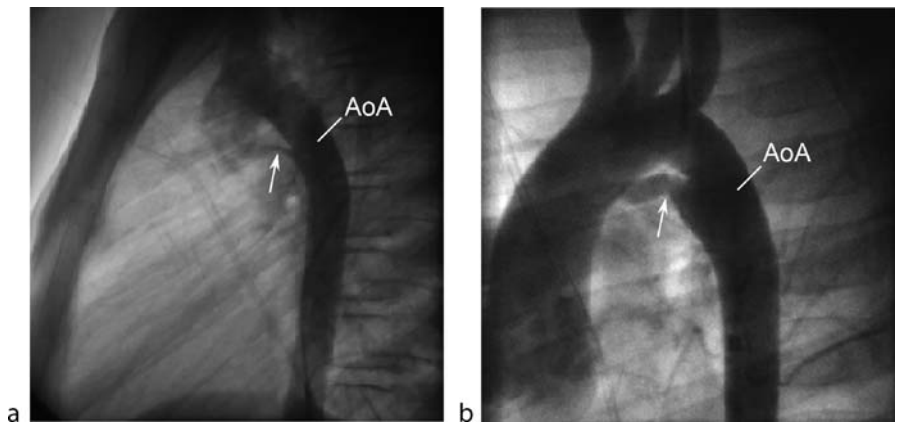
As a reaction, pulmonary arteriolar damage occurs, pulmonary vascular resistance increases, and the shunt can disappear. When the pulmonary vascular resistance exceeds the systemic vascular resistance, the ductal shunt can reverse, leading to cyanosis. Right ventricular failure due to irreversible pulmonary hypertension will develop as a final complication of PDA.

## Diagnostic Principles

Beyond the neonatal period, clinical diagnosis of uncomplicated PDA is suspected in presence of the pathognomonic "machinery" murmur. ECG changes reflect the pathophysiological conditions and show left ventricular hypertrophy in small- to moderate-sized PDA and biventricular hypertrophy in large PDA and right ventricular hypertrophy in patients after shunt reversal. X-ray shows the combination of cardiomegaly and pulmonary engorgement with large left-to-right shunt and the typical dilated central pulmonary arteries and rarefied peripheral pulmonary arteries with a normal-sized heart in PDA with shunt reversal. The combination of two-dimensional and Doppler-echocardiography including color-flow-mapping is conclusive in the vast majority of patients with PDA. During cardiac catheterization, oxygen step-up in the pulmonary artery, angiographic visualization of the PDA, and direct catheterization of the ductus document the presence of PDA.

## Therapeutic Principles

Most of uncomplicated PDA are amenable to transcatheter closure with endovascular devices. Surgical closure



**Patent Ductus Arteriosus. Figure 1** Angiocardiograms of the persistent ductus arteriosus (PDA). Arrows indicate a small PDA in (a) and a large PDA in (b) connecting the pulmonary trunk to the aortic arch (AoA).

of isolated PDA is indicated in symptomatic small infants after full-term birth and if medical therapy using the prostaglandin synthesis inhibitors, indomethacin and ciboprofen, is contraindicated or has failed in premature infants [2]. In complicated PDA with irreversible pulmonary hypertension ductal closure is contraindicated. In case of ductus-dependent anomalies, PDA is medically maintained by prostaglandin treatment that inhibits ductal contraction.

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Patent vitelline duct; Enteroumbilical fistula; Umbilical enteric fistula

## Definition and Characteristics

A patent omphalomesenteric duct typically presents with an umbilical discharge which is often feculent, but may also be bilious or serous (Fig. 1) [1].

Less commonly, it presents with an umbilical mass. If the patent omphalomesenteric duct is large enough, prolapse or intussusception of the small bowel may occur [2]. This may necessitate urgent surgical intervention to prevent infarction of the bowel [2]. Other complications include bleeding from the umbilical mucosa, umbilical infection, and the potential for malignancy [2].

## Prevalence

Anomalies of the omphalomesenteric duct occur in approximately 2% of the population. Patent omphalomesenteric duct accounts for about 2% of the omphalomesenteric duct anomalies. The sex distribution is equal.

## Genes

Plastin 1 (also known as Fimbrin) is a distinct plastin isoform which is specifically expressed at high levels in the small intestine [3]. It has been hypothesized that plastin 1 (PLS1) is a candidate gene for the persistence of omphalomesenteric duct.

## Molecular and Systemic Pathophysiology

In fetal life, the omphalomesenteric duct connects the primitive mid-gut to the yolk sac of the embryo through the umbilical cord. The duct forms a conduit for nourishment until the placenta is formed. The omphalomesenteric duct contains the omphalomesenteric arteries which nourish the yolk sac and the omphalomesenteric veins which drain into the sinus venosus. As the placental circulation increases, the omphalomesenteric duct involutes and disappears by the 7th–9th week of fetal life [1]. One murine study suggests that absence of inhibitory mesodermal interactions during development might result in a patent omphalomesenteric duct [4]. Its persistence may result in a completely patent omphalomesenteric duct (umbilical enteric fistula); a partially patent omphalomesenteric duct (an umbilical sinus will result if the peripheral portion is involved; a vitelline cyst, if the intermediate portion is involved; and a Meckel diverticulum, if the enteric portion is involved); a mucosal remnant at the umbilicus (umbilical polyp); and a congenital band (obliterated omphalomesenteric duct).

## Diagnostic Principles

Umbilical discharge may be due to a patent omphalomesenteric duct, a patent urachus, or an umbilical granuloma. The nature of the discharge can often give

**Patent Omphalomesenteric Duct. Figure 1** A newborn infant with a patent omphalomesenteric duct, presenting with fecal discharge from the umbilicus.

clue to the diagnosis. A patent omphalomesenteric duct should be suspected if an "umbilical granuloma" fails to respond to cauterization with silver nitrate or the presence of a non-vascular lumen in a transected umbilical cord. If the diagnosis is in doubt, a contrast study via the stoma or ultrasonography can be used to delineate the nature of the lesion.

### Therapeutic Principles

A patent omphalomesenteric duct should be ligated and excised. Perioperative intravenous antibiotics should be given. Full exploration and identification of all umbilical structures should be performed [5].

## Patent Vitelline Duct

►Patent Omphalomesenteric Duct

## Pathological Gambling

Undine E. Lang
Department of Psychiatry and Psychotherapy, Charité University Medicine Berlin, Berlin, Germany

### Synonyms

Impulse control disorders; Addiction

### Definition and Characteristics

Pathological gambling is classified in the DSM-IV as a disorder of impulse control with the essential feature being recurrent and maladaptive gambling behavior. Pathological gambling is a male dominated chronic progressive disease characterized by the overwhelming wish to gamble, with harmful consequences, thus sharing typical features with other impulse control disorders like trichotillomania, kleptomania or pyromania [1].

### Prevalence

With rates of about 0.2–3.4%, pathological gambling is a prevalent and highly disabling impulse control disorder, which also represents a form of non-pharmacological addiction. Gambling is strongly connected with antisocial personality disorder and substance abuse disorder but associations exist with depression, cyclothymia, bipolar disorder, alcohol, tobacco and attention deficit hyperactivity and with obsessive-compulsive, antisocial, narcissistic and borderline personality disorders.

## Genes

As with most other behavioral syndromes, pathological gambling is a multifactorial, polygenic disorder. Male pathological gamblers in particular have up to 20% of pathological gamblers in their first-degree relatives and twin studies also indicate that genetic factors play a role in pathological gambling [1,2]. In accordance with therapeutic efforts and several neurochemical findings in gamblers, defects in a number of neurotransmitters have been implicated including dopamine, norepinephrine, serotonin and endorphins. Several specific genes have been implicated as risk factors, including the DRD2, DRD1, DRD4, DAT1, TPH, ADRA2C, NMDA1 and PS1 genes [2–4].

## Molecular and Systemic Pathophysiology

Increased impulsiveness and behavioral disinhibition is a key feature of several pathological states, i.e., attention deficit hyperactivity disorder, drug addiction, pathological gambling and frontal lobe syndrome. A pathological modulation of frontal lobe function was presumably involved in all of these conditions. In fact, there is evidence that an interplay between several competing decision making networks, which is involved in impulsive decisions exists in the brain. While economical planning is mediated by lateral prefrontal and parietal areas, immediate rewards seem to recruit paralimbic areas associated with midbrain dopamine neurons, including the nucleus accumbens, medial orbitofrontal cortex and medial prefrontal cortex. Common "timeless" decisions might be modulated by the prefrontal cortex and posterior parietal cortex, whereas general impatience craving for an immediate reward might be generated in limbic areas.

There is ample evidence that the modulation of dopamine levels as well as dopaminergic areas in the brain affect impulsive choice behavior. Several studies found that systemic administration of $D_2$ antagonists, but not $D_1$ antagonists increased impulsive choice behavior and there is increasing awareness that pathological gambling can occur as a complication of Parkinson's disease in up to 10% of patients mostly those receiving dopamine agonists.

Lesions of the main serotonergic source in the brain, the rat raphe nucleus result in preference for immediate rewards and correspondingly, selective 5-HT reuptake inhibitors and 5-HT agonists decrease impulsive behavior in pigeons and rats [3].

## Diagnostic Principles

DSM-IV diagnostic criteria of persistent and recurrent maladaptive gambling behavior are indicated by at least five of the following [5]:

1. Is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture or thinking of ways to get money with which to gamble).
2. Needs to gamble with increasing amounts of money in order to achieve the desired excitement.
3. Has repeated unsuccessful efforts to control, cut back or stop gambling.
4. Is restless or irritable when attempting to cut down or stop gambling.
5. Gambles as a way of escaping from problems or of relieving a dysphoric mood (feelings of helplessness, guilt, anxiety, depression).
6. After losing money gambling, often returns another day in order to get even ("chasing" one's losses).
7. Lies to family members, therapist or others to conceal the extent of involvement with gambling.
8. Has committed illegal acts, such as forgery, fraud, theft or embezzlement, in order to finance gambling.
9. Has jeopardized or lost a significant relationship, job or educational or career opportunity because of gambling.
10. Relies on others to provide money to relieve a desperate financial situation caused by gambling [5].

## Therapeutic Principles

Several outcome studies have shown cognitive-behavioral therapy to be effective in the treatment of pathological gambling. Pharmacological treatment has been proven to be effective partly depending on the main psychopathological background of the gambling. Based on this clinical concept, gamblers have been divided into three subgroups, the obsessive-compulsive subtype, the impulsive subtype and the addictive subtype. The obsessive-compulsive subtype, typically also displaying depressive and compulsive symptoms, might primarily respond to serotonin reuptake inhibitors and venlafaxine treatment.

In the addictive subtype, opioid antagonists such as naltrexone or nalmefene might serve as first line agents, while impulsive subtype patients might respond best to mood stabilizers or bupropion [1].

# Pectus Carinatum

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Pigeon chest; Pigeon breast; Chicken breast

### Definition and Characteristics

Pectus carinatum is characterized by anterior protrusion of the chest wall and sternum, which is often accentuated by lateral depression of the costal cartilage (Harrison's groves) (Fig. 1).

When the protrusion is in the sternal manubrium, it is called a chondomanubrial deformity or "pigeon breast" [1]. On the other hand, when the protrusion occurs in the body of the sternum, it is called a chondrogladiolar deformity or "chicken breast" [1]. The deformity can be unilateral or bilateral. The latter can be symmetrical or asymmetrical. Torsion and angulation of the sternum is seen in 10% of cases. The deformity is usually mild but can be severe. In contrast to pectus excavatum which is usually noted at birth, pectus carinatum usually becomes apparent at about 3–4 years of age and progressively increases as the child grows. The deformity becomes much more severe during the period of most rapid growth in adolescence. Most patients are asymptomatic; occasional patients may have bone pain or tenderness at the site of protrusion. Unlike pectus excavatum, pectus carinatum does not appear to be associated with significant abnormalities of cardiovascular or respiratory function [2]. Pectus excavation is often an isolated malformation but can be a component manifestation in various genetic syndromes such as trisomy 18, Ehlers-Danlos syndrome, and Marfan syndrome [2]. Associated anomalies include scoliosis, kyphosis, coarctation of the aorta, and mitral valve disease.

### Prevalence

The overall prevalence is 1 in 1,700. The male to female ratio is 4:1 [1].

### Genes

A genetic component is suggested by the fact that approximately 25 to 30% of patients have a family history of chest wall defect [1]. It has been postulated that pectus carinatum might be due, at least in part, to defects in connective tissue genes such as fibrillin, collagen, and transforming growth factor ß [3]. Mutations in different homeobox (HOX) genes (e.g. HOXA11,

**Pectus Carinatum. Figure 1** A 2-year-old child with pectus carinatum.

HOXA13, HOXD10, and HOXD13) and balanced translocations affecting regulatory elements around the HOXD gene cluster might result in pectus carinatum [4].

## Molecular and Systemic Pathophysiology

Pectus carinatum results from overgrowth of the adjacent costal cartilage which push the sternum into an exaggerated anterior position. It may also result from sternal growth plate damage. The condition is usually congenital. Pectus carinatum may result from stenotomy, following treatment for pectus excavatum.

## Diagnostic Principles

The diagnosis is mainly clinical. X-ray and computed tomography may be used to determine the extent of the chest wall deformity. Torso models from optical imaging offer 3-D images of the chest wall deformity with no radiation exposure as an index of pectus deformities [5]. A preliminary study showed promising results for the use of torso surface measurements [5].

## Therapeutic Principles

The condition is often asymptomatic and treatment is usually not necessary. Orthotic bracing or surgery might be considered for cosmetic or psychological reasons [2]. Compliance is critical to the success of bracing [2]. Surgical treatment consists of costochondral resection of the deformed costal cartilages and sternal osteotomy [1,2]. Complications of surgical repair such as pneumothorax, excessive scarring, and acquired Jeune's syndrome are uncommon.

# Pectus Excavatum

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Funnel chest; Trichterbrust; Thorax en entonnoir

## Definition and Characteristics

Funnel chest is a depression deformity of the anterior chest wall and sternum (Fig. 1) [1].

The deformity may be mild, moderate or severe. Funnel chest is most commonly noted in infancy and usually progresses slowly as the child grows. Rapid progression of the deformity may occur during puberty. Most patients are tall and have an aesthetic habitus [2]. Deep inspiration commonly accentuates the severity of the deformity [2]. Funnel chest is often an isolated malformation but can be a component manifestation in various genetic syndromes (e.g. Marfan syndrome, Noonan syndrome, Ehlers-Danlos syndrome, Pierre Robin syndrome, Poland syndrome, Aarskog syndrome). Individuals with pectus excavatum may have reduced exercise tolerance and diminished cardiac index [3]. The depth and extent of the depression determine the degree of compromise of cardiac and pulmonary function. The deformity may be cosmetically unsightly and affected patients might have a poor self-esteem. Approximately 10% affected individuals have associated scoliosis.

## Prevalence

The incidence is between 1 in 400 and 1,000 live births [2,4]. The male to female ratio is 4:1 [4]. The condition is rare in blacks and Latinos [2].

## Genes

It has been postulated that pectus excavation might be due, at least in part, to defects in connective tissue genes such as fibrillin, collagen, and transforming growth factor β [4]. Mutations in different homeobox (HOX) genes (e.g. HOXA11, HOXA13, HOXD10, and HOXD13) and balanced translocations affecting

**Pectus Excavatum. Figure 1** A 15-year-old boy with pectus excavatum.

regulatory elements around the HOXD gene cluster might result in pectus excavatum [5].

### Molecular and Systemic Pathophysiology

Funnel chest can be congenital or acquired. The latter may be secondary to chronic upper airway obstruction such as enlarged adenoids and tonsils, laryngomalacia, rickets, abnormalities of the diaphragm producing posterior traction on the sternum, or external pressure applied for long periods against the anterior surface of the chest [1]. Congenital funnel chest is often sporadic and might result from intrauterine pressure. Majority of familial cases have a multifactorial mode of inheritance although an autosomal dominant trait has been described [1]. Biochemical studies have shown abnormalities in the structure of type 2 collagen in costal cartilage, abnormal levels of zinc, magnesium, and calcium, and a disturbance in collagen synthesis [4].

### Diagnostic Principles

The diagnosis is mainly a clinical one and no laboratory test is usually necessary.

### Therapeutic Principles

The condition is usually benign and no treatment is necessary. Surgical correction may be considered for cosmetic reason or when cardiopulmonary function is compromised. Pulmonary function tests, chest radiograph, electrocardiogram, echocardiogram and computed tomography of the chest are useful to determine the need for surgical correction. The minimally invasive Nuss technique has gained wide acceptance by the surgical community.

## Pelizaeus-Merzbacher Disease

►Leukodystrophy

## Pellagra

Muammer Seyhan
Department of Dermatology, Inonu University, Malatya, Turkey

### Synonyms

Niacin deficiency; Alpine scurvy; Mayidism; Maidism; Mal de la rosa; Mal rosso; Saint Ignatus' itch

### Definition and Characteristics

The term pellagra is derived from the Italian "pelle", and "agra", meaning "skin" and "rough", respectively (thickened rough skin) [1,2]. Pellagra can be either primary or secondary. The primary form results from inadequate dietary niacin and/or its precursor, tryptophan [3]. In the secondary form, other diseases/conditions interfere with its absorption and/or processing despite adequate quantities in the diet [1,2]. Pellagra is characterized by four classic symptoms, traditionally remembered as the mnemonic of the 4D: dermatitis, diarrhea, dementia, and, when untreated, although very seldom, death [1–3]. Full symptoms occur in only 22%, dermatitis alone in 33% [4]. The clinical characteristics are shown in Table 1.

Untreated pellagra gradually progresses to death within 4–5 years, due to multiorgan failure. If it is treated appropriately, the prognosis is excellent [1].

### Prevalence

The current incidence is unknown; epidemics are no longer evident [1]. It is still endemic in areas of

**Pellagra. Table 1** Clinical characteristics findings of pellagra

|---|---|
| **The classical findings: 4D** | Dermatitis, diarrhea, and dementia, when untreated, death |
| **Early symptoms** | Weakness, loss of appetite, abdominal pain, diarrhea, photosensitivity, and psychiatric or emotional distress |
| **Skin findings** | Early lesions<br>• Symmetrical, erythematous, photosensitive pruritic rash on the dorsa of the hands, face, neck and chest<br>• "Butterfly" eruption on the face, looks like lupus erythematosus<br>• "Casal's necklace" on the front of the neck and<br>• Anterior continuation, also known as "cravat"<br>• A dull erythema of the bridge of the nose, with fine, yellow, powdery scales: "sulfur flakes"<br>• Sometimes vesicles and bullae develop: "wet pellagra"<br>• Symmetrical and clearly demarcated dermatosis of the hands forms the "glove" or "gauntlet"<br>• Eruption of the feet, between malleoli and toes forms a "boot"<br>Late lesions<br>• Erythema fades with dusky, brown-red coloration<br>• Hard, rough, scaly, hyperkeratotic, cracked and brittle dermatosis: "rough skin" or "goose skin"<br>• Parchment-like appearance develops<br>• Follicular hyperkeratosis on the face<br>• Painful fissures in the palms, soles and digits |
| **Mucosal manifestations** | • Cheilitis<br>• Angular stomatitis<br>• Glossitis: tongue is erythematous and hypertrophic with pseudo-membranous furrows, erosions, or ulcers, later atrophy and loss of papillae occurs<br>• Painful fissures, ulceration, and atrophy on buccal mucosa and vagina<br>• Scrotal, vaginal and perineal erythema, erosions |
| **Gastrointestinal manifestations** | • Poor appetite, nausea, vomiting, abdominal pain<br>• Diarrhea, gastritis, and achlorhydria; stools are typically watery but occasionally can be bloody and mucoid |
| **Neuropsychiatric manifestations (late stage findings)** | • Headache, fatigue, poor concentration, anxiety, insomnia, delusions, hallucinations, stupor, apathy, tremor, ataxia, spastic paresis, depression, confusion, dementia, and psychosis<br>• Occasionally peripheral neuritis and myelitis<br>• Coma may develop in the later stages |

South Africa and Asia (particularly India) where major dietary intake is maize (low in tryptophan) and millet (interferes with tryptophan metabolism due to its high leucin content) [2,3]. In developed countries, it occurs sporadically among chronic alcoholics, food faddists, and patients with malabsorption. Other possible causes are carcinoid tumors, which divert tryptophan to serotonin, and Hartnup disease, which has impaired tryptophan absorption [1,3]. Some medications may induce pellagra by interfering with the niacin biosynthesis, such as isoniasid, azathioprine, 5-fluorouracil, chloramphenicol, antiepileptics and pyrazinamide [1,3,4].

## Molecular and Systemic Pathophysiology

Generic terms of niacin are nicotinic acid, nicotinamide or niacinamide [1,2]. Niacin can be obtained directly from the diet or synthesized from dietary tryptophan [1]. It is required for adequate cellular function and metabolism of essential component of nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) [2]. These compounds are important coenzymes for numerous oxido-reductases involved in glycolysis, protein, amino-acid, fatty acid and pyruvate metabolism, pentose biosynthesis, generation of high-energy phosphate bonds, glycerol metabolism, tissue respiration, and detoxification [1,2]. It has been theorized that manifestations of pellagra result from the inadequacy of NAD and NADP levels to maintain cellular energy transfer reactions. Hence, tissues with high-energy requirements such as brain or those with high turn-over rates such as skin or gut are particularly affected [2].

It has been postulated that photosensitivity reaction occurs due to urocanic acid deficiency, which protects the skin from ultraviolet (UV) rays by absorbing light in the UVB range. Moreover, kynurenic acid, a metabolic by-product of the tryptophan–kynurenine–nictonic pathway, accumulates in pellagra as a result of nicotinamide deficiency. Kynurenic acid induces phototoxic changes when subjected to UV radiation. Atrophy of sebaceous glands and decrease in wax esters in sebum probably leads to dry skin [1,2].

Histopathological changes in the skin are relatively nonspecific. Vesicles, if present, may arise sub- or intraepidermally, as a result of vacuolar degeneration of the basal layer, or of intense spongiosis, respectively. There is also perivascular lymphocytic infiltrate of the superficial vascular plexus. Older lesions may have epidermal hyperkeratosis and parakeratosis, with variable acanthosis. Eventually, there may be epidermal atrophy overlying dermal fibrosis and sebaceous gland atrophy [1].

Mucosal inflammation and atrophy involves most of the gastrointestinal (GI) tract. Pathological changes in the nervous system can be found in the brain, spinal cord, and peripheral nerves. The posterior and lateral columns are demyelinated due to prolonged niacin deficiency. Peripheral neuritis and myelitis are occasionally encountered [1,4].

## Diagnostic Principles

The diagnosis of pellagra should focus on the presence of the "3 D's," localization, and seasonal appearance. Low serum niacin, tryptophan, NAD and NADP levels can confirm the diagnosis. A combined excretion of *N*-methylnicotinamide, a normal metabolite of niacin, and pyridone of less than 1.5 mg in 24 h indicates niacin deficiency [1,2,4]. Response to therapy is a partial diagnostic criterion [1].

## Therapeutic Principles

Administration of niacin or nicotinamide cures the syndrome; the latter, causing no vasomotor disturbance, is preferred.

The adult and childhood dose is 100–300 mg/day, and 10–50 mg/day orally in three separate doses for several days, respectively, followed by the oral administration of 50 mg every 8–12 h until all skin lesions heal. Mental changes disappear within 24–48 h but skin lesions may take 3–4 weeks. If the symptoms are severe or GI absorption is poor, 1g niacin 3–4 times daily should be provided, initially by the parenteral route [1–3].

Bed rest, avoiding alcohol intake and sun exposure is necessary in acute cases. Dehydration due to diarrhea, severe glossitis and dry skin requires symptomatic management. Underlying pathology of secondary pellagra should also be treated [1].

Prevention of pellagra is possible with 8 mg niacin in the daily diet of infants and 9–20 mg/day for older children [4]. Food sources of niacin, and/or tryptophan include nutritional yeast, eggs, liver, lean pork, bran, peanuts, red meat, poultry, fish, whole-grain cereals, rice and milk [2–4].

In recent times, niacin has been investigated as a potential AIDS prevention factor, because HIV infection induces niacin depletion [1,2].

# Pellagrosis

►Niacin Deficiency
►Pellagra

# PEM

►Malnutrition

# Pemphigoid

►Bullous Pemphigoid

# Pemphigoid Gestationis

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

## Synonyms

Gestational pemphigoid; Herpes gestationis

## Definition and Characteristics

Pemphigoid gestationis (PG) is a peculiar variant of bullous pemphigoid with tissue-bound and circulating autoantibodies against collagen XVII/BP180, a transmembrane protein of hemidesmosomes. Being a self-limited disease, it is characterized by a pruritic papulovesicular eruption on the abdomen during pregnancy, with or without recurrences in subsequent gestations [1].

## Prevalence

Not known. The estimated incidence is 1:10,000–1:40,000 pregnancies.

## Genes

Association with HLA class II alleles DRB1* 0301, DQA1* 0501, DQB1* 0201 and DQB1* 0401/0407 has been observed.

## Molecular and Systemic Pathophysiology

Hemidesmosomes are multiprotein complexes which mediate attachment of basal keratinocytes to the underlying basement membrane zone. Collagen XVII is a type II transmembrane protein extending from the cytoplasm of the basal keratinocyte to the extracellular matrix. Autoantibodies in PG specifically recognize the membrane-adjacent NC16a domain of the collagen XVII ectodomain [2]. The observation of infants developing transient skin lesions due to transplacental passage of maternal autoantibodies suggests that these autoantibodies are pathogenic. Similar to bullous pemphigoid, deposition of $IgG_1$ antibodies in the dermoepidermal junction activates complement which generates an inflammatory infiltrate with increased protease activity leading to blister formation. Hormonal factors certainly play a role in the pathogenesis of PG and exacerbations have been observed during subsequent pregnancies, but also due to hormone producing tumors and oral contraceptives.

## Diagnostic Principles

The diagnosis is based on subepidermal blister formation in histology, linear C3 deposits at the dermoepidermal junction in direct immunofluorescence and deposition of circulating IgG at the epidermal side of saline-separated human skin. Autoantibodies to the NC16a-domain of collagen XVII can be detected in the majority of patients by ELISA [3].

## Therapeutic Principles

Topical corticosteroids in combination with antihistamines or low dose systemic corticosteroids are mostly sufficient. Immunoapheresis or rituximab represent treatment options in severe cases. The therapy should be monitored in collaboration with obstetricians.

# Pemphigus Foliaceus

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

## Definition and Characteristics

Pemphigus foliaceus (PF) and the endemic Brazilian pemphigus (fogo selvagem) are autoimmune bullous dermatoses characterized by autoantibodies against desmoglein 1, a surface protein of keratinocytes. Impaired cell-cell adhesion leads to fragile, superficial blisters which result in scaly, crusted erosions on the skin. Mucosal involvement is usually absent.

## Prevalence

The incidence of pemphigus is estimated to range from 1 to 5 new cases per million per year. Except in Tunisia and Brazil, PF has a lower incidence than pemphigus vulgaris. The endemic fogo selvagem affects young adults and has a prevalence of up to 3.4% in some rural areas of Brazil [1].

### Genes

Association with HLA class II alleles DRB1*0402, DRB1*1401 and DQB1*0302 in caucasians and DRB1*14 and DQB1*0503 in Japanese has been reported.

### Molecular and Systemic Pathophysiology

PF sera specifically bind to the 160 kDa-transmembrane glycoprotein desmoglein 1, which is predominantly expressed in the superficial layers of the epidermis and only minimally expressed in mucous membranes. Therefore, anti- desmoglein 1 antibodies induce loss of cell-cell adhesion (acantholysis) in the upper epidermis, while desmoglein 3 compensates for the loss of functional desmoglein 1 in the oral epithelium (desmoglein compensation theory). The pathogenicity of antibodies against desmogleins has been demonstrated by various mouse models. Peritoneal injection of patients' autoantibodies against desmoglein 1 or desmoglein 3 in newborn mice has been shown to reproduce the typical clinical features of pemphigus [2]. In contrast to the pathogenesis of bullous pemphigoid, complement activation is dispensable in the development of pemphigus lesions. Mechanisms for acantholysis in pemphigus include steric hindrance by binding of autoantibodies to their epitopes, proteinase activation, and down-regulation of adhesion by cellular signaling events [3].

### Diagnostic Principles

The diagnosis is made on the basis of subcorneal acantholysis in histology and intercellular IgG and C3-deposits in the upper epidermis by direct immunofluorescence. Circulating autoantibodies against desmoglein 1 can be detected by indirect immunofluorescence or ELISA with recombinant desmogleins.

### Therapeutic Principles

Severe forms of PF are treated with oral corticosteroids alone or in combination with immunosuppressive agents similar to the treatment of pemphigus vulgaris. In localized forms of PF, superpotent topical steroids or topical calcineurin inhibitors may be sufficient to obtain clinical remission.

## Pemphigus Vulgaris

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

### Definition and Characteristics

Potentially life-threatening autoimmune blistering dermatosis associated with autoantibodies against intercellular adhesion proteins of keratinocytes. In pemphigus vulgaris (PV), autoantibodies are predominantly directed against desmoglein 3 leading to intraepidermal, suprabasal blisters. Clinical hallmarks are painful erosions of the oral mucosa with or without flaccid cutaneous blisters and erosions.

### Prevalence

The prevalence of pemphigus is not known; the incidence is estimated to range from 1 to 5 new cases per million per year. The disease is found all over the world, it affects women and men equally and typically manifests between 30 and 60 years of age. People of Jewish ancestry have a higher incidence of pemphigus.

### Genes

Association with HLA class II alleles DRB1*0402, DRB1*1401 and DQB1*0302 in caucasians and DRB1*14 and DQB1*0503 in Japanese has been reported.

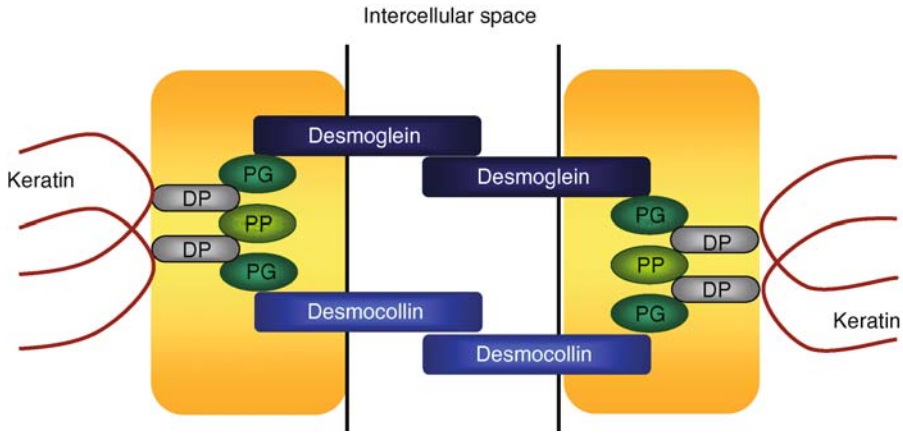
### Molecular and Systemic Pathophysiology

The antigenic target in PV, desmoglein 3, is a transmembrane glycoprotein of desmosomes (Fig. 1).

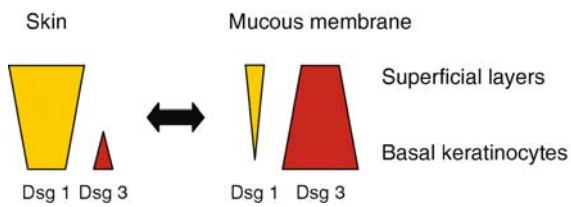
By anchorage of the cytokeratin filaments, desmosomes mediate strong intercellular adhesion between keratinocytes [1]. As demonstrated by an active mouse model anti-desmoglein 3 antibodies interfere with the function of desmogleins leading to loss of keratinocyte cell adhesion (known as acantholysis) and subsequent blister formation in the epidermis [2].

The pemphigus vulgaris antigen, 130 kD desmoglein 3, and the pemphigus foliaceus antigen, 160 kD desmoglein 1, belong to the cadherin supergene family and compensate for each other functionally, when expressed in the same cell (Fig. 2).

However, in PV anti-desmoglein 3 antibodies impair the function of desmoglein 3 and lead to erosions in mucous membranes, where desmoglein 1 cannot compensate for the loss of function of desmoglein 3 [3].



**Pemphigus Vulgaris. Figure 1** Structure of the desmosome. Desmosomes contain two types of transmembrane proteins, desmogleins and desmocollins, which are always expressed as a pair and bind to plakoglobin (PG). The desmosomal cytoplasmic constituents plakoglobin (PG) and plakophilin (PP) associate with desmoplakin (DP) which itself interacts with the keratin filaments.



**Pemphigus Vulgaris. Figure 2** Distribution of desmoglein 1 and desmoglein 3 in skin and mucous membranes. The distribution of desmoglein 1 (Dsg1) and desmoglein 3 (Dsg3) varies between skin and mucous membranes. While desmoglein 1 is significantly expressed throughout the epidermis, desmoglein 3 is restricted to the basal layers. In contrast, desmoglein 3 is expressed at a higher level in mucous membranes than desmoglein 1. When coexpressed in the same cell, desmoglein 1 and desmoglein 3 can compensate for each other explaining the clinical features of the different pemphigus variants (desmoglein compensation theory).

### Diagnostic Principles

Histology shows suprabasal acantholysis and direct immunofluorescence intercellular IgG and C3 deposits in the lower epidermis. Circulating autoantibodies react with human skin or monkey esophagus by indirect immunofluorescence. The molecular specificity of the antibodies is determined by ELISA with recombinant desmogleins.

### Therapeutic Principles

Oral prednisone alone or combined with immunosuppressive agents (azathioprine, mycophenolate mofetil, dapsone, cyclophosphamide, methotrexate) are the mainstay of therapy for PV. In recalcitrant PV, the anti-CD20-antibody rituximab, protein A-immunoadsorption or high-dose intravenous immunoglobulins may help to achieve a clinical and serological remission.

## Pendred Syndrome

►Pendred's Syndrome

## Pendred's Syndrome

Peter Kopp[1], Douglas Forrest[2]
[1]Feinberg School of Medicine, Northwestern University, Chicago, IL, USA
[2]National Institutes of Health, NIDDK, Bethesda, MD, USA

### Definition and Characteristics

Pendred's syndrome (OMIM 274600) is an autosomal recessive disorder characterized by sensorineural deafness, goiter, and impaired iodide organification.

Deafness is often prelingual, but it may be progressive and become apparent only later in childhood; it is associated with enlargement of the endolymphatic system. The thyroid enlargement is variable and may be influenced by nutritional iodide intake. Hypothyroidism occurs in some, but not all patients and it is not causally involved in the development of hearing impairment.

## Prevalence

Estimations in the United Kingdom predicted a frequency of about 0.000,075. The true prevalence may be higher because of unrecognized allelic variants.

## Genes

The disorder is caused by mutations in the PDS/SLC26A4 gene located on chromosome 7q31, and is thought to be genetically homogenous. Expression of the thyroid phenotype is influenced by the amount of nutritional iodine intake. Mutations in SLC26A4 identified in patients with Pendred syndrome or with non-syndromic deafness display allelic heterogeneity. More than 150 mutations are known including a large number of missense mutations and a small number of nonsense and intronic mutations. The loss-of-function of some of these mutations is in part due to retention of the mutated protein in intracellular compartments.

*Allelic variants without thyroid phenotype*: Non-syndromic (familial) enlarged vestibular aqueduct, non-syndromic autosomal recessive deafness DFNB4.

## Molecular and Systemic Pathophysiology

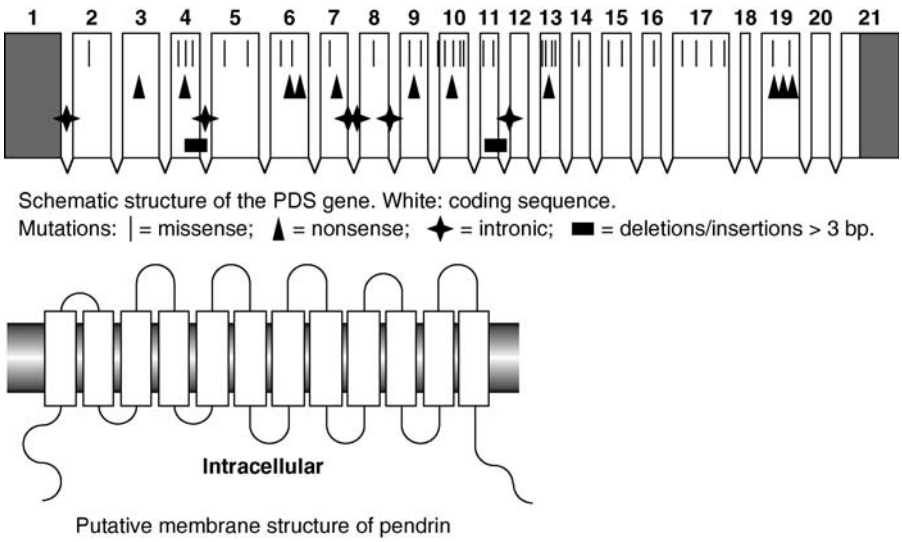
Pendrin is predominantly expressed in the inner ear, the thyroid and the kidney. Functionally, pendrin has been shown to transport chloride and iodide, and to exchange bicarbonate, hydroxide and formate in oocyte and mammalian cell systems. Based on the typical enlargement of the endolymphatic system in patients with Pendred's syndrome and the Pds null mouse [1], pendrin is assumed to be involved in anion and fluid transport in the inner ear. The exact role remains to be defined but $Pds^{-/-}$ mice have progressive degeneration of the stria vascularis, acidification of the endolymph and an associated loss of the endocochlear potential [2]. In thyroid follicular cells, pendrin is inserted into the apical membrane and, together with other, unidentified channels, it is involved in iodide transport into the follicular lumen. There is no overt renal phenotype, possibly because of the existence of other transporters with redundant function. PDS gene mutations display significant allelic heterogeneity and include numerous inactivating missense, nonsense and splice site mutations (Fig. 1).

## Diagnostic Principles

In its classic presentation, the combination of congenital sensorineural deafness and goiter, the diagnosis of Pendred's syndrome can be confirmed by a positive perchlorate test in most patients [3]. If the phenotype is limited to deafness with an enlarged endolymphatic system documented by imaging of the inner ear, mutational analysis of the PDS gene is essential for making a definite diagnosis [4].

## Therapeutic Principles

Early diagnosis is essential in order to avoid further progression in children with hearing impairment since cochlear implants have been useful in acquiring normal language development in a small number of patients.



**Pendred's Syndrome. Figure 1** PDS/SLC 26A4 gene and secondary protein structure.

In case of hypothyroidism, patients with Pendred's syndrome are treated with levothyroxine. Large goiters may occasionally need surgical correction.

# Pentalogy of Fallot

Emine Dibek Misirlioğlu[1], Nursel Alpan[2]
[1]Department of Pediatrics, Kırıkkale University Faculty of Medicine, Kırıkkale, Turkey
[2]Department of Cardiology, Ministry of Health, Ankara Diskapi Children's Diseases Training and Research Hospital, Ankara, Turkey

## Synonyms

Tetralogy of Fallot (TOF) with atrial septal defect (ASD) or patent foramen ovale (PFO)

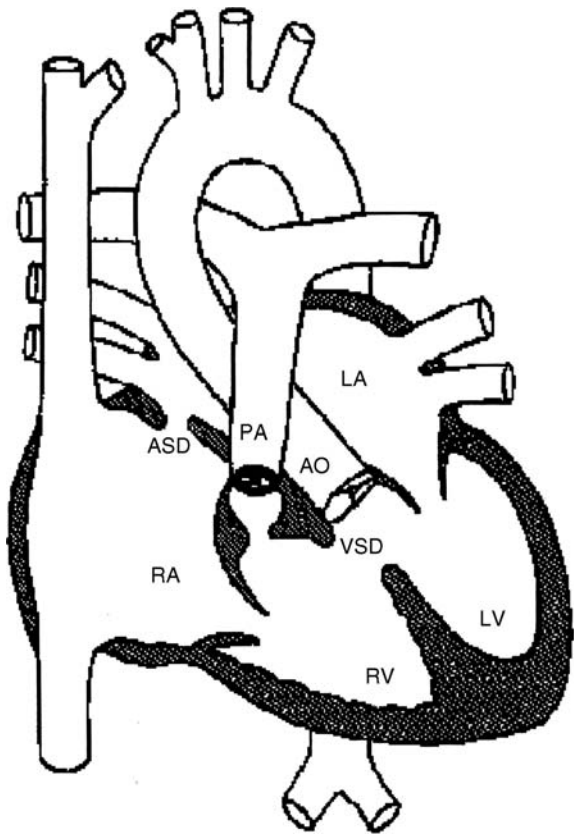
## Definition and Characteristics

Pentalogy of Fallot is a congenital heart defect with five anatomical components:

1. Ventricular septal defect (VSD) consists of an unrestricted large anterior, subaortic perimembranous malalignment. It leads to equalization of right and left ventricular pressures.
2. Right ventricular outflow tract obstruction (pulmonary stenosis, PS); infundibular (subvalvular) stenosis is found in all patients and may be accompanied by valvular and supravalvular stenosis. The patient's clinical picture and prognosis is most affected by the degree of pulmonary stenosis. It is more severe when the pulmonary valve is atretic.
3. Right ventricular hypertrophy is not an anatomical pathology and develops secondary to pulmonary stenosis.
4. Overriding of the aorta over the septal defect, due to a malalignment type of VSD. Part of the aorta exits from the right ventricle [1,2].
5. When ASD or PFO accompany the four components mentioned above it is called Pentalogy of Fallot [3] (Fig. 1).

## Prevalence

Data on the incidence of the pentalogy of Fallot are not consistent. In addition to reports where it was found rarely in patients with heart disease, some report an incidence as of concurrent TOF and ASD or PFO as high as 83% [1]. This may be due to the frequent



**Pentalogy of Fallot. Figure 1** Anatomic abnormalities in pentalogy of Fallot. RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; PA, pulmonary artery; AO, overrriding aorta; ASD, atrial septal defect; VSD, ventricular septal defect.

occurrence of ASD as a congenital cardiac anomaly, and its evaluation is coincidental in TOF cases and not as a component of the pentalogy.

## Genes

Pentalogy of Fallot can be associated with a syndrome or patients may have chromosomal anomalies as reported in the literature. There have been case reports of pentalogy of fallot associated with Down's syndrome, Steinfeld syndrome, Holt-Oram syndrome, and incomplete trisomy 22 (22q13) [3,4]. Microdeletion of 22q11 is the most frequent chromosomal anomaly associated with conotruncal defects. Concurrence of TOF and atrioventricular septal defect may be seen especially in Down's syndrome [1,3].

## Molecular and Systemic Pathophysiology

*Embryonic Development*: Tetralogy of Fallot is a result of abnormal conotruncal development that consists of incomplete rotation and faulty partitioning of the conotruncus during septation. The deviation of the conal septum is the reason for the VSD and the overriding aorta.

The subpulmonic obstruction is believed to be created by abnormal anterior septation of the conotruncus by the bulbotruncal ridges but this remains uncertain. The degree and nature of the anterior and cephalad deviation of conal spectrum determine the severity of subpulmonic obstruction [1].

Atrial septal defects are classified according to their location relative to the fossa ovalis, their proposed embryogenesis, and their size. The foramen ovale represents a normal interatrial communication that is present throughout fetal life. Functional closure of the foramen ovale occurs postnatally, and fibrous adhesion may develop during the first year of life. Patent foramen ovale may develop if anatomical closure does not occur. Secundum ASD is the result of excessive resorption of septum primum and the inability of septum secundum to close ostium secundum [1].

*Molecular Pathophysiology*: Although there are no data on the molecular pathophysiology of the pentalogy of Fallot, conotruncal heart defects such as TOF are due to alterations in migration of a specific neural crest cell population called cardiac neural crest (NC). It is possible that cardiac NC may influence the myocardial $Ca^{2+}$ channels development and the expression of the proteins involved. This cellular and molecular interaction can be assigned not only to the structural characteristics of the congenital heart defect but also to the embryonic development of the heart defect. Conotruncal defects have been shown to be associated with an increase in intracellular Ca reserves in cardiac neural cells. Sarcoplasmic reticulum Ca ATPase (SERCA) is a membrane protein and catalyzes the ATP-dependent transport of Ca from the cytosol to the sarcoplasmic reticulum ($Ca^{2+}$ re-uptake into the sarcoplasmic reticulum (SR) through the SR $Ca^{2+}$/ATPase pump (SERCA)). Its activity is inhibited by phospholamban (PLN) and sarcolipin (SLN). PLN and SLN have been shown to be low in TOF patients [5].

*Systemic Pathophysiology*: The pathophysiology varies depending on the degree of right ventricular outflow obstruction. The pulmonary infundibulum is hypertrophic and the right ventricular outlet narrows. In addition, the pulmonary valve annulus, main pulmonary artery, and pulmonary artery branches may be narrow. The lungs therefore receive less blood than normal. The right ventricular pressure is equal to or higher than the left ventricular pressure due to PS. Part of the blood arriving at the right atrium and right ventricle from the systemic veins goes into the systemic circulation by the way of overriding aorta and by the route of VSD because PS causes shifting of blood from pulmonary artery [1,2].

If the PS is very severe, the right-to-left shunt increases and the clinical findings become more marked. Pulmonary perfusion for maintaining life can only take place if PDA or aortopulmonary collaterals develop.

With mild PS, the lungs receive adequate blood, there may be a two-way shunt through the VSD and there is no cyanosis. Mild PS patients have mild clinical findings and occasionally presents in adulthood. Cases with uncorrected pentalogy of Falloto living until the seventh decade have been reported.

## Diagnostic Principles

The clinical manifestations reflect the variable severity of right ventricular outflow obstruction. Newborns and infants may present either with cyanosis or systolic murmur. A worsening clinical picture is seen in newborns with critical right ventricular outflow obstruction after closure of the ductus arteriosus due to decreased pulmonary perfusion [1,2]. Hypercyanotic episodes are characterized by a severe and prolonged decrease in arterial saturation and most often seen at the ages of 2 to 4. There is substantial increase in right-to-left shunting due to a change in the ratio of pulmonary and systemic vascular impedance. Episodes usually develop in the morning following crying, feeding, and defecating. They are characterized by severe cyanosis and often associated with hyperpnea. If prolonged and severe, lethargy and death may result. Children may assume a knee-chest position. Squatting is another sign and seen following exercise. During exercise sytemic vascular resistance decreases. This causes decrease in left ventricular pressure. As a result right-to-left shunt increases so the lungs receive less blood. Decreased lung perfusion cause increase in hypoxia and cyanosis. The patient can no longer walk and squats.

At physical examination, cyanosis is the most prominent finding and may not be present at birth if the PS is mild. There is marked cyanosis from birth in patients with pulmonary valve atresia. The right ventricle pressure increases as the infundibular stenosis increases, the blood supply to the lung decreases, and right-to-left shunt starts, with cyanosis occurring later in the first year of life. Clubbing of nailbeds can be present in longstanding cases. A systolic murmur is located at the left upper sternal border as expected with valvular PS. The intensity of the murmur inversely related to the degree of pulmonary obstruction. The severity of the murmur decreases as the PS increases. There is no murmur in case of pulmonary valve atresia or there may be a mild PDA or aortopulmonary collateral continuous murmur in some patients. An accentuated right ventricular impulse will be found. Growth and development may be delayed in the untreated patient with severe disease. Clubbing of nailbeds can be present in longstanding cases.

Polycythemia and relative iron deficiency are usually seen in laboratory tests. The polycythemia is due to the hypoxia and the resultant production of erythropoietin. In radiography, the heart size is normal and the cardiac apex turned upward (right ventricular hypertrophy), the pulmonary conus is collapsed (hypoplasic pulmonary artery), and lung vascularity is decreased (hypoplasic pulmonary artery branches due to PS). This creates a cardiac silhouette that resembles a boot-shaped heart or coeur en sabot (wooden shoe).

Electrocardiography reveals right axis and right ventricular hypertrophy. Arrhythmias are uncommon in young patients, but ventricular ectopy and other arrhythmias may appear in untreated older children.

Two-dimensional echocardiography provides noninvasive diagnosis of all anatomical findings. Doppler echocardiography analysis provides further data regarding hemodynamic characteristics. The degree of PS may be determined with Doppler. The indications for diagnostic catheterization have diminished substantially with advances in noninvasive technology. Invasive studies are helpful when deciding on surgical or medical management strategies.

Right ventricular angiography will usually provide reliable imaging of the infundibular and pulmonary artery anatomy. Left ventricular angiography will usually define left ventricular function, VSD, the degree of aortic override, and the presence of ASD.

## Therapeutic Principles

The definitive treatment for pentalogy of Fallot is surgical. Primary repair is performed electively at 6–12 months of age in well grown infants with less severe cyanosis and without hypercyanotic spells. Early complete repair may be performed safely and prevents development of complications from additional palliative procedures, long-standing cyanosis, and other serious comorbidities (systemic arterial emboli, cerebrovascular complications). Prevention or prompt treatment of dehydration is important to avoid hemoconcentration and possible thrombotic episodes [1,2]. Medical treatment is used for newborns with critical right ventricular outflow obstruction and for hypercyanotic spells.

Neonates who have ductal-dependent pulmonary blood flow should be given prostaglandin E1 (0.05–0.20 μg/kg/min) but this situation does not develop frequently. Hypercyanotic spells require medical treatment including oxygen, volume expansion, sedation with morphine or ketamine, and, if needed, vasopressors such as phenylephrine. Although it is currently accepted that hypercyanotic spells provide an important rationale for earlier palliative surgical intervention, propranolol (1 mg/kg every 6 hr) has been suggested for minimizing or eliminating these events. Iron treatment may decrease the frequency of spells.

Interventional catheterization procedures are performed to relieve of various levels of pulmonary obstruction and to embolize accessory and duplicated sources of pulmonary blood flow. The frequency and indications for catheter-based intervention are determined to a large degree by the preferences of the clinician and institution.

Surgical intervention is required for resection of hypertrophic muscular trabeculations that narrow the right ventricular outlet. The patient's pulmonary valve remains competent. A pulmonary valvotomy is performed if the pulmonary valve is stenotic, and a valvectomy may be performed if the pulmonary valve annulus is small or the valve is extremely thickened. The VSD and ASD are completely closed. A small patent foramen ovale may be left as a possible source for right to left atrial decompression in the postoperative period [1,2].

The surgical risk of total correction is less than 5% [2].

Shunt surgery should be carried out urgently if severe cyanosis or frequent spells are seen within the first year of life. Palliative systemic-to-pulmonary artery shunt is performed to increase pulmonary artery blood flow and decrease the amount of hypoxia to augment the growth of the branch pulmonary arteries. Corrective surgery is performed later [1].

An anastomosis between the right or left pulmonary artery and right or left subclavian artery (modified Blalock-Taussig Shunt) provides a communication using a vascular graft between the pulmonary artery and the subclavian artery (modified Blalock-Taussing Shunt). A Waterston-Cooley Shunt anastomoses the ascending aorta to right pulmonary artery, a Pott's Shunt provides

an anastomosis of the descending aorta to left pulmonary artery, and Central shunts generate an anastomosis between the main pulmonary artery and ascending aorta using a vascular graft [1,2].

The overall survival of patients who have had operative repair is excellent, provided the VSD has been closed and the right ventricular outflow tract obstruction has been relieved. All Pentalogy of Fallot patients should have regular cardiology follow-up by a cardiologist. The patients are still at risk if endocarditis after complete repair and prophylaxis is recommended [1]. Death may occur from endocarditis or congestive heart failure.

## Synonyms

Gastric ulcer; Duodenal ulcer

## Definition and Characteristics

An ulcer of the mucosa is defined by disruption of the surface integrity leading to a local defect >5 mm in size with excavation to the submucosa due to inflammation [1]. The disease may affect all parts of the gastrointestinal tract, but the predominant manifestation is ulcering of the lower part of the stomach and the upper part of the duodenum (duodenal bulb). More than 80% of duodenal ulcers and 60% of gastric ulcers are induced by Helicobacter pylori infection. Majority of other cases are associated with the use of nonsteroidal anti-inflammatory drugs (NSAID). Rarely the cause is Zollinger-Ellison syndrome.

Clinical symptoms of peptic ulcer consist of upper abdominal discomfort, pain, nausea, and weight loss. The pain pattern of gastric ulcer is aggravation during food intake; patients with duodenal ulcer complain of pain in fasting condition, especially at night. However, the predictive value of pain for the presence of ulcers is low. Complications of ulcer disease are penetration or perforation of the affected site, gastrointestinal bleeding, and, rarely, gastric outlet obstruction.

## Prevalence

It is estimated that the lifetime incidence of duodenal ulcers is 6–10% in the western population. Gastric ulcer tends to occur later in life in comparison with duodenal ulcers and affects more males than females. Autopsy studies suggest a similar incidence of gastric and duodenal ulcers [1]. As a result of widespread application of eradication therapy of H. pylori infection, the prevalence of peptic ulcer is declining since the 1980s.

However, there is evidence that peptic ulcer not induced by H. pylori or NSAID use is rising [2].

## Molecular and Systemic Pathophysiology

The mucosal surface is constantly challenged by a large number of different noxious agents, e.g., acid, pepsin, pancreatic and biliary secretions, drugs, alcohol, or infectious organisms. The epithelial defense and repair system consists of three major elements. The pre-epithelial part is a mucous-bicarbonate layer containing mucin, fatty acids, and phospholipids, serving as a physicochemical barrier. The middle layer is represented by the cellular wall. The third element of defense is represented by the submucosal microvascular system. It provides bicarbonate to neutralize the secretion of HCl and supplies the mucosa with micronutrients and oxygen while removing metabolic end-products. The cellular release of mucus and bicarbonate is regulated by prostaglandins, which occur in high concentrations in the gastric mucosa. Further tasks of the prostaglandins are the inhibition of acid production, the regulation of mucosal blood flow, and epithelial cell restitution.

HCl (produced by parietal cells) and pepsinogen (produced by chief cells) are the major secretory products that induce mucosal damage. Continuous submucosal blood perfusion and an alkaline environment are required for effective mucosal repair. Epithelial regeneration is modulated by prostaglandins, epidermal growth factor (EGF), and transforming growth factor (TGF) α. Restitution of smaller defects is induced by EGF, TGF-α, and basic fibroblast factor (FGF). FGF and vascular endothelial growth factor (VEGF) stimulate angiogenesis.

H. pylori infection of the gastric mucosa is the major etiology of peptic ulcer [3]. However, less than 15% of affected patients develop peptic ulcers. Important virulence factors are CagA, a signaling protein, VacA, a cytotoxin, and BabA, an adhesin, all secreted by the bacterium [3]. CagA induces a proinflammatory response and cell proliferation in the host, VacA results in cell surface perforation and induction of apotosis, BabA facilitates adhesion to the cell surface. Furthermore, phospholipases and proteases produced by the bacterium breakdown the glycoprotein lipid complex of the surface mucus. Genetic polymorphisms leading to enhanced secretion of the proinflammatory cytokine interleukin 1β are host factors with increased risk of hypochlorhydria induced by H. pylori. Although patients with blood group O have an increased risk of ulcer development, no genetic predisposition of ulcer disease has been established. Smoking is an important environmental factor associated with ulcer disease. No dietary factors have been identified as causative agents.

In cases with gastric ulcer, a diffuse colonization pattern of H. pylori with pangastritis in histology examination is regularly found. Gastric adenocarcinoma and lymphoma are associated with this manifestation. Basal and stimulated acid output is normal or diminished. Duodenal ulcer is associated with antral-predominant colonization of H. pylori. This constellation leads to increased gastrin secretion mediated by H. pylori-induced reduction of somatostatin-producing cells. The increased acid secretion results in protective gastric metaplasia of the duodenal bulb. This epithelial compartment is infected by H. pylori with the consequence of inflammation and ulceration.

The use of NSAID leads to peptic ulcer by inhibition of prostaglandin production, reduction of epithelial blood perfusion, direct toxicity by intracellular trapping of ionized drug forms, and disturbed healing of lesions.

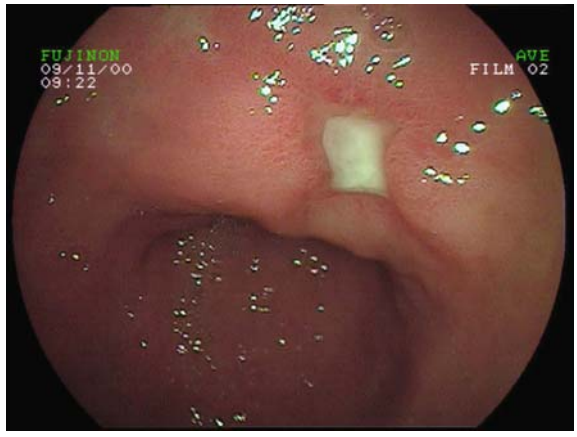
## Diagnostic Principles

The diagnosis of gastrointestinal ulcer is established by endoscopy (see Figs. 1 and 2). A further use of endoscopy is differentiating inflammatory bowel disease, non-ulcer dyspepsia, malignant disorders, and others. Other techniques like radiographic examination or ultrasound do not play a significant role in the diagnosis of gastrointestinal ulcers.

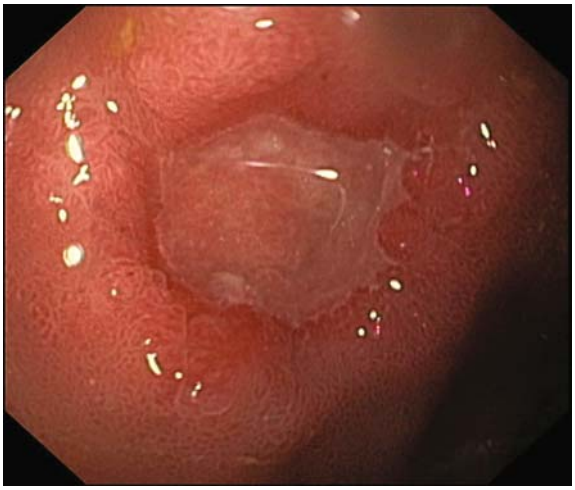
Testing for H. pylori may be applied during endoscopy using the urease test of a biopsy or histology of gastric mucosa. In cases with recurrence of disease after eradication therapy, a biopsy specimen can be used for culture and resistance testing. Non-invasive tests with inferior sensitivity and specificity are serology, $^{13}C$ urea breath test, and stool antigen test.

## Therapeutic Principles

The leading therapeutic principle in the treatment of peptic ulcer is inhibition of acid secretion. Antacids, $H_2$-receptor antagonists, or cytoprotective agents may be used. The best efficacy is documented for proton pump inhibitors. These inhibit the $H^+$, $K^+$-ATPase of the gastric



**Peptic Ulcer. Figure 1** Gastric ulcer.



**Peptic Ulcer. Figure 2** Duodenal ulcer.

mucosa irreversibly. Standard doses of proton pump inhibitors in combination with either amoxicillin/clarithromycin or metronidazol/clarithromycin over 1 week are used for eradication therapy of H. pylori infection [4]. Nowadays, surgery is needed only for complications.

### Definition and Characteristics

Acquired acute inflammatory disease of the pericardium.

### Prevalence

The incidence of pericarditis in postmortem studies ranges from 1 to 6%. It is diagnosed antemortem in only 0.1% of hospitalized patients and in 5% of presentations to emergency departments for nonacute myocardial infarction chest pain [1,2]. In a prospective study on 274 consecutive cases of pericarditis from an urban area, the incidence of new cases of acute pericarditis was 27.7 cases per 10,000 population/year [3].

### Genes

Additional research is in progress on the possible link between recurrent pericarditis and autoinflammatory diseases.

The autoinflammatory diseases comprise both hereditary (familial Mediterranean fever, FMF; mevalonate kinase deficiency, MKD; TNF receptor associated periodic syndrome, TRAPS; cryopyrin associated periodic syndrome, CAPS; Blau syndrome; Pyogenic sterile arthritis, pyoderma gangrenosum and acne syndrome, PAPA; chronic recurrent multifocal osteomyelitis, CRMO) and multifactorial (Crohn's and Behçet's diseases) disorders. Mutations responsible for FMF, TRAPS, CAPS, PAPA include proteins involved in the modulation of inflammation and apoptosis [4].

Recurrent attacks of pericarditis are a feature of the FMF, nevertheless mutations related to FMF were not found in Caucasian patients with sporadic cases of recurrent idiopathic pericarditis [5].

### Molecular and Systemic Pathophysiology

Pericarditis is an inflammatory disease of the pericardium characterized by both pericardial inflammatory infiltrate and exudate, usually consisting of fibrin and

inflammatory cells [6,7]. The type of inflammatory cells and pericardial fluid depend on the cause of pericarditis (Table 1). Histological findings include granulocyte or lymphocytic-mononuclear infiltration of the pericardium, and sometimes of the subepicardium. Lymphocytes dominate in viral infections, whereas polymorphonuclear cells are predominant in bacterial infections. Pericardial fluid is hypercellular and purulent in bacterial infections, mainly hemorrhagic in tuberculous and neoplastic pericarditis, and serofibrinous in viral and autoreactive forms. Higher titers of antimyolemmal and antisarcolemmal antibodies are found in viral and autoreactive forms. Some cytokines such as IL6 and IL8 are significantly increased in pericardial effusion compared to the serum and are markers of the local inflammatory response. Elevation of biomarkers has been reported in acute pericarditis. Persistent cTnI elevations suggest myopericarditis. The rise in cTnI in acute pericarditis is roughly related to the extent of myocardial inflammation, but unlike acute coronary syndromes, is not a negative prognostic marker [3,8].

## Diagnostic Principles

The typical clinical manifestations of acute pericarditis consist of chest pain (usually pleuritic), a pericardial friction rub, and widespread ST segment elevation on the electrocardiogram, and the possible appearance of pericardial effusion. At least two of these four features should usually be present for the diagnosis [9]. In all cases elevation of inflammatory markers (ie. C-reactive

**Pericarditis, Acute. Table 1** Etiology of acute pericarditis

| Etiology | Frequence* | Pathogenesis |
|---|---|---|
| *Idiopathic* | Up to 85% | Generally a viral infection, sometimes autoimmune and postinfectious pathogenesis |
| *Infectious* | >60% | Spread and multiplication of the infectious agent with serofibrinous (viral), hemorrhagic (bacterial, viral, tuberculous), or purulent inflammation (bacterial) |
| Viral (common: Coxsackie, Echovirus, Adenovirus, Influenza, CMV, EBV) | | |
| Bacterial (Tbc, other rare: *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pneumococcus*, *Meningococcus*, *Hemophilus*, Coxiella burnetii, etc.) | | |
| Fungal (rare: Candida, Histoplasma) | | |
| Parasitary (rare) | | |

Relative frequencies based on Imazio M et al. (2004) J Am Coll Cardiol 43:1042–1046, and Imazio M et al. Indicators of poor prognosis of acute pericarditis. Circulation 2007, May:29; 115(21):2739–2744.

protein) should be recorded. Due to possible limitations of standard diagnostic techniques many cases remain etiologically unclear and are assigned as "idiopathic." In most cases idiopathic forms are viral, while some cases may have an autoimmune etiology and are considered as "autoreactive pericarditis" [4].

The number of "idiopathic" cases may be substantially reduced with an invasive approach including a comprehensive and systematic implementation of new techniques of pericardiocentesis, pericardial fluid analysis, pericardioscopy, epicardial and pericardial biopsy, as well as the application of molecular biology and immunology techniques for pericardial fluid and biopsy analyses. In this setting, true idiopathic cases could be reduced to less than 5% of all cases [4].

However, a complex and exhaustive testing strategy is typically not justified in all cases because of the self-limited and benign course of most cases and the limited implications for their clinical management [1,2,9,10].

## Therapeutic Principles

If a specific cause of pericarditis is identified, a tailored treatment should be prescribed. In most cases (viral or idiopathic cases) non-steroidal anti-inflammatory drugs (NSAIDs) are the mainstay of therapy. Aspirin (2–4 g daily), indomethacin (75–150 mg daily), and ibuprofen (1,600–3,200 mg daily) are commonly prescribed. Corticosteroid therapy (for instance prednisone 1–1.5 mg/kg/day) should be considered as a second choice since it has been reported as an independent risk factor for recurrences in viral and idiopathic cases. Animal studies have shown that corticosteroids may exacerbate virally induced pericardial injury. Colchicine (initial dose 1.0 mg BID followed by a maintenance dose of 0.5 mg BID daily for 3 months for patients ≥70 kg, and halved doses: 0.5 mg BID as attack dose, and 0.5 mg daily as maintenance for patients <70 kg) as adjunct to conventional therapy might be safe and effective in the treatment of the index attack as well as in the prevention of recurrent pericarditis.

## Synonyms

Pericardial constriction

## Definition and Characteristics

Constrictive pericarditis (CP) is an unremitting and disabling disease of diastolic dysfunction, characterized by elevated pulmonary and systemic venous pressures and low cardiac output [1]. CP is characterized by a thick, non-compliant pericardium that encases the heart that results in decreased diastolic filling of the heart [1]. Common etiologies of CP are viral pericarditis, post-cardiac surgery, post-irradiation, chronic inflammatory diseases such as systemic lupus erythematosus and rheumatoid arthritis, uremia and malignancies. Cardiac surgery is the most common cause of CP in the modern era [2]. Clinical presentation is indolent and non-specific with symptoms of fatigue and decreased exercise tolerance due to biventricular diastolic dysfunction and the limited ability of the stiff, encased heart to increase cardiac output with exercise [2].

## Prevalence

The disease is uncommon.

## Genes

Camptodactyly arthropathy coxa vara pericarditis (CACP) syndrome is an autosomal recessive disorder resulting from mutations in a gene encoding a secreted proteoglycan, both in skeletal and non-skeletal tissues. Homozygosity mapping has demonstrated the CACP gene to be located on chromosome 1q25–q31 [3]. Pericardial thickening occurs due to intimal overgrowth in the fibrous pericardium. Clinical pericarditis manifests in patients with incomplete genetic penetrance. A rare inherited disease with constrictive pericarditis as the primary cardiac involvement is Mulibrey (MUscle-LIver-BRain-EYe) nanism. It is an autosomal recessive disease with prenatal onset of growth failure and dystrophy of tissues of mesodermal origin. The causative mutations have been localized to the TRIM37 gene that encodes a RING-B-box-Coiled-coil zinc protein residing in peroxisomes. This disorder occurs more frequently in the Finnish population [3].

## Molecular and Systemic Pathophysiology

CP usually takes years to develop although the constrictive process can result from an initial insult within a few months [2]. This usually results in dense fibrosis and often calcification. Adhesions of the parietal and visceral pericardium are common. The scarring process restricts filling of all the cardiac chambers with predominant signs and symptoms of right-sided heart failure. Almost all ventricular filling occurs in early diastole when intracardiac volume reaches the limit set by the noncompliant pericardium and ventricular filling is abruptly halted [1]. Hepatic congestion, peripheral edema, ascites, and sometimes anasarca and cardiac cirrhosis result from systemic venous congestion [2]. Reduced cardiac index, a consequence of impaired filling, results in fatigue, muscle wasting, and weight loss. An important contributor to the pathophysiology of constrictive pericarditis is lack of transmission of intrathoracic pressure changes to the cardiac chambers during respiration. However, these changes continue to be transmitted to the pulmonary circulation resulting in a drop in intrathoracic pressure (and therefore pulmonary venous pressure) on inspiration. The interventricular septum shifts to the left with the inspiratory decrease in left ventricular filling. The opposite sequence occurs with expiration. This results in pulsus paradoxus, with an exaggerated fall in stroke volume and aortic systolic pressure by >10–12 mmHg with inspiration, mediated by the leftward displacement of the interventricular septum due to increased right heart filling [2]. Compensatory retention of sodium and water by the kidneys occurs due to high systemic venous pressure and reduced cardiac output.

## Diagnostic Principles

Physical findings are consistent with left and right heart failure, with predominance of the latter. The extent of peripheral edema is consistent with the magnitude of right heart failure. Chest examination is usually clear. Jugular venous pressure is elevated. Ventricular noncompliance and atrial constraint by the pericardium are reflected by a prominent a-wave [1]. A sharp x descent is seen, attributable to accelerated atrial relaxation and decrease in pericardial pressure during ventricular emptying [1]. A sharp y descent (Friedreich's sign) is also seen, reflecting rapid, resistance-free early diastolic filling. An inspiratory increase in jugular venous pressure (Kussmaul's sign) may be present but is not specific for CP. A "pericardial knock" may be evident, occurring in timing between an opening snap and third heart sound [1]. The second heart sound may be widely split due to earlier aortic valve closure related to the inspiratory decrease in left ventricular stroke volume [1].

Two-dimensional echocardiography typically reveals small ventricles with intact systolic function. The atria may dilate due to the noncompliant ventricles. Abrupt termination of diastolic filling may be evident by "septal bounce" dilatation of the inferior vena cava and hepatic veins with blunted respiratory fluctuation (plethora) may be seen [2]. Diastolic function examination focuses on pulsed Doppler recordings of left-sided mitral inflow E and A waves and pulmonary vein systolic, diastolic, and atrial reversal waves and the corresponding right-sided tricuspid inflow and hepatic vein flow waves. The hallmark of Doppler examination in CP is reciprocal respiratory variation of right and left heart flows caused by the interventricular dependence [4]. Respiratory variations in Doppler flow velocities are >25% expiratory increase in mitral E velocity, an expiratory decrease in hepatic vein diastolic flow velocity and >25% increase in diastolic flow reversals compared to the inspiratory flow velocity [5].

Computed tomography (CT) and magnetic resonance imaging (MRI) provide excellent visualization of the pericardium in most patients. The thickness of the normal pericardium by either modality is <2 mm. Pericardial thickness of 4 mm or more indicates abnormal thickening and, when it is accompanied by clinical findings of heart failure, is highly suggestive of constrictive pericarditis). Thickening of the pericardium may be limited to localized areas. CT may offer an additional advantage with its high sensitivity in detecting pericardial calcification [2].

As revealed by invasive hemodynamic evaluation, ventricular chamber compliance is nearly normal at the

beginning of diastole and the chambers fill and reach the limits of the noncompliant pericardial sac. However, there is a sudden cessation of rapid filling resulting in a sharp rise in diastolic pressure, seen as the "dip and plateau" or "square root" pattern on ventricular waveforms. Respiratory discordance of ventricular systolic pressures due to the interventricular dependence in CP may be a reliable hemodynamic factor to distinguish CP from restrictive cardiomyopathy [1] (Table 1).

### Therapeutic Principles

Pericardiectomy is the treatment of choice in patients with CP [2]. Diastolic filling abnormalities after pericardiectomy correlate well with clinical symptoms. These abnormal findings tend to persist in patients who have had preoperative symptoms over longer periods of time. Therefore, prompt diagnosis and referral for surgical pericardiectomy is of paramount importance in these patients. Long-term survival after pericardiectomy for CP is found to be dependent on the underlying etiology, LV systolic function, renal function, serum sodium, and pulmonary artery pressure.

## Peridontitis

►Hypotrichosis - Osteolysis - Peridontitis - Palmoplantar Keratoderma Syndrome

## Perinatal Asphyxia

Mushtaq A. Bhat, Javeed I. Bhat
Department of Pediatrics, Shere-Kashmir Institute of Medical Sciences (SKIMS), Srinagar, Kashmir, India

### Synonyms

Birth asphyxia; Hypoxic ischemia (HI); Hypoxic ischemic encephalopathy; HIE; Neonatal asphyxia; Prenatal cerebral injury; Hypoxia; Acidosis; Ischemia

### Definition and Characteristics

American Academy of Pediatrics (AAP) and American College of Obstetrics and Gynecology (ACOG) define perinatal asphyxia when all the following criteria are met.

1. Profound metabolic or mixed acidemia (pH < 7.00) in an umbilical arterial blood sample
2. Apgar score of 0–3 > 5 min after birth
3. Neonatal encephalopathy (e.g., seizures, coma, hypotonia)
4. Multiple organ involvement (kidney, lungs, liver, heart, intestines)

Hypoxic ischemic encephalopathy (HIE) is one of the major causes of neonatal mortality, morbidity and long term neurodevelopmental sequelae. HIE is classified into mild, moderate and severe types depending on the degree of central nervous system (CNS) and systemic involvement. In severe HIE, mortality is 50–89% and the majority of the deaths occur in the newborn period due to multiorgan failure. Among survivors the sequelae include mental retardation,

epilepsy and cerebral palsy (either hemiplegia, paraplegia, or quadriplegia). In moderate HIE, severe disability occurs in 30–50% and 10–20% have minor deficits. Infants with mild HIE are free from serious complications. In the absence of obvious neurodeficits during infancy, 15–20% patients develop significant learning difficulties. Surrogate markers of fetal distress are present in the majority of patients during the perinatal period. However, early recognition and intervention of fetal distress by monitoring technologies does not eradicate the problem.

## Prevalence

In developed countries prevalence of severe HIE is 2–4/1,000 live births and in developing countries it is 5–10/1,000 live births. According to the World health organization, world wide one million children die with diagnosis of asphyxia and nearly the same number of children survive with significant handicap.

## Molecular and Systemic Pathophysiology

The initiating mechanisms of perinatal asphyxia include hypoxia, ischemia, hemorrhage, perinatal infection, inflammation, metabolic disturbances etc. and in a neonate either single or multiple factors may initiate the chain of events triggering HIE. Significant hypoxia depresses myocardium, reduces cerebral perfusion leading to ischemia. Cerebral autoregulation in sick neonates is impaired. The range of systemic blood pressure over which cerebral autoregulation is functional is 40 mm Hg in adults as opposed to 10–20 mm Hg in neonates which narrows further with HIE. There is increased expression of nitric oxide synthase including both, inducible and neuronal, forms (iNOS and nNOS) in the newborn period which also narrow the autoregulatory window. Further cerebral vasoconstriction secondary to systemic hypertension does not occur because of down regulation of prostaglandin receptors in the newborn period due to high prostaglandin levels. Therefore, cerebral blood flow becomes pressure passive in patients with perinatal asphyxia. With drop in systemic blood pressure, cerebral blood flow (CBF) falls below critical levels causing ischemia and reduced delivery of energy substrates (glucose and oxygen) to brain tissue leading to primary energy failure, cytotoxic edema and neuronal death. Encephalopathic neonates with evidence of cerebral damage on amplitude integrated electroencephalography (a EEG) display impaired cerebral autoregulation. Utilization of metabolites like glucose, ketones and lactate (normally) increases during the perinatal period and the pattern of injury after HIE can be explained on the basis of this high metabolic demand in subcortical area's. Anaerobic metabolism that ensues following asphyxia rapidly depletes stores of high energy phosphate (ATP and phosphocreatinine) in the brain resulting in accumulation of lactate and inorganic phosphate. Ischemia followed by reperfusion exacerbates neuronal injury secondary to generation of oxygen free radicals and delivery of therapeutic agents. Although there is some recovery of high energy phosphates with reperfusion, 6–24 h later delayed or secondary energy failure ensues. The extent of depletion of high energy phosphates and accumulation of lactate correlates with the severity of HIE. This phase which lasts for 48–72 h is characterized by edema, apoptosis and secondary neuronal death.

The biochemical events that lead to secondary energy failure, necrosis apoptosis and secondary neuronal death include following:

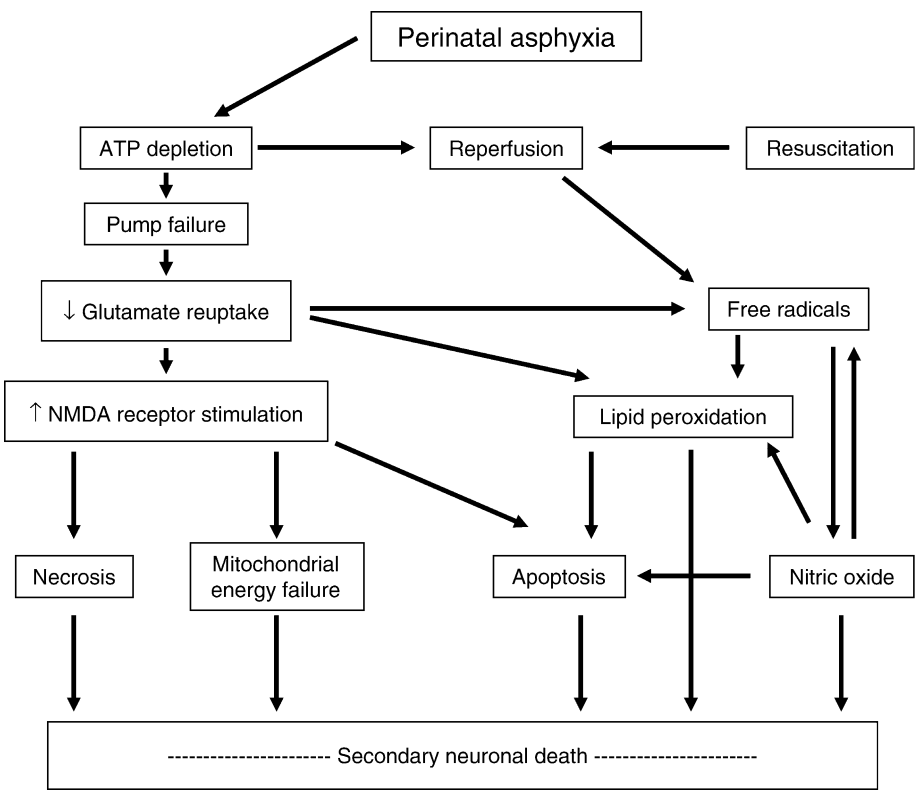
*Excitotoxicity*: Hypoxic ischemic encephalopathy (HIE) manifests as seizures and burst suppression on electroencephalography suggesting a prominent role for neuronal excitability and excitotoxicity. Excitotoxicity refers to excessive glutamatergic neurotransmission which leads to cell death. Glutamate is the main excitatory neurotransmitter and its release, uptake and resynthesis is tightly coupled to cerebral glucose oxidation as shown by magnetic resonance spectroscopy. Elevated glutamate has been documented by proton magnetic spectroscopy in cerebrospinal fluid (CSF) of patients who have suffered HIE and CSF levels of excitatory amino acids are directly proportional to the severity of HIE. After stimulating its receptors (NMDA, AMPA or Kaninate), glutamate is removed from the synapse by glutamate transporters on glial cells. The glia convert glutamate to glutamine which is then transported out of glial cells in to neurons which convert it back to glutamate [1]. The process requires energy and is disrupted by secondary energy failure. Overactivation of NMDA receptor is the commonest mechanism of neuronal injury in HIE. The receptor is composed of four heteromeric subunits, the combinations of which create different functional modules. The receptor has multiple functional sites including a cation selective ion channel which transports $Na^+$, $K^+$ and $Ca^+$. The NMDA receptor is overexpressed in neonatal brain which allows synaptogenesis and plasticity. However, uninhibited stimulation of receptor as occurs in HIE leads to massive influx of $Na^+$, and water with associated cellular swelling and necrosis, elevated intracellular $Ca^+$ concentration and associated mitochondrial dysfunction, energy failure and apoptosis [2]. Neuronal death that occurs depends on the developmental expression and function of these receptors.

Adenosine receptors are also expressed by excitatory neurons and levels of adenosine increase exponentially during ischemia stimulating these receptors. This excessive adenosine receptor activation inhibits axonal growth and white matter formation. Non specific adenosine receptor antagonists, which are beneficial

in preventing renal and tubular damage due to perinatal asphyxia when given early could potentially have a role in limiting neuronal injury in HIE.

*Oxidative Stress*: Increased production of reactive oxygen radicals also contributes to the pathogenesis of neonatal HIE. Under physiological conditions, more than 80% of oxygen in the cell is reduced to adenosine triphosphate (ATP) by cytochrome oxidase and the rest is converted to superoxide and hydrogen peroxide. Superoxide and hydrogen peroxide are scavenged enzymatically by superoxide dismutase, catalase, and glutathione peroxidase and non-enzymatically by reaction with alphatocopherol and ascorbic acid. Damage to mitochondria during asphyxia results in accumulation of superoxide and immaturity of antioxidant defenses will result in conversion of superoxide to hydroxyl radicals. With reperfusion after ischemia these free radicals directly damage DNA, proteins and membrane lipids, cause lipid peroxidation, initiate apoptosis and react with nitric oxide to produce peroxynitrile radicals. All these are implicated in the secondary neuronal death. Neonatal brain is particularly vulnerable to free radical attack and lipid peroxidation because of three factors; (i) Polyunsaturated fatty acid content of brain is high. There is a basal level of lipid peroxidation that is high at term. Lipid peroxidation causes phospholipase activation that increases free radical production which in turn increase lipid peroxidation and a vicious cycle occurs in brain. (ii) Antioxidant enzymes like superoxide dismutase, catalase, and glutathione peroxidase are immature in neonates. (iii) There is increased free iron relative to the adults. The damaging potential of free iron and immaturity of enzymatic oxidant defenses are interrelated. Free iron catalyses the production of various reactive oxygen species. Increased free iron is detectable in the plasma and CSF of asphyxiated newborns.

*Nitric Oxide*: Nitric oxide (NO) functions both physiologically and pathologically. Its production by enzymes of endothelial cells, astrocytes and neurons is stimulated by intracellular calcium. NO thus produced has a role in pulmonary, systemic and cerebral vasodilatation and exerts a compensatory vascular effect after ischemia during reperfusion. NO is also produced by inducible NO synthase (iNOS) in response to stress which modifies the NMDA receptor facilitating calcium entry and enhancing cytotoxicity. Nitric oxide and nitric oxide synthase are also implicated in the programmed cell death that results from HIE [3]. The combined effect of all these pathways leading to secondary neuronal death is shown in Fig. 1.



**Perinatal Asphyxia. Figure 1** Mechanism of secondary neuronal death in perinatal asphyxia.

*Inflammation*: Cytokines are the final common mediators of brain injury that is initiated by hypoxic-ischemia, reperfusion and infection. In neonates CSF concentrations of IL-ß, IL-6 and IL-8 increase after perinatal asphyxia in comparison to controls and increased magnitude correlates with severity of encephalopathy. Also other mediators like platelet activating factor, arachidonic acid and their metabolites like prostaglandins, leukotrienes, thromboxanes and cyclo-oxygenase are involved in the inflammatory response during evolution of brain injury after ischemia and reperfusion.

*Genetic Effects*: Same type of injury manifests differently in different neonates with regards to clinical presentation, imaging studies and neurodevelopmental outcome. Such variability appears to be genetically based. However, susceptibility factors for neonatal brain injury have not been identified clearly. Study of very preterm infants showed an association of single-nucleotide polymorphisms such as endothelial nitric oxide synthase A (922) G, factor VII (Arg353Gln) and del (−323)10 bp-ins, and lymphotoxin *a* (Thr26Asn) with spastic cerebral palsy. Such type of associations increases the assumption that certain polymorphisms may increase the susceptibility to perinatal asphyxia.

## Diagnostic Principles

Diagnosis of HIE is based on history and neurological examination. Fetal distress or surrogate markers of fetal distress are present in the majority of the patients in the perinatal period. There is a history of resuscitation at birth and umbilical arterial blood shows acidosis or increase in base deficit. The involvement of the central nervous system depends on the severity of HIE. In mild HIE, there is transient irritability, increase in sympathetic activity and muscle tone which improves over 3–4 days. In moderate HIE, there is hypotonia, increased parasympathetic activity and weak neonatal reflexes. Seizures occur in 80%. All features normalize in 1–2 weeks with only 20–30% patients developing long term disability. In severe HIE, patients are comatose, hypotonic with absent neonatal reflexes. Seizures occur initially, are resistant to treatment and subsequently frequency decreases due to extensive neuronal injury. Electroencephalogram shows burst suppression or is isoelectric which portends poor prognosis. Involvement of other systems like kidneys, lungs, gastrointestinal tract and cardiovascular system also occur in severe HIE. Laboratory and imaging studies help to know the extent of involvement of CNS and other systems:

1. Electrolytes and renal function tests should be done daily till improvement occurs. Serum sodium, potassium and chloride determinations are important to rule out SIADH and other complications. Also serum creatinine, creatinine clearance and BUN estimation should be done during initial few days.
2. Study of liver function tests and cardiac enzymes (Tropoin 1, Tropoin T, & CK – MB) should be done to look for the involvement of these organs. Echocardiography for myocardial contractility is needed if ionotropic support is required.
3. Ultrasound of the head is easy and can be performed at bedside. It shows presence of cerebral edema, intracerebral or intraventricular hemorrhage. However posterior fossa hemorrhage cannot be visualized.
4. CT scan of the head is important to confirm cerebral edema (obliteration of ventricles, flattening of gyri) and any hemorrhage seen on ultrasound. Areas of reduced density on CT scan are compatible with evolving infarcts. Also CT is important in ruling out posterior fossa hemorrhage.
5. MRI brain is very helpful in moderate to severe HIE during early stages and follow-up. It may show grey-white matter injury, developmental defects and status of myelination. Diffusion weighted MRI is more accurate to identify areas of edema early in the course of the disease.
6. Amplitude electroencephalography helps in the early identification of patients with poor outcome.

## Therapeutic Principles

1. Maintain adequate ventilation and perfusion. Mechanical ventilation may be required in severe cases.
2. Fluid and electrolyte status should be maintained to prevent SIADH and other complications. Two third fluids should be given if there is hyponatremia and weight gain in initial few days. Subsequently fluid intake is individualized depending upon urine output, weight gain and renal parameters. Avoid hypoglycemia, hypocalcaemia or hyperglycemia as all exacerbate neuronal injury.
3. Avoid acidosis, hypoxia, hypercarbia and hypocarbia. All, especially the last, exacerbate brain injury. Maintain $PaO_2$ between 60 and 80 mm Hg, $PaCO_2$ between 35 and 40 mmHg and pH between 7.35 and 7.45.
4. Maintain mean blood pressure at 45–50 mmHg in term babies. Inotropic support may be needed to maintain mean blood pressure in the desired range.
5. Seizures should be controlled early and effectively. Phenobarbitone may be used initially. If needed phenytoin may be added in resistant seizures. Continuous EEG monitoring should be done as clinically asymptomatic seizures have been shown to increase neuronal injury.
6. Brain cooling due to whole body hypothermia has been shown to be very effective in the management of HIE. It has a therapeutic window of 6 h

and brain is cooled for 48–72 h after which slow rewarming is done. The possible mechanisms of action include: (i) reduced metabolic rate and energy depletion; (ii) decreased excitatory transmitter release; (iii) reduced alterations in ion flux; (iv) reduced apoptosis due to HIE; and (v) reduced vascular permeability, edema, and disruptions of blood-brain barrier functions. In a recent study on whole body hypothermia by Shankaran et al. [4], death or disability occurred in 44% of patients in hypothermic group vs. 62% in the control group (RR 0.72, C.I.0.54–0.95). Hypothermia not only decreases the incidence of cerebral palsy at 18 months of age but also improves outcome in the neonatal period.

7. Renal and tubular damage in perinatal asphyxia is caused by adenosine. Theophylline, a non specific adenosine receptor antagonist has protective effect if given within 1 h of birth [5].

# Periodic Catatonia

Gerald Stöber[1], André Reis[2]
[1]Department of Psychiatry and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany
[2]Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany

## Synonyms

Catatonic schizophrenia; Catatonia; Kahlbaum's syndrome, periodic catatonia

## Definition and Characteristics

Periodic catatonia is a bipolar disorder in the schizophrenic spectrum with prominence of qualitative psychomotor changes. Two psychotic poles, psychomotor excitement and inhibition, involve parakinesia, grimacing or mask-like facies, iterations and posture stereotypies, as well as distorted stiff movements or akinetic negativism. In most cases, acute psychotic episodes are accompanied by hallucinations and delusions, but in remission there remains a distinct mild to severe catatonic residual state with psychomotor weakness and diminished incentive [1].

## Prevalence

1:10,000 in periodic catatonia; the morbidity risk is ~27% for first-degree relatives; penetrance of the disorder is estimated to be ~40% [2,4].

## Genes

Periodic catatonia is the first sub-phenotype of the schizophrenic psychoses with confirmed linkage despite considerable genetic heterogeneity in two independent genome-wide linkage scans (GS) on twelve and four extended multiplex pedigrees [3,4]. Major disease loci, supported by independent pedigrees, were observed at chromosome 15q15 and 22q13, with further putative loci on chromosomes 1, 6, 11, 13, 16 and 20. Parametric, non-parametric and haplotype analyses were consistent with an autosomal dominant transmission with reduced penetrance.

*Chromosome 15q15*: In GS I, non-parametric analyses found the most significant allele sharing between affected individuals on chromosome 15q15 at position 35.3 cM ($p = 2.6 \times 10^{-5}$, maximum non-parametric lod score 3.57), replicated by GS II with the main peak on chromosome 15q at position 32.3 cM ($p = 0.003$). Linkage and haplotype analyses in three exceptionally large pedigrees linked to chromosome 15q15 disclosed a critical region between markers D15S1042 and D15S659, which could be further refined to a 7.49 Mb interval, containing 123 known genes (unpublished results). The current positional cloning project involves a systematic mutation scan of all genes from the critical region in search of disease-associated haplotypes and/or mutations in linked pedigrees and a cohort of 250 index cases.

*Chromosome 22q13*: Mainly supported by a single four-generation pedigree, a second locus was identified on chromosome 22q13 with a maximum multipoint LOD score of 2.59 ($\theta = 0.0$) under an autosomal dominant model. Previously, a sequence variant in the gene MLC1 (coding for autosomal recessively inherited megaloencephalic leukoencephalopathy with subcortical cysts; MLC) had been proposed to cause periodic catatonia

and recently a small sample of cases produced a weak association to a two-locus haplotype in the promoter region. However, a systematic mutation scan of MLC1 had earlier produced compelling evidence that MLC1-variants are not associated with periodic catatonia in sample of 140 cases [5].

## Molecular and Systemic Pathophysiology

In catatonia, systemic pathophysiology and the involved neuro-anatomical structures remain undetermined, but basal ganglia and thalamo-cortical loops seem to be involved. Using broadly defined criteria for catatonia, imaging techniques revealed a decreased blood flow in right lower and middle prefrontal and parietal cortex during acute akinesia; motor activation was reduced in the contralateral motor cortex and in a single case study, acute akinesia caused a reversible complex dysregulation of glucose metabolism in large brain areas. Animal models of catatonia unfortunately reduce disturbed human psychomotor behavior, i.e., expressive and reactive movements, excessively to animal immobility or antipsychotic drug-induced catalepsy.

## Diagnostic Principles

Diagnosis is made by clinical observation; diagnostic laboratory and specific neuro-imaging abnormalities are missing. In the framework of international classification systems, catatonia is recognized as a cluster of gross, non-specific psychomotor traits and mostly identifies a state of extreme motor inhibition. In view of K. Leonhard's nosological differentiation, psychomotor disturbances are complex, and as a basic point quantitative hyperkinetic or akinetic changes (motility psychoses with phasic remitting course) have to be discriminated from qualitative changes, true "catatonic" signs (periodic and systematic catatonia.

Psychomotor disorders: catatonia phenotypes, and etiological aspects

*Motility psychosis*:

- Subphenotype of the cycloid psychoses
- Bipolar phasic with quantitative psychomotor disturbances
- Low genetic loading according to family and twin studies
- Multifactorial etiology (environmental factors, modifying genes?)

*Systematic catatonias*:

- Distinct subtypes; involvement of discrete functional psychic units
- Chronic progressive without remission
- Low genetic loading according to family and twin studies
- Multifactorial etiology, early noxious events (gestational infections)

*Periodic catatonia*:

- Subphenotype of the unsystematic schizophrenias
- Bipolar with residual syndrome and qualitative psychomotor disturbances
- Genetically mapped in two independent genome scans
- Autosomal dominant transmission with reduced penetrance
- Major gene locus on chromosome 15q15, and genetic heterogeneity

Gjessing's concept of periodic catatonia pooled bipolar psychomotor disorders with phasic course and those with episodes of worsening.

## Therapeutic Principles

In catatonia, specific therapies are not available. Acute hyperkinetic attacks respond well to first- and second-generation antipsychotic drugs, benzodiazepines reduce affective tensions. Electroconvulsive therapy should be applied in cases with severe stupor or excessive psychomotor agitation, combined with dysregulation of autonomic status. Patients with periodic catatonia seem to benefit from modern low dose antipsychotic maintenance therapy, but still develop the characteristic catatonic residual syndrome.

## Periodic Movements in Sleep

►Periodic Limb Movement

## Periodic Leg Movements

►Periodic Limb Movement

## Periodic Limb Movement

Jan Rémi, Soheyl Noachtar
Section of Sleep, Department of Neurology, University of Munich, Munich, Germany

### Synonyms

Periodic leg movements; Leg jerks; Periodic movements in sleep, PLMs

### Definition and Characteristics

Periodic limb movements (PLMs) are repetitive, stereotypic movements of the extremities preferably during sleep. PLMs can be a part of the Restless-Leg-Syndrome (RLS). In this case, also unpleasant sensations of the urge to move and paresthesias are part of the syndrome. However, PLMs also represent a separate nosological entity. Typically the big toe is extended and ankle, knee and hip can be flexed to a small extent. The patients can be aware of the leg jerks and complain of bad sleep, or sometimes they are unaware of the sleep events and will complain about excessive daytime sleepiness alone. Next to RLS, PLMs can accompany other sleep disorders like narcolepsy and sleep apnea and may disappear upon successful treatment of the primary sleep disorder [1].

### Prevalence

The prevalence increases with age. It is very low under the age of 30 and can reach 34% in patients over the age of 60 [2].

### Molecular and Systemic Pathophysiology

As in restless-legs-syndrome, the dopamine transmitter system plays a role in the pathophysiology of PLMs, with L-Dopa and dopamine agonists relieving symptoms and dopamine blockers worsening the symptoms [3].

### Diagnostic Principles

Diagnosis is based on (i) complaints of insomnia and/or excessive daytime sleepiness, (ii) repetitive stereotypic extremity movements, (iii) polysomnographic demonstration of the movements and subsequent arousal reactions, (iv) no other medical illness or medication accounting for the PLMs, and (v) other sleep disorders may be present but should not contribute to the PLMs. Polysomnography can document the PLMs and can lead to the diagnosis of other, accompanying sleep disorders [1].

### Therapeutic Principles

The treatment of PLMs is similar to the treatment of the restless legs syndrome, consisting mainly of dopaminergic medication, namely L-Dopa or dopamine agonists [3].

P

## Periodic Paralyses, Familial

Karin Jurkat-Rott, Frank Lehmann-Horn
Applied Physiology, Ulm University, Ulm, Germany

### Synonyms

Hyperkalemic periodic paralysis; HyperPP; Hypokalemic periodic paralysis; HypoPP; Andersen syndrome (AS)

### Definition and Characteristics

Two dominant episodic types of weakness with or without myotonia, HyperPP and HypoPP, are distinguished by the serum $K^+$ level during attacks. Intakes of $K^+$ and glucose have opposite effects in the two disorders; while $K^+$ triggers attacks and glucose is a remedy in HyperPP, glucose-induced hypokalemia provokes attacks in HypoPP, which are ameliorated by $K^+$ intake. Due to additional release of $K^+$ from

muscle in HyperPP and uptake of $K^+$ by muscle in HypoPP, the resulting dyskalemia can be so severe that cardiac complications arise. During an attack, death can also occur due to respiratory insufficiency. Independently of the severity and frequency of the paralytic episodes, many patients develop a chronic progressive myopathy in the forties, an age at which the attacks of weakness decrease. An additional form of familial PP is the Andersen syndrome, which is also dominantly inherited and affects not only the skeletal but also the cardiac muscle. It may show hyper-, normo- or hypo-kalemia during paralytic attacks. Another type of dyskalemic periodic paralysis has been reported by Abbott et al. (2001) but questioned, since the prevalence of the underlying genetic variant is the same in patients and controls and no paralytic attacks could be provoked in the carriers [1].

## Prevalence

1:200,000 in HyperPP, 1:100,000 in HypoPP and 1:1,000,000 in AS.

## Genes

*HyperPP*: Point mutations in SCNA4 (17q23) encoding Nav1.4, the voltage-gated sodium channel of skeletal muscle [2].

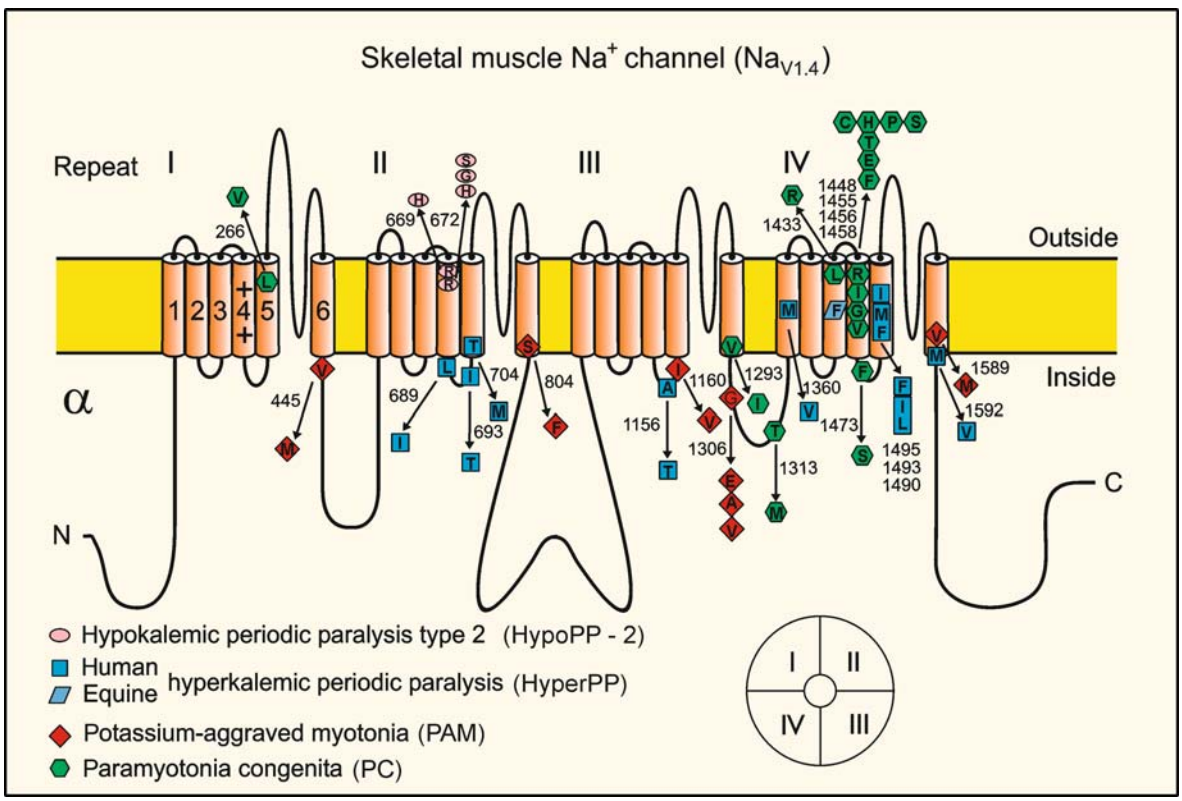
*HypoPP*: Point mutations in SCNA4 (HypoPP-2) (2) or CACNA1S (1q23) encoding Cav1.1, the L-type calcium channel of skeletal muscle (HypoPP-1) [3]; all amino acid changes are situated in voltage sensors.

*AS*: Mutations in KCNJ2 (17q23) encoding Kir2.1, the inward rectifier potassium channel of skeletal and cardiac muscle [4].

## Molecular and Systemic Pathophysiology

HyperPP is caused by mutations in the voltage-gated sodium channel $Na_v1.4$ that is essential for the generation of muscle fiber action potentials. Most $Na_v1.4$ mutations are situated at inner parts of transmembrane segments or in intracellular loops and affect structures that may form the three-dimensional docking site for the fast inactivation particle. Any malformation may reduce the affinity between the "latch bar and the catch" (Fig. 1).

The α subunit consists of four highly homologous domains I-IV with six transmembrane segments each (S1–S6). The S5–S6 loops and the transmembrane segments S6 form the ion selective pore, and the S4 segments contain positively charged residues every third amino acid, conferring voltage dependence to the protein. The S4 segments are thought to move outward upon depolarization thereby inducing channel opening. When inserted in the membrane, the four



**Periodic Paralyses, Familial. Figure 1** Scheme of the voltage-gated $Na^+$ channel.

repeats of the protein fold to generate a central pore as schematically indicated on the right bottom of the figure (see insert). The repeats are connected by intracellular loops. One of them, the III-IV linker, contains the inactivation particle (amino acids IFM close to the shown G to E/A/V) which potential-dependently binds to its docking site. The mutations associated with HyperPP and HypoPP-2 and other muscle sodium channelopathies (see ►Myotonia and paramyotonia), are indicated in the one-letter code for amino acids.

The mutant channels avoid the inactivated state and, in contrast to normal $Na^+$ channels, reopen from the inactivated to the open state, corresponding to a gain-of-function defect. As a result, sodium influx is increased as shown in vitro and in vivo. This inward current is associated with a sustained membrane depolarization that increases the electrical driving force for potassium, and potassium released from muscle elevates its serum concentration. Sodium influx into muscle fibers is accompanied by water, causing hemoconcentration and further increase in serum potassium. This is a vicious cycle that spreads out and affects the surrounding muscle fibers.

In contrast to the gain-of-function changes in HyperPP, HypoPP is associated with a loss-of-function defect of $Na_v1.4$ or $Ca_v1.1$, the main subunit of the voltage-gated L-type $Ca^{2+}$ channel complex (dihydropyridine receptor) located in the t-tubular system. HypoPP-1 and 2 are clinically similar, and in both channel types, the mutations are located exclusively in the voltage-sensing S4 segments; those of $Na_v1.4$ are located in domain 2 and those of $Ca_v1.1$ in domains 2 or 4. Functionally, the inactivated state is stabilized in the $Na^+$ channel mutants, while the channel availability is reduced for the $Ca^{2+}$ channel mutants. It is still unclear how the loss-of-function mutations of these two cation channels can produce the long-lasting and pronounced membrane depolarization that inactivates the sodium channels and thereby leads to the fiber inexcitability.

AS has mutations affecting the Kir2.1 channels, which are essential for maintaining the highly negative resting membrane potential of muscle fibers and accelerating the repolarization phase of the cardiac action potential. The mutations mediate loss of channel function by haploinsufficiency or by dominant-negative effects on the wild type allele and lead to long-lasting depolarization and membrane inexcitability.

## Diagnostic Principles

In the past, provocative tests have been carried out for diagnostic reasons. As they have harbored the risk of inducing a severe attack they had to be performed by an experienced physician and a stand-by anesthesiologist; the serum potassium and glucose levels and the ECG had to be closely monitored. Nowadays, provocative tests should be restricted to patients in whom molecular genetics fail to identify the underlying mutation. Since histological alterations are not specific, a muscle biopsy should only be performed in patients with atypical features or for documentation of a vacuolar myopathy.

## Therapeutic Principles

*HyperPP*: During an attack of weakness, serum potassium levels should be reduced by stimulation of the sodium-potassium pump, e.g. by continuous mild exercise or carbohydrate ingestion or salbutamol inhalation. Permanent stabilization of serum potassium at a low level should be achieved by thiazide diuretics. Alternatively, carbonic anhydrase inhibitors are the second choice and may be effective via myoplasmic acidification.

*HypoPP*: All substances which decrease serum potassium levels either by shifting potassium into the cells or by excretion by the kidney should be avoided including high carbohydrate/sodium meals, bicarbonate and potassium-lowering diuretics, a sedentary lifestyle or strenuous physical exercise. Attacks should be treated orally with potassium chloride. Carbonic anhydrase inhibitors are the prophylactic medication of choice. Potassium-sparing diuretics, such as triamterene, amiloride, and spironolactone may be administered in addition.

*AS*: The most important task is to find out whether the cardiac arrhythmia is potentially fatal or not. Drugs or provocative tests that induce hypokalemia can provoke ventricular tachycardia and must be avoided. Patients with former syncopes or bursts of ventricular tachycardia in the resting or Holter ECG recordings are at high risk. Such symptoms and signs may demand the implantation of a defibrillator or a pacemaker.

# Periodic Vestibulocerebellar Ataxia

►Episodic Ataxia Type 1 and Type 2

# Periodontal Diseases

Marinella Holzhausen, Nathalie Vergnolle
Department of Pharmacology and Therapeutics, University of Calgary, Calgary, AB, Canada

## Synonyms

Gum disease; Periodontopathia; Gingivitis; Periodontitis

## Definition and Characteristics

The human periodontal diseases encompass a group of oral disorders characterized by infection and inflammation that affect the surrounding and supporting tissues of the teeth, including gingival tissue, periodontal ligament, cementum, and alveolar bone.

The two major forms of periodontal diseases are gingivitis and periodontitis, but they can be subclassified as gingival diseases (plaque-induced and non-plaque induced), chronic periodontitis, aggressive periodontitis, periodontitis as a manifestation of systemic diseases, necrotizing periodontal diseases, abscesses of the periodontium, periodontitis associated with endodontic lesions and developmental or acquired deformities and conditions [1].

Gingivitis is gingival inflammation, characterized by redness, swelling, and tendency to bleed, without clinical attachment loss or with non-progressing attachment loss. Periodontitis is inflammation that reaches both gingival tissues and adjacent attachment apparatus, and is characterized by progressive loss of connective tissue attachment and alveolar bone. Periodontitis is an insidious destructive condition, which, if left untreated can lead to tooth mobility and potential exfoliation of teeth.

## Prevalence

Periodontal diseases constitute the most common oral infections in humans and the major cause of tooth loss in adults.

It is estimated that the prevalence of severe periodontal destruction is remarkably consistent in different populations affecting around 10% of the population in the world.

## Molecular and Systemic Pathophysiology

The presence of a bacterial biofilm is a sine qua non condition for the initiation and progression of most of the periodontal diseases [2]. The subgingival growth of certain species of primary Gram-negative anaerobic bacteria has been implicated in the complex bacterial etiology of the disease. Interestingly, the presence of periodontal bacteria solely is not sufficient to explain periodontal disease episodes. In fact, in periodontal healthy individuals, the saliva, the gingival crevicular fluid (a serum exudate), the epithelial surface, and the initial stages of inflammatory response are able to maintain an ecological balance with the bacteria. Protective response of the host involves the recruitment of neutrophils, production of antibodies, and the possible production of anti-inflammatory mediators including transforming growth factor-β (TGF- β), interleukin-4 (IL-4), IL-10, and IL-12.

It is believed that periodontal tissue breakdown occurs as a result of alterations in the number or in the pathogenicity of certain microorganisms, mainly porphyromonas gingivalis, bacteroides forsythus, and actinobacillus actinomycetemcomitans. In addition, modifications in the host susceptibility may accentuate the activation of destructive host immuno-inflammatory responses. Host tissues and immune cells may respond to bacterial infection by producing pro-inflammatory mediators such as arachidonic acid metabolite prostaglandin $E_2$, matrix metalloproteinases (connective tissue degrading enzymes) and the cytokines IL-1, IL-6 and tumor necrosis factor-α (TNF- α), which are potent periodontal tissue degrading agents responsible for connective tissue and alveolar bone destruction. Environmental, acquired and genetic risk factors, such as cigarette smoking, stress, diabetes and IL-1 gene polymorphisms, may exacerbate the host response and, therefore, increase the susceptibility to periodontal diseases.

## Diagnostic Principles

The diagnosis of periodontal disease relies on traditional clinical and radiographic assessments, and it is based on the patient's medical and dental histories, on the amount of observable plaque and calculus, and presence of clinical signs of inflammation (e.g., bleeding following probing), periodontal probing attachment levels, and radiographic analysis of the alveolar bone height [3].

The use of culture DNA probes or assessment of specific cell surface antigenic profiles, and enzymatic activity may identify the presence of periodontal pathogens. In addition, the host response can be assessed by gingival crevicular fluid detection of host-derived enzymes, tissue breakdown products or inflammatory mediators. Furthermore, a genetic test for polymorphisms in the IL-1 gene cluster identifies individuals that

may have an increased secretion of IL-1β in response to inflammation-induced stimuli.

### Therapeutic Principles

The aim of periodontal therapy is to minimize or eliminate inflammation and to stop the progression of periodontal attachment loss [4]. In many patients, personal plaque control measurements, and professional plaque and calculus removal (scaling and root planning) are essential for controlling inflammatory periodontal diseases. However, in some advanced and aggressive forms of periodontal disease, or in medically compromised patients, supplemental therapeutic approaches may be required, such as the use of systemic antibiotics, subgingival delivery of antibiotics/antimicrobials, and host modulatory therapies.

The surgical periodontal treatment has to be considered in those cases in which elimination/reduction of excessive probing depths is necessary to facilitate the patient's personal periodontal maintenance. There are also surgical procedures that attempt the regeneration of lost periodontal tissues or improvement of esthetics in exposed root surfaces.

## Peripheral Artery Disease

Martin Schillinger
Division of Angiology, Department of Internal Medicine II, University of Vienna, Medical School, Vienna, Austria

### Synonyms

PAD; Peripheral arterial occlusive disease; Atherosclerosis

### Definition and Characteristics

PAD is defined by atherosclerotic obstruction of lower limb arteries and may affect all vascular segments, i.e. the aorta, the pelvic arteries, the femoropopliteal segment and the tibioperoneal arteries. Conventional risk factors for atherosclerosis account for only about 50% of the cases [1].

### Prevalence

The prevalence of PAD clearly increases with age, and the disease affects approximately 9% of the population above the age of 50 years and 15% of the population above 65 years. More than two thirds of the patients remain asymptomatic.

### Genes

Accumulating evidence suggests that PAD has an important hereditary component [2]. Among the panel of novel risk factors various genetic abnormalities potentially play a relevant role. Identification of target genes responsible for an increased risk of PAD, however, has been a slow and difficult process [3].

Polymorphisms in many different genes have been attributed to convey an increased risk for atherosclerosis and PAD. Single nucleotide polymorphisms (SNP) are the most frequently described changes in the DNA sequence which are thought to exert a pathogenetic effect in PAD. Insertion and deletion polymorphisms and variable number of tandem repeats (VNTR) also have been reported to be functionally relevant in this context. Interpreting the numerous publications in this field of research it seems important to consider

the following issues: First, most studies on genes and PAD are cross-sectional association studies investigating specific genotypes in patients and controls. These studies are mostly underpowered and prone to publication bias, as positive studies are far more likely to be published than negative ones. E.g., for evaluation of a single polymorphism with a frequency of 10% within the target population a sample size above 400 participants is needed to detect a clinically relevant effect size of a doubled risk, the number of participants of course increases when multiple polymorphisms are investigated. Second, studies infrequently report a functional relevance of the investigated polymorphisms in the respective study populations. An ideal study reports on the genetic variant, changes in expression pattern on the level of the RNA, changes in the levels of the gene product (enzyme, protein) – the so called intermediate phenotype – and changes of the clinical phenotype (presence of disease or disease severity). This pathophysiologic chain of evidence hardly has been demonstrated for any polymorphism presumably involved in the pathogenesis of PAD. Third, PAD is a multifactorial and polygenetic disease. "Multifactorial" indicates that the interaction of multiple risk factors determines the individual's risk, in particular, gene-environment interactions seem relevant. "Polygenetic" indicates that gene–gene interactions likely contribute to the initiation and progression of atherosclerosis.

Genetic polymorphisms, investigated in the context of peripheral artery disease are involved in the pathogenesis of traditional cardiovascular risk factors (dyslipidemia, hypertension, diabetes and insulin resistance), inflammation, anti-oxidant effects. Endothelial dysfunction, coagulation and thrombosis, and platelet dysfunction, as amplified below.

## Molecular and Systemic Pathophysiology

*Dyslipidemia*: More than 230 mutations in the gene encoding for the LDL-receptor are known (http:/www.ucl.ac.uk/fh), which account for homozygous or heterozygous familial hypercholesterolemia. Another less severe cause for familial hypercholesterolemia is the Arg3500Gln (or exceptionally, Arg3531Cys) mutation of apolipoprotein B, the molecule that acts as a ligand for LDL receptors. Apolipoprotein E binds VLDL and IDL and occurs in three main versions: apo-E3, the natural isoform, apo-E2 and apo-E4, which are caused by SNPs at positions 158 and 112, respectively. Apo-E4 seems to exert a deleterious effect on atherosclerosis as shown in the 4S-trial whereas apo-E2 seems to be beneficial. Rarely, familial dysbetalipoproteinemia affects patients with the apo-E2 allele causing a complete deficiency of apo-E.

The serum concentration of lipoprotein (a) is determined by >90% by genetic causes, elevated levels above 30 mg/dL and particularly a coincidence with the apo-E4 allele have been demonstrated to exert particularly unfavorable effects with respect to atherosclerosis development. With respect to PAD, however, one study demonstrated that genetic variability of apo-B contributes to atherosclerosis risk, but not specifically to PAD, and another study investigated the apolipoprotein AI-CIII-IV gene cluster and found no association with the disease. For HDL mutations a specific association with PAD has not been demonstrated unequivocally as yet, although states of low HDL and respective polymorphism like in the lecithin-cholesterol acyl transferase (LCAT) seem to promote PAD. Several other polymorphisms in the cholesterol ester transfer protein (CETP) have also only been investigated with respect to coronary atherosclerosis. The gene of the lipoprotein lipase is particularly prone to mutations (www.ncbi.nlm.gov/omin) which lead to increased triglyceride levels. The role of these genetic variants with respect to PAD remains to be investigated. A rare Mendelial disease – Tangier's disease is characterized by premature atherosclerosis including PAD – is due to a mutation in the ABC1 transporter gene, which forms a channel for cholesterol egress through cell membranes. Recently, a SNP in the plasma PAF-acetylhydrolase (PAF-AH) at position 994G > T in exon 9 has been described to be associated with PAD and seemed to interact with hypercholesterolemia in a Japanese population.

Focusing on gene-drug interactions, the LEADER trial found no modulating effect of three polymorphisms in the peroxisome proliferators activated receptor alpha gene, two apolipoprotein CIII polymorphisms and one beta fibrinogen polymorphism with respect to treatment effects of bezafibrate.

*Hypertension*: Molecular variants of the genes encoding for the renin-angiotensin-aldosterone and sympatho-adrenergic system are related to hypertension development and thus may promote PAD development. Particularly the insertion/deletion polymorphism of the ACE gene clearly has functional relevance as it influences plasma ACE activity and was investigated with respect to atherosclerosis development and progression. In the context of PAD, the relation of the ACE polymorphism with restenosis after percutaneous interventions, insulin resistance and hypertension may be relevant, although an implication of this polymorphism in PAD remains debatable due to divergent findings. Polymorphism of the angiotensin II receptor, chymase A and aldosterone synthase have only been studied in the context of cardiac atherosclerosis.

*Insulin Resistance and Diabetes*: Several mutations causing rare forms of insulin resistance have been described involving the insulin receptor and the insulin receptor substrate (IRS). In particular, the G972R polymorphism of the IRS-1 gene, which can be found

in 6–7% of the population is clearly associated with insulin resistance and premature atherosclerosis.

*Inflammation*: Atherosclerosis is considered a chronic inflammatory disease and several genes encoding for mediators of inflammation have been studied in the context of PAD. These include ICAM-1, interleukin 6 polymorphisms (G/C -174), interleukin 1 (including its receptor antagonist) and IL-5 polymorphisms revealing partly positive associations, but no convincing evidence as these findings were not confirmed in independent cohorts. Furthermore, genetic variability in the CRP gene has been discussed potentially relevant for atherosclerosis development and variability of the E-selectin Ser128-Arg polymorphism was analyzed with respect to restenosis after endovascular treatment of PAD patients. Various chemokines are thought to be associated with atherosclerosis. In this context the homozygous Delta 32 mutation of the gene of the chemokine receptor CCR5 was suggested to differentiate PAD from aneurismal disease.

*Anti-oxidant Effects*: Various anti-oxidants are thought to play a role in the development of atherosclerosis. In patient with peripheral artery disease, a GT length polymorphism in the heme oxygenase-1 (HO-1) gene promoter has been demonstrated to be associated with future cardiovascular adverse events and restenosis after endovascular treatment, however, an association with development of PAD has not been shown as yet. Another enzyme potentially relevant for anti-oxidant defense in the vascular wall particularly in diabetic subjects is glutathione peroxidase-1 (GPx-1). Four polymorphisms in GPx-1 were identified and associated with increased intima media thickness and risk for peripheral artery disease. The haptoglobin 2–2 genotype also was shown to be associated with PAD in one study.

*Endothelial Dysfunction*: Polymorphisms in the NADH/NADPH oxidase, NO-synthase and methylene tetrahydrofolate reductase (MTHFR) seem to be associated with endothelial dysfunction. However, for the p22 phox gene polymorphism (C242T), a component of the NADH/NADPH oxidase system, negative findings were reported with respect to an association with PAD. The C677T polymorphism of MTHFR, which causes a less efficient catabolism of homocysteine into methionine and thus increases homocysteine by 25% in states of folate deficiency, presumably increases the risk for PAD particularly in diabetic subjects. This polymorphism has to be separated from rare causes of severe hypercysteinemias capable of producing homocysteinuria like homozygous CBS deficiency, an exceptional Mendelian disease. A SNP in the human paroxonase-1 (PON-1) gene (Q192R) which may reduce LDL oxidation has been demonstrated to show a direct relation with brachial flow mediated vasodilation in PAD patients.

*Coagulation and Thrombosis*: Fibrinogen levels partly depend on the genotype and several polymorphisms particularly in the beta-chain of fibrinogen have been described in PAD patients, and an association with PAD was demonstrated for the -455GG genotype of fibrinogen. Polymorphisms of factors VII and XIII were discussed to have protective effects against coronary artery disease, polymorphisms in factors VIII and IX or vWF were also suggested to be involved in coronary artery disease. However, for PAD, negative results exist for factor VII (R/Q353) and XIII (V34L) polymorphism. Other genetic variants involved in coagulation and venous thrombosis like factor V Leiden and MTHFR C677T showed no associations with chronic limb ischemia, discrepant data exist for prothrombin mutation G20210A. An increase in plasma PAI-1 levels is considered an important prothrombotic and proatherogenic factor. This protein is under control of the 4G/5G polymorphism in the promoter zone. Carriers of the 4G allele were thought to have a higher risk for atherosclerosis and PAD, although negative results were found in the Edinburgh Artery Study.

*Platelet Dysfunction*: Polymorphisms modifying platelet function are found in genes encoding for the Glycoprotein IIb/IIIa receptor for fibrinogen, the Glycoprotein Ib-IX V receptor for vWF (Kozak polymorphism) and the Glycoprotein Ia-IIa receptor for collagen. For PAD, however, a negative report on the PI(A) polymorphism of platelet glycoprotein IIIa, the HPA-3 polymorphism of platelet glycoprotein IIb and a VNTR polymorphism of glycoprotein IIb in subjects with diabetes was published. Addressing drug-response, a functional polymorphism in the clopidogrel target receptor gene P2Y12 has been demonstrated to modulate the susceptibility for future cardiovascular events in patients with PAD receiving clopidogrel.

## Diagnostic Principles

Clinical symptoms are typical: Intermittent claudication impairs patients' walking distance by exercise-induced pain of the muscles of the calf or thigh. Advanced stages of PAD are characterized by ischemic rest pain of the toes or foot, and ischemic tissue loss. Diagnosis is made by palpation of the pulses, measurement of ankle-brachial pressure index, oscillography and by various imaging techniques like duplex ultrasound, magnetic resonance imaging angiography, computed tomography angiography and conventional intra-arterial digital subtraction angiography.

## Therapeutic Principles

Best medical treatment should be administered for all stages of PAD including platelet inhibitors like aspirin or clopidogrel, statins (irrespective of the cholesterol level) and control of risk factors like hypertension or

diabetes mellitus. Furthermore, life-style modification with cessation of smoking and exercise training has to be performed, although the latter is contra-indicated for patients with critical limb ischemia. Revascularisation by endovascular or surgical techniques is optional for patients with severe claudication, but has to be performed in all patients with critical limb ischemia. Gene-therapeutic approaches are not yet available. According to animal experiments, administration or induction of VEGF and stem-cell therapy seem promising approaches.

# Peripheral Facial Paralysis

►Facial Paralysis

# Peripheral Nerve Hyperexcitability Syndrome

►Neuromyotonia, Autoimmune and Idiopathic

# Peripheral Neuropathies, Acquired

Hans-Jürgen Gdynia, Albert C. Ludolph
Department of Neurology, University of Ulm, Ulm, Germany

## Definition and Characteristics

The term acquired peripheral neuropathies describes non-inherited damage of the peripheral nervous system, which consists of motor and sensory neurons, nerve roots, plexus and peripheral nerves. More than 100 types of peripheral neuropathy have been identified, each with its own characteristic spectrum of symptoms, pattern of development and prognosis. Impaired function and symptoms depend on the type of nerves that are damaged, but most peripheral neuropathies affect all fiber types to some extent. The disorders can be defined by the pattern of nerve-fiber involvement; some disorders can involve single peripheral nerves (mononeuropathies), others numerous individual peripheral nerves (mononeuritis multiplex). Generalized disorders conform to a polyneuropathy syndrome, which usually implies both sensory- and motor-fiber involvement in a symmetric or asymmetric distribution and typically with a distal-to-proximal gradient of involvement consistent with a length-dependent axonal degeneration. Furthermore, the disorders can be classified into acute neuropathies (e.g. Guillain-Barré syndrome) or chronic disorders (e.g. polyneuropathy due to diabetes mellitus).

A broad spectrum of symptoms is characteristic for peripheral neuropathies; some combinations of symptoms may be recognized as specific syndromes. Sensory symptoms include sensory loss including touch, pain, thermal sensation, vibratory sense and joint position sense and burning pain, especially at night. Motor symptoms can include weakness, muscular atrophy, muscle cramps and fasciculation. Damage to autonomic nerves can cause orthostatic hypotension, hypohidrosis, gastrointestinal dysmotility, urinary bladder dysfunction and erectile dysfunction.

## Prevalence

Peripheral neuropathies affect 2.4% of the population [1].

## Molecular and Systemic Pathophysiology

There are numerous reasons for peripheral nerves to malfunction. Damage to nerves can result from one of the specific conditions associated with acquired neuropathy, including:

- Physical injury to a nerve, e.g. acute or prolonged compression
- Metabolic neuropathy, e.g. diabetes mellitus, renal failure, liver dysfunction
- Nutritional neuropathy, e.g. Vitamin B12 deficiency, chronic alcohol abuse with thiamine deficiency
- Infections, e.g. HIV, leprosy, diphtheria, syphilis, Lyme, Colorado tick fever
- Immune mediated neuropathy, e.g. CIDP, Guillain-Barré syndrome
- Autoimmune disorders, e.g. periarteriitis nodosa, rheumatoid arthritis, SLE, Sjögren syndrome
- Drugs and toxins, e.g. cisplatin, arsenic, mercury
- Miscellaneous causes, e.g. ischemia

The specific mechanisms by which the above-mentioned causes induce pathological changes in the nerves are individual in each disease and not completely understood. Molecular mechanisms include disruption of axonal transport, enzyme and coenzyme inhibition and protein glycosylation. Despite the diverse causes, peripheral nerves exhibit only a few distinct pathophysiological reactions due to injury:

- Wallerian degeneration where the axon degenerates distal to a lesion
- Axonal degeneration, often at the most distal extent of the axon
- Segmental demyelination i.e. degeneration of the myelin sheath with sparing of the axon

Wallerian degeneration often occurs in focal mononeuropathies, axonal degeneration and segmental demyelination can be seen in generalized polyneuropathies. Whereas axonal degeneration is the most common type of pathological reaction in polyneuropathies of "metabolic/toxic" etiology, segmental demyelinating polyneuropathies are often of inflammatory origin or immune-mediated.

### Diagnostic Principles

Despite a detailed history and neurological examination to determine the part of the peripheral nervous system that is affected, appropriate investigations are necessary: Electromyography and nerve conduction velocities are important to localize and characterize the nature and severity of the neuropathy. To screen for an underlying cause, e.g. diabetes, vitamin deficiencies or antibodies, blood tests should be performed. A lumbar puncture can be necessary when infectious agents or immune mediated or autoimmune disorders are suspected. A nerve biopsy can occasionally be performed to confirm the presence of nerve inflammation, e.g. in vasculitic neuropathy.

### Therapeutic Principles

The treatment will depend on the underlying cause and the type of neuropathy, e.g. optimizing blood sugar in diabetic neuropathy, immune globulins or steroids in some immune-mediated neuropathies, surgical decompression in some cases of carpal tunnel syndrome. In patients who have neuropathy-associated pain, specific pain management should be instituted. Typically, neuropathic pain responds to a variety of drugs, including antiepileptic drugs, membrane stabilizers and tricyclic antidepressants [2,3,4]. Additionally, various strategies of physical therapy are known to be helpful, as well as ankle-foot orthosis in patients with foot drop.

## Peritonitis

Thomas Namdar, Claus Ferdinand Eisenberger, Wolfram Trudo Knoefel
Department of General, Visceral and Pediatric Surgery, University Hospital Duesseldorf, Heinrich-Heine-University, Duesseldorf, Germany

P

### Synonyms

Diffuse abdominal sepsis

### Definition and Characteristics

Peritonitis implies an inflammatory response of the peritoneal layer (surface: about 2 $m^2$) caused by bacteria, fungi, viruses, or chemical agents. A localized peritoneal inflammation may cause diffuse peritonitis if untreated and can result in sepsis. The mortality is still high (20–60%) and depends on factors such as age, time of intervention, and obesity. A combined treatment of surgical intervention, intensive care management, and conservative management is mandatory [1].

### Prevalence

Secondary peritonitis is responsible for 99% of all peritonitis cases, primary peritonitis only for one percent. Primary peritonitis occurs in 8–22% of all cases of

patients with liver cirrhoses/ascites or other underlying diseases, which may cause primary peritonitis.

Diffuse peritonitis is the reason for surgery in about 7% of all laparotomies in german university hospitals. 25% of all patients in a surgical intensive care unit are diagnosed as having intraabdominal infections. Secondary peritonitis can be diagnosed in different extents and severity in all cases of patients with bowel, stomach or other perforation in the abdomen. Peritonitis occurs in about 5–20% of all patients undergoing laparotomy for different reasons (i.e.: bowel, colon, pancreas, liver).

## Molecular and Systemic Pathophysiology

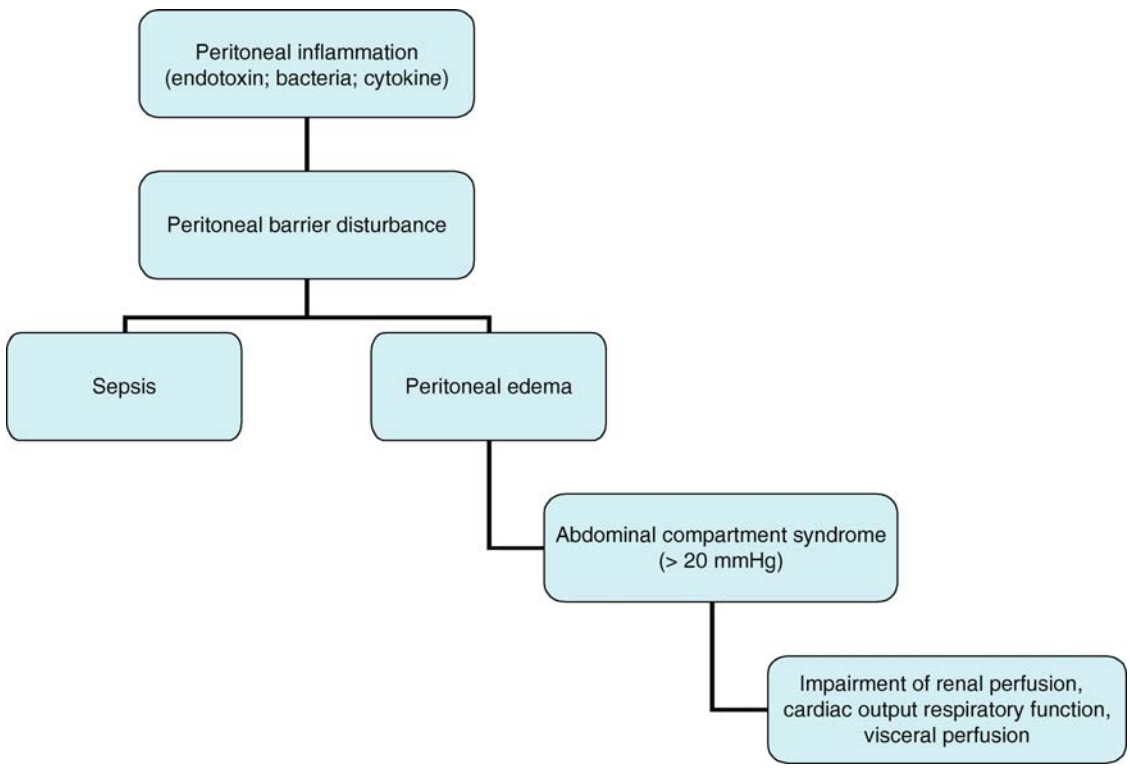
*Primary Peritonitis*: Infection of the peritoneal fluid in absence of intra-abdominal focus (spontaneous bacterial peritonitis in patients with cirrhosis; hematogeneous peritoneal infection in pneumonia, i.e., streptococcus, pneumococcus, or tuberculosis); CAPD-related chronic peritonitis (sclerosing peritonitis; [2]).

*Secondary Peritonitis*: Infection of the peritoneal cavity (stomach a bowel perforation, ischemic necrosis, penetrating injuries or abscess) and chemical peritonitis (barium peritonists).

*Tertiary Peritonitis*: Persistent peritoneal inflammation and clinical signs of peritonism following secondary peritonitis from nosocomial pathogens.

The peritoneal function is to equilibrate the intra-abdominal fluid and constitute a barrier against pathogens. The peritoneal mesothelial cells represent an ultrafiltration barrier for microorganisms. Additionally, they produce cytokines, prostaglandines, and growth factors. In case of local peritoneal inflammation, cellular (macrophages, lymphocytes, neutrophiles, etc.) and humoral defense mechanisms get activated. Untreated inflammation releases a systemic response by lymphatic and hematogeneous spreading.

Interleukin (IL)-1 and tumor-necrosis-factor (TNF)-alpha activate peritoneal mesothelial cells. Bradykinine and histamine cause a hyperperfusion of the infected area. Neutrophil cells are recruited by IL-6, IL-8, and prostaglandins are secreted [3]. In proinflammatory situations, peritoneal fibroblasts proliferate and synthesis of extracellular matrix increases to avoid a peritoneal infectious spreading. To facilitate the cellular migration to the abdominal cavity, the capillary permeability increases, regulated by the kallikreine-kinine-system, leukotriene, and eicosanoide. A peritoneal edema is caused, which may lead to the sequestration of several liters of fluid into the peritoneum (Figure 1). The following intra-vasal fluid loss leads to a hypovolemic situation, leading to acute renal insufficiency. The increasing pressure in the abdomen caused by the systemic inflammatory reaction and fluid sequestration may lead to an abdominal compartment syndrome,



**Peritonitis. Figure 1** Peritonitis cascade caused by local peritoneal inflammation results in ACS und sepsis, if untreated.

compromising renal and hepatic perfusion and function. The tense abdomen with high intra-abdominal pressure can result in a reduced lung function (Figure 1). The compensatory activation of the sympatho-adrenal-system tries to resist these systemic inflammatory effects like continuous hypotonia and hypovolemia, which follow interstitial and peritoneal edema.

## Diagnostic Principles

The intra-abdominal pressure (IAP, normally <5 mmHg), measured indirectly by transduction in the urinary bladder, is increased by peritoneal edema and sequestration in the third space. Intra-abdominal hypertension (IAP > 12 mmHg) is caused, which may result in an abdominal compartment syndrome (ACS) with IAP > 20 mmHg. The ACS affects renal function, liver function, reduces cardiac output, pulmonary ventilation, and visceral perfusion [4] (Figure 1).

As an early predictive parameter for patient mortality, the blood serum level of IL-6 increases 2–4 h after inflammatory start-up. High or persisting high IL-6 levels are a prognostic sign for a severe clinical course [5].

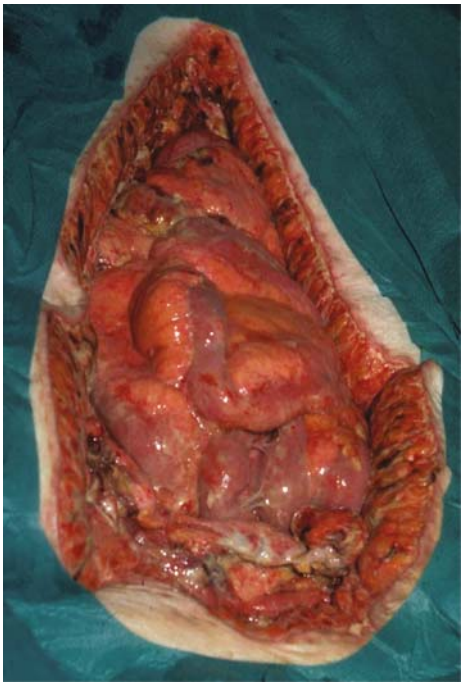
The serum level of pro-Calcitonine (PCT) is a prognostic parameter in septic patients. A PCT elevation is a specific sign of a bacterial infection [5]. Bedside tests for IL-6 and PCT are available.

Many authors tried to score peritonitis, but the APACHE Score remains the only widely used score for the evaluation of the prognosis in critically ill surgical patients in intensive care medicine.

## Therapeutic Principles

Primary peritonitis, usually a monomicrobial infection, is treated by systemic antibiotics. A surgical treatment is only indicated if the conservative therapy fails or if conservative therapy is associated with deterioration of organ function such as renal, cardiovascular, or respiratory disturbances [1].

In secondary peritonitis, immediate surgical eradication of the infectious focus is mandatory. Ascites should be collected and an empiric antimicrobiological therapy should be started. The antibiotic management should be changed after receiving the intra-operative microbiological results (escalation or deescalation). Therefore third-generation cephalosporins or broad-spectrum penicillins each combined with metronidazole are widely used as primary empiric therapy [1]. Antibiotic therapy should be maintained until fever or other signs of inflammation disappear. Depending on the intra-operative findings and postoperative course, a relaparotomy should be performed on demand when indicated by septic signs or by insufficient primary source control (Figure 2). A planned relaparotomy aims at mechanical cleansing and allows a control of the infected area. Other concepts like continuous abdominal lavage or instillation of antibiotic fluids in the peritoneal cavity



**Peritonitis. Figure 2** Intra-operative situs of a patient with fibrinous/purulent peritonitis after perforation of the colon.

are not well established except for pancreatitis. However, regular reoperations are often necessary. To prevent an abdominal compartment it may be necessary to leave a temporary laparostomy (Figure 2). Paralytic bowel obstruction may lead to a temporary colostomy or iceostomy.

To prevent ACS complications, adequate intensive care with support of respiratory function, fluid management, and circulatory support is mandatory. Nonsurgical options like gastric or rectal decompression, application of gastric and colon prokinetics, and sedation are recommended. Continuous veno-venous hemofiltration with aggressive ultrafiltration should be evaluated individually [4]. There are a variety of dressing and closure options, including vacuum dressing.

For tertiary peritonitis with persistent inflammatory changes in the abdominal cavity, despite effective control of the infectious focus there is no surgical treatment because the underlying mechanism is a profound rearrangement of the inflammatory response during septic disease [1]. Clinical studies using antimediator treatment showed disappointing results [3].

# Peritonitis, Spontaneous Bacterial

Pere Ginés, Mónica Guevara
Liver Unit, Hospital Clinic and University of Barcelona, CIBERHED, IDIBAPS, Barcelona, Spain

## Synonyms

SBP

## Definition and Characteristics

Spontaneous bacterial peritonitis (SBP) is defined as a bacterial infection of ascitic fluid without any intra-abdominal surgically treatable source or infection [1].

## Prevalence

The prevalence of SBP in cirrhotic patients with ascites admitted to the hospital ranges between 10 and 30%. The prevalence is higher in patients with previous episodes of SBP.

## Molecular and Systemic Pathophysiology

The exact mechanism by which ascites fluid becomes infected in patients with cirrhosis is unknown. However, the finding of enteric organisms in the mesenteric lymph nodes of animal models with portal hypertension and SBP suggest bacterial translocation of intestinal organisms from the lumen through the intestinal wall to the ascites fluid via the lynphatics as one of the most important mechanisms. Mechanisms involved in the pathogenesis of bacterial translocation include impairment of the intestinal barrier, intestinal bacterial factors, and alterations in the local immune response. Portal hypertension may produce vascular stasis and edema of the intestinal mucosa. These features have been considered as responsible for the increased permeability of the intestinal barrier. Among bacterial factors, an intestinal bacterial overgrowth mainly due to a decreased intestinal motility may play a role. The cause of the impairment of small bowel motility in cirrhosis is unknown. Finally, in cirrhotic patients the alterations in systemic immune defense mechanisms are represented by impairment in the activity of the reliculoendothelial system, neutrophils, and macrophages dysfunction, and low levels of complement and other proteins with opsonic activity. Some characteristics of ascitic fluid are predisposing factors in developing SBP. In fact, patients with low ascites fluid levels of complement and total protein have less bactericidal and opsonic activities of ascitic fluid and are at increased risk to develop SBP.

## Diagnostic Principles

In some patients with SBP, signs and symptoms may be suggestive of peritoneal infection, such as abdominal pain, fever, and/or alteration in gastrointestinal motility. In other cases, the main manifestations of SBP are an impairment of liver function or renal failure. Finally, in some cases SBP may be asymptomatic [1]. A diagnostic paracentesis should be performed on hospital admission in all cirrhotic patients with ascites to investigate the presence of SBP, even in patients admitted for reasons other than ascites. The analysis of ascitic fluid should also be performed in any cirrhotic patient who develops compatible signs or symptoms of a peritoneal infection or an impairment of liver or renal function without any other causes. The diagnosis of SBP is made whenever ascites polymorphonuclear count (PMN) is greater than 250/mm$^3$. Culture of ascites fluid identifies the responsible organism in 30–50% of ascites fluid infections. Culture should be performed in blood culture bottles at the bedside of the patient to increase the sensitivity of the method. Bacterascites is a positive ascitic fluid culture with ascites PMN count <250 mm$^3$ and no evidence of local or systemic infection. Once bacterascites is diagnosed, repeated paracentesis should be performed to rule out the progression of bacterioascitis to SBP.

Peritonitis secondary to an infection or perforation of intrraabdominal organs should be suspected when any of the following situations are present: lack of response to antibiotic treatment, two or more organisms are isolated from the cultures, and/or at least two of the following findings are present in ascites fluid: glucose < 50 mg/dl, protein >10 g/l, lactic dehydrogenase > normal serum levels [1].

## Therapeutic Principles

Once an ascites PMN count >250 mm$^3$ is detected, antibiotic therapy needs to be started. The empirical treatment of SBP should be third-generation cephalosporins i.v. [1]. The combined administration of antibiotics plus albumin has been shown to decrease the incidence of renal failure and improve survival in patients with SBP. Antibiotic treatment can be safely discontinued once ascitis PMN count decreases below 250/mm$^3$, which occurs in a mean period of 5 days. A control paracentesis should be performed 48 h after starting therapy. It is useful in assessing antibiotic

response and the need to modify the treatment. Patients who have recovered from an episode of SBP are at high risk of developing recurrence of ascites infection usually weeks or months after the first infection. Long-term prophylaxis with oral quinolones (norfloxacin 400 mg/day p.o.) at a dose of 400 mg every day is indicated in these patients.

## Definition and Characteristics

Inappropriate insulin release for the level of glycemia. HI is a heterogeneous disorder where the pathophysiological base is a failure of the pancreatic β-cell to suppress insulin secretion during hypoglycemia.

## Prevalence

Incidence in general population is about 1/50,000 births, and 1/2,500 births in countries with high rate of consanguinity.

## Genes

The pancreatic β-cell sulfonylurea receptor (SUR1) ABCC8, and the inward rectifying potassium channel (Kir6.2) gene KCNJ11 (ch11p15). Glucokinase (GCK) (ch7p15.3 – p15.1). Glutamate dehydrogenase GLUD 1 (ch10q23.3). Short-chain 3-hydroxyacil CoA dehydrogenase enzyme gene SCHAD (ch4p24–4q25). These genes are responsible for 50% of the cases of HI.

## Molecular and Systemic Pathophysiology

*KATP Channels and Insulin Secretion*: SUR1 and Kir6.2 are subunits of the $K_{ATP}$ channel of the β-cell. Kir6.2 determines the $K^+$ selectivity, rectification, and gating, and is inhibited by ATP, and SUR1 acts as a conductance regulator of Kir6.2. The $K_{ATP}$ channels complex links the metabolic demands of pancreatic β-cell with insulin release by transducing the metabolic status of the β-cell into cell membrane electrical activity. Changes in the intracellular ATP/ADP ratio regulate the function of these channels. ATP inhibits Kir6.2 and ADP counteracts by activating SUR1 [1].

Defects in $K_{ATP}$ channels due to mutations in SUR1 and Kir6.2 genes lead to a spontaneous depolarization of β-cell membrane (−30 mV) in the absence of glucose metabolism, causing constant activation of $Ca^{2+}$ channels, unregulated entry of $Ca^{2+}$, and uncontrolled release of insulin [2]. Autosomal recessive inheritance of two

P

abnormal SUR-1 or Kir6.2 alleles results in diffuse HI and inheritance of an abnormal paternal SUR1 allele with somatic loss of the maternal chromosome 11p15 to focal adenomatosis.

*GK, GDH, SCHAD and Insulin Secretion*: Glucokinase (GK) is a glycolytic enzyme that functions as a "glucose sensor" in pancreatic β-cell by controlling the rate-limiting step of β-cell glucose metabolism. GK governs glucose-stimulated insulin secretion (GSIS). Autosomal dominant gain-of-function mutation of GCK led to an activation of the GK that lowers the threshold for GSIS. The high activation of GK will increase the glucose metabolism leading to an excess of ATP production in β-cell, which in turn will lead to inappropriate closure of $K_{ATP}$ channels, unregulated $Ca^{2+}$ influx, and insulin release, thus causing hypoglycemia [3].

Glutamate dehydrogenase enzyme (GDH) catalyzes the conversion of glutamate to α-ketoglutarate in islet and liver. GDH is activated by ADP and inhibited by GTP. The amino acid leucine allosterically activates GDH and stimulates insulin secretion via increasing the rate of oxidation of glutamate in the tricarboxylic acid cycle. In liver, glutamate governs the synthesis of *N*-acetylglutamate, a critical activator of carbamoyl-phosphate synthetase; the oxidation of glutamate by GDH provides free ammonia as well [4].

Defects in GLUD1 gene can lead to a decrease in the sensitivity of GDH to GTP that will create an activated enzyme, which in turn will increase the mitochondrial metabolism resulting in high ATP/ADP ratio and hence the high insulin secretion. Simultaneously, the excessive activity of GDH in liver will cause excessive ammonia production.

SCHAD catalyzes the conversion of L-3OH-acyl-CoA to 3-ketoacyl-CoA in the fatty acid oxidation cycle in the mitochondria of the β-cell. Gene defects in SCHAD are expected to lead to an increase in intramitochondrial L-3-hydroxybutyryl-CoA, which can inhibit carnitine palmitoyltrnasferase-1 and elevate cytosolic long-chain acyl-CoA, which has pleiotropic actions on β-cell function.

## Diagnostic Principles

The clinical diagnosis is based on evidence of the effects of HI, including hypoglycemia, inappropriate suppression of lipolysis and ketogenesis, and (more traditionally) positive glycemic responses after the administration of glucagon when hypoglycemic. The first clinical manifestations of HI are mainly experienced shortly after birth. Cyanosis, respiratory distress, sweating, hypothermia, irritability, poor feeding, hunger, jitteriness, lethargy, apnea, which can progress to vomiting, seizures, tachycardia, and averted neonatal death. In older children and adults, symptoms tend to be confusion, headaches, dizziness, syncope, and when severe, loss of consciousness. The definition of a glucose requirement to maintain normoglycemia is a key indicator as well as therapeutic step in HI, and the demonstration of an increased glucose requirement is the sign of underlying HI. Diagnostic criteria for patients with severe early-onset HI are (i) a glucose requirement of >6–8 mg $kg^{-1}$ $min^{-1}$ to maintain blood glucose above 2.6–3 mM; (ii) blood glucose values <2.6 mM; (iii) detectable insulin at the point of hypoglycemia with raised C-peptide; (iv) inappropriately low-blood FFA and ketone body concentrations at the time of hypoglycemia; (v) a glycemic response after the administration of glucagon when hypoglycemic; and (vi) the absence of ketonuria. Due to lack of fuels to sustain normal brain metabolism, failure to recognize, and to promptly treat hypoglycemia carries a substantial risk of severe brain damage and mental retardation. The genetic diagnosis is based on the detection of the mutation in any of the gene involved.

## Therapeutic Principles

Treatment aims to prevent hypoglycemia. This could be achieved by administration of glucose and/or glucagon and by suppressing insulin release with diazoxide, somatostatin analogues, and nifedipine.

## Perthes' Disease

Henk Eijer
Orthopedic Department, Sonnenhof Clinic, Bern, Switzerland

### Synonyms

Morbus Legg-Calvé-Perthes; LCP; Legg-Calvé-Perthes' disease; LCPD; Juvenile/idiopathic avascular necrosis of the head of the femur; Osteochondropathia deformans coxae juvenilis; Ischemic necrosis of the hip; Coxa plana; Osteochondritis coxae juvenilis

### Definition and Characteristics

Osteochondritis was independently identified by AT. Legg, J. Calvé, and G. Perthes' at the beginning of the nineteenth century [1], and is associated with avascular necrosis of the capital femoral epiphysis and often the most proximal part of the metaphysis, related to an intermittent vascular occlusion. The necrosis of the femoral head develops in sequential radiologic stages (I subchondral fracture, II fragmentation, III re-ossification, and IV healing), and heals at the latest after closure of the epiphyseal plate, with a residual deformity of the proximal femur and acetabulum.

### Prevalence

Occurs in children mainly between the age of 2 and 14 years with an incidence of 0.05–0.11‰, a boy-to-girl ratio of 5:1, and with 15% of the patients suffering bilateral disease. The mean age at onset is 5.8 years. Comparison of the incidence of Perthes' disease in relatives with that in the general population of the same sex already in 1986 revealed a gradient of 35:4:4:1 from first-: second-: third-degree relatives to the general population. Estimates of heritability from first cousin and sibling data were both found to be 84%, giving a recurrence risk of 2.6%.

### Genes

Genetic factors have been implicated in the etiology, but the causal gene has not been identified [2]. Recently, for the first time, a missense mutation (p.G1170S) in the type II collagen gene (COL2A1) was located in a Japanese family with an autosomal dominant hip disorder manifesting as Perthes' disease and showing considerable intra-familial phenotypic variation [3].

### Molecular and Systemic Pathophysiology

The etiology remains a factor of discussion, although it has now become generally accepted to be initiated by an intermittent vascular occlusion, the precise origin of which and its underlying mechanism still remains unclear. A large recent nationwide study of Perthes' disease in Norway supports earlier findings and points toward a single cause of the disease [4]. Theories have suggested trauma, inflammation, endocrine, and nutritional disturbances to be causative, and more recently an elevated platelet count or pathology in their function has been advanced, but as yet all remains unproven. In view of the existence of possible pre-necrotic acetabular variances, a recent theory stipulates the possibility of an intermittent movement depending abnormal loading pressure on the dorsal femoral head–neck junction and the lateral epiphyseal arteries, which can lead to insufficient blood supply to the femoral epiphysis and to local necrosis, as these vessels are the only local blood supply in children [5].

### Diagnostic Principles

Clinically, the child may complain of pain in the hip, and/or (referred) in the knee and limp, due to the inflammation and irritation that develops as the result of the necrosis. So-called impingement of the hip may develop following deformation of the femoral head, leading to especially inguinal symptoms worsening on flexion and internal rotation of the hip. Final diagnosis is generally made using radiography (Fig. 1), although MRI may be used in the first stage of the disease and for specific morphological purposes.

### Therapeutic Principles

Treatment is pointed at alleviating the inflammation of the hip, at restoring the motion of the hip, and trying to keep the femoral head in the acetabulum, guided by radiography. Surgery, especially osteotomies, may be

**Perthes' Disease. Figure 1** Perthes disease of the right hip. The radiograph shows an AP view of a pelvis of a 9-year-old boy with clear necrosis of the epiphysis and proximal metaphysis of the femoral head.

necessary especially for this last goal. There is general agreement that an important factor in the outcome of patients is severity of the residual deformities of the hip joint and especially its congruence. Natural history studies have demonstrated that a misshapen femoral head in the adult leads to the early onset of hip osteoarthritis with a 50% chance of requiring a total hip arthroplasty in the fifth decade of life. Residual deformities are reported to be determined by the size of the epiphysis involved in the necrosis, the age at onset of the disease, sex, persistent lateral uncovering of the femoral head, premature arrest of the epiphysis leading to leg length discrepancy, and the adequacy of treatment.

# Peutz-Jeghers Syndrome

Markus Böhm, Thomas A. Luger
Department of Dermatology,
University Hospital of Muenster, Muenster, Germany

## Synonyms

PJS

## Definition and Characteristics

Autosomal dominant disorder characterized by the co-occurrence of mucocutaneous lentigines and gastrointestinal polyposis.

## Prevalence

Peutz-Jeghers syndrome (PJS) is one of the most common syndromes associated with lentiginosis (MIM#175200).

## Genes

There is genetic heterogeneity. One locus was identified at 19p13.3 encoding serine threonine kinase 11 (STK11) also named LKB1. A second locus was identified at 19q13.4 [1,2].

## Molecular and Systemic Pathophysiology

Loss of heterozygosity of 19p13 markers suggests that the responsible gene functions as a tumor suppressor [3]. More than half of the patients with PJS have mutations of STK11/LKB1 at 19p13.3. STK11/LKB1 shows high homology with Xenopus egg and embryo kinase 1. The core kinase domains of human and murine STK11/LKB1 are highly homologous. Functional in vitro studies on mutations identified in the germline of patients with PJS revealed a loss of function in the majority of mutations or an altered subcellular localization of STK11 in one case. STK11 exerts a growth-inhibitory activity by causing G1 arrest. Therefore, mutations involving the kinase domain or residues involved in nuclear translocation abrogate the tumor suppressor function of STK11 providing a background for subsequent development of cancer.

## Diagnostic Principles

The presence of lentigines on the lips first apparent in early childhood reaching a peak at puberty is a hallmark of PJS. The gastrointestinal polyps can occur solitary but are usually multiple. They often develop in the jejunum but can arise throughout the whole gastrointestinal tract. The gastrointestinal hamartomatous polyps in patients with PJS are histologically characterized by a smooth muscle component infiltrating the connective tissue core in a branching pattern. In addition, hyperplastic and adenomatous lesions can occur.

### Therapeutic Principles

PJS is associated with high morbidity and increased mortality [4]. The incidence of cancer in patients with PJS varies from 20 to 50%. In addition to cancers arising from gastrointestinal polyps patients with PJS are at increased risk for cancers in other tissues including thyroid, cervix, testicles, breast and ovarian. Regular gastrointestinal imaging and endoscopic screening including the above organs are advised. Genetic counseling is essential. Diagnostic and predictive genetic testing is recommended for at-risk family members.

### Synonyms

Phenylketonuria; PKU

## Definition and Characteristics

Autosomal recessive phenylalanine hydroxylase (PAH) defect leading to hyperphenylalaninemia and, in severe forms, mental retardation.

## Prevalence

The prevalence in European populations is ~1/10,000, with an estimated carrier frequency of 2%.

## Genes

PAH, localized on chromosome 12q24.1, encoding a peptide of 451 amino acids.

## Molecular and Systemic Pathophysiology

PAH catalyzes the conversion of phenylalanine to tyrosine in the presence of molecular oxygen and (6R)-5,6,7,8-tetrahydrobiopterin ($BH_4$) (Fig. 1).

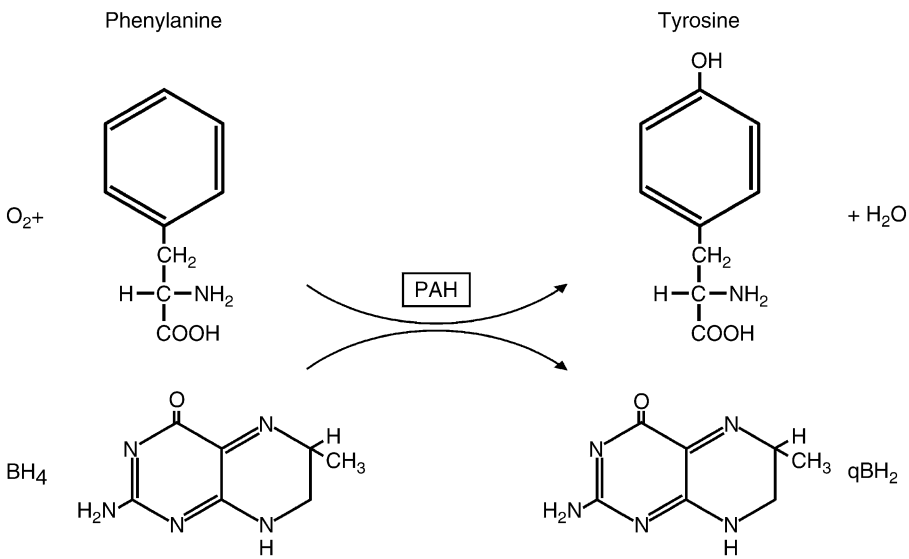
Impaired activity of PAH results in systemic accumulation of phenylalanine and formation of secondary metabolites, e.g., phenylpyruvate, phenyllactate, phenylacetylglutamine, and phenylacetate [1]. The most important and consistent phenotype in untreated patients with severe forms of PAH deficiency is irreversible mental retardation. Other symptoms include severe neurophysiological dysfunction, various neuropsychiatric complications, decreased pigmentation, and eczematous conditions of the skin [1,2]. Phenylalanine excess during pregnancy (maternal PKU) is a severe hazard for the fetus and may cause microcephaly, impaired cognitive development, intrauterine growth retardation, and congenital heart disease. PAH deficiency is a phenotypically complex trait associated with a wide range of biochemical, metabolic, and clinical phenotypes. Carefully controlled correction of phenylalanine intake is required to ensure normal physical, neurological, and cognitive development in patients with phenylalanine levels >600 mmol/l and a daily phenylalanine tolerance of <50 mg/kg. Individuals with phenylalanine levels persistently below 600 μmol/l do not develop neurological symptoms on a normal diet [1,2]. An extensive allelic variation at the PAH locus (>400 mutant alleles) explains the large interindividual variation in metabolic phenotype (PAHdb, http://www.pahdb.mcgill.ca). For >100 PAH mutations, the associated metabolic phenotypes have been ascertained [3,4].

## Diagnostic Principles

Systematic neonatal screening for hyperphenylalaninemia identifies all newborns with PAH deficiency. The metabolic phenotype and the inherent dietary requirements are usually determined by indirect means, for example by determining the dietary intake of phenylalanine tolerated while keeping serum phenylalanine concentrations within the desired therapeutic range (phenylalanine tolerance), or the rate of phenylalanine elimination following an oral protein challenge or an oral or intravenous dose of phenylalanine [1,2]. Responsiveness to treatment with $BH_4$ (see below) can be assessed by measuring the plasma phenylalanine response after $BH_4$ loading. Diagnosis by PAH mutation analysis is feasible in the vast majority of cases. Genotype usually predicts phenotype [3].

## Therapeutic Principles

All disease manifestations associated with PAH deficiency can be effectively prevented by the implementation of a low-phenylalanine diet in the neonatal period. The diet should be maintained for life to prevent the



**Phenylalanine Hydroxylase Deficiency. Figure 1** The phenylalanine hydroxylating system.

development of symptoms associated with "phenylalanine intoxication," i.e., lack of power of concentration, sustained reaction time, headache, and depression. The amount of dietary phenylalanine tolerated to maintain the blood phenylalanine within the therapeutic range depends on the severity of the disorder. PAH mutation analysis provides the basis for predicting the metabolic phenotype and anticipating dietary requirements [3]. Treatment with $BH_4$ has been reported to decrease the plasma phenylalanine concentrations in patients with milder forms of PAH deficiency [5].

# Phenylketonuria

Richard Koch[1], Kathryn Moseley[2]
[1]Department of Genetics, Children's Hospital Los Angeles, Los Angeles, CA, USA
[2]CHEAR, University of Michigan Medical School, Ann Arbor, MI, USA

## Synonyms

Hyperphenylalaninemia; PKU

## Definition and Characteristics

Autosomal recessive defect in untreated patients usually results in profound mental retardation and neurodegenerative changes.

## Prevalence

Prevalence varies with ethnicity: Heterozygosity ranges from less than 1% of the black race to 2% in Caucasians. The number of mutations of the phenylalanine (Phe) hydroxylase (PAH) gene is already greater than 500 and they vary in severity from mild to moderate and severe. The gene defect is located on the chromosome number 12 at the q22–q24 region. Recently the PAH gene has been crystallized, as well.

## Molecular and Systemic Pathophysiology

Neuropathology affects primarily the central nervous system. The competition theory on the transport of amino acids to the brain seems to be the most extensively studied. Recent research suggests that the elevated blood Phe levels interfere with the transport of large neutral amino acids (LNAA) into the brain, thus protein synthesis in the brain is compromised. Studies on the mouse brain show that protein synthesis is reduced when phenylalanine levels are increased. Since Phe has the lowest km for the transporter, this reduces the entrance of the other eight LNAA into the brain. There are many other theories; none have been proven, other than the fact that high blood and brain levels of phenylalanine lead to a cascade of events that result in white matter disease. It may well be that not only one metabolic pathway is affected that contributes to the pathology of PKU.

## Diagnostic Principles

Confirmation of the diagnosis of PKU during the newborn period requires a careful evaluation of the status of Phe metabolism by plasma amino acid analysis and identification of the PAH mutation. Tetrahydrobiopterin metabolic defects should be ruled out, as well as a dihydropteridine reductase disorder.

## Therapeutic Principles

Once the diagnosis of PKU is established, a Phe-restricted diet should be initiated with the goal of establishing a blood Phe level of 2–6 mg % (120–360 µmol/l). These are the established guidelines in the United States suggested by the National Institute of Health after a worldwide review of treatment practices, however, clinics in different countries may have their own established guidelines. Infants born with two severe mutations of the PAH gene will need dietary therapy throughout their life, however guidelines vary after 10–12 years. These individuals are considered to have classic PKU. Persons with a moderate degree of hyperphenylalaninemia of 12–20 mg % (720–1,080 µmol/l) usually exhibit one severe mutation, such as R408W and one mild mutation, such as F39L still need treatment, but may follow a more relaxed diet if the guidelines permit. Persons with blood Phe levels of less than 10 mg % (600 µmol/l) usually are not treated with a

Phe-restricted diet. Mental illness, especially depression, may be seen in those not adhering to the diet.

Finally, women must be aware during their productive years, that blood Phe levels greater than 6 mg % (300 μmol/l) may be harmful to the development of their fetus during pregnancy.

# Pheochromocytoma

Graeme Eisenhofer, Karel Pacak
Clinical Neurocardiology Section, NINDS, National Institutes of Health, Bethesda, MD, USA

## Synonyms

Intra-adrenal paraganglioma

## Definition and Characteristics

Pheochromocytomas are usually defined as catecholamine-producing neuroendocrine tumors arising from chromaffin cells of the adrenal medulla or extra-adrenal paraganglia [1]. According to the 2004 World Health Organization classification of endocrine tumors, only those tumors derived from adrenal chromaffin cells are defined as pheochromocytomas. Those derived from extra-adrenal chromaffin tissue are defined as paragangliomas.

Sustained or paroxysmal hypertension is the most common clinical sign of a pheochromocytoma, although some patients present with normotension, or even hypotension [1]. Headaches, excessive truncal sweating and palpitations are the most common symptoms. Others include pallor, dyspnea, nausea, constipation and episodes of anxiety or panic attacks. Signs and symptoms that occur in paroxysms reflect episodic catecholamine hypersecretion. Paroxysmal attacks may last from a few seconds to several hours, with intervals between attacks varying widely and as infrequent as once every few months.

## Prevalence

Pheochromocytomas are rare with an annual detection rate of 2–4 per million. Relatively high prevalences of the tumor in autopsy studies (1:2,000) suggest that many are missed during life, resulting in premature death. The actual annual incidence is therefore likely to approach 10 per million.

## Genes

Current estimates indicate that close to 30% of pheochromocytomas occur due to mutations of five genes [2]. Family-specific mutations of the von Hippel-Lindau (VHL) tumor suppressor gene determine the varied clinical presentation of tumors in VHL syndrome that, apart from pheochromocytomas, can include retinal and central nervous system hemangioblastomas, and tumors and cysts in the kidneys, pancreas and epididyma. Mutations of the RET proto-oncogene in multiple endocrine neoplasia type 2 (MEN 2) result in pheochromocytoma, medullary thyroid cancer and parathyroid disease in MEN 2a and additional cutaneous and mucosal neuromas in MEN 2b. Mutations of the neurofibromatosis type 1 (NF 1) gene carry a relatively small risk of pheochromocytoma, presenting commonly as multiple fibromas on skin and mucosa and "café au lait" spots. More recently discovered mutations of succinate dehydrogenase subunits B and D (SDHB & SDHD) genes lead to familial paragangliomas. Clinical features of pheochromocytomas – such as the frequency of malignancy, adrenal and extra-adrenal locations of tumors, and types of catecholamines produced – vary according to the particular mutation (Table 1).

## Molecular and Systemic Pathophysiology

The molecular mechanisms linking known gene mutations to development of pheochromocytomas have not been precisely elucidated. Recent evidence, however, suggests that hereditary tumors may develop from neural crest progenitor cells arrested during embryonic development due to failure of apoptosis [3]. Systemic pathophysiology associated with pheochromocytoma is mainly the result of the hemodynamic and metabolic actions of catecholamines produced and secreted by the tumor. Variability in pathophysiology may reflect differences in types of catecholamines produced,

**Pheochromocytoma. Table 1** Genes and characteristics of hereditary pheochromocytoma

Abbreviations: NE-Norepinephrine; EPI-Epinephrine; DA-Dopamine.

paroxysmal versus sustained patterns of catecholamine secretion, co-secretion of neuropeptides, and underlying mutations (Table 1). Strokes, cardiac hypertrophy, cardiogenic shock, cardiomyopathy, multiple organ failure, pulmonary edema, and intestinal pseudo-obstruction represent a few of the many possible sequelae of a pheochromocytoma that can make differential diagnosis troublesome.

## Diagnostic Principles

Biochemical evidence of excessive catecholamine production is crucial for diagnosis of pheochromocytoma. Recognition that metabolism of catecholamines to metanephrines occurs continuously within tumor cells by a process independent of catecholamine release has led to emphasis on measurements of plasma free or urinary fractionated metanephrines as the recommended tests for diagnosis of pheochromocytoma. With a diagnostic sensitivity approaching 100%, normal results for plasma free metanephrines allow reliable exclusion of any tumor producing significant amounts of norepinephrine or epinephrine, thereby avoiding the need for multiple tests and unnecessary imaging studies [4]. Computed tomography and magnetic resonance imaging provide high sensitivity for initial localization of pheochromocytoma. Metaiodobenzylguanidine scintigraphy is useful for detecting extra-adrenal tumors and metastases. The high specificity of this imaging modality also provides confidence in correctly identifying a pheochromocytoma.

## Therapeutic Principles

Surgery provides the only effective curative treatment for pheochromocytoma. Because of the potentially fatal consequences of catecholamines released by tumors during surgical anesthesia, it is imperative that patients with pheochromocytoma be appropriately prepared for surgery. Maintenance of adequate blood pressure control using alpha-adrenergic blockers (e.g., phenoxybenzamine) or calcium channel blockers for 2-weeks before surgery is important. Laparoscopic surgery, a procedure that reduces post-operative morbidity and recovery time, has fast become the standard of care for surgical resection. There is currently no effective treatment for malignant pheochromocytoma [5]. Chemotherapy with cyclophosphamide, vincristine, and dacarbazine may produce partial remission. Radiotherapy using $^{131}$I-labeled MIBG provides benefit in some patients with malignant pheochromocytoma, but again is not curative.

# PHHI

►Persistent Hyperinsulinemic Hypoglycemia of Infancy

# Phosphoenolpyruvate Carboxykinase Deficiency

James V. Leonard
Clinical and Molecular Genetics Unit, Institute of Child Health, University College London, London, UK

## Synonyms

PEPCK deficiency; PEPCK 1 (cytosolic) deficiency; PEPCK 2 (mitochondrial) deficiency

## Definition and Characteristics

Autosomal recessive disorder whose phenotype is poorly characterized.

## Prevalence

Unknown (apparently very rare).

## Genes

PEPCK1 is localized on chromosome 20q13.31. The gene encodes a cytosolic protein of 622 aminoacids whose sequence shows 91% sequence identity with that of the rat.

PEPCK2 is localized on chromosome 14q11.2 and encodes for a 640 aminoacid polypeptide expressed in mitochondria with a 78% sequence identity to that of the human PEPCK1 [1].

PEPCK is a key enzyme in gluconeogenesis. The cytosolic enzyme is regulated by several mechanisms and pathways including hormones (insulin and glucagon), substrate supply and purine nucleotides.

## Molecular and Systemic Pathophysiology

Suspected deficiency of one enzyme has not been easy to prove and only a small number of patients with putative PEPCK deficiency has been reported [2,3]. There is no clear clinical phenotype but the most common problems have been hypoglycaemia, lactic acidemia, liver abnormalities and hypotonia.

## Diagnostic Principles

All the patients reported so far have been diagnosed with enzyme studies, either in liver homogenates or fibroblasts. But only the mitochondrial isoenzyme is expressed in fibroblasts. In no patient have mutations been identified in either gene. However this is now essential as some of the reports of PEPCK deficiency are most probably secondary. The patient reported by Vidnes and Sovik [4] almost certainly was hyperinsulinaemic with secondary suppression of the cytosolic PEPCK. PEPCK is also reduced secondarily in patients with the mitochondrial DNA depletion syndrome [5].

## Therapeutic Principles

Apart from maintaining normoglycaemia and correcting metabolic acidosis, no specific treatment has been suggested. Fasting should be avoided.

# Phosphofructokinase

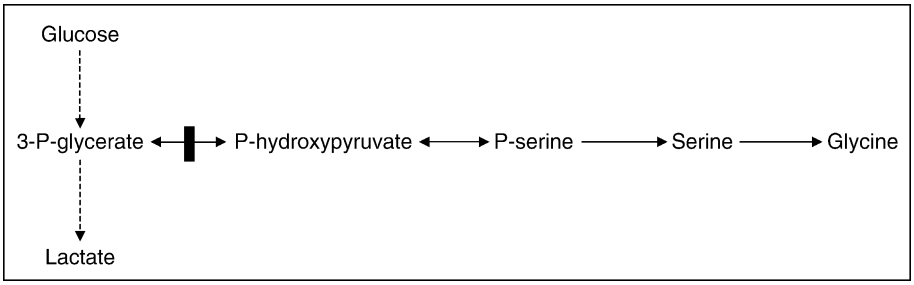
►Tarui's Disease

# 3-Phosphoglycerate Dehydrogenase Deficiency

Jaak Jaeken
Department of Pediatrics, Center for Metabolic Disease, University of Leuven, Leuven, Belgium

## Definition and Characteristics

Autosomal recessive defect in serine synthesis causing a severe neurological syndrome comprising



**3-Phosphoglycerate Dehydrogenase Deficiency. Figure 1** Scheme of the serine biosynthesis. The vertical bar indicates the defect in 3-phosphoglycerate dehydrogenase deficiency.

microcephaly, psychomotor retardation, spastic tetraplegia, and seizures. Some patients show megaloblastic anemia in addition [1,2].

## Prevalence

The prevalence of this disease is unknown.

## Genes

The gene PHGDH has been localized to chromosome 1q12 [3].

## Molecular and Systemic Pathophysiology

This enzyme defect (Fig. 1). causes decreased concentrations of serine and, to a lesser extent, of glycine in fasting plasma, in cerebrospinal fluid (CSF), and most probably also in brain. Serine is thus an essential amino acid in these patients.

The substrate of the reaction, 3-phosphoglycerate, is unlikely to accumulate since it is an intermediate of the glycolytic pathway. Deficiency of brain serine is thus the sole (or main) determinant of disease. Serine plays a major role in the synthesis of important brain and myelin constituents, such as proteins, glycine, cysteine, serine, phospholipids, sphingomyelins, and cerebrosides.

## Diagnostic Principles

The association of the aforementioned clinical features (see Definition and Characteristics) with decreased serine and glycine in the CSF points to a defect in serine synthesis. The diagnosis is confirmed by measuring the activity of 3-phosphoglycerate dehydrogenase deficiency in fibroblasts and by performing mutation analysis of the gene.

## Therapeutic Principles

Treatment with L-serine (oral; up to 500 mg/kg/day in six divided doses) corrects the biochemical abnormalities and has a significant clinical effect abolishing the convulsions in most patients. In some patients, the convulsions stop only after adding glycine (200 mg/kg/day) [4]. Prenatal treatment with serine has been performed in one fetus with successful outcome after birth.

# Phosphoribosylpyrophosphate Synthetase Overactivity

Michael A. Becker
University of Chicago Medical Center, Chicago, IL, USA

## Synonyms

PRPP synthetase superactivity; PRPP

## Definition and Characteristics

PRPP synthetase (PRS) over-activity is an X chromosome-linked disorder of purine metabolism characterized by over-expression of PRS isoform 1 [1,2], purine nucleotide and uric acid overproduction, hyperuricemia and gout and, in some affected families, neurodevelopmental impairment, especially sensorineural deafness [1].

### Prevalence
Rare, about 30 affected families identified worldwide. Hemizygous males are propositi in all but one family and are more severely affected than heterozygous females.

### Genes
PRPS1 (Xq22-q24); no defects in PRPS2 (Xp22.2–p22.3) or PRPS3 (7q) known.

### Molecular and Systemic Pathophysiology
PRPP is a substrate in the pathways of purine, pyrimidine and pyridine nucleotide synthesis and is an allosteric regulator of the rate-limiting enzyme (amidophosphoribosyltransferase) in purine nucleotide synthesis de novo [3]. PRPP is synthesized from MgATP and ribose-5-P in an allosterically regulated reaction catalyzed by independently active and structurally homologous PRS isoforms encoded by separable PRPS genes. Excessive PRS1 activity results in increased intracellular PRPP availability, which, in turn, accelerates purine nucleotide and uric acid production and results in hyperuricemia and gout [1,2]. Two inherited alterations increasing PRPS1 expression are described, (i) point mutations in the PRPS1 coding region resulting in mutant PRS1 isoforms with diminished allosteric control of PRS1 activity [1]) and (ii) increased rates of PRPS1 transcription, resulting in increased PRS1 transcript and isoform levels and increased PRS1 activity [2]. The pathophysiology of the neurological features of PRS overactivity is unknown [1].

### Diagnostic Principles
Gout with uric acid over-production and over-excretion, especially occurring in infancy or childhood with neurological sequelae, should prompt measurement of PRS [4] as well as HPRT activities in erythrocyte lysates. PRS1 cDNA sequencing is definitive only in the case of point mutations in PRPS1. Otherwise, confirmation is difficult. Low NAD concentrations in red cell nucleotide extracts of blood from a non-transfused patient, together with normal ATP and NADP concentrations, should alert the investigator to the possibility of PRPS overactivity.

### Therapeutic Principles
Metabolic abnormalities associated with PRS overactivity (hyperuricemia, hyperuricosuria, gout and uric acid urolithiasis) are controlled with xanthine oxidase/dehydrogenase inhibition (e.g. allopurinol), hydration and, where appropriate, urinary alkalinization. No specific therapy is known for neurological abnormalities.

►Photosensitivity and Reflex Epilepsies

## Photosensitive Epilepsy

►Photosensitivity and Reflex Epilepsies

## Photosensitivity and Reflex Epilepsies

Ulrich Stephani
Clinics for Neuropediatrics of Kiel University, Kiel, Germany

### Synonyms
Visual sensitivity; Photosensitivity; Photoparoxysmal response (PPR; EEG); Photosensitive epilepsy (disease)

### Definition and Characteristics
In photosensitivity and reflex epilepsies, defined exogenous trigger factors and endogenous (predispositional, e.g. genetic and other) factors are needed to precipitate an "epileptic" reaction of the central nervous system. Exogenous and endogenous trigger factors for epileptic reflex seizures [1]:

- Visual stimuli
- Thinking
- Music/Sounds
- Eating
- Praxis
- Somatosensory (proprioceptive) stimuli
- Reading
- Startle
- Others

Reflex epilepsies are epileptic syndromes in which all epileptic seizures are precipitated by defined sensory stimuli. Reflex seizures that occur in focal and generalized epilepsies and that occur additionally to other "spontaneous" seizures are listed as reflex seizure types. Isolated reflex seizures also can occur in situations that do not necessarily require a diagnosis of epilepsy. Television is the most common visual trigger of these seizures in daily life (demonstrated in Japan with the "Pokémon" experience) [2]. By the ILAE acknowledged reflex epilepsy syndromes:

- Idiopathic photosensitive occipital lobe epilepsy
- Other visual sensitive epilepsies
- Primary reading epilepsy
- Startle epilepsy

In these absences, myoclonic seizures and generalized tonic clonic seizures occur as response of the brain to the respective triggers, esp. photic stimulation.

Brain reactions measurable with EEG only can be also reflectoric: Of these the intermittent photic stimulation (IPS) with white light is the most widely used (preferably standardized) laboratory method in the EEG-laboratory to search for the elicitability of a photoparoxysmal response (PPR). It consists of (ir) regular (poly)spikes and waves which can be generalized (in grade 4 PPR) or localized in occipitals leads only (in grade 1 PPR) (for review see [2,3]). Standardized stimulation procedures have been strongly recommended [4].

PPR can be evoked most commonly in patients with idiopathic generalized (IGE), less common in idiopathic and symptomatic focal epilepsies and in healthy persons. EEG response types to IPS and other visual stimuli [4]:

- Photic "driving" (EEG waves following a certain flash rate changes)
- Orbitofrontal photomyoclonus (OPM) (photomyogenic response)
- Posterior-stimulus-dependent response
- Posterior-stimulus independent response (type 1,2 Waltz) (limited to the stimulus train or self sustaining)
- Generalized photoparoxysmal response (type 3,4 Waltz) (limited to the stimulus train or self sustaining)
- Activation of pre-existing epileptogenic area
- Eyelid closure sensitivity
- Fixation off sensitivity

The "eye(lid) closure sensitivity" occurs mainly in IGE type epilepsies. In "Progressive Myoclonus Epilepsies" and some other neurodegenerative diseases PPR can be elicited by single or double flashes mostly without clinical signs [4].

The PPR is different from visually evoked potentials. Photic driving is a reflectoric response of the occipital cortex to certain frequencies of flash lights. Clinical symptoms and consequences of PPR [4]:

- Mild subjective symptoms
- Orbitofrontal photomyoclonus
- Eyelid myoclonus (EM): with absences (EMA)/with self inducing behavior
- Myoclonus: Focal, asymmetrical, (FM) or Generalized myoclonus (GM), with or without impairment of consciousness
- Tonic, versive phenomena
- Absence seizures
- Generalized tonic clonic seizures
- Partial seizures with simple or complex visual or with limbic symptoms
- Unclassified
- Individuals with a PPR in the EEG and no history of epileptic seizures
- Patients with spontaneous seizures and with a PPR in the EEG
- Patients with an isolated visually induced seizure in special circumstances
- Recurrent visually induced seizures and no spontaneous seizures (with or without a PRB in the EEG)
- Visually induced and spontaneous seizures[a]

## Prevalence

Photosensitivity occurs in 0.3–3% of the population. The estimated prevalence of seizures from light stimuli is 1 per 10,000, or 1 per 4,000 individuals age 5–24 years. People with epilepsy have a 2–14% chance of having seizures precipitated by light or visual patterns [1].

## Genes

A recent study found that photosensitivity is significantly more common in 5–10 year-old siblings of probands being offsprings of a photosensitive parent (50%) than in siblings of photosensitive children without parental photosensitivity (14%). The inheritance of PPR was compatible with an autosomal dominant transmission with age–dependent penetrance of the PPR. The inheritance of PPR seems to be independent from the transmission of epilepsy/epileptic seizure type itself.

Photoparoxysmal responses are sometimes observable in children with chromosomal aberrations.

A single genetic mutation for photosensitivity itself has not yet been identified despite genome wide linkage studies. In patients with the progressive myoclonus epilepsies (PME, e.g. Unverricht Lundborg disease) and the Dravet syndrome, an increased rate of PPR-carriers is found [3].

## Molecular and Systemic Pathophysiology

In photosensitive individuals, the visual system itself is functionally normal – beside its ability to generate hypersynchronous activity – concerning acuity, stereopsis, grating contrast and color vision.

There are several animal models of reflex epilepsy, such as the genetically epilepsy-prone rat (GEPR) and the DBA/J2 mouse esp. with audiogenic reflex seizures. In these rodents, repeated exposure to specific sensory stimuli, often within a limited age window, results in the persistent phenotype of a seizure. Beside of humans the Baboon Papio papio and the Fayoumi chicken exhibit a particular response to IPS (for review see [1]). Stimulation related factors of PPR:

- Wave-length-dependency (PPRs are elicited only when the flashing light contains long-wavelength red light (>670 nm) stimulating L-cones in the retinal ganglion cells
- The quantitative amount of light

Since many factors influence the penetrance of PPR it is not correct to conclude that a patient is "PPR-negative" from a single IPS test session.

In summary, when a critical amount of occipital cells is involved into the synchronous activity, an initial local epileptic discharge will be produced. Subsequently, the neuronal activity will rapidly propagate through cortico-reticular and cortico-cortical pathways and can cause a generalized epileptic discharge. Patient related factors of PPR:

- Age (PPR is most prominent in the first and second decade of life)
- Vigilance (PPR is prominent during tiredness after sleep deprivation and not evocable during sleep)
- Eyes open or closed during IPS (additional provocative maneuver)
- Daytime of EEG (in the morning more prominent than in the afternoon – in some epilepsy syndromes)
- Sex (photopositive females ratio 0.55–0.75)

GABA-ergic and dopaminergic mechanisms were suggested to be involved into the regulation of occipital (and frontal) cortical excitability in animal studies. In the Papio papio animal model of photosensitivity, the epileptiform discharges during photic stimulation occur in the motor cortex, the epilepsy arises in the frontal cortex with secondary generalization via corticocortical pathways. However, frontal cortical areas may also constitute a protective mechanism against propagation of epileptic activity, since visual stimulation induces an abnormal increase in inhibition and decrease in neuronal activity in the motor cortex in subjects with the propagating PPR [5].

## Diagnostic Principles

PPR is diagnosed by a (standardized) IPS protocol [4] with distinct methodological prescriptions. As a rule, PPR can be elicited only by binocular stimulation.

## Therapeutic Principles

Intake of several antiepileptic drugs (e.g. valproate, clobazam, lamotrigine, topiramate, levetiracetam) may reduce photosensitivity. The PPR is particularly controlled by drugs enhancing GABAergic inhibition. Compound optical filters reducing the light in the visible spectrum (neutral density filters) as well as reflecting long-wavelength red light inhibit the PPR at a rate of about 90% [2], recommended for patients with television-induced seizures only.

## Physeal Dysplasia

Kendall S. Frazier
Safety Assessment, GlaxoSmithKline, King of Prussia, PA, USA

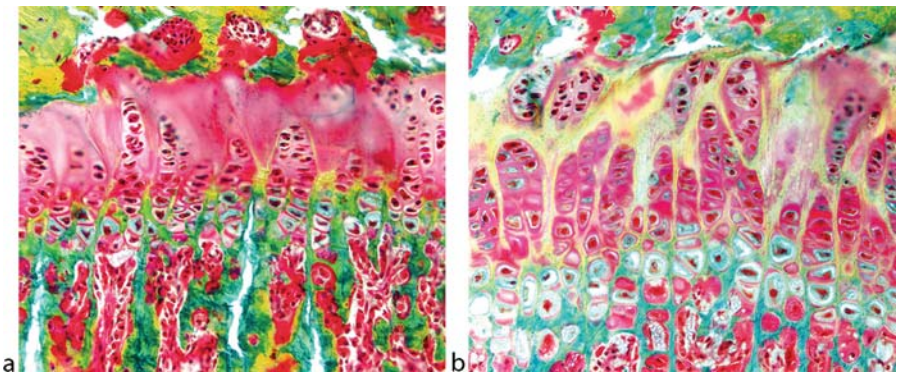
### Synonyms

Physeal hypertrophy; Osteochondrodysplasia; Bone dysplasia; Osteodysplasty; Achondroplasia

### Definition and Characteristics

Physeal dysplasia is a term referring to bone effects observed in a heterogenous group of disorders affecting endochondral ossification. The physeal dysplastic phenotype is common to several distinct multicentric disorders including primary genetic defects, chromosomal aberrations, storage disorders, metabolic bone diseases, and toxicities. Examples include achondroplastic dwarfism, Jansen's metaphyseal chondrodysplasia (JMC), mucopolysaccharidosis, osteogenesis imperfecta, deferoxamine toxicity, Ellis-van Crefeld syndrome and Meckel syndrome, among many others. It is characterized by disordered appositional bone growth and microscopically by altered chondrocyte development, proliferation and/or maturation within the growth plate. A variety of physeal changes may occur in this spectrum of diseases. In achondroplasia, the zones of proliferation and hypertrophy are narrowed and may be disorganized with premature deposition of horizontal struts of bone sealing the plate, while in other conditions such as JMC, Ellis-van Crefeld syndrome, or toxicities involving the physis, the growth plate is expanded with disorganization of cartilage columns and altered mineralization fronts (Fig. 1).

Retained cartilaginous cores, subphyseal hyperostosis, cortical hypertrophy and premature closure can all be noted histologically, depending on the specific pathogenesis of the particular syndrome. Limb shortening (dwarfism) and joint pain are common clinical manifestations regardless of primary disease. Physeal dyplasia is primarily an affliction of children, as physeal closure occurs in most human bones at or prior to adulthood. As many as 150 transgenic knockout mouse strains have been characterized with the physeal dysplastic morphologic phenotype. Physeal dysplasia has also been recognized in a variety of inherited diseases in dogs, cats, horses, pigs and cows. Many therapeutic drugs now in development by pharmaceutical or biotechnology companies directly or indirectly target growth factors and signaling pathways involved in chondrocyte differentiation and maturation. As a consequence, physeal dysplasia is becoming more commonly noted as a toxicologic event in preclinical studies in rodents, dogs or primates [1].



**Physeal Dysplasia. Figure 1** Physeal dysplasia in a rat given a growth factor inhibitor. (a) Normal rat femoral physis stained with Movat procedure demonstrates (top to bottom:) epiphysis (green), and chondrocytes embedded in a saffron-pink stained cartilage matrix consisting of reserve zone, zone of proliferation, zones of prehypertrophy and hypertrophy. The metaphysis or zone of mineralization encompasses the green and red stained area at the bottom half of the figure. (b) Physis from a rat treated with a TGF-beta receptor inhibitor and stained with Movat demonstrates disruption and disorganization of the chondrocytic columns, pronounced lengthening of proliferative and hypertrophic zones, as well as marked alcian blue staining of the hypertrophic zone (indicative of changes in proteoglycan composition) of physeal cartilage.

## Prevalence

Physeal dysplasia is a morphologic feature of over 175 heritable diseases, nutritional deficiencies, and toxicities. Congenital skeletal dysplasias have been reported with an incidence of 75.7 per 100,000 births in a Danish study, but due to infant lethality, prevalence in the general population is much less (33 per 100,000). Achondroplasia is the most common nonlethal form (2.53 per 100,000 live births), but osteogenesis imperfecta and multiple epiphyseal dysplasias are the other more common groups of dysplastic disorders affecting the physis [2].

## Genes

FGFR3 missense mutation (e.g. Gly375Cys) on chromosome 4p is the most common inherited form of achondroplastic dwarfism, and the same gene is also implicated in thanatophoric dysplasia, a lethal, but related disorder affecting the physis [3]. However, defects in a wide variety of genes involved in growth plate morphogenesis may result in physeal dysplasia, and occur as one component of multiple morphologic defects seen in this spectrum of genetic diseases. Examples include a mutation in the diastrophic dysplasia sulfate transporter (DTDST) gene on chromosome 5 causing various chondrodysplastic syndromes [2,4] or a mutation in COL1A1 or COL1A2 (on chromosome 17q or 7q, respectively) resulting in osteogenesis imperfecta [4,5].

## Molecular and Systemic Pathophysiology

Normal endochondral ossification requires the interaction of a large number of tightly regulated growth factors, receptors and cytokines acting in precise sequences and at specific zones within the growth plate to maintain ordered chondrocyte proliferation, hypertrophy, maturation and allow organized long bone growth. Apoptosis, vascularization and mineralization are also precisely temporally and spatially regulated. The disruption of any one of a number of factors or their coordinated interactions with extracellullar matrix elements can perturb physeal homeostasis and result in the physeal dysplastic phenotype [1]. This includes defects in endochondral growth factors or their receptors such as TGF-β1, VEGF, ALK5 and FGFr 1, 2, or 3; abnormalities in chondrocyte or osteoblast regulatory factors such as IHH, PTH, PTHrP, Wnt, or Crt1; disruption of factors regulating cartilage metabolism such as IGF-1, IRS-1; defects in physeal collagenases such MMP9, MMP13, collagen defects such as Col2A1, Col2A2, or perlecan; defects in genes essential for extracellular matrix deposition and function such as N-acetylgalactosamine-6-sulfate sulfatase (GALNS), DTDST, matrilin-1/3, integrin α10β1, or Ilk; disrupted function of transcription factors involved in chondrocyte or osteoblast proliferation signaling such as histone deacetylase, Stat1/5 and Runx2; ricketic conditions such as hypovitaminosis D or vitDr defects; or even deficits in growth hormones such as GH, GHRH or Gsh-1. Many of these genes and proteins are differentially regulated at multiple levels and are expressed or secreted differentially in different zones of the physis. Due to precise upregulation or feedback loop inhibition between these regulatory factors, when one protein is deleteriously affected, multiple others are also dysregulated, and physeal dysplasia appears to be the resulting default morphologic phenotype.

## Diagnostic Principles

Radiographic examination and MRI will successfully demonstrate physeal lesions, and in some conditions such as achondroplasia, survey radiographs may be pathognomonic. A definitive diagnosis for a specific syndrome more often requires genotypic characterization and molecular analysis, as many of these diseases may present with similar appearances. Even within a given familial disease, there may be extremely variable phenotypic expression. Genetic counseling after diagnosis in one child may allow prenatal diagnosis in subsequent siblings using ultrasound or CT.

## Therapeutic Principles

As most of the diseases associated with this condition have a genetic basis, treatment is largely palliative, and depends on therapy aimed specifically at symptoms associated with the principal disease. Analgesics and anti-inflammatory therapy are most commonly administered. Treatment for achondroplasia, the most common disease of the growth plate, is generally limited to addressing complications using techniques such as spinal decompression or limb lengthening. Sequelae to physeal dysplasia in children include genu varum or valgus deformities of the limbs, and this can be alleviated via hemichondrodiastasis, femoral or tibial osteotomy or other alternative surgical techniques. Other genetic diseases, where physeal changes are only a minor component of the overall phenotype such as Mucopolysaccharidosis or Osteogenesis imperfecta, may require extensive therapy to alleviate concomitant clinical signs, and may be candidates for gene therapy or other forms of enzyme replacement therapy. In cases of drug-induced physeal dysplasia, treatment withdrawal (or treatment delay until post adolescent physeal closure has occurred) may be curative. Hypovitaminosis D can be successfully treated with aggressive nutritional therapy.

## Synonyms

Partial albinism

## Definition and Characteristics

Autosomal dominant disorder of the development of melanocytes (MIM#172800) characterized by congenital poliosis and leukoderma [1].

## Prevalence

The exact prevalence is unknown. In most cases with piebaldism mutations of the KIT protooncogene, a cell surface receptor tyrosine kinase located on chromosome 4q12, are the molecular base. In other cases deletions of the SLUG (SNAI2) gene have been shown.

## Genes

In most cases with piebaldism mutations of the KIT protooncogene located on chromosome 4q12 are the molecular causer [2]. In other cases deletions of the SLUG (SNA12) gene have been shown [3].

## Molecular and Systemic Pathophysiology

Piebaldism is caused by defective melanoblast proliferation, differentiation, survival and migration from the neural crest during early development. The KIT protein is composed of an extracellular domain, a transmembrane domain and an intracellular tyrosine kinase domain. It is the receptor for mast cell growth factor (MGF), also known as stem cell factor, steel factor, or kit-ligand. Stimulation of human melanocytes with MGF leads to tyrosine autophosphorylation of KIT and subsequent activation of downstream signaling intermediates including the mitogen-activated protein kinases-1/2 crucially involved in proliferation and melanogenesis. Point mutations, deletions, nucleotide splice mutations and insertions of KIT have been detected in patients with piebaldism. The severity of the clinical phenotype correlates with the site of the mutation within KIT. The most severe phenotypes are caused by mutations within the intracellular tyrosine kinase domain followed by mutations within the transmembrane region. The mildest clinical manifestations are caused by mutations involving the N-terminal extracellular ligand binding domain resulting in haploinsufficiency. The human phenotype of piebaldism is replicated in mice with c-KIT mutations resulting in dominant white spotting but with additional defects in hematopoiesis and germ cell development. In some patients with piebaldism lacking mutations of the KIT gene aberrations of the SLUG (SNAI2) gene have been described. The affected patients had heterozygous deletions of the entire coding region of SLUG. Slug is a zinc-finger neural crest transcription finger factor crucially involved in development of hematopoiesis, germ cells and melanoblasts in the mouse.

## Diagnostic Principles

Congenital poliosis and leukoderma (forehead, trunk, limbs), often with hyperpigmented macules on both depigmented lesions and on normal skin are characteristic. The presence of the lesions at birth, its mostly static nature and the hyperpigmented macules within the lesions and on normal skin distinguish piebaldism from vitiligo.

## Therapeutic Principles

Melanocyte grafting with autologous melanocytes has been successfully performed on leukoderma of patients with piebaldism for cosmetic reasons.

## Synonyms

Robin sequence; Pierre Robin syndrome

## Definition and Characteristics

Pierre Robin sequence is a congenital anomaly characterized by micrognathia, glossoptosis, U-shaped cleft palate, and upper airway obstruction (Fig. 1) [1].

Pierre Robin sequence can occur in isolation but more often it is associated with other syndromes or congenital anomalies. Stickler syndrome is the most commonly associated diagnosis followed by velo-cardio-facial syndrome [2]. Other associated syndromes include Treacher-Collins syndrome, Marshall syndrome, Freeman-Sheldon syndrome, Nagar syndrome, Miller syndrome, Christian syndrome, foetal alcohol syndrome, Cerebrocostostomandibular syndrome, Toriello-Carey syndrome, and microdeletion 22q11.2 syndrome [2]. Associated deformities include clubfoot, crumpled ear, or limb contractures. Airway obstruction is caused mainly by the posteriorally attached tongue falling backward and down into the pharynx. Periodic cyanosis, labored inspiratory breathing, and sleep apnea may occur [1]. Feeding difficulties and gastro-esophageal reflux are common and may result in bronchial aspiration.

## Prevalence

The prevalence is between 1 in 2,000 and 30,000 in the general population [3]. The male to female ratio is equal.

## Genes

Non-syndrome Pierre Robin sequence may be caused by dysregulation of the genes GAD67, PVRL1, SOX9,

**Pierre Robin Sequence. Figure 1** A neonate with Pierre Robin sequence. Note the U-shaped cleft palate and micrognathia.

and KCNJ2 [4]. Two thirds of Stickler syndrome cases are caused by mutations in the COL2A1 gene.

### Molecular and Systemic Pathophysiology

Micrognathia is a primary pathogenetic event and the basic component of the Pierre Robin sequence. Because the floor of the mouth is foreshortened and the buccal cavity is smaller than normal, the posteriorly displaced tongue is partially interposed between the palatal shelves [1]. This prevents palatal closure. The position of the tongue into the palate explains the "U" shape of the cleft seen in Pierre Robin sequence, as opposed to the "V" shape of the typical cleft palate [1]. The high incidence of twinning (9% vs. 1% in the general population) and the discordance in monozygotic twins suggest that Pierre Robin sequence might be the result of mechanical constraint early in utero, with the chin compressed in such a way as to limit its growth [3,4].

### Diagnostic Principles

The diagnosis is mainly clinical. Once the diagnosis is made, one should proceed with the process of seeking a syndromic diagnosis. Molecular analysis is currently restricted to research laboratories.

### Therapeutic Principles

Affected infants should be kept prone or partially prone. Depending on the severity of symptoms, some infants may require nasopharyngeal airway, gavage feeding, glossopexy, or even tracheostomy. Most infants outgrow the feeding and respiratory difficulties by the time they are 6 months old because of maturation of the neuromuscular control of the tongue and growth of the mandible [5].

## Pierre Robin Syndrome

►Pierre Robin Sequence

## Pierson Syndrome

Verena Matejas, Martin Zenker
Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany

### Synonyms

Microcoria-congenital nephrosis syndrome

### Definition and Characteristics

Autosomal recessive disorder characterized by nephrotic syndrome and distinct ocular anomalies [1]. Renal disease usually starts shortly after birth or may already be noticed in utero. It rapidly progresses to end stage renal failure. A fixed narrowing of the pupils (microcoria) is characteristic. However, ocular maldevelopment is of more complex nature and includes lens abnormalities, hypoplastic ciliary muscle, abnormal retina, and retinal detachment. Muscular weakness and neurodevelopmental deficits may become apparent in long-term survivors. Milder variants of the disease have been described [2].

### Prevalence

Rough estimate of 1:250,000–500,000.

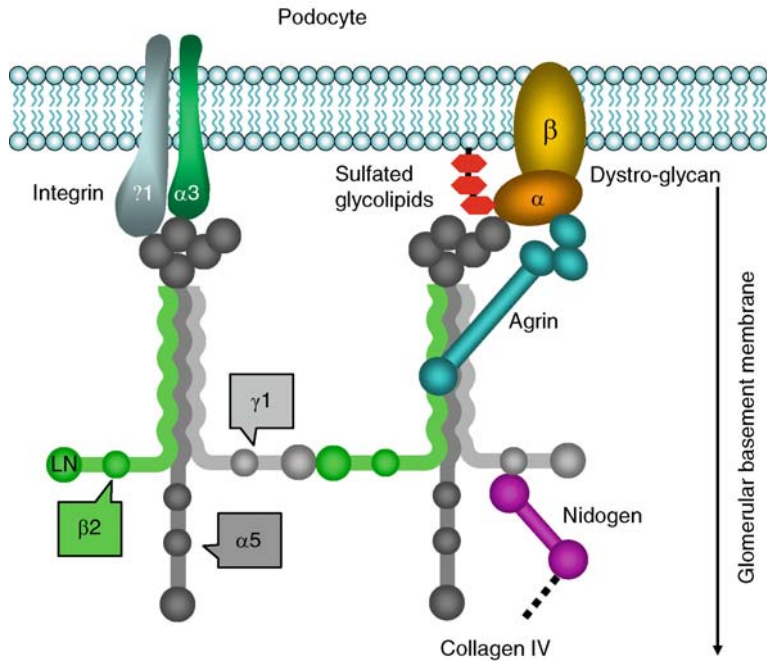
### Genes

Mutations of LAMB2, the gene encoding laminin β2, can be found in virtually all patients with the typical expression of the syndrome [3]. Most mutations found to date are truncating ones (nonsense, frameshift or splice site mutations) probably leading to complete lack of the protein, while few are missense changes mainly located in the in the N-terminal LN domain.

### Molecular and Systemic Pathophysiology

Laminins constitute a family of heterotrimeric glycoproteins each consisting of α, β and γ subunits joined together through a coiled-coil. They represent major basement membrane constituents playing important roles for its architecture and matrix-cell interactions, thereby being involved in cell adhesion, differentiation and migration (Fig. 1).

The laminin β2 isoform is specifically expressed in the glomerular basement membrane, ocular structures and the neuromuscular synapse. The consequences of a defect in laminin β2 are incompletely understood. Findings in transgenic animals suggest that the lack of laminin β2 in the glomerular basement leads to persistent expression of the β1 isoform [4]. The observation of abnormal podocyte foot processes in laminin β2-deficient mice and in kidney biopsies from individuals affected by Pierson syndrome has lead to the hypothesis that the laminin β2 defect causes abnormal



**Pierson Syndrome. Figure 1** Laminin-521 (α5, β2 and γ1 subunits) at the glomerular basement membrane: Laminin molecules polymerize to form a network anchored to the the podocyte plasma membrane through sulfated glycolipids and/or dystro-glycan. This network represents a scaffold for other essential basement membrane components (nidogen, collagen IV). Integrin α3β1 acts as a laminin receptor probably mediating signaling events in podocytes.

podocyte differentiation or adhesion. However, there has also been provided experimental evidence that the lack of laminin β2 alters the filtration properties of the glomerular basement membrane itself [5]. Based on the finding of specific expression of laminin β2 at the basal site of myoepithelial cells forming the dilatator muscle of the iris, it was speculated that a lack of the protein may lead to defective differentiation of these cells, eventually resulting in aplasia or early degeneration of the dilatator pupillae [3]. Abnormal lens shape may result from a lack of laminin β2 in the lens capsule. Milder variants of Pierson syndrome are associated with missense mutations probably representing hypomorphic alleles [2].

## Diagnostic Principles

The diagnosis of typical Pierson syndrome is based on clinical findings. Identification of the causative LAMB2 mutation in affected families is indicated for purposes of prenatal testing or carrier identification. In atypical cases with nephrosis and less specific ocular abnormalities a positive mutational screening of LAMB2 is confirmative. In isolated congenital or infantile nephrotic syndrome LAMB2 mutational screening is not in the first line, but it may be considered if other genetic causes have been excluded. Severely reduced laminin β2 expression can also been demonstrated by immunohistology in a kidney biopsy, but the sensitivity of this method is unknown. It has to be considered that mutant laminin β2 proteins may not always show a quantitative reduction in their expression.

## Therapeutic Principles

Only symptomatic treatment is available. This may include albumin substitution to prevent symptomatic hypoproteinemia. Rapid deterioration of urine output often leads to regression of renal protein waste and requires early kidney replacement therapy (dialysis, transplantation). Eye surgery (widening of the pupillary opening, lens ectomy) may improve visual function.

## Pilomatricoma

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Pilomatrixoma; Calcifying epithelioma of Malherbe

### Definition and Characteristics

Typically, a pilomatricoma presents as a firm to hard, solitary, painless nodule in the dermis or subcutaneous tissue covered by normal skin [1]. The color varies from white, pink, blue, to red-blue [2]. The blue color is more common for superficially located lesions (Fig. 1).

Most lesions measure 5 mm to 3 cm in diameter, although lesions up to 15 cm have been reported [2].

**Pilomatricoma. Figure 1** An 8-year-old girl with a pilomatricoma. Note the bluish nodule in the right zygomatic area.

Most lesions increase in size slowly over a period of months to years. Some may rupture spontaneously. The nodule may become hardened if the lesion is calcified. Calcification and ossification occurs in 70–85% and 15–20% of patients, respectively [3]. Downward pressure directed at one end of the lesion may cause the other end to spring upward in the skin ("teeter-totter" sign). Multiple facets and angles may appear when the overlying skin in stretched ("tent" sign) [2]. Pilomatricoma most commonly occurs in the head and neck, followed by upper extremities [3]. Most cases are sporadic. Multiple pilomatricomas occur in 2–4% of cases and have been associated with myotonic dystrophy, Gardner syndrome, Turner syndrome, Rubinstein-Taybi syndrome, basal cell nevus syndrome, xeroderma pigmentosum, and trisomy 9 [3]. Although the tumor is generally benign, malignant transformation rarely has been described [4].

### Prevalence

The exact incidence is not known. The condition most frequently appears in the first or second decade of life. Pilomatricomas account for approximately 10% of all skin nodules/cysts in childhood [1]. The female to male ratio is 2:1 [1].

### Genes

Activating mutations in β-catenin have been identified in a high percentage of patients with pilomatricomas [1]. The locus of this tumor has been mapped to CTNNB1 gene on 3p22-p21.3 [5]. The myotonic dystrophy gene on chromosome 19 and the CREB-binding protein gene on chromosome 16 responsible for Rubinstein-Taybi syndrome might account for the association of multiple pilomatricomas with these conditions.

### Molecular and Systemic Pathophysiology

A pilomatricoma is a benign adnexal subcutaneous tumor derived from primitive epidermal germ cells

differentiating toward hair matrix cells. Histologically, the tumor is composed of basophilic cells and shadow cells. Basophilic cells are seen at the periphery of the lesion. Shadow cells have a well-defined border and a central unstained area where the nucleus has been lost. Pilomatricoma is generally surrounded by a fibrous capsule [3]. Approximately 10% of patients have a history of trauma several weeks to years before the development of the lesion.

### Diagnostic Principles

The list of differential diagnosis is extensive and includes a dermoid cyst, epidermal cyst, adenopathy, foreign body, calcified hematoma, and lipoma [3]. Accurate preoperative diagnosis is achieved in approximately 30–43% of cases [5]. Ultrasonography of the lesion demonstrates a well-defined, round, hyperechogenic mass with a posterior dense acoustic shadow [3].

### Therapeutic Principles

Treatment consists of surgical excision with clear margins. The use of laser surgery may help minimize the scar. Incomplete removal may lead to local recurrence [1].

## Pityriasis Alba

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

### Synonyms

Pityriasis simplex faciei; Pityriasis sicca faciei; Pityriasis alba faciei; Achromatous pityriasis faciei

### Definition and Characteristics

Pityriasis alba is characterized by hypopigmented, round or oval macules with fine, loosely adherent scales and indistinct margins (Fig. 1) [1].

Initially, the lesions are pale and pink. The lesions appear mainly on the face, especially the forehead and malar areas, and occasionally on the shoulders, upper arms and back [1]. The lesions range from 0.5 to 5 cm in diameter [2]. Confluent lesions can give the appearance of larger, more amorphous lesions [2]. Most lesions are asymptomatic although some are mildly pruritic [1].

**Pityriasis Alba. Figure 1** Hypopigmented lesions on this 9-year-old boy's cheeks are characteristic of pityriasis alba.

## Prevalence

Pityriasis alba occurs predominantly in children between the ages of 3 and 16 years [3]. The sex incidence is approximately equal [3]. The condition is noted in up to 40% of dark-skinned children and approximately 2% of Caucasian children [2].

## Molecular and Systemic Pathophysiology

The exact etiology is not known. The condition is more common in atopic patients and during the spring and summer [1]. Xerosis is an important pathogenetic factor [4]. The hydration state of the affected stratum corneum is lower than that of the surrounding skin [2]. Ultraviolet radiation might diminish the number and activity of the melanocytes and lead to hypomelanosis [4]. Exposure to sunlight or tanning lamps accentuates the condition because the adjacent skin is darker. Microorganisms such as Pityrosporum, Aspergillus, Streptococcus and Staphylococcus have been considered as possible causes, but none of these microorganisms has been consistently isolated from skin lesions. Histologic features include hyperkeratosis, parakeratosis, mild acanthosis, exocytosis, and reduced melanocytes and melanosomes in the basal layer of the epidermis [2].

## Diagnostic Principles

Pityriasis alba is distinguished from vitiligo by the indiscrete margin and the presence of melanin on Wood's lamp examination [1]. Tinea versicolor is rarely restricted only to the face, is uncommon in childhood, and has a distinct margin. Tinea versicolor can be excluded by the demonstration of the fungus with a potassium hydroxide preparation. The lesion of nummular eczema is usually plaque-like, sharply circumscribed, and more pruritic [1]. Nevus depigmentosus is characterized by nonprogressive, well-circumscribed macules or patches of hypopigmentation and the appearance before 3 years of age [5]. The hypopigmented lesions of tuberous sclerosis are usually present at birth or develop during the first 2 years of life, and have the appearance of an "ash-leaf" [5]. Nevus anemicus can be diagnosed by stroking the affected area, which cause the pale area to become erythematous. Postinflammatory, chemical-induced, or drug-induced hypopigmentation is usually evident by history.

## Therapeutic Principles

The condition is self-limited and usually lasts 2–3 years [1]. No treatment is usually necessary. If treatment is preferred for cosmetic reasons, repigmentation can be accelerated by the use of a mild to moderate strength non-fluorinated topical hydrocortisone or immunomodulator.

►Pityriasis Lichenoides Mucha-Habermann

# Pityriasis Lichenoides Mucha-Habermann

Stefan Beissert
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Pityriasis lichenoides et varioliformis acuta; Mucha-Habermann disease; Guttate parapsoriasis

## Definition and Characteristics

Pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC) are two ends of a disease spectrum [1]. Both entities are characterized by recurrent crops of spontaneously regressing erythematous papules, more pustular in PLEVA and more scaly in PLC.

## Prevalence

Pityriasis is more prevalent in children, but patients in all age groups, races, and regions can be affected.

### Molecular and Systemic Pathophysiology

The etiology of PLEVA and PLC is unknown. Both PLEVA and PLC contain lesional T-Cell infiltrates, with a predominance of CD4 + T-Cells in PLC and CD8 + T-Cells in PLEVA.

### Diagnostic Principles

The diagnosis is made by the correlation of clinical features with lesional histopathology.

### Therapeutic Principles

All treatments of PLEVA/PLC are based on uncontrolled case series, case reports, and anectotal reports. Antibiotics, phototherapy (UVB, PUVA, Aciretin and PUVA), and systemic immunosuppressants (MTX, Cyclosporine A, Dapsone) have been used successfully to treat this disease.

## Pityriasis Maculata et Circinata

►Pityriasis Rosea

## Pityriasis Rosea

Alexander K. C. Leung[1],
William Lane M. Robson[2], Tom Y. Woo[3]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada
[3]Department of Medicine, The Univesity of Calgary, Calgary, AB, Canada

### Synonyms

Roseola annulata; Pityriasis maculata et circinata; Pityriasis rubra aigu disséminé

### Definition and Characteristics

Pityriasis rosea is an acute self-limited papulosquamous dermatosis that primarily affects children and young adults. The most common presenting sign is a herald or "mother" patch, which begins as a smooth, erythematous macule or papule, which expands over 1–2 weeks to form a round or oval, erythematous scaly lesion that is 1–10 cm in diameter [1]. A herald patch is found in 50–90% of cases [2]. Multiple herald patches are found in ~5% of cases [3]. A generalized, bilateral, and symmetrical eruption develops about 1–3 weeks after the appearance of the herald patch (Fig. 1) The typical lesions are 5–10 mm, pinkish to brown, with a delicate collarette of scale at the periphery. The long axes are along lines of cleavage (Langer lines) (Fig. 1) [1,4].

The distribution on the back has a "Christmas tree" or "fir tree" appearance. The face, palms, and soles are usually spared [4]. Some children, particularly African-Americans, show an inverse distribution with lesions mostly on the face, and in the axillary and inguinal areas. Oral lesions are uncommon and include punctate hemorrhages, vesicles, and bullae. Pruritus is present in ~25% of cases [3,4]. Resolution usually occurs over a period of 2–12 weeks [2]. In dark-skinned individuals, postinflammatory hyperpigmentation or hypopigmentation can persist after the resolution of the acute lesions.

**Pityriasis Rosea. Figure 1** Pityriasis rosea. Note the generalized, bilateral and symmetrical eruption on the body of a 12-year-old girl.

### Prevalence

Approximately 75% of cases occur in individuals between the ages of 10 and 35 years [3]. The peak incidence is during adolescence. There is a slight female predominance [3]. Most cases occur in the spring and autumn. The disease is worldwide. The average annual incidence is estimated to be ~160 per 100,000 in the USA.

### Molecular and Systemic Pathophysiology

A viral etiology has been proposed because of the seasonal variation, clustering in communities, and preceding upper respiration tract infection, which is present in up to 20% of affected patients [2]. Human herpesvirus 7 has been implicated but the causative role is still controversial [5]. Focal parakeratosis, spongiosis, and a superficial lymphohistiocytic perivascular infiltrate might be present [5].

### Diagnostic Principles

The diagnosis is clinical and based on the characteristic findings. The differential diagnosis includes tinea corporis, guttate psoriasis, secondary syphilis, nummular eczema, pityriasis lichenoides, pityriasis versicolor, and drug eruption. A pityriasis rosea-like drug eruption can be caused by penicillamine, captopril, and isotretinoin.

### Therapeutic Principles

The patient should be reassured that the rash will resolve spontaneously within about 4–12 weeks [4]. Pruritus can be treated with a topical corticosteroid or an oral antihistamine. Treatment options for severe cases include erythromycin and UVB phototherapy.

►Pityriasis Alba

## Pityriasis Versicolor

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Tinea versicolor

### Definition and Characteristics

Pityriasis versicolor is characterized by scaly hypo- or hyperpigmented macules, most commonly affecting areas of skin that are rich in sebum production, such as the neck, trunk, and upper arms [1]. Facial involvement is not uncommon in children. Lesions arise as multiple small, circular macules that enlarge radially. The eruption varies in color from patient to patient, but each person's tinea versicolor lesions are usually of a single hue. Hyperpigmented, pink, red, brown, or black lesions erupt in fair-skinned patients, whereas those with dark skin tend to have hypopigmented lesions (Fig. 1) [1,2].

The characteristic macules are covered with a fine scale and are typically asymptomatic, although some patients complain of mild pruritus.

### Prevalence

Pityriasis versicolor occurs worldwide. Its prevalence is very high in hot and humid climates. In some tropical countries, the prevalence is as high as 50% whereas in Scandinavia the prevalence is as low as 1% [3]. Other predisposing factors include excessive sweating, skin occlusion, an excess of lipid-containing sebaceous secretions, malnutrition, poor general health,

**Pityriasis Versicolor. Figure 1** A 20-year-old man with tinea versicolor. Note the round to oval hypopigmented macules on the neck, chest and upper arm.

immunosuppression, and a genetic predisposition to the disorder. Pityriasis versicolor is uncommon before puberty and is most commonly seen in adolescents and young adults [3]. Both sexes are more or less equally affected [4].

## Molecular and Systemic Pathophysiology

Pityriasis versicolor is a superficial mycosis infection caused by the dimorphic lipid-dependent yeasts, notably Malassezia furfur, M. globosa, and M. sympodialis [2]. Skin colonization with these Malassezia yeasts increases with age; 25% of children and almost 100% of adolescents and adults are affected. Tinea versicolor occurs when the yeast form of the organism converts to the hyphal form. Tryptophan-derived metabolites of M. furfur might be significant in the pathogenesis of depigmentation [5].

## Diagnostic Principles

The diagnosis is usually clinical. If necessary, the diagnosis can be confirmed by direct examination of scrapings from the border of a lesion with a potassium hydroxide wet mount preparation which shows numerous short, stubby hyphae intermixed with clusters of spores (the "spaghetti and meatballs" appearance). The border of a lesion contains the highest number of fungi and potassium hydroxide helps to dissolve the keratin and debris [3]. Wood's lamp examination may show gold yellow or yellow-greenish fluorescence [1,5]. The differential diagnosis of hypopigmented lesions includes vitiligo, pityriasis alba, corticosteroid-induced hypopigmentation, and postinflammatory hypopigmentation. Hyperpigmented lesions associated with tinea versicolor must be distinguished from seborrheic dermatitis, contact dermatitis, tinea corporis, pityriasis rosea, melasma, post inflammatory hyperpigmentation, secondary syphilis, erythrasma, and nevi.

## Therapeutic Principles

Most patients respond to topical treatment with selenium sulfide or sodium thiosulfate lotion; or miconazole, clotrimazole, ketoconazole, or terbinafine cream. Oral ketoconazole, fluconazole, itraconazole, or terbinafine may be appropriate for patients with extensive disease, frequent recurrences, or disease that is refractory to topical therapy. Mycological cure is usually achieved soon after treatment with antifungals although the discoloration may persist for months.

### Synonyms

Bernard-Soulier syndrome; Bss; Platelet glycoprotein Ib deficiency; Glycoprotein Ib, platelet, deficiency of; von Willebrand factor receptor deficiency; Macrothrombocytopenia, familial, Bernard-Soulier type, Included Bernard-Soulier syndrome, autosomal dominant

### Definition and Characteristics

A severe bleeding tendency associated with a mild thrombocytopenia with quantitative and qualitative defects in the GP Ib/IX/V complex formation on platelet membranes. To date more than 30 different mutations involving glycoproteins (GP) Ibα, GP Iβ or GP IX have been described. Heterozygous carriers have a moderate bleeding diathesis, mild macrothrombocytopenia and reduced amount of GP Ib/IX/V complex [1,2]. A heterozygous Val156Ala substitution of GP1bα was characterized as the origin of a 50% reduced binding of antibodies against the specific epitope (Bolzano mutation). A heterozygous missense mutation in the GPIbβ caused a giant platelet thrombocytopenia, associated with reduced expression of the GPIb/IX/V complex on platelets. A homozygous Asn-45-Ser mutation in GPIX may be a frequent cause of BSS in the Caucasian population [3]. The major proof of concept comes form direct disruption of the GP Ibα gene, which produced a mouse with a BSS phenotype [4].

### Prevalence

Estimated at 1 per million people, heterozygous frequency estimated at 1:500.

### Genes

The most likely characterization is of an autosomal dominant macrothrombocytopenia with incomplete penetrance. Rare homozygous patients are phenotypically more severe than heterozygous individuals [1].
*Gene map locus*: 22q11.2, 17pter-p12

### Molecular and Systemic Pathophysiology

Several different mutations have been identified in the GPIb/IX/V complex.

The combination of thrombocytopenia and defective GPIb/IX/V complex assembly underlies the

pathogenesis of BSS. The GP Ib/IX/V complex is a major site of attachment for von Willebrand factor (vWF) upon vessel damage. In addition, GPIbα interacts with thrombin, which may contribute to platelet aggregation [1]. The exact role of the GPIb/IX/V complex is however still unknown. GP Ibα is linked to intracellular actin filaments, and other parts of the GP's from this complex may be involved in cell signaling properties.

*Clinical features*: Patients with classical BSS are either homozygous or compound heterozygotes for mutations in the GPIα, GPIbβ, or GP IX genes. In homozygous BSS a bleeding diathesis is usually present from childhood onwards, but the interindividual variability is extensive, also among family members. In addition, within the individual, severity of bleeding tendency may alter upon aging. Spontaneous bleeding presents in the form of epistaxis, gastrointestinal bleeding, metro-menorrhagia and ecchymoses. Upon surgical trauma severe bleeding may occur. Fatal bleeding is rare. Heterozygous patients usually have a mild bleeding tendency.

### Diagnostic Principles

Macrocytosis of platelets is a constant finding and blood smear analysis is imperative in the diagnostic workup. Thrombocytopenia may be a highly variable feature and counts range from very low to apparently normal. Bleeding time is oftentimes prolonged, but as with other bleeding tendencies, its diagnostic accuracy is limited. Platelet aggregation studies show absent response to ristocetin and botrocetin and diminished reaction to low dose thrombin. Responses to other agonists that act by other GP's, including ADP and collagen are usually normal. Confirmation can be obtained by flow cytometry with conformation dependent monoclonal antibodies against GPIb.

### Therapeutic Principles

In general supportive care is advised. In most BSS patients at some point transfusions have to be given. After the age of 3 years DDAVP may be useful as prophylaxis for minor surgery or in case of menorrhagia. When major hemorrhage cannot be controlled by platelet and red cell transfusions, recombinant factor VIIa may be used as rescue therapy.

### Synonyms

Wet pleurisy; Empyema; Hemothorax; Chylothorax; Hepatic hydrothorax

## Definition and Characteristics

Systemic factors or local factors lead to the accumulation of fluid in the space between the lung and the chest wall. When systemic factors are responsible, the patient has a transudative pleural effusion. When local factors are responsible, the patient has an exudative effusion.

## Prevalence

In the United States approximately 1,000,000 individuals develop a pleural effusion each year. The most common causes are heart failure (500,000), parapneumonic effusion (300,000), metastatic malignancy (200,000), pulmonary embolism (150,000), viral illness (100,000), post coronary artery bypass surgery (60,000) and cirrhosis (50,000) [1,2].

## Molecular and Systemic Pathophysiology

Fluid accumulates in the pleural space producing a pleural effusion when the rate of pleural fluid formation exceeds the rate of pleural fluid absorption. The normal rate of pleural fluid formation is about 0.01 ml/kg/h. Since this is such a low rate of pleural fluid formation (~12 ml/day), most instances in which pleural fluid accumulates are associated with an increased rate of pleural fluid formation. Fluid is removed from the pleural space through lymphatics in the parietal pleura. The normal capacity of the lymphatics for fluid removal is 0.20 ml/kg/h. The most common cause of increased rates of pleural fluid formation is increased interstitial fluid in the lungs. Twenty percent of all the pulmonary interstitial fluid exits the lung via the pleural space. Increased pulmonary interstitial fluid is the cause of the increased pleural fluid formation seen with heart failure, pneumonia and pulmonary embolus. With pleural malignancy, the permeability of the pleura capillaries is increased and this leads to increased pleural fluid formation. Other causes of increased pleural fluid formation include a ruptured blood vessel (hemothorax), a ruptured thoracic duct (chylothorax) and ascitic fluid moving through the diaphragm (hepatic hydrothorax).

## Diagnostic Principles

When a pleural effusion is discovered, the first question to answer is whether the patient has a transudative or an exudative pleural effusion. This is done by measuring the levels of protein and lactic acid dehydrogenase (LDH) in the pleural fluid and serum. Patients with an exudative effusion meet at least one of the follow criteria: (i) ratio of pleural fluid to serum protein > 0.5, (ii) ratio of pleural fluid to serum LDH > 0.6, or (ii) absolute pleural fluid LDH > two thirds the upper normal limit for serum. Diagnostic tests, which provide specific diagnoses for pleural effusions, include pleural fluid cytology for malignancy, pleural fluid cultures for pleural infections, and spiral CT scan for pulmonary embolus. The diagnosis of pleural effusions at times requires biopsy of the pleural tissue which is best done with thoracoscopy [3].

## Therapeutic Principles

There are many different diseases that have an associated pleural effusion. In general therapy is directed at the underlying disease responsible for the pleural effusion; antibiotics for the patient with pneumonia, anticoagulation for the patient with pulmonary embolism, diuresis for the patient with cirrhosis, heart failure therapy for the patient with heart failure. There are some instances, however, in which therapy is directed to the pleural fluid. If a patient is dyspneic from a large pleural effusion, a therapeutic thoracentesis should be done to relieve the dyspnea. If a patient has a bacterial infection of the pleural fluid, the pleural fluid must be drained using chest tubes with or without the use of fibrinolytics or thoracoscopy [4]. If a patient has a recurrent pleural effusion from malignancy, attempts should be made to create a pleurodesis by injecting an agent into the pleural space, which will result in fusion of the visceral and parietal pleura. An alternative approach in patients with recurrent symptomatic pleural effusions is to insert an indwelling catheter, which can be used to drain the pleural fluid intermittently by attaching it to suction bottles [5].

## Synonyms

Pleuritis; Pleural inflammation; Pleural effusion

## Definition and Characteristics

Pleurisy arises as a result of pleural inflammation either as a consequence of primary pleural disease or secondary to a systemic insult. Infection of the pleura is the most frequent cause of pleurisy and often results from disease arising in the ipsilateral lung, but trauma and vascular dissemination also play important roles. Every class of infectious organism is capable of causing pleural infection (see Table 1 for etiology). However, non-infectious diseases such as cancer, pancreatitis, trauma, systemic autoimmune diseases, pulmonary embolism and occupational disorders may present with pleurisy [1,2]. Sharp chest pain that worsens with deep inspiration, fever and dry cough are the most common clinical manifestations.

## Prevalence

Two thirds of all pleural space infections arise from infection in the underlying lung or from chest trauma. Despite the widespread use of antibiotics for respiratory tract infections, pleural empyema still occurs as a significant complication of pneumonia (7–10 cases per 100,000 inhabitants per year) [1,2].

## Genes

Pleurisy encompasses a wide array of clinical disorders; therefore no specific gene is associated to pleurisy. A few causes of pleurisy are, however, associated with genetic abnormalities. They are presented below.

The NRAMP1 genetic polymorphisms, especially INT4 and 3′UTR, are associated with tuberculous pleurisy [3].

Malignant mesothelioma (MM) results from the accumulation of a number of acquired genetic events, especially deletions, which lead to the inactivation of multiple onco-suppressor genes in a multistep cascade mechanism. Asbestos fibers induce DNA and chromosomal damage. Most MM cases have shown multiple chromosomal abnormalities. The most common cytogenetic abnormality in MM is a deletion in 9p21, the locus of CDKN2A, a tumor suppressor gene (TSG). The deletion of CDKN2A is a negative prognostic marker. Loss of TSG CDKN2A/p14 (ARF) is also common and mutations in NF2 occur in approximately half of the cases [1,2].

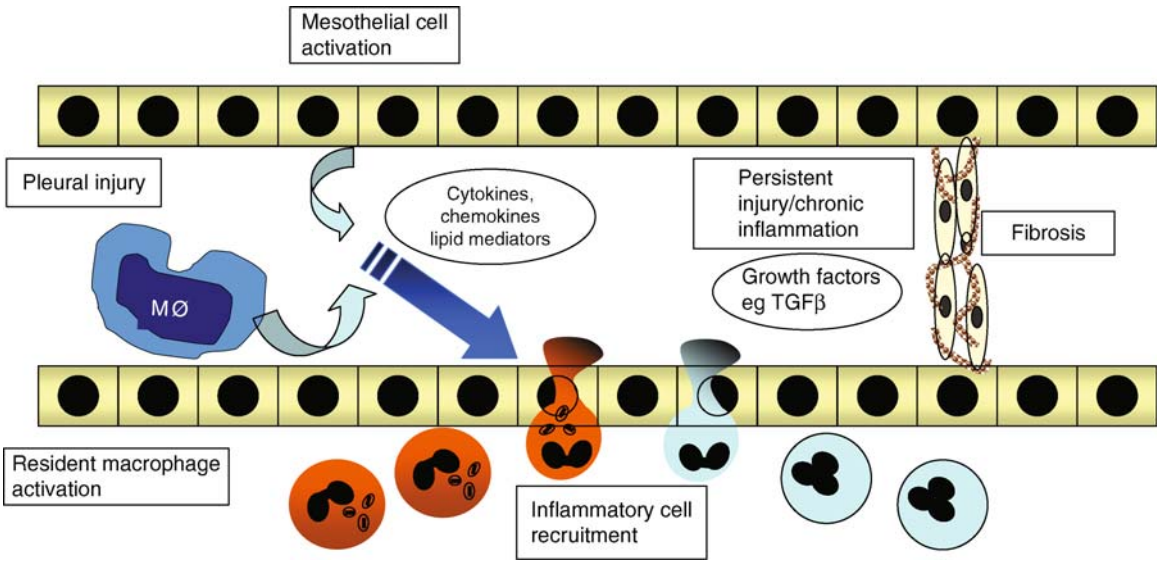
## Molecular and Systemic Pathophysiology

When the pleura are faced with an infectious organism, it responds with edema and exudation of protein and neutrophils. Within the pleural space, this translates to the classically observed exudative effusion. Mesothelial cells and resident macrophages coordinate inflammatory reactions through the release of cytokines, chemokines, lipid mediators, and proteases (Fig. 1) [1,4].

The recruitment and subsequent activation of neutrophils, eosinophils and lymphocytes perpetrate and amplify the local inflammatory response. Mesothelial cells are also capable of phagocytosis and surround infectious organisms as a direct defense mechanism. In the case of severe or persistent inflammatory damage, structural integrity may be reconstituted with the addition of a fibrotic reaction produced by submesothelial fibroblasts. TGF-β has been implicated in fibrous deposition. During this fibrotic response, the pleural space may become obliterated and be accompanied by the formation of dense fibrous adhesions.

**Pleurisy. Table 1** Causes of pleurisy

| Infectious causes | Non-infectious causes |
|---|---|
| Bacterial pneumonias | Systemic autoimmune diseases (e.g., lupus, reumatoid arthritis, Wegner's granulomatosis, Sjogren's syndrome) |
| Tuberculosis | Uremia |
| Esophageal rupture | Pancreatitis |
| Extra-pulmonary sepsis | Trauma |
| Fungal infections | Pulmonary embolism |
| Protozoan infections | Drug-induced (e.g., carbamazepine, nitrofurantoin, bromocriptine) |
| Viral diseases | Asbestosis |
| | Cancer |



**Pleurisy. Figure 1** Pathophysiology of pleurisy. Mesothelial cells and resident macrophages orchestrate inflammatory reactions through the release of inflammatory mediators. The recruitment and subsequent activation of neutrophils, eosinophils and lymphocytes perpetrate and amplify the local inflammatory response. Persistent inflammatory injury may lead to fibrosis.

## Diagnostic Principles

A thoracocentesis is usually performed as first step towards a diagnosis of pleurisy. As the pleural fluid is recovered, samples are examined for the presence of microorganisms (Gram and Ziehl-Nielsen and other specific stains, and pathogenic microorganisms grown in culture media), biochemical analysis (glucose, proteins, cholesterol, amylase, C-reactive protein, pH, adenosine deaminase), cytologic evaluation (for neoplastic cells, total and differential leukocyte count) and other less usual tests as cancer related antigens or pro and anti-inflammatory cytokines. A pleural biopsy may be performed, if the fluid analysis is inconclusive or if there is a high suspicion of tuberculosis or malignancy [5].

## Therapeutic Principles

Antimicrobial agents directed to the causative pathogen are the mainstream of treatment of parapneumonic effusions. However, complicated effusions often require closed tube drainage for a complete resolution.

Neoplastic effusions are alleviated by drainage and pleurodesis but the definite treatment usually requires chemotherapy.

Systemic auto-immune diseases related pleurisy is treated with immunossupressors, most often by high doses of systemic corticosteroids.

Currently gene therapy is still limited to experimental studies, mainly in mesothelioma.

## Synonyms

Coal workers' pneumoconiosis; CWP; Silicosis; Asbestosis; Berylliosis (chronic beryllium disease)

## Definition and Characteristics

The term pneumoconiosis refers to non-neoplastic reactions of the lungs to inhaled mineral or organic dusts and the resultant alteration in their structure, excluding asthma, bronchitis, and emphysema. Inhalation of mineral or organic dusts typically results from occupational exposures.

## Prevalence

For coal workers' pneumoconiosis (CWP), the prevalence was 3.2% in underground miners and 1.9% in surface miners within the United States during the years of 1996–2002. During the years 1987 through 1996, there were between 3,600 and 7,300 cases per year of silicosis in the United States. There were approximately 1,250 deaths due to asbestosis in the United States in 1999. The rate of berylliosis appears to be between 1 and 5% of exposed workers.

## Genes

In a study of Belgian coal minors with CWP, the frequency of tumor necrosis factor-α (TNF-α) polymorphism TNF-α-308 was significantly increased in miners with lung disease (50%) as compared to miners without lung disease (25%) or non-miners (29%) (OR 3.0; 95% CI 1.0–9.0) [1]. Increased frequency of the TNF-α-308 variant was also found in Japanese and Korean miners with CWP. In French miners, TNF-α-308 showed an interaction with erythrocyte glutathione S-transferase (GST) activity, and the lymphotoxin-α NcoI was associated with increased prevalence of CWP in miners with low blood catalase activity. Interactions in chemokine and chemokine receptor genes with the development of CWP have also been studied. The CCR5 Δ32 variant associated with a higher radiologic score while the CX3CR1 V249I variant was associated with a lower progression of radiologic score. Genetic differences in manganese superoxide dismutase, GST-M1, and GST-T1 genes were investigated in Chinese coal minors with no difference in genotype frequencies between cases and controls.

In silicosis, a significant association was found between disease severity and the TNF-α-238 variant (OR 4.0, CI 2.4–6.8). In South African miners, the TNF-α polymorphisms in positions -238, -376-, and -308 of the promoter region were associated with severe silicosis. In addition, TNF-α-308 and interleukin-1 receptor antagonist (IL-1RA) + 2,018 variants were associated with increased risk of silicosis.

For berylliosis, the HLA allele HLA-DPB1 (glu69) variant has been associated with the development of chronic beryllium disease [2]. The TNF-α-308 variant has been reported to be linked to high levels of beryllium-stimulated TNF-α levels and disease severity. In addition, the transforming growth

factor-β1 (TGF-β1) codon 25 variant has been associated with the development of berylliosis.

## Molecular and Systemic Pathophysiology

The pathogenesis of fibrotic lung diseases, including those related to the pneumoconioses, involves inflammatory cell activation, proliferation of fibroblasts, and synthesis of extracellular matrix components. Pulmonary fibrosis appears to result from persistent inflammation with pro-inflammatory cytokines such as TNF-α, interleukin-1 (IL-1), and IL-6 playing a significant role. IL-1α and IL-1β induce fibroblasts to produce cytokines such as IL-6 and collagens. IL-6, a pro-inflammatory cytokine, has been shown to mediate interstitial lung disease either alone or in combination with TNF-α. IL-1RA can attenuate IL-1 signaling and helps resolve inflammation after lung injury. TGF-β is a widely studied cytokine in fibrotic lung diseases due to its pleiotropic effects of inflammatory cells, connective tissue cells, wound healing, and tissue remodeling. Disrupted balance between matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) appears to play a crucial role in the formation of extracellular matrix and tissue remodeling. There is also evidence of various profibrotic factors such as platelet-derived growth factor (PDGF), macrophage chemotactic protein (MCP-1), insulin-like growth factor (IGF-1), macrophage inflammatory protein (MIP-1α), endothelin-1, and IL-8 being involved in the pathogenesis of diseases causing pulmonary fibrosis. In addition, mineral dusts are potent generators of reactive oxygen species. The antioxidant enzymes glutathione S-transferase (GST) and manganese superoxide dismutase (MnSOD) are important components of lung defense against oxidative stress. Polymorphisms in these genes may potentially modify disease activity [3].

In CWP, inhaled coal dust enters the terminal bronchioles, and the carbon pigment is engulfed by alveolar and interstitial macrophages. Phagocytosed coal particles are transported by macrophages up the mucociliary elevator and are expelled in the mucus or through the lymphatic system. When this system becomes overwhelmed, the dust-laden macrophages accumulate in the alveoli and may trigger an immune response. Areas of focal deposition of coal dust and pigment-laden macrophages are known as coal macules and are the histologic hallmark of CWP. As these macules extend, they join other macules in the vicinity, forming discrete areas of interstitial fibrosis. The fibrosis may cause distention of the respiratory bronchioles, forming focal areas of emphysema. The coal macules may stabilize with limited fibrosis (simple pneumoconiosis) or may continue to enlarge and form nodules that produce progressive massive fibrosis (PMF) when they coalesce. In patients with CWP, changes in release of TNF-α, IL-6, TGF-β, MCP-1, and PDGF from alveolar macrophages have been noted.

The toxicity of crystalline silica appears to result from the interaction of crystalline silica with aqueous media to generate oxygen radicals and injury to pulmonary cells such as alveolar macrophages [4]. The resultant generation of inflammatory cytokines such as TNF-α, IL-1, TGF-β, PDGF, and IGF-1 by target cells leads to recruitment of inflammatory cells and fibroblasts with subsequent collagen deposition and development of fibrosis. The earliest histopathologic changes in chronic or accelerate silicosis are dust-laden macrophages and loose reticulin fibers in the peribronchial, perivascular, and subpleural areas. Silicotic nodules develop over time. As the disease progresses, the periphery of the silicotic nodule moves farther from the hyalinized center, enmeshing the small airways, pleural, blood vessels, and lymphatics in the fibrotic process. Coalescence of silicotic nodules produces progressive massive fibrosis (PMF) lesions. With acute silicosis, silicotic nodules are rarely seen and the predominant finding is alveolar filling with proteinaceous material consisting of phospholipids or surfactant like material. The interstitium is thickened with inflammatory cells.

Asbestosis results from the direct toxic effects of fibers on pulmonary parenchymal cells including epithelial cells and alveolar macrophages. Reactive oxygen and nitrogen free radicals are formed either via reactions catalyzed by iron molecules within the asbestos fibers or via activation of inflammatory cells. Asbestos-activated macrophages produce a variety of growth factors, including fibronectin, TNF-α, IL-1β, PDGF, IGF-1, and fibroblast growth factor, which interact to induce fibroblast proliferation with subsequent collagen deposition and fibrosis. A plasminogen activator, which is also released by macrophages, further damages the interstitium of the lung by degrading matrix glycoproteins [5].

Beryllium elicits immunologic reactions in exposed and sensitized individuals. This reaction consists of a delayed-type hypersensitivity reaction in which beryllium functions as a hapten and acts as a class II restricted antigen, stimulating local proliferation and accumulation in the lung of beryllium-specific T cells (CD4+). Lung inflammation and granuloma formation is produced and maintained by accumulation of CD4 + T-cells specific for beryllium associated with major histocompatibility complex (MHC) II or beryllium bound to an exogenous or endogenous peptide. The inflammatory response is predominantly a Th1 response involving interferon-gamma and IL-2. In addition, cells collected via bronchoalveolar lavage from patients with berylliosis express increased levels of TNF-α and IL-6. These cytokines in conjunction with other T-cell cytokines are thought to be important in the initiation and maintenance of the

granulomatous inflammatory response which is a hallmark of berylliosis.

## Diagnostic Principles

Patients present with respiratory symptoms that are nonspecific. Cough, sputum production, progressive dyspnea, and wheezing are commonly reported. The occupational history is of utmost importance in the evaluation of the pneumoconioses (see Table 1).

The employer, job title, specific job activity, specific exposures, length of time of exposure, and use of personal respiratory protection should be elicited. Initial evaluation will include chest radiography. Chest CT and high resolution chest CT can be performed as an adjunct to plain chest radiography. Complete pulmonary function testing should be obtained.

CWP and silicosis have a similar radiologic appearance. There are round opacities which are usually found in the upper lobes in the initial stages. Later stages of disease demonstrate increasing profusion of opacities and coalescence of small opacities into the larger opacities of complicated pneumoconiosis (PMF). The opacities may have irregular or regular borders and are predominantly oval in shape. Silicoproteinosis occurs following overwhelming exposure to respirable crystalline silica over a short period of time. Radiographs demonstrate bilateral alveolar infiltrates and ground glass opacities. Pulmonary function testing may be normal in early disease and demonstrate airflow obstruction or mixed obstruction and restriction in more advanced disease. The diagnosis of CWP and silicosis are most commonly made using exposure history, chest imaging, and physiologic evaluation. Lung biopsy may be performed when the diagnosis cannot be made clinically.

The chest radiograph in asbestosis usually reveals small bilateral parenchymal opacities with a multinodular or reticular pattern, often with associated pleural abnormalities. The interstitial process typically begins in the lower lung zones and may be associated with mid-lung and lower lung zone pleural plaques. Honeycombing and upper lobe involvement develops in advanced stages of disease. The diagnosis is suggested by history of exposure and evidence of interstitial fibrosis on imaging and pulmonary function testing. Diagnosis may be confirmed if necessary by demonstrating asbestos fibers or asbestos bodies in bronchoalveolar lavage fluid or lung biopsy.

In berylliosis chest radiographs may be normal or may show hilar adenopathy with reticulonodular opacities. Pulmonary function testing may be normal or show an isolated reduction in diffusing capacity early in the disease. With more advanced disease pulmonary function tests may show airflow obstruction, restriction, or a mixed pattern. The diagnosis may be confirmed by demonstrating noncaseating granulomas on lung biopsy and a positive blood or bronchoalveolar lavage beryllium lymphocyte proliferation test. If the blood beryllium lymphocyte proliferation test is negative, a bronchoalveolar lavage fluid test should be performed given the 10–35% false negative rate of the blood test.

## Therapeutic Principles

The mainstay of treatment for CWP and silicosis is to remove the affected individuals from further exposure. No proven therapy exists to reverse or slow the disease process. Supportive therapy is the foundation of care and includes smoking cessation, bronchodilators in patients with airway obstruction, routine immunizations, prompt treatment of respiratory infections, home oxygen therapy, and pulmonary rehabilitation. The possibility of superimposed mycobacterial disease, of which these patients are at increased risk, should be considered in patients with unexplained weight loss, increased cough, fevers, or nightsweats. There is currently no specific treatment for asbestosis. Management

**Pneumoconiosis. Table 1** Occupational exposures associated with pneumoconioses

| Disease | Occupational exposure |
|---|---|
| Coal workers pneumoconiosis | Cutting machine operators, continuous miner operators, roof bolters, shot firers, long-wall return workers, headgate workers |
| Silicosis | Underground and surface coal mining, hard rock mining, tunneling, quarrying, stonework, metal foundry, sand blasting, silica flour production or use, cement and concrete production, glass manufacturing, ceramics production, gemstone workers, dental technicians |
| Asbestosis | Ship building and repair, plumbing, pipefitting, electricians, insulation workers, steamfitters, brake lining manufacture and repair, asbestos cement products, welders and cutters |
| Berylliosis | Nuclear reactors and weapons, defense industries, computer industries, aerospace industries, electronics, electronics and computer recycling, ceramic applications, metal alloy machining, radiographic equipment manufacturing |

includes supportive care as outlined above. Patients with asbestosis are at risk for malignant mesothelioma and bronchogenic carcinoma. Although no controlled clinical trials have evaluated corticosteroid therapy for berylliosis, response to such therapy has been well documented. Patients who are in the early stage of disease may be followed without treatment. Oral corticosteroid therapy in the form of prednisone may initiated when there has been an approximately 10% decline in lung volumes or diffusing capacity or if the patient already has abnormal physiology. Immunosuppressive agents such as methotrexate may be used if patients fail to respond to corticosteroids or experience severe side effects.

# Pneumocystis Pneumonia

Sergio L. Vargas
University of Chile School of Medicine, Santiago, Chile

## Synonyms

P. carinii pneumonia; P. jiroveci pneumonia; P. carinii f. sp. hominis pneumonia; PcP; PCP

## Definition and Characteristics

**P**neumo**c**ystis **P**neumonia (PcP) is a life-threatening pulmonary infection that affects immunocompromised persons. Clinically, it is characterized by marked progressive hypoxemia and dyspnea with relative absence of auscultatory signs. Infiltrates are normally present in the chest radiography. Paradoxically, the clinical course is more abrupt and severe in less immunocompromised individuals, suggesting that the clinical presentation and outcome of the disease is more dependent on the type and extent of the immune response mounted by the patient than on the pathogenic potential of pneumocystis itself [1–5].

## Prevalence

PcP occurs in direct proportion to the number of immunocompromised susceptible individuals not receiving anti-pneumocystis prophylaxis. Without chemoprophylaxis, the risk of PcP is 5–25% in transplant patients, 2–6% in patients with collagen vascular disease, and 1–25% in oncology patients [2]. Historically, PcP remained as an occasional disease of undernourished infants since it was first reported, during World War II, to 1956 when reports on adults began to appear as a result of progressive implementation of anticancer chemotherapy. Numbers increased dramatically with the AIDS epidemic. HIV-infected persons are the highest risk group, as over half of AIDS patients developed PcP, before chemoprophylaxis and highly active antiretroviral agents (HAART) were adopted in 1989 and 1996, respectively [3]. The prevalence in industrialized countries decreased after 1998 to 0.3 cases/100 person-years. Despite this achievement, PcP remains the most common severe opportunistic infection of AIDS. Available data on prevalence of PcP in non-industrialized countries is limited, and the number of reported cases may be low owing to shorter patient survival and/or difficulties in diagnosis [2].

## Genes

PcP is an airborne-transmissible infectious disease. Phylogenetic analysis of the pneumocystis 16S-like small-ribosomal RNA subunit indicates pneumocystis is a fungus. The pneumocystis genome is being sequenced and comprises ~8 million base pairs of DNA divided into 15 linear chromosomes. A few genes coding for important host–pathogen interaction processes have been cloned [1].

## Molecular and Systemic Pathophysiology

An underlying T-lymphocyte defect is the main factor predisposing to PcP. Adult patients are at risk when their T cell CD4+ lymphocyte count falls below 300–200 cells per mm. This generally occurs as a result of HIV infection or administration of immunosuppressive agents including corticosteroids that affect T-lymphocyte number or function. In addition, a variety of genetic immune defects like severe combined immunodeficiency Syndrome (SCIDS) T-B − and T-B+, hyper-immunoglobulin E syndrome or X-linked hyper-IgM syndrome may predispose to PcP [3]. Molecularly, pneumocystis attaches to alveolar pneumocyte type I cells inducing cellular immune responses with participation of innate and adaptive immune mechanisms [4,5]. Contact with alveolar macrophages and pneumocyte type II cells activate complex and expanding, CD4+ T cells, CD8+ T cells, neutrophils, host proteins, and other interactions that lead to cytokine and chemokine expression and inflammation. Balanced CD4 + and CD8+ T-cell

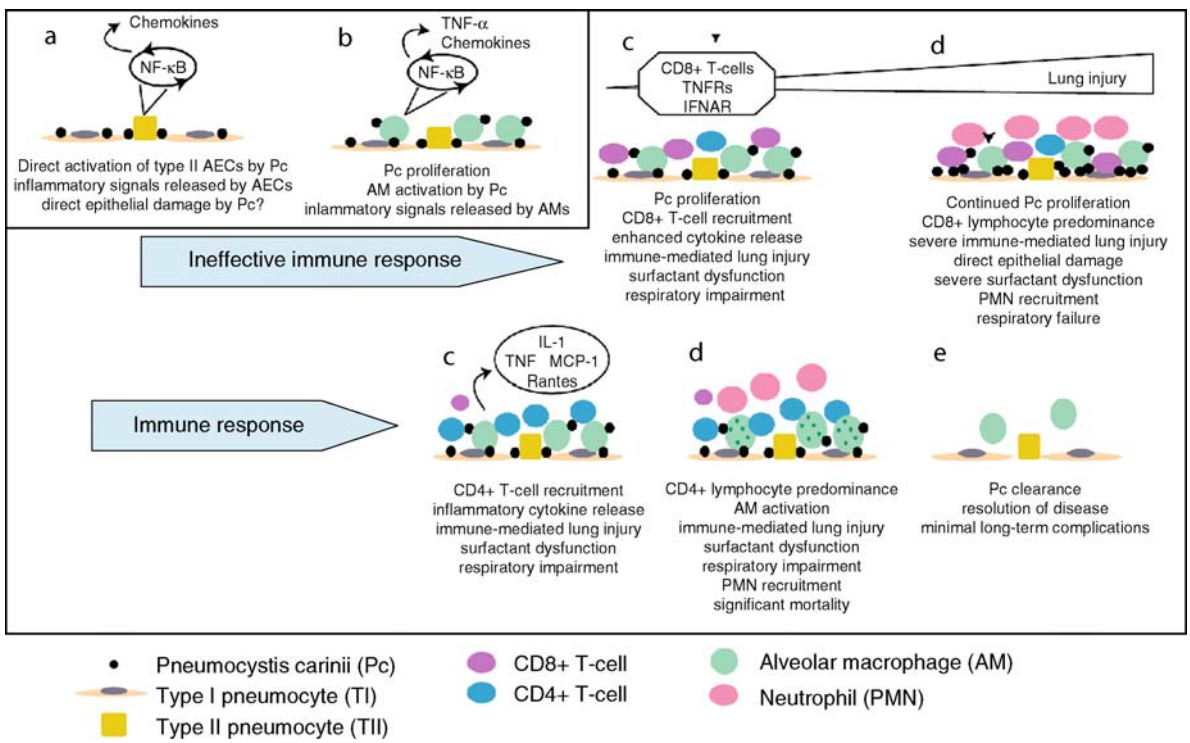
responses and B-cell lymphocytes are required to clear the infection (Fig. 1) [4].

## Diagnostic Principles

Clinical diagnosis of PcP is difficult due to non-specific signs and symptoms. Therefore, the diagnosis necessarily relies on the demonstration of pneumocystis cyst or trophozoite forms in respiratory specimens by microscopy. Molecular tools like the polymerase chain reaction (PCR; real-time PCR) detect nucleic acids of pneumocystis, and their use for diagnosis needs better definition. More immunocompromised individuals may harbor larger numbers of pneumocystis organisms per diagnostic specimen than less immunocompromised individuals, implying that the sensitivity and specificity of the diagnostic tests is highly dependent on the type and quality of the diagnostic specimen and on the patient's underlying immunodeficiency condition. This way, the sampling procedure and the diagnostic specimen volume and processing in the laboratory are critical, especially when specimens are from non-AIDS patients. The most frequently used stains for microscopy are Gomori Grocott methenamine silver and Toluidine Blue O that stain the cyst form, Wright-Giemsa that stains trophozoites, and fluoresceine-conjugated monoclonal antibodies may stain both forms depending on the monoclonal antibody that is used. Other stains used for diagnosis are calcofluor white, cresyl echt violet, Gram-Weigert, and Papanicolaou.

## Therapeutic Principles

PcP is uniformly fatal if untreated. Anti-PcP drugs in chemoprophylaxis schemes aiming to prevent the disease should be indicated to susceptible immunocompromised patients at risk and can be discontinued in AIDS patients with sustained response to HAART, and in other patients, if predisposing factors are resolved. Treatment of PcP aims to decrease the pneumocystis burden with therapeutic doses of an anti-pneumocystis agent for 2–3 weeks, to control hypoxemia with supportive oxygen, and to modulate the host immune response with steroids when more severe disease is present. The preferred prophylactic and therapeutic drug scheme is the combination of Trimethoprim and Sulfamethoxazole. These drugs target enzymes that participate in the folic acid cycle pathway and produce a Pneumocystis-"static" effect. Anti-pneumocystis drug alternatives are few, and no "cydal" drugs are available



**Pneumocystis Pneumonia. Figure 1** Schematic representation of the progression of immune-mediated lung injury during PcP. Pneumocystis attaches to Pneumocyte type I in the alveolar epithelium and activates Pneumocyte type II cells leading to NF-B activation and the release of proinflamatory signals. PcP progresses differently in the absence of an effective CD4+ lymphocyte immune response (as in AIDS), than when residual immune response is present as may be the case in chemotherapy-mediated immunodeficient cancer patients. (Adapted from [4] with permission).

**Pneumocystis Pneumonia. Table 1** Anti-pneumocystis drugs and their metabolic targets. Adapted from [1] with permission.

| Agent | Therapeutic use | Prophylactic use | Primary molecular target |
|---|---|---|---|
| Trimethoprim sulfamethoxazole | First choice | First choice | DHPS/DHFR |
| Primaquin clindamycin | Second choice | Not used | Uncertain/protein synthesis inhibition |
| Pentamidine | Alternative choice | Aerosolized/rarely used | DNA synthesis |
| Atovaquone | Alternative choice[a] (for mild to moderate infection) | Alternative choice | Cytochrome b complex |
| Dapsone trimethoprim | Alternative choice[b] | Dapsone alone or dapsone with pyrimethamine and leucovorin | DHPS/DHFR |

[a]Administer with high-fat meals to maximize absorption.
[b]Hemolysis can occur with G6PD deficiency.

(Table 1). Given access to standard of care, the outcome is better in AIDS patients than in patients with immunosuppression resulting from chemotherapy or other disorders [1,4].

# Pneumonia

Rade Tomic, Jesse Roman
Division of Pulmonary, Allergy and Critical Care Medicine and VA Medical Center, Emory University, Atlanta, GA, USA

## Definition and Characteristics

An acute infection of the lung parenchyma distal to the terminal bronchiole associated with clinical or radiologic evidence of consolidation of part or parts of one or both lungs.

## Prevalence

Annually, there are between 2 and 3 million cases of pneumonia in the United States. Of these, 45,000 result in death. Between 1979 and 1994, the overall death rate due to pneumonia increased by more than 50% in the United States, and currently is the sixth leading cause of the death in that country.

## Genes

Although genetic and environmental factors leading to depression of the immune system can predispose to pneumonia, no single genetic mutations have been identified that account for its development. Recently, polymorphisms in the promoter of the gene coding for tumor necrosis factor resulting in decreased secretion of this cytokine has been found to predispose patients with community acquired pneumonia for respiratory failure [1].

## Molecular and Systemic Pathophysiology

The respiratory tract has a vast array of local and systemic defense mechanisms that work to maintain sterility of lung parenchyma and terminal bronchioles. If an infectious agent eludes those defenses and reaches the alveolar milieu, humoral and cellular factors of the lower respiratory tract are activated to eradicate the organism. These mechanisms include non specific antibacterial activity of surfactant, opsonization by immunoglobulin, opsonization or direct lysis by complement activation, phagocytosis and intracellular killing by alveolar macrophages, cell mediated immunity, and recruitment of polymorphonuclear leukocytes for phagocytosis and intracellular killing. Deficiencies in a specific

pulmonary defense mechanism may be associated with a particular type of respiratory infection. For example, impaired epiglottic function will allow aspiration of oropharyngeal secretion; enteric gram negative bacilli will colonize the oropharynx in debilitated patients and patients on prolonged antimicrobial therapy. Granulocytopenia facilitates the development of gram-negative bacillary pneumonia. Impairment of cellular immunity will predispose patients to intracellular pathogens, herpesviruses, pneumocystis jiroveci and endemic mycoses. Variables related to microorganisms such as virulence, presence of a capsule, extracellular toxins, and magnitude of bacterial challenge are also important in determining the outcome of the bacterial challenge to lungs.

## Diagnostic Principles

Patients typically present with fever, new or increased cough, sputum production and dyspnea. Chest radiograph is essential in the evaluation of patients with suspected pneumonia. Except for patients with very early infections or granulocytopenia, the absence of infiltrates on chest radiographs essentially rules out the diagnosis of pneumonia [2]. Laboratory studies including CBC, glucose, electrolyte measurements, liver function tests, urine analysis and pulse oximetry or arterial blood gas measurement should be performed to determine severity and extent of disease [3]. The cause of community acquired pneumonia can be determined in 40–60% of patients with sputum and blood cultures.

## Therapeutic Principles

The therapeutic plan must address three issues: choice of antimicrobial agent or agents, correction of remediable host abnormalities, and general supportive care throughout the illness. Antibiotic therapy should be initiated promptly but all specimens for cultures including blood and sputum should be obtained before treatment [4,5]. Defects related to the host's immune system may impede recovery from pneumonia. Recently, interest has focused on the role of Granulocyte Colony Stimulating Factor and Granulocyte/Macrophage Colony Stimulating Factor in the treatment of pneumonia due to its recruitment of polymorphonuclear cells and effect on pneumocytes type II. Patients with pneumonia may require metabolic, nutritional and ventilatory support throughout the period of acute illness.

# Pneumonia, Cryptogenic Organizing

Abdullah F. Mobeireek, Mohammad Khalid
Pulmonary Section, Department of Medicine,
King Faisal Specialist Hospital and Research Center,
Riyadh, Saudi Arabia

## Synonyms

Idiopathic bronchiolitis obliterans with organizing pneumonia; COP; Idiopathic BOOP

## Definition and Characteristics

The hallmark of COP is organizing pneumonia and alveolar fibrosis that extends to adjacent alveoli through the pores of Kuhn, and to the alveolar ducts and bronchioles (proliferative bronchiolitis) [1,2]. There is also interstitial inflammation, which is mild and non-progressive, distinguishing COP from other fibrotic lung diseases such as idiopathic pulmonary fibrosis (IPF). Compared with the Adult respiratory distress syndrome (ARDS), the injury is less severe; there is no hyaline membrane, and a significant response to corticosteroids [1,2].

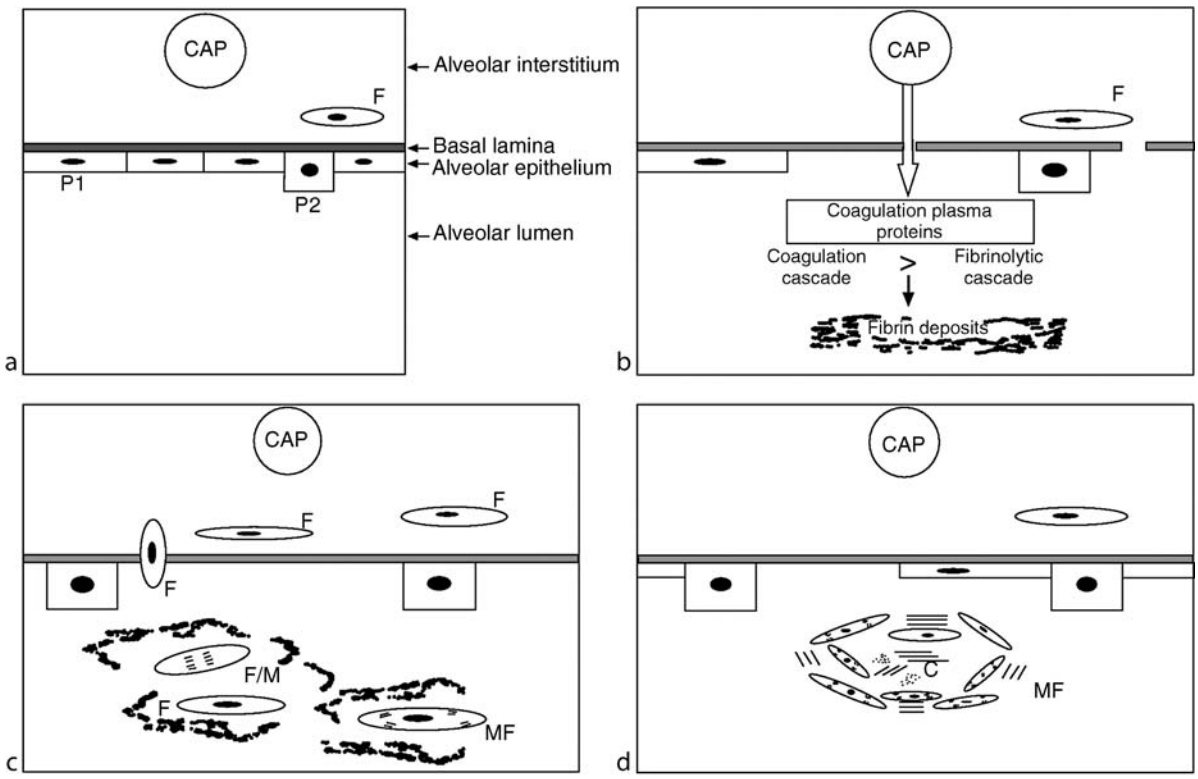
## Prevalence

Prevalence is unknown. However, a study in an academic hospital in Canada found a cumulative prevalence of 12.0/100,000 admissions [3].

## Molecular and Systemic Pathophysiology

The initial event in COP is epithelial denudation and mild endothelial injury, possibly from an external inhaled antigen (infectious or noxious) (Fig. 1) (see [1,4]).

Loss of pneumocytes leads to gaps in basal lamina. Inflammatory cells (mainly lymphocytes and neutrophils) infiltrate the interstitium, and release inflammatory mediators. Specifically, granulocyte/macrophage stimulating factor (GM-CSF) is thought to be involved in the initial inflammatory recruitment. Within the alveolar space, an inflammatory exudate is formed from clusters of inflammatory cells and fibrin. The fibrin is believed to form as a result of the imbalance between the coagulant and the fibrinolytic systems; evidence suggests that there is an increased level of inhibitors of the fibrinolytic



**Pneumonia, Cryptogenic Organizing. Figure 1** Mechanisms of intra-alveolar organization. (a) Normal alveolus. (b) Epithelial alveolar injury with necrosis of pneumocytes (especially type I pneumocytes; P1), formation of gaps in the basal lamina, and intra-alveolar leakage of coagulation plasma proteins. The balance between coagulation and fibrinolytic cascades favors coagulation and results in intra-alveolar deposits of fibrin. (c) Activation, proliferation and migration of the fibroblasts (F) within the alveolar lumen through gaps in the basal lamina. (d) Most fibroblasts have acquired a phenotype of myofibroblasts (MF) and produce connective matrix proteins forming mature fibrotic intra-alveolar buds composed of concentric circular layers of MF and connective matrix. CAP: capillary; P2: type 2 pneumocyte; F/M: fibroblast undergoing mitosis; C: connective matrix (collagens, fibronectin, glycoproteins). (With permission from [1]).

system such as thrombin activable fibrinolysis inhibitor and protein C inhibitor which results in clotting.

Subsequently, fibrin is degraded and inflammatory cells start to diminish; this is believed to be related to macrophages expressing CD44 and then ingesting apoptotic neutrophils. Meanwhile, fibroblasts start to influx through the gaps in the basal lamina into the alveolar space and undergo phenotypic modulation to myofibroblasts. As a result, the fibro-inflammatory bands change to mature fibrotic buds which are composed of rings of fibroblasts/myofibroblasts and connective tissue. The latter cells subsequently start to phagocytize the collagen. Throughout this process, lung structure remains preserved, which may be an important reason for the complete resolution in the majority of patients.

The exact molecular events and interactions are complex and remain unknown. However, a number of studies provide information on some of its elements. The bronchoalveolar lavage fluid (BALF) in COP shows an increase in all cell types, particularly lymphocytes, neutrophils to a lesser degree, and also eosinophils, mast cells and macrophages. The CD4+/CD8+ ratio is significantly decreased in most patients. Also, a number of cytokines were noted to be increased in BALF from patients with COP including: monocyte chemotactic protein-1, IL-10, IL-12, and IL-8 indicating macrophage and lymphocyte activation. In addition, elevated levels of the soluble form of Fas level were found in BALF, which may abrogate the cytotoxicity of the Fas Ligand, leading to better prognosis in COP. Finally, studies on lung tissue have suggested that platelet derived growth factor and Interlukin-8 (IL-8) may be involved in the fibrotic process.

The healing process that characterizes COP has been of interest to investigators, searching for the factors leading to reversal of fibrosis, which contrasts to other fibrotic conditions with much worse prognosis such

as IPF and ARDS. Re-epthelialisation of the basal lamina occurs and resolution of fibro-inflammatory material ensues with complete recovery in most cases.

There is evidence to suggest that the following factors play key role in the resolution of fibrosis which characterizes COP:

1. Type of collagen: The presence of collagen IV and collagen III as opposed to collagen I. In addition, fibroblast cell lines produce higher collagenase levels than other fibrotic conditions such as IPF.
2. The prominent neovasculaization in the granulation tissue mediated by vascular endothelial growth factor (VEGF) and basic fibroblast growth factor.
3. An imbalance between the matrix metalloproteinases (MMP), produced by the inflammatory cells, and their inhibitors: tissue inhibitors of metalloprotienases (TIMP) found on studies from BALF specimens.
4. Laminin-5, which is a glycoprotein involved in the cellular regulatory process.
5. Finally, apoptosis of fibroblasts and myofibroblasts is higher in COP compared with IPF. This might be related to vascular growth factors and also the loss of transforming growth factor-ß signaling.

## Diagnostic Principles

The word cryptogenic implies that no cause or an association is found. Hence, the objective of the diagnostic process is to exclude secondary causes of organizing pneumonia, for example, related to infection, drugs, radiation, and connective tissue disease.

COP may be initially suspected from the presenting clinical picture. Usually the illness starts with a flu-like illness and may be associated with fever, generalized body aches, dry cough and mild to no shortness of breath. Typically symptoms are insidious with duration of 4 to 6 weeks. Physical exam may reveal sparse crackles. Usually diagnosis is suspected when patient failed to respond to antibiotics given for community acquired pneumonia.

Typical findings on the chest radiograph include multiple bilateral peripheral patchy alveolar opacities with air bronchogram. Other less common presentations include nodular opacities (which may cavitate) and irregular linear opacities. Honeycombing is rare and, if present, should raise the possibility of an associated interstitial lung disease. Computerized tomography scan is more sensitive and may show additional opacities such as ground glass, small nodular opacities and bronchial wall thickening.

Pulmonary function tests typically show mild to moderate restrictive lung disease with a reduction in the transfer factor. Obstructive pattern is rare and is almost always found in background history of cigarette smoking.

Laboratory investigations may reveal elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Other immunological markers are usually negative.

Once COP is suspected, lung tissue should be obtained to establish the diagnosis, since long term management with steroids and in some cases cytotoxic drugs is required. Because of its small size, transbronchial biopsy may establish the diagnosis only in a minority of cases; the finding of organizing pneumonia is not specific. Therefore, larger samples of lung tissue should be obtained, through video-assisted thoracotomy, which now has become the standard practice. This will help to establish the diagnosis with a high degree of certainty, and rule out secondary causes of organizing pneumonia such as other interstitial lung diseases and infections.

## Therapeutic Principles

Corticosteroid therapy is the mainstay of the treatment; the usual recommended dosage is prednisone is 0.75–1.5 mg/kg of ideal body weight as initiation therapy [1]. This should be maintained for 4–8 weeks, and then is tapered to 0.5–1 mg/kg for the next 4–8 weeks. The dose is reduced further to 10–20 mg daily or alternate day doses, and then stopped completely over a period of 6–12 months. An initial higher dose or pulse steroid therapy may be used in more severe cases.

Progress is monitored by performing routine chest radiograph and pulmonary function tests every 6–8 weeks, and also by following the inflammatory markers such as CRP and ESR. These tests may be helpful in the detection of early relapse, which are usually managed by increasing the prednisone dose to the previous maintained level.

Other therapies in patients with relapse or poor tolerance to steroid include cytotoxic drugs such as cytophosphamide, cyclosporine A, methotrexate, and tarcolimus. Alternative therapies include macrolides, which were found to have beneficial effects in few case reports, presumably through an anti-inflammatory action [5].

Rare entity of rapidly progressive COP leading to respiratory failure had been reported to be successfully treated with higher doses of steroids used in combination with cyclophosphamide or cyclosporin A.

About 13–58% of patients may experience at least one relapse during the course of their disease [1]. Most of these patients will improve with the treatment without any significant effect on long-term prognosis. Patients with frequent (>3) relapses may require continuous treatment with prednisone preferably in combination with cyclophosphamide or some other alternative agents mentioned earlier.

Overall response to treatment is very favorable with complete resolution of clinical symptoms and

radiological findings in 70–80% of patients. The overall prognosis of COP is much better than that of other interstitial lung disease.

# Pneumonia, Cytomegalovirus

Harrys A. Torres, Roy F. Chemaly
Department of Infectious Diseases, Infection Control and Employee Health, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA

## Synonyms

CMV pneumonia; CMV pneumonitis

## Definition and Characteristics

Cytomegalovirus (CMV) pneumonia is the most common presentation of CMV disease in immunocompromised patients with impaired cellular immunity, including patients with hematologic malignancies; transplant recipients; and therapeutically immunosuppressed patients [1,2]. Interestingly, CMV pneumonia is rare among patients with HIV infection or AIDS.

## Prevalence

CMV pneumonia is less common among patients with lymphoma (1.1%) than among patients with leukemia (2.9%) or patients who have undergone autologous haematopoietic stem cell transplantation (HSCT) (2%), allogeneic HSCT (7–20%), or solid organ transplantation (17–90%) [1,2].

## Genes

The human CMV genome is a linear, double-stranded DNA molecule (230 million Da) that contains nonoverlapping open reading frames for more than 200 proteins. A large number of genetically distinct human CMV strains exist.

Classification of CMV strains has most frequently been based on the CMV glycoprotein B (gB) (UL55), which plays an important role in cell-to-cell transmission and is a major target of neutralizing antibodies. To date, four main gB genotypes have been identified (gB-1, gB-2, gB-3, and gB-4), along with some rare nonprototypic variants (gB-5, gB-6, and gB-7). Subtypes have also been classified according to the glycoprotein N (UL73) sequence, and significant diversity has also been found in the gCIII complex, consisting of gO (UL74), gH (UL75), and gL (UL115). Polymorphisms between virus strains have also been demonstrated in other parts of the CMV genome [3,4].

The CMV genome encodes a DNA polymerase that is targeted by several antiviral drugs. The open reading frame UL54 encodes the CMV DNA polymerase, and UL97 encodes the CMV phosphotransferase [3].

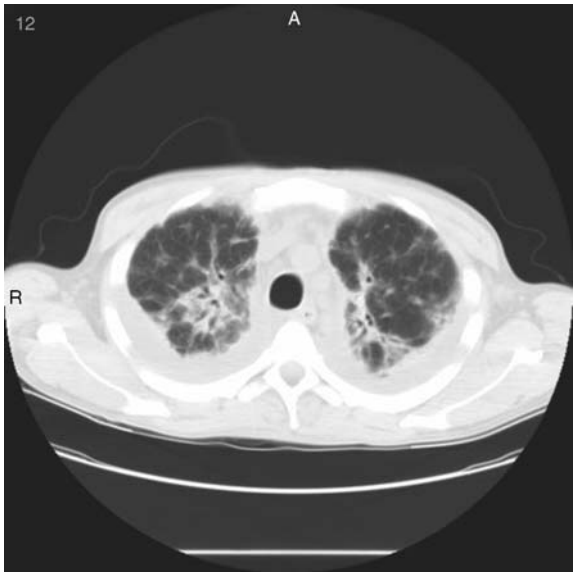
## Molecular and Systemic Pathophysiology

CMV has developed a variety of mechanisms for immune evasion. For example, CMV induces expression of Fc receptors, upregulates expression of complement regulatory proteins CD55 and CD46, incorporates CD55 and CD59 into the virion envelope, and decreases presentation of HLA class I molecules at the infected cell surface. Other pathogenic strategies include molecular mimicry of host genes involved in the immune response and encoding of products that can interfere with numerous host cell defense mechanisms [3]. CMV remains latent in tissues after a patient's recovery from the initial infection. Several studies have attempted to correlate CMV genomic variants with specific CMV manifestations or sites of infectivity. However, the results have been inconclusive. Mixed-CMV-strain infections seem to be associated with symptomatic CMV infection in solid organ transplant recipients.

A suppressed cellular immune response is the major predisposing factor for CMV disease. Lymphocytes, particularly CMV-specific major histocompatibility complex-restricted cytotoxic T-cells, play a crucial role in maintaining CMV in the latent stages and in controlling CMV infection. Their impairment may contribute to the development of CMV pneumonia in HSCT recipients. CMV pneumonia has been associated with the use of traditional cytotoxic immunosuppressants and depressors of T-cell function such as methotrexate, corticosteroids, and cyclosporine. More selective chemotherapeutic drugs such as fludarabine (purine analog), and alemtuzumab (anti-CD52 monoclonal antibody) appear also to be associated with the development of CMV pneumonia.

## Diagnostic Principles

A diagnosis of CMV pneumonia requires both clinical and radiographic evidence of pulmonary infection (Fig. 1). and identification of CMV in bronchoalveolar lavage fluid or lung-tissue specimens by culture, cytology, immunohistochemical staining, histopathologic examination, or in situ hybridization.



**Pneumonia, Cytomegalovirus. Figure 1** Computed axial tomography scan of the chest in a patient with lymphoma and CMV pneumonia shows a pulmonary parenchymal process with large areas of ground-glass opacities surrounding some regions of consolidation.

Early detection of CMV infection is critical for its optimal management. Detection of CMV in bronchoalveolar lavage fluid correlates highly with detection in lung biopsies and is therefore the preferred method of diagnosis. Moreover, high CMV viral load in bronchoalveolar lavage fluid of lung transplant recipients may be associated with CMV pneumonia [5]. In HSCT recipients, CMV antigenemia is a predictor of the development of CMV pneumonia.

## Therapeutic Principles

The mortality rate from CMV pneumonia varies according to the underlying condition and has been reported to be 30% in lymphoma patients, 57% in leukemia patients, and up to 90–100% in HSCT recipients [1]. To date, therapy for CMV pneumonia in cancer patients or HSCT recipients is suboptimal; with current treatment, the mortality rate for such patients is approximately 60%.

Currently, marketed systemic antivirals against CMV include ganciclovir, foscarnet, and cidofovir, usually used in that order and sometimes used in combination. Ganciclovir resistance results from mutations in UL97 (phosphotransferase), UL54 (viral DNA polymerase), or both, whereas cidofovir and foscarnet resistance results from mutations in UL54 only. The use of ganciclovir is limited by the associated development of neutropenia and emergence of resistance. Foscarnet is used in patients who experience myelosuppression with ganciclovir and is associated with nephrotoxicity and electrolytes imbalance. Valganciclovir is an oral prodrug of ganciclovir with a tenfold greater bioavailability than oral ganciclovir. Cidofovir causes nephrotoxicity and occasionally neutropenia. The combination of ganciclovir and high-dose intravenous immunoglobulin appears to be more effective than ganciclovir alone in the treatment of CMV pneumonia in HSCT recipients. However, combinations of antivirals against CMV pneumonia have not been evaluated in randomized trials. A new oral antiviral against CMV, Maribavir, is still under investigation and a recently completed phase II trial with Maribavir prophylaxis showed reduction in the rate of CMV infection compared to placebo in allogeneic HSCT recipients up till 3 months after engraftment.

# Pneumonia, Eosinophilic

Rade Tomic, Jesse Roman
Division of Pulmonary, Allergy and Critical Care Medicine and VA Medical Center, Emory University, Atlanta, GA, USA

## Definition and Characteristics

A group of pulmonary disorders characterized by the accumulation of blood-borne eosinophils in the lung

parenchyma presumably elicited by an altered immunological response to exogenous allergens or infectious agents. The disorder can present in acute or chronic forms resulting in pulmonary infiltrations that lead to respiratory distress.

## Prevalence

The prevalence of chronic eosinophilic pneumonia is unknown. Although reported in all ages, the peak incidence is in the fifth decade and there is 2:1 female to male ratio. Approximately half of the patients will have preexisting asthma or atopic disease [1]. The prevalence of acute eosinophilic pneumonias is also unknown. It can affect all ages with an average of 29 years. Men and women are affected equally and 40% of patients have a history of cigarette smoking.

## Molecular and Systemic Pathophysiology

The accumulation of activated eosinophils results in the release of basic proteins, oxygen radicals, proteases, and soluble mediators that promote inflammation (e.g., leukotrienes). This results in damage to different lung cell types including epithelial cells and interstitial cells, degradation of extracellular matrix and induction of postcapillary leakage. The mechanisms responsible for the accumulation of activated eosinophils in the acute and chronic eosinophilic pneumonias are presently unknown. The temporal association between recent onset of smoking and the development of acute eosinophilic pneumonia suggests a possible hypersensitivity reaction against inhaled antigens as a pathogenetic mechanism. This response appears associated with the induction of inflammatory mediators with chemotactic activity toward eosinophils including eotaxine, and these can be detected in the bronchoalveolar lavage fluid of patients with eosinophilic pneumonia. Other mediators found elevated in the bronchoalveolar lavage fluid of these patients are thymus- and activation-regulated chemokine (TARC) in parallel with high concentrations of the Th2 cytokines interleukin-5 and interleukin-13. These agents have chemotactic activity toward eosinophils and can inhibit their apoptosis leading to their accumulation in lungs [2].

## Diagnostic Principles

There are no aspects of the clinical presentation and radiographic imaging of eosinophilic pneumonias that are considered diagnostic. The eosinophilic pneumonias present with cough, dyspnea and fever which can occur for days (acute form) or weeks to months (subacute or chronic form). Both presentations are associated with pulmonary infiltrations detected by chest radiograph [3]. Chest radiographs in chronic eosinophilic pneumonia show peripheral alveolar infiltrates, whereas acute eosinophilic pneumonia is often associated with mixed interstitial and alveolar infiltrates, Kerley B lines and pleural effusions. Spirometry and lung volumes will be normal in one third of patients, show obstruction in one third of patients, and show restriction in one third of patients. Diffusing capacity for carbon monoxide will be low in one half of patients. Bronchoalveolar lavage fluid examination reveals increased percentage of eosinophils in both disorders, but high numbers of eosinophils in blood is characteristic only for chronic eosinophilic pneumonia. Histological analysis of tissue after lung biopsy is sometimes necessary to confirm the diagnosis.

## Therapeutic Principles

Corticosteroids are the mainstay of therapy for both acute and chronic eosinophilic pneumonias. The clinical response to corticosteroids is usually dramatic. Recurrence in acute eosinophilic pneumonia is exceedingly rare so it is possible to taper steroids rapidly [4,5]. In contrast, chronic eosinophilic pneumonia has frequent relapses and most patients require treatment for more than a year with an average duration of treatment of 82 weeks.

# Pneumothorax

Richard W. Light
Division of Allergy, Pulmonary, and Critical Care Medicine, Vanderbilt University, Nashville, TN, USA

## Synonyms

Collapsed lung

## Definition and Characteristics

There is a potential space between the lung and the chest wall that is called the pleural space. When air is present in this space, a pneumothorax is present. There are three different types of pneumothorax. A primary spontaneous pneumothorax is a pneumothorax that occurs spontaneously in an individual without pre-existing lung disease. A secondary spontaneous pneumothorax is a pneumothorax that occurs spontaneously in an individual with underlying lung disease, most commonly chronic obstructive pulmonary disease. A traumatic pneumothorax is a pneumothorax that results from trauma, which in many instances is iatrogenic in nature [1].

## Prevalence

In the United State the annual incidence of primary spontaneous pneumothorax is about 10,000, that of secondary spontaneous pneumothorax is about 10,000, and that of traumatic pneumothorax about 50,000. Of the traumatic pneumothoraces, more than 15,000 are iatrogenic.

## Molecular and Systemic Pathophysiology

The pressure in the pleural space is normally negative throughout the respiratory cycle. Therefore, if there is a communication between the atmosphere or the alveoli and the pleural space, air will flow into the pleura space until either the communication closes or the pressures become equal. The pathogenesis of the pneumothorax in patients with spontaneous pneumothorax is usually the rupture of a bleb on the visceral pleural surface of an upper lobe of the lung. Once a patient has experienced one spontaneous pneumothorax, the likelihood of the patient having a recurrent pneumothorax is at least 50%, if something is not done to prevent a recurrence. In patients who experience trauma, the pathogenesis of the pneumothorax is frequently a communication through the chest wall. However, compression injuries can lead to alveolar rupture with dissection of the air to the visceral pleura or the mediastinal pleura. If the pleura subsequent ruptures, a pneumothorax will develop. If the communication creating the pneumothorax closes, air will be reabsorbed from the pleural space at a rate of about 1.25% of the hemithorax each day.

## Diagnostic Principles

The main symptoms of a pneumothorax are dyspnea and chest pain. The diagnosis is usually established with an upright chest radiograph. The demonstration of a line parallel to the inside of the chest wall with no lung markings between the line and the chest wall is diagnostic of pneumothorax. In trauma victims, frequently no pneumothorax is visible on the chest radiograph but a very small pneumothorax is present on the CT scan. This is termed an occult pneumothorax.

## Therapeutic Principles

When dealing with a patient suffering from a spontaneous pneumothorax, there are two underlying considerations: (i) the removal of air and (ii) the prevention of recurrence. Observation is the recommended therapy for all patients with small pneumothoraces who are asymptomatic [2]. If the patient has a primary spontaneous pneumothorax, the preferred treatment is aspiration of the pneumothorax. If all the air can be removed with this procedure and if the lung remains expanded after a couple hours of observation, the patient can be sent home [3]. If the air cannot be removed with aspiration or if the lung collapses, a chest tube should be inserted. Consideration should be given to performing a procedure that prevents a recurrence such as thoracoscopy with the stapling of blebs and pleural abrasion [4,5]. Secondary spontaneous pneumothoraces are more serious than primary spontaneous pneumothoraces and all patients should be hospitalized and treated with tube thoracostomy. Consideration should be given to performing thoracoscopy with the stapling of blebs and pleural abrasion in all patients with secondary spontaneous pneumothoraces. Large traumatic pneumothoraces are treated with tube thoracostomy to remove both the air and blood from the pleural space. Most iatrogenic pneumothoraces are best treated with aspiration.

## POEMS Syndrome

Angela Dispenzieri
Division of Hematology and Internal Medicine, Mayo Clinic and Mayo Foundation, Rochester, MN, USA

### Synonyms

Osteosclerotic myeloma; Takatsuki disease; Crow-Fukase syndrome

### Definition and Characteristics

This rare plasma cell dyscrasia, which is associated with a complex constellation of paraneoplastic symptoms, began to be recognized as a syndrome in the 1950s [1]. Though as many as 10% of classic multiple myeloma cases had clinically significant neuropathy associated, as many as 50% of patients with the osteosclerotic variant of myeloma were recognized to have peripheral neuropathy. In addition, these patients commonly had other seemingly unrelated symptoms and signs (Table 1). In 1980 Bardwick coined the acronym POEMS, to represent polyneuropathy (P), organomegaly (O), endocrinopathy (E), M-protein (M), and skin changes (S), but this term omitted several other important elements like papilledema (P), extravascular volume overload (E), sclerotic bone lesions (S), thrombocytosis and erythrocytosis (T) [2]. Over the ensuing decades pulmonary abnormalities have become increasingly recognized [3]. The disease is most commonly seen in the context of osteosclerotic myeloma, but may also be seen in the context of Castleman Disease. In the latter case, the peripheral neuropathy appears to be much less dominant.

### Prevalence

The syndrome is rare and is likely under-diagnosed; hence no prevalence figures are available.

### Molecular and Systemic Pathophysiology

The pathophysiology is not well understood, other than the fact that these patients have a very significant imbalance in pro-inflammatory cytokines [4,5]. Vascular endothelial growth factor (VEGF) has been implicated in this disorder, and appears to correlate with disease activity. When POEMS syndrome occurs in the context of Castleman's Disease, interleukin-6 will also be elevated.

### Diagnostic Principles

Of major importance in making the diagnosis is considering the disease in the differential. Any patient who has a lambda restricted monoclonal protein or a monoclonal lambda plasmacytoma and a peripheral neuropathy should be considered as a possible POEMS patient, and a radiographic survey looking for sclerotic bone lesions should be done. A thorough review of systems and physical exam focusing on the elements of the syndrome are essential. Because POEMS is a syndrome, a critical assessment of the patient's signs and symptoms is required to avoid either over- or under-diagnosing they syndrome. The presence of papilledema or thrombocytosis or elevations in plasma VEGF levels should heighten one's confidence in the diagnosis of POEMS. Primary systemic amyloidosis should also be in the differential in a patient who has a small plasma cell clone and peripheral neuropathy, hepatomegaly, peripheral edema, and/or thrombocytosis.

**POEMS Syndrome. Table 1** Criteria for the diagnosis of POEMS syndrome[a]

| Elevatal VEGF | Polyneuropathy |
|---|---|
| Major criteria | Monoclonal plasma cell-proliferative disorder |
| | Sclerotic bone lesions[b] |

POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.
[a]Modified from research that was originally published in [2]. © The American Society of Hematology.
[b]Two major criteria and at least one minor criterion required for diagnosis.
[c]Osteosclerotic lesion or Castleman's disease is almost always present.
[d]Because of the high prevalence of diabetes mellitus and thyroid abnormalities, this diagnosis alone is not sufficient to meet this minor criterion.

## Therapeutic Principles

Treatment has primarily focused at treating the underlying plasma cell disorder. In patients who have a solitary or a couple of dominant sclerotic plasmacytomas driving the process, radiation is the treatment of choice. In patients with more extensive bone disease and in patients with a significant clone found on iliac crest bone marrow biopsy, systemic therapy is indicated. Systemic therapy has typically been alkylator based, and there are increasing data on the application of high dose chemotherapy with autologous peripheral blood transplantation. Corticosteroids may be a useful temporizing measure, but plasmapheresis and intravenous gammaglobulin are not effective therapies. Though thalidomide may reduce the clone, it cannot be recommended because of its known neurotoxicity. There have been case reports of the use of anti-VEGF antibodies with mixed results.

Though the disease is not thought to be curable, it is usually treatable. Overall survival is generally superior to that of classic multiple myeloma. The cause of death for patients with POEMS is most commonly initiation, respiratory failure, or uncontrollable vascular leakage.

## Synonyms

Idiopathic inflammatory myopathy; IIM

## Definition and Characteristics

Idiopathic inflammatory myopathies are multisystemic acquired muscle diseases in which muscle inflammation occurs without a recognized infectious cause. These include polymyositis and dermatomyositis characterized by chronic inflammation of skeletal muscle, which can result in initially proximal, persisting muscle weakness with significant disability and increased levels of serum muscle enzymes [1].

Dermatomyositis (DM) occurs as childhood-onset and adult-onset forms in both genders and all ethnic groups and can involve skin changes as well as gastrointestinal, pulmonary and cardiac dysfunction. Muscle weakness can vary from mild to severe (quadriparesis) with myalgia and muscle tenderness. The typical cutaneous manifestations including Gottron's papules, heliotrope rash and macular erythemas may be worsened by UV light and may precede the disease onset. Serum muscle enzymes are elevated up to 50-fold, but rarely normal. Additional extramuscular manifestations may occur: subcutaneous calcifications, joint contractures, dysphagia, fever, malaise, weight loss, arthralgia, Raynaud's phenomenon and neoplasm.

Polymyositis (PM) is a slow-onset, subacute proximal myopathy occurring as adult-onset and rarely childhood-onset forms with occasional pulmonary involvement. Female to male ratio is 3:1. The history is negative for cutaneous symptoms, involvement of extraocular and facial muscles, family history of hereditary neuromuscular diseases, endocrinopathy and exposure to myotoxic drugs or toxins. Myalgia is less frequent in PM as compared to DM whereas severity and distribution of muscle weakness and wasting are similar to those described for DM. Serum creatine kinase is elevated up to 50-fold. PM is frequently associated with connective tissue diseases or systemic autoimmune disorders.

## Prevalence

Overall prevalence rates of idiopathic inflammatory myositis were reported from 1 to 6.3 per 100,000 [2].

## Genes

Association with HLA genes such as DRB1*0301 and DQB1*0201 alleles for PM, DQA1*0501 for juvenile DM or tumor necrosis factor-α-308A allele for increased photosensitivity in DM.

## Molecular and Systemic Pathophysiology

Histopathological changes suggest that DM is a humoral, complement-mediated microangiopathy. The factors that activate the complement cascade via the classic or alternative pathway and the antigenic target on the endothelium remain unknown. Early findings include C5b-9 membranolytic attack complex deposition on endomysial capillaries resulting in capillary destruction and muscle ischemia. Endofascicular hypoperfusion probably leads to perifascicular atrophy. As the disease progresses, CD4 + T cells, B cells and macrophages traffic from the circulation to the muscle. The mononuclear cells release cytokines, which induce endothelial expression of VCAM and ICAM and facilitate the migration of activated lymphoid cells to the peri- and endomysium. The corresponding muscle fibers express various γ and α/β-interferon-inducible markers including MHC-I, NCAM, β-APP, cathepsin-L, calpain, STAT-1 and the MxA protein, indicating a significant local inflammatory response [3].

In PM, T cell-mediated cytotoxicity is likely. MHC expression is not detectable in normal muscle fibers. Aberrantly expressed MHC-I on the sarcolemma recruits CD8 + T cells along with macrophages that invade and destroy non-necrotic muscle fibers by releasing perforin and granzyme granules. Sequence analysis of the T cell receptor expressed by infiltrating cells revealed clonal expansion and a restricted use of Jβ genes and a CDR3 consensus motif suggesting an antigen-driven CD8 + T cell interaction which is additionally stabilized by co-stimulatory molecules on the muscle fiber namely the B7–1/B7–2 (CD80/CD86) and their receptors CD28/CTLA-4, the inducible costimulatory ligand (ICOSL) and its receptor ICOS (a T cell specific costimulatory molecule homologous to CD28/CTLA4) and the receptor PD-1 (programmed death gene 1), which interacts with two B7 family members, PD-L1 (B7-H1) and PD-L2 (B7-DC). All these coreceptors can enhance or attenuate T cell activation [3,4]. T cell migration and attachment

is facilitated by metalloproteinases. Death of muscle fibers is mediated by necrosis rather than apoptosis, presumably due to anti-apoptotic molecules Bcl-2, hILP and FLIP, which are up-regulated in inflammatory myopathies. HLA-G, an atypical HLA molecule, protecting target cells from cytotoxic T and natural killer cells, is upregulated in IIM [4]. The exact role of myositis specific autoantibodies directed against antigens that are not specific for muscle tissue remains unresolved.

### Diagnostic Principles

The clinically suspected diagnosis of PM or DM is established by serum enzyme levels and electromyography (EMG) findings and confirmed by diagnostic muscle biopsy. In DM, perifascicular, perimysial or perivascular inflammatory infiltrates are characteristic. The intramuscular blood vessels show endothelial hyperplasia, fibrin thrombi and obliteration of capillaries, leading to ischemia and muscle fiber necrosis often seen in groups (microinfarcts) or at the periphery of the muscle fascicle. The resulting perifascicular atrophy is diagnostic of DM even in the absence of inflammation. PM is characterized by a mononuclear cell infiltrate located primarily endomysially (mainly cytotoxic CD8 + T lymphocytes and macrophages), which surrounds and eventually invades single non-necrotic muscle fibers. MHC class I molecules are ubiquitously expressed on the sarcolemma, even in muscle fibers not invaded by CD8 + cells. Autoantibodies against tRNA synthetases are frequently associated with interstitial lung disease that requires specific treatment.

### Therapeutic Principles

The treatment of both PM and DM is similar. High-dose daily steroids are a common initial therapeutic strategy. Once weakness has begun to resolve, the steroid dose is gradually tapered. Patients failing to respond to steroid therapy may benefit from the addition of other immunosuppressant therapy or immunomodulating therapies including azathioprine, methotrexate, cyclosporine, mycophenolate mofetil, chlorambucile and cyclophosphamide. High-dose intravenous immunoglobulin also has been utilized in the treatment of refractory DM. The superiority of any specific therapy remains unproven due to a lack of high quality randomized controlled trials to assess the efficacy and toxicity of immunosuppressants in inflammatory myositis [5].

## Polyarteritis Nodosa Group

►Vasculitis, of Medium-sized Vessels

## Polychondritis Recidivans

►Polychondritis, Atrophic

## Polychondritis, Atrophic

Julia Weihrauch, Thomas Krieg
Department of Dermatology, University of Cologne, Cologne, Germany

### Synonyms

Polychondritis recidivans; Systemic chondromalacia; Relapsing polychondritis

### Definition and Characteristics

Relapsing polychondritis (RP) is an episodic and progressive inflammatory disease of the cartilaginous structures, including elastic cartilage of the ear and nose, hyaline cartilage of peripheral joints, fibrocartilage at axial sites, and cartilage of the tracheobronchial tree. Inflammation of other proteoglycan-rich structures, such as the eyes, heart, blood vessels, inner ear, and kidneys may also be present [1].

### Prevalence

Relapsing polychondritis is rare. Luthra [2] estimated the annual incidence as 3.5 cases per million in Rochester, NY. More than 600 cases have been reported worldwide. The average time of diagnosis is 44–51 years [3], but may appear as early as 5 and as late as 84 years of age [4]. The male-to-female ratio has been estimated to be between 1:1 and 1:3 [3].

## Molecular and Systemic Pathophysiology

RP is an autoimmune disease that targets cartilaginous tissues. The primary target cartilage antigen of the autoimmune response in RP is, however, unknown, and as in many autoimmune diseases, several candidates have been suggested. Antibody responses to type II collagen (CII) have been detected in patients with RP, as well as in a subset of patients with Rheumatoid arthritis, indicating a role of CII in both diseases. Immune reactivities to types IX and XI collagen have also been shown in some patients with RP. The immune response against type II collagen (CII) has been examined most extensively. Antibodies against CII have been found in 30–50% of RP patients [2], and alterations in levels of these antibodies have been correlated with disease activity in many cases [5].

In patients with tracheal involvement matrilin-1 seems to be the primary target. Matrilin-1 (also known as cartilage matrix protein) is a cartilage-specific extracellular matrix protein, prominently expressed in the tracheal cartilage, but not in the joint cartilage. Matrilin-1 is the inducing antigen in a rat and mouse model of RP that mimics the human symptoms of respiratory distress, nasal septum erosions and kidney involvement. It was found that inflammation in the respiratory tract in patients with RP strongly correlates with autoantibodies to matrilin-1 and that even the serum concentration of the protein correlates with the severity of the respiratory symptoms.

Matrilin-1 immunization induces a disease in mice and rats that primarily affects the nasal and tracheolaryngeal cartilage, whereas immunization with CII in rats causes an arthritis that is followed by inflammation of the ears weeks to months later indicating that involvement of the ears is a secondary effect of cartilage destruction in the joints and of the response to released CII.

Unlike the findings for matrilin–1 response, no correlation between antibodies to CII and respiratory symptoms were found.

## Diagnostic Principles

RP is characterized by recurrent chondritis of both auricles, chondritis of nasal cartilages, chondritis of the larynx, trachea or respiratory tract, ocular inflammation, cochlear or vestibular lesions and non-erosive polyarthritis. Three or more of these features are required for the diagnosis. RP can also affect the skin, heart, kidney and blood vessels.

## Therapeutic Principles

A standardized therapeutic protocol for RP has not been established because the disease is rare and has a wide diversity of presentations and an unpredictable recurrence rate and course. Systemic steroids are beneficial in acute flares. Milder cases with nonsteroidal anti-inflammatory drugs and colchicines. Some studies have pointed to the efficacy of dapsone as a single agent. Because of the relapsing and chronic nature of this disease steroid-sparing agents such as methotrexate, azathioprine, cyclophosphamide and cyclosporine are often required.

Recently infliximab was reported to be effective, especially after failure of conventional therapeutic approaches.

# Polychondropathia

►Relapsing Polychondritis

# Polycystic Disease (Kidney)

Wolfgang Kühn, Gerd Walz
Department of Nephrology, University Medical Center Freiburg, Freiburg, Germany

## Synonyms

Autosomal dominant polycystic kidney disease; ADPKD; Autosomal recessive polycystic kidney disease; ARP KD

## Definition and Characteristics

ADPKD refers to enlarged cystic kidneys during adulthood leading to hypertension and progressive renal failure. Cysts also occur in the liver and the pancreas. Aneurysms of intracranial arteries

occasionally rupture, and are associated with a high morbidity and mortality.

ARPKD refers to neonatal death due to respiratory insufficiency in 30–50%. A second group of children experiences hepatic fibrosis, which occurs during childhood in 30–40%, or adulthood (10–20%) with or without renal involvement.

## Prevalence

ADPKD, 1:400 to 1:1,000; ARPKD, 1:20,000.

## Genes

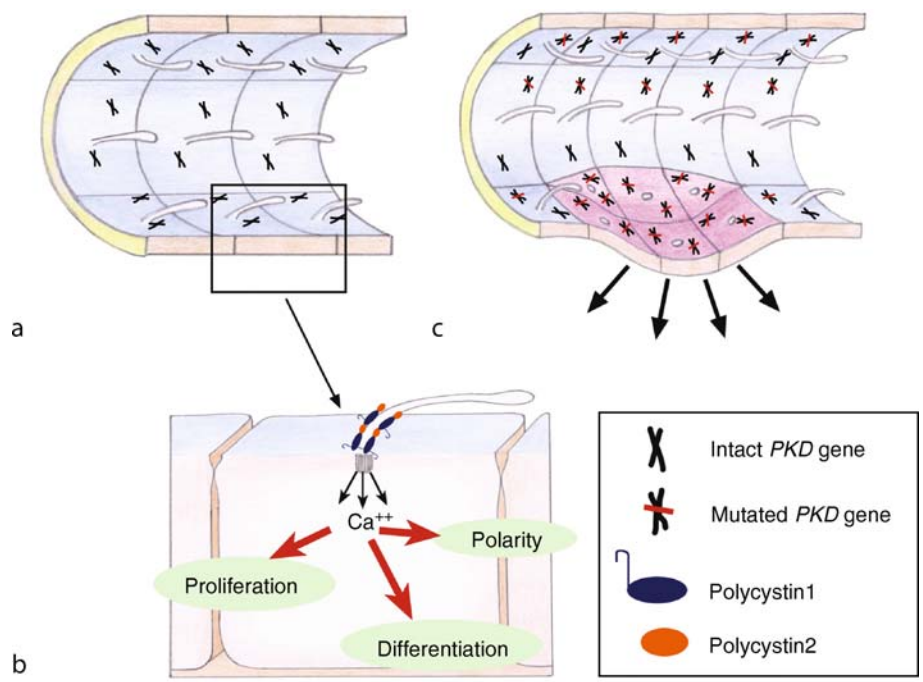
*ADPKD*: The PKD1 gene on chromosome 16p13.3 encodes a 460-kDa integral membrane protein, called polycystin 1. It is mutated in 85% of patients with ADPKD. The remaining 15% of patients have a mutation in the PKD2 gene on chromosome 4q22, which codes for a voltage-gated cation channel (polycystin 2), also known as TRPP2.

*ARPKD*: The PKHD1 gene on chromosome 6p12 codes for a 447-kDa integral membrane protein called fibrocystin/polyductin.

## Molecular and Systemic Pathophysiology

*ADPKD*: The entire spectrum of cystic kidney diseases is characterized by mutant proteins that are localized in primary cilia of epithelial cells. Primary cilia are thought to function as mechano- and chemosensors, mediating an increase in intracellular calcium in response to flow (Fig. 1). Polycystin 1 is a large transmembrane protein with 11 membrane-spanning regions and a long N-terminal extracellular domain. The C terminus of polycystin-1 is cleaved and translocated to the nucleus, where it activates transcription. Since epithelial cells from $PKD1^{-/-}$ mice fail to increase calcium in response to flow, polycystin-1 appears to play a direct role in mechanosensation and/or transduction [1]. Polycystin 1 is involved in various signaling pathways, most notably interacting with G proteins, the Wnt pathway, JAK/STAT, and mTOR signaling, and has been shown to participate in cell adhesion, migration, tubulogenesis, and proliferation.

Polycystin 1 interacts directly with polycystin 2 via their C termini. This interaction is important for the targeting and function of polycystin 2. Additionally, PACS proteins have been shown to control polycystin 2 trafficking between the plasma membrane and the ER,



**Polycystic Disease (Kidney). Figure 1** (a) Renal tubular cells with two intact alleles for PKD1 and PKD2 are characterized by the presence of cilia, protruding from the apical surface, and a regular tubular diameter. (b) Cilial bending in response to urine flow results in an increase of intracellular calcium. This is dependent on the presence of polycystin-1 and -2 that are expressed in the cilium. Cilial function controls proliferation, differentiation, and polarity of the cell. (c) The presence of one intact allele of PKD1 (or PKD2, depending on the genotype) in patients with ADPKD is sufficient for the function of the ciliary system. Mutation of the second allele in individual cells results in the loss of cilial function, disturbances in proliferation, differentiation, and polarity, causing cyst formation.

thus regulating polycystin 2 channel function at the plasma membrane [2]. Polycystin 2 is a calcium channel expressed in the cilium and in the endoplasmic reticulum. Ciliary polycystin 2 is also required for flow-induced calcium responses [1]. On the genetic level, cystogenesis is believed to result from loss of heterozygosity (Fig. 1); individual tubular cells with a germline mutation in PKD1 or PKD2 acquire an additional somatic mutation in the second allele [3]. Mutated epithelial cells acquire a dedifferentiated state with increased proliferation as well as altered cell–cell and cell–matrix interaction. Cyst lining cells are characterized by increased TOR activation [4].

*ARPKD*: Fibrocystin/polyductin is a large integral membrane protein that localizes to the cilium. It is involved in cell–cell and cell–matrix interaction as well as proliferation and apoptosis [5]. The mechanism of cystogenesis is currently unknown.

## Diagnostic Principles

*ADPK*: Patients are identified by renal cysts on ultrasound examination. A positive family history confirms the diagnosis in approximately 70% of all cases.

*ARPKD*: The diagnosis is made in patients with cystic kidneys and liver abnormalities, documenting hepatic fibrosis by biopsy. The family history is negative.

## Therapeutic Principles

The mainstay of treatment is blood pressure control. Ongoing studies evaluate the efficacy of combined ACE and AR inhibitors, vasopressin analogues and mTOR inhibitors, which have been demonstrated to slow progression in rodent animal models. The preferred treatment for end-stage renal disease is kidney transplantation.

# Polycystic Liver Disease

Georg H. Merker, Ralf Kubitz, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

PCLD

## Definition and Characteristics

Autosomal-dominant polycystic liver disease (PCLD) is a rare disorder that is characterized by the progressive development of fluid-filled biliary epithelial cysts in the liver. PCLD is genetically distinct from polycystic liver which may develop in the context of autosomal-dominant polycystic kidney disease type 1 (ADPKD-1), and type 2 (ADPKD-2) [1,2].

Symptoms include abdominal distension, early satiety, dyspnea, and back pain and are related to mass effects of the cysts leading to hepatomegaly. Extrahepatic findings of PCLD may comprise intracranial aneurysms and mitral valve abnormalities (e.g. mitral valve prolaps). Complications of PCLD, such as intracystic hemorrhage or rupture of cysts, can cause acute abdominal pain. Cyst infections can lead to fever and chills. Rarely, development of ascites due to hepatic or portal venous obstruction or of lower extremity edema due to inferior vena cava compression occurs.

## Prevalence

PCLD has been described in fewer than 50 families from Finnish, Dutch, American, Belgian, and Spanish-Belgian ancestry. Hepatic cysts are rarely observed prior to puberty, arise with the onset of puberty, are more prevalent and prominent in women, and increase dramatically in number and size through the child-bearing years confirming the role of estrogens in the development of PCLD.

## Genes

Two separate genes, protein kinase C (PKC) substrate 80K-H (PRKCSH) and SEC63, have been identified to cause familial PCLD [3]. PRKCSH encodes for hepatocystin, the beta-subunit of glucosidase II, an N-linked glycan-processing enzyme in the endoplasmic reticulum (ER), whereas SEC63 encodes a component of the protein translocation machinery in the ER. Both proteins are components of the molecular machinery involved in the translocation, folding and quality control of newly synthesized glycoproteins in the endoplasmic

reticulum. Most mutations are truncating and probably lead to a complete loss of the corresponding proteins and the defective processing of key regulators of cell proliferation and biliary cell growth.

## Molecular and Systemic Pathophysiology

Hepatocystin is the beta-subunit of glucosidase II in the endoplasmatic reticulum (ER) [2]. The trimming of glucose residues catalyzed by glucosidase II is essential for further processing of N-linked oligosaccharides by other carbohydrate-modifying enzymes, and plays an important role in quality-control mechanisms in the ER. Glucosidase II-catalyzed removal of the second and third glucosyl residues from the N-linked oligosaccharides regulates interactions with the lectins calreticulin and calnexin, which promote co-translational folding of the polypeptide part of the glycoproteins. If folding is defective, glycoproteins are targeted towards degradation by proteasomes in the course of the ER-associated degradation pathway.

The current concept is that PCLD results from altered carbohydrate processing or ER quality control of some key regulator of biliary cell proliferation and differentiation leading to overgrowth of the biliary epithelium and supportive connective tissue. Why this results in cyst and not in solid tumor formation is currently unknown.

## Diagnostic Principles

Radiologic studies such as abdominal ultrasound (US) and computer-assisted tomography (CT) scanning are the preferred methods of investigation: On US, the cysts are anechoic and appear as round and smooth-walled with distal echo enhancement. On CT, these cysts typically have smooth contours with fluid attenuation values of −5 to +20 Houndsfield units. The cysts also maintain distinct margins with the surrounding hepatic parenchyma and do not show contrast enhancement. Changes in wall thickness or contour, the appearance of septations, changes in echogenicity or CT attenuation, or rapid growth should prompt consideration of hemorrhage or infection.

Laboratory studies are often normal. In symptomatic patients abnormalities may include elevated alkaline phosphatase, GGT and total bilirubin values.

## Therapeutic Principles

Most patients with PCLD remain asymptomatic and therefore do not require treatment. In case of complications or severe hepatomegaly cyst aspiration and sclerosis, cyst fenestration, partial hepatectomy, and even liver transplantation may be warranted.

# Polycythemia Rubra Vera

►Polycythemia Vera and Secondary Polycythemias

# Polycythemia Vera and Secondary Polycythemias

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Department of Vascular Medicine, Amsterdam Vascular Medicine Group, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms

Polycythemia rubra vera

## Definition and Characteristics

Polycythemia vera is a chronic myeloproliferative disease caused by acquired mutations within early hematopoietic progenitor cells, leading to an elevated red blood cell mass. Headaches, weakness, thrombotic complications, pruritus, erythromelalgia (painful erythema of hands or feet), splenomegaly, and hematologic malignancies are the main symptoms and complications of the disease. Secondary polycythemia is usually the result of increased erythropoietin (EPO) production, either appropriate (e.g. in heavy smokers, patients with intra-cardiac shunts or living at high altitudes) or inappropriate (e.g. EPO producing neoplasm).

## Prevalence

The incidence of polycythemia vera is estimated to be approximately 2 per 100,000 per year in the USA. The median age of clinical presentation is 60 years (range 20–85 years).

## Genes

Janus Kinase 2, JAK2 (9p24). Erythropoietin receptor (EPO-R; 19p13.3–13.2) in some cases of congenital polycythemia.

## Molecular and Systemic Pathophysiology

EPO, the most important regulator of erythropoiesis, is essential for the maturation of erythroid cells. Effects of EPO are mediated by the specific EPO-R. EPO production is stimulated by decreased oxygen saturation of hemoglobin (secondary polycytemia due to appropriate EPO production) or reduced oxygen delivery in case of anemia. Secondary polycythemia due to inappropriate EPO production is observed in EPO producing tumors and some kidney diseases. The underlying molecular mechanism of polycythemia vera is unknown. However, recently a unique and clonal mutation in the JAK homology 2 (JH2) domain of JAK2 that results in a valine to phenylalanine substitution at position 617 (V617F) was found in the majority of PV patients. This mutation leads to constitutive JAK2 activation and abnormal signaling and induces erythrocytosis in an animal model. This mutation is also present in other myeloproliferative disorders, and the precise molecular mechanisms leading to polycythemia vera are still unclear.

It was expected that alterations in EPO or its receptor would be involved. Although gain of function mutations of this receptor have been observed in some forms of congenital polycythemia, in polycythemia vera neither mutations of the EPO gene, nor the EPO-R gene, have been observed. The formation of endogenous erythroid colonies in the absence of EPO is common in polycythemia vera, but also in other myeloproliferative disorders. Nonspecific cytogenetic abnormalities, such as trisomy 8 or 9 and 20q-, are observed in 33% of patients. Impaired expression of the thrombopoietin receptor by platelets and megakaryocytes is characteristic of polycythemia vera, but the significance of this finding remains to be established. As a result of upregulation of Bcl-x, an inhibitor of apoptosis, erythroid-lineage cells may have prolonged survival.

The discovery of these abnormalities may lead to a better understanding of the underlying pathophysiological mechanism of polycythemia vera.

## Diagnostic Principles

Low EPO levels in a patient with features suggestive of polycythemia vera are indicative of the disease, whereas high EPO levels are suggestive of a secondary polycythemia. An increased red cell mass in combination with an increased plasma volume is also a strong indicator for polycythemia vera. In certain clinical situations confirmation by bone marrow examination and determination of the presence of endogenous erythroid colonies is warranted. The exact place for the determination of the presence of the JAK2 V617F mutation has not been established yet.

## Therapeutic Principles

Regular phlebotomies are effective for ameliorating symptoms due to the increased red cell mass and may also reduce splenomegaly. Pruritus and erythromelalgia are treated with supportive measures. Splenectomy may be necessary in case of splenomegaly with chronic discomfort and portal hypertension. Alpha-interferon is effectivse in most patients in suppressing red cell production, pruritus and splenomegaly. Hydroxyurea is effective as well, but may be leukemogenic.

## Synonyms

APS1; Autoimmune polyendocrynopathy syndrome; APECED

## Definition and Characteristics

Autoimmune polyendocrinopathy ectodermal dystrophy (APECED) is a rare m onogenic disease with autosomal recessive inheritance. It results from poor tolerance to self antigens leading to destructive autoimmune disorders of the endocrine organs, chronic mucocutaneous candidiasis, hypoparathyroidism and adrenocortical failures.

## Prevalence

The disease is reported worldwide but it is exceptionally prevalent among the Finnish population (incidence 1:25,000), the Iranian Jews (incidence 1:9,000) and Sardinians (1/14,500). It usually occurs in children aged 3–5 years or in early adolescence, but it always occurs by the early part of the third decade of life.

## Genes

Mutations in the autoimmune regulator gene AIRE1 (chromosome 21p22.3), give rise to APECED [1,2]. Over 50 pathological mutations, including truncations and point mutations, have been identified throughout the coding region of the AIRE1 gene [3]. AIRE1 encodes the multidomain AIRE1 protein (545 amino acids) of largely unknown function. AIRE1 is predominantly localized in the nuclear matrix and is most highly expressed in immunologically relevant tissues such as the spleen and thymus. AIRE1 has transcriptional activating properties [4] regulating the thymic transcription of peripheral tissue self-antigens [5]. The protein harbors an N-terminal homogeneously staining region, a nuclear localization signal, four LXXLL motifs, a SAND domain likely to mediate DNA binding and two plant homeodomain (PHD)-type zinc fingers. Both of the PHD fingers are mutational hot-spots for AIRE1, they contain the sites of several pathological point mutations and are absent in several APECED-causing truncation mutants, thus suggesting a crucial role for the domains.

## Molecular and Systemic Pathophysiology

AIRE1 has an important role in the expression of a variety of peripheral tissue antigens in the medullary epithelial cells (MECs) of the thymus. This function appears to be crucial as it seems to be required for purging the immune system of autoreactive T cells. However the real function of AIRE1 is still unknown. Studies of AIRE1 deficient mice have provided evidence that AIRE1 plays a pivotal role in preventing autoimmunity. Indeed knock-out mice show evidence of spontaneous organ specific autoimmunity, similarly to what observed in APECED patients. Furthermore it has been suggested that AIRE1 might exert its immunological effect by facilitating the production of organ-specific transcripts in medullary thymic epithelial cells (mTECs). These organ-specific proteins are presented on the surface of mTECs by MHC molecules to developing T cells. Thymocytes recognizing these organ specific proteins in the context of MHC undergo negative selection, thus preventing autoimmune processes. However an alternative working model suggest that thymocytes recognizing this complex are selected as regulatory T cells.

## Diagnostic Principles

Diagnosis of APECED requires at least two of the following symptoms: Addison disease, and/or hypoparathyroidism, and/or chronic mucocutaneous candidiasis. In addition to these common features a variety of other characteristics has been reported, including autoimmune hepatitis, intestinal malabsorption, alopecia and vitiligo, keratoconjunctivitis, immunologic defects (cellular and humoral), asplenia, and cholelithiasis.

Patients are usually screened for endocrine autoantibody. The screening panel may include autoantibodies to 21-hydroxylase, 17-hydroxylase, thyroid peroxidase (TPO) and thyroid-stimulating immunoglobulins (TSI), glutamic acid decarboxylase and islet cellantibodies, and parietal cell enzyme (H+/K+-ATPase) antibodies, P450c21. Not all patients have positive antibodies; therefore, the absence of these antibodies does not exclude the disease.

### Therapeutic Principles

Treatment is targeted to cure the symptoms of the disease.

- Mucocutaneous candidiasis:
  It is treated with oral fluconazole and ketoconazole.
- Hypoparathyroidism:
  Oral calcium and vitamin D usually are adequate therapy. If associated to malabsorption, tetany may occur and IV calcium gluconate and magnesium may be necessary.
- Adrenal insufficiency (Addison disease):
  Corticosteroids are used for adrenocortical insufficiency replacement. These agents have anti-inflammatory properties with varied metabolic effects. Vitamin and mineral replacement occasionally is needed to compliment hormonal replacement.

### Synonyms

CIDP

### Definition and Characteristics

Chronic inflammatory demyelinating polyneuropathy (CIDP) was recognized as a clinical entity differing from GBS by Prineas and McLeod and by Dyck et al. in 1975. CIDP causes slowly progressive or relapsing and progressive, largely symmetrical weakness involving proximal and distal muscles and usually marked sensory impairment [1,2]. The rare acute-onset CIDP patient may mimic GBS, but either progressively deteriorates over more than 8 weeks or exhibits a chronic relapsing-remitting course (CRIDP). The histopathological hallmark is chronic demyelination of motor and sensory nerve fibers. Less common variants

include pure motor CIDP, multifocal acquired demyelinating sensory and motor neuropathy (MADSAM) and multifocal motor neuropathy with conduction block (MMN). CIDP often requires long-term immunosuppressive treatment.

## Prevalence

Incidence in the general population is at least 1–2 cases/100,000.

## Molecular and Systemic Pathophysiology

The histopathological hallmark of CIDP is immune-mediated segmental demyelination of motor and sensory peripheral nerves. Establishment of CIDP as an inflammatory disorder of presumed autoimmune origin is based on the observation of multifocal T-cell and macrophage infiltrates and on the clinical response to corticosteroids or other immunomodulatory treatments (see below). Diagnostic sural nerve biopsies reveal thinly myelinated nerve fibers and onion bulb formation with typical perivascular clustering of scarce inflammatory cells [3]. A similar immune-mediated demyelination can be induced in experimental animals by immunization with the myelin antigens $P_0$, $P_2$, PMP22, MBP and galactocerebroside and is referred to as experimental autoimmune neuritis (EAN). Once established, EAN can be transferred to naive animals by adoptive transfer of autoreactive T-cells and augmented by additional passive transfer of antibodies (abs). Depending on the preponderance of cellular or humoral immunity against peripheral myelin components, a GBS- or a CIDP-like disorder can be modeled [4]. CIDP can be mimicked most closely when rabbits are immunized with the glycolipid galactocerebroside (GalC-EAN). In GalC-EAN, like CIDP, nerve roots and peripheral nerves show acute and chronic demyelination with myelin splitting at initial stages, myelin phagocytosis by macrophages and perivascular macrophage clustering. Despite our advanced experimental models and several candidates as the crucial autoantigen, the autoimmune nature of CIDP is not yet proven beyond any doubt. Recently, neuromuscular inhibitory IgG antibodies were demonstrated. While abs against myelin proteins, in particular $P_0$, are present in the serum of only some classical CIDP patients, 50% of patients with the MMN variant have abs against the ganglioside GM-1.

## Diagnostic Principles

The variable presentation of CIDP makes a definite clinical diagnosis sometimes difficult. The following consensus criteria define typical CIDP, 1. progressive or relapsing motor and sensory (rarely only motor or sensory) dysfunction of the limbs developing over at least 2 months, 2. reduced or absent tendon reflexes, 3. absence of an alternative cause (for example toxin exposure, hereditary neuropathy), 4. neurophysiological examination revealing multifocal demyelination in at least one segment of three nerves (conduction block, temporal dispersion or abnormal nerve conduction velocity (NCV)) and 5. cerebrospinal fluid protein > 45 mg/dl and white cell count <10/mm$^3$. A sural nerve biopsy may provide proof by showing de- and re-myelination and small clusters of macrophages and less pronounced T cells. Up to 10% of clinically typical CIDP patients show a monoclonal gammopathy, which requires bone marrow studies and antibody testing before one assumes a pathogenic role; rarely, CIDP may be a paraneoplastic manifestation. Pure motor CIDP with reduced motor NCV and prolonged distal motor latencies have been described. It is still a matter of debate, whether MNN with conduction block represents a different entity or another variant of CIDP. Patients with MNN show multifocal nerve paralyses without the sensory involvement seen in vasculitic mononeuritis multiplex. As a unique feature, nerve conduction studies reveal multifocal proximal motor conduction blocks with abrupt loss of compound muscle action potential (CMAP) amplitudes over short nerve segments. Recognition of MNN is important since a different therapeutic approach is required.

## Therapeutic Principles

It is well supported by one controlled and several uncontrolled series that corticosteroids may be effective in CIDP. Short-term improvement at least is seen in two-thirds of patients [5]. Subsequently, placebo-controlled studies revealed that plasma exchange (PE) and intravenous immunoglobulin (ivIG) treatment also ameliorated CIDP. By direct comparison, ivIG and PE were about equally effective, and ivIG was not significantly better compared to oral prednisolone during a short observation period of 6 weeks. With regard to the high costs and effort of ivIG and PE and the relative invasiveness of PE, corticosteroids are recommended as first choice treatment while ivIG or PE are restricted to patients who are severely disabled and do not or incompletely respond to corticosteroids. Since the diagnosis of CIDP may be difficult in individual cases, responsiveness to corticosteroids, ivIG or PE may also help in establishing the diagnosis. About 70–80% of patients respond to these treatments, but in addition long-term immunosuppression is required in most CIDP patients. Unfortunately, the choice of an appropriate drug is mainly supported by anecdotal evidence and large randomized trials are lacking. Small open label case series with a crossover design reported therapeutic benefit from azathioprine and cyclosporin A in patients refractory to established measures. Azathioprine is now largely accepted in CIDP patients, in part to spare steroid doses and to prevent long-term side effects

of continuous steroid application. Cyclosporin A is an alternative in patients not tolerating azathioprine. In severe cases, treatment escalation includes mycophenolate mofetil or cyclophosphamide. MMN patients may deteriorate paradoxically after corticosteroid treatment, probably via direct inhibitory effects on the demyelinated axon membrane. In MMN, ivIG or immunosuppressive agents are the treatments of choice [4].

# Polyorchidism

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Supernumerary testes

## Definition and Characteristics

Polyorchidism is defined as the presence of two or more testes. Most patients are asymptomatic and present with a painless extra testicular mass during infancy or adolescence. Approximately 75% of the supernumerary testes are intrascrotal, 20% inguinal, and 5% intra-abdominal [1]. Triorchidism is the most common type of polyorchidism, but patients with five testes have been reported [1]. The supernumerary testis is usually superior to the ipsilateral testis and the size is smaller than the ipsilateral or contralateral testis (Fig. 1) [2].

In about 75% of reported cases, polyorchidism has been left-sided [1]. This tendency may be related to the reportedly greater size of the left testis which may subdivide more readily. Associated anomalies include inguinal hernia and maldescent of either the supernumerary or ipsilateral normal testis [1]. Complications include torsion of the testis, epididymitis, varicocele, hydrocele, and testicular cancer [1]. A potential complication is unexpected fertility after bilateral vasectomy.

## Prevalence

Polyorchidism is a rare congenital anomaly with approximately 100 cases reported in the literature.

## Molecular and Systemic Pathophysiology

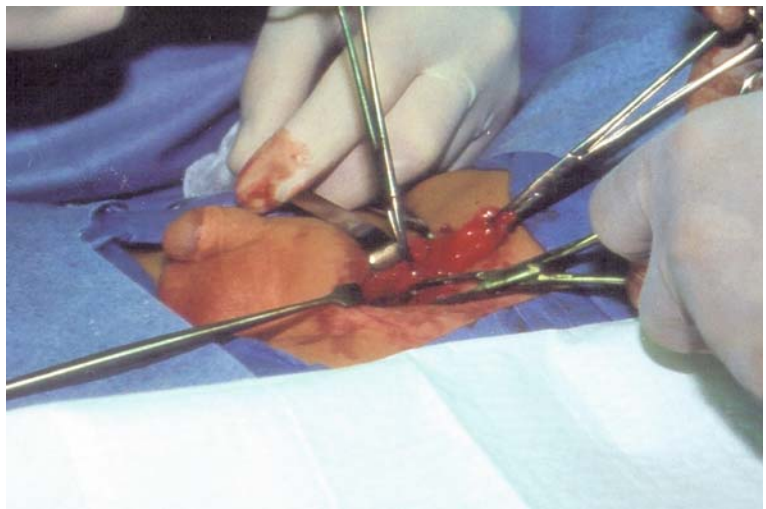
At about the sixth week of embryonic life, the primordial testis begins to develop from the primitive genital ridge medial to the mesonephros [1]. At about the eighth week, the primordial testis takes shape, and the epididymis and vas deferens arise from the mesonephric duct. Polyorchidism can be explained by doubling over or transverse division of the genital ridge possibly by the development of peritoneal bands [1]. On the basis of embryonic development, Leung classified polyorchidism into four types [1]. In type A, the supernumerary testis lacks an epididymis and vas deferens. In type B, the supernumerary testis has its own epididymis. In type C, the supernumerary testis has its own epididymis and shares the vas deferens with the ipsilateral testis. In type D, there is complete duplication of testes, epididymides and vas deferens [1].

## Diagnostic Principles

A supernumerary testis in the inguinal canal may simulate an inguinal hernia. Differential diagnosis of an intrascrotal supernumerary testis includes hydrocele, varicocele, spermatocele, epididymal cyst, and splenogonadal fusion. The sonographic feature of polyorchidism is a scrotal mass that has an echo texture identical to the ipsilateral testis [3]. Color Doppler sonography shows vascular flow pattern as that of the ipsilateral testis [3]. If splenogonadal fusion is suspected, a technetium sulfur colloid scan should be performed to confirm the presence of ectopic splenic tissue [3]. Transverse testicular ectopia is a condition in which both testes lie in the same side of the scrotum [4]. Therefore, a diagnosis of polyorchidism should not be made without careful examination of the contralateral side. In transverse testicular ectopia, the two testes have two different sets of blood vessels and vas deferens [4].

## Therapeutic Principles

Management of polyorchidism remains controversial. Some authors argue that in the absence of any apparent malformation and if a testicular tumor can be ruled out by sonography, surgical exploration and biopsy are unnecessary. Other authors favor surgical exploration which has the advantage of allowing orchidopexy to prevent



**Polyorchidism. Figure 1** Polyorchidism. Surgical exploration showed two testes on the left side. A single right testis was noted.

torsion and creation of a single testicular mass with biopsy if indicated [5]. Patients with polyorchidism need to have regular follow-up for early detection of malignancy. Indications for orchidectomy of the supernumerary testis include atrophic or dysplastic testis, absent spermatogenesis, suspicion of malignancy, and poor patient compliance.

# Polythelia

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Synonyms

Supernumerary nipple(s); Accessory nipple(s)

## Definition and Characteristics

A supernumerary nipple presents as a small, brown- or pearl-colored macule, or as a concave spot, and is usually located just below and slightly medial to a normal breast (Fig. 1).

A supernumerary nipple can be present with or without the areola, and vice versa. A supernumerary nipple can be located within the areola of normal breast tissue, and in this rare circumstance the problem is believed to be due to intrauterine dichotomy of the developing nipple. The presence of a supernumerary nipple in an atypical location, such as the neck, arm, leg, buttock, shoulder, scapula, spine, vulva, or perineum is rare [1]. Breast tissue is occasionally present beneath the nipple. The ectopic breast tissue might enlarge and swell with hormonal changes during puberty, pregnancy, and lactation [2]. Discomfort or milk secretion can occur during lactation.

Urinary tract anomalies associated with polythelia have been reported in Jewish, Hungarian, and Italian individuals, but not in African-American individuals [3,4]. The cardiovascular problems reported in association with polythelia include hypertension, conduction defects, congenital heart defects, mitral valve prolapse, and cardiomyopathy. Polythelia is a component manifestation of mandibular-facial-digital-nipple syndrome and Simpson-Golabi-Behmel syndrome [2].

## Prevalence

A supernumerary nipple usually presents as an isolated anomaly. A single supernumerary nipple is more common than multiple supernumerary nipples. The incidence decreases with the number of nipples. The reported incidence varies from 0.2 to 6% [3]. The sex

**Polythelia. Figure 1** Bilateral supernumerary nipples (*arrows*) in a male infant.

incidence and laterality is approximately equal [2]. The condition is more prevalent in African-American, Japanese, and Jewish individuals than in Caucasian individuals [2]. Familial occurrence has been described, but most cases are sporadic [3,5].

## Molecular and Systemic Pathophysiology

Between the fourth and fifth weeks of fetal development, two parallel lines of thickened epithelium appear along the ventral surface of the embryo. This thickened ectodermal tissue forms the mammary ridge or milk line and extends inferio-medially from the axilla, over the chest, through the lateral border of the pubic region, to the upper medial surface of the thigh [1]. In the course of normal development, this tissue is fragmented and forms a series of ectodermal accumulations. The paired ectodermal accumulations at the level of the fourth intercostal space persist and develop into breasts. In humans, the redundant ectodermal accumulations usually atrophy and disappear. An ectodermal accumulation that otherwise persists results in polythelia [1]. When a supernumerary nipple is found outside the milk line, the lesion might represent the reversion of certain characteristics to a more primitive state [3].

## Diagnostic Principles

The differential diagnosis includes melanocytic nevus, neurofibroma, verruca, and skin tag. The occurrence in a typical location along the milk line helps confirm the diagnosis of polythelia.

## Therapeutic Principles

Patient education and reassurance is important. Surgical excision should be considered if there is a cosmetic concern, physical discomfort, mastitis, or evidence of neoplastic changes. Females who present with ectopic breast tissue should be counseled about the potential physiologic consequences associated with puberty, pregnancy, and lactation. A thorough history, careful physical examination, and urinalysis are indicated for all patients with polythelia. If these investigations suggest the possibility of a urinary problem, renal ultrasonography should be considered. If a cardiovascular problem is suspected, an electrocardiogram and an echocardiogram should be considered.

# Pompe Disease

►Glycogen Storage Disease Type II
►Glycogenosis Type II

# PONV

►Nausea and Vomiting

# Porokeratosis

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Definition and Characteristics

An autosomal dominant cutaneous disorder characterized by circular lesions exhibiting a central atrophy and a keratotic ridge with a longitudinal furrow. At least six clinical variants are distinguished: superficial actinic porokeratosis (DSAP), porokeratosis of Mibelli (PM), linear porokeratosis (LP), porokeratosis palmaris et plantaris disseminata (PPPD), porokeratosis punctata palmaris et plantaris and giant porokeratosis.

## Prevalence

DSAP appears is the most common form and is often not recognised.

## Genes

Two loci have been reported for DSAP (MIM#175900) at 12q23.2–24.1 [1] and 15q25.1–26.1 [2]. PPPD (MIM#175850): one locus at 12q24.1–24.2 [3].

## Molecular and Systemic Pathophysiology

The etiology is unclear. In addition to the genetic background repeated actinic exposure and immunosuppression have been linked to porokeratosis, especially for DSAP. It has been suggested that a mutant clone of keratinocytes expands peripherally. Aneuploidy was detected in lesional keratinocytes. Chromosomal abnormalities and increased chromosomal instability after X-ray radiation of keratinocytes cultured from lesional epidermis was also reported. Overexpression of the tumor protein p53 has also been demonstrated in lesional skin of porokeratosis [4]. However, mutations of p53 appear to be a rare event in microdissected skin lesions. Recently, premature apoptosis was detected by terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick-end labeling in lesional skin in patients with DSAP, PM and LP [5]. Identification of candidate genes within the so-far identified loci of DSAP and PPPD may further elucidate the molecular base of these diseases.

## Diagnostic Principles

The patient's history, distribution and morphology of the lesions are often distinctive for each clinical variant. DSAP becomes clinically apparent by the third and fourth decades of life and is often symmetrically distributed on the extensor surfaces of the extremities. Both PM and LP often manifest in early childhood and occur unilaterally on an extremity. Different forms of porokeratosis may coexist in one patient. An excisional skin biopsy involving the keratotic ridge of the lesion reveals a characteristic parakeratotic column known as the "cornoid lamella."

## Therapeutic Principles

There is no established effective treatment for porokeratosis. In anecdotal reports topical 5-fluorouracil, retinoids, vitamin D analogues (calcipotriol, tacalcitol) as well as surgery, dermabrasion, cryotherapy, laser treatment and systemic retinoids had beneficial effects. Since malignant transformation (squamous and basal cell carcinoma, Bowen carcinoma) has been described in all clinical variants of porokeratosis protective clothing and use of an UV A and B topical sunscreen are advised. Long-term follow-up is necessary.

# Porphobilinogen Deaminase Deficiency

►Porphyria, Acute Intermittent

# Porphyria, Acute Intermittent

Elena Pischik, Raili Kauppinen
Porphyria Research Centre, Biomedicum-Helsinki, University of Helsinki, Helsinki, Finland

## Synonyms

Hydroxymethylbilane synthase deficiency; Porphobilinogen deaminase deficiency; Pre-uroporphyrinogen

synthase deficiency; Uroporphyrinogen I-synthase (UROS-I) deficiency; HMBS deficiency; PBGD deficiency

## Definition and Characteristics

AIP is an inherited metabolic disease, which results from a partial deficiency of HMBS in the haem biosynthesis causing accumulation of porphyrins and their precursors in the body [1]. The major clinical manifestation of AIP is an occasional acute attack, which includes mental symptoms and signs of autonomic dysfunction. Increased excretion of porphyrin precursors is mandatory to show the causality of clinical manifestations to biochemical abnormalities [1]. AIP has no dermatological features, but acute attacks are clinically indistinguishable from those of other acute porphyrias. Attacks may be provoked by certain drugs, alcohol, fasting, infections and hormonal fluctuations during the menstrual cycle (Fig. 1) [1].

In a protracted attack, acute peripheral neuropathy and signs of CNS involvement may occur [2].

## Prevalence

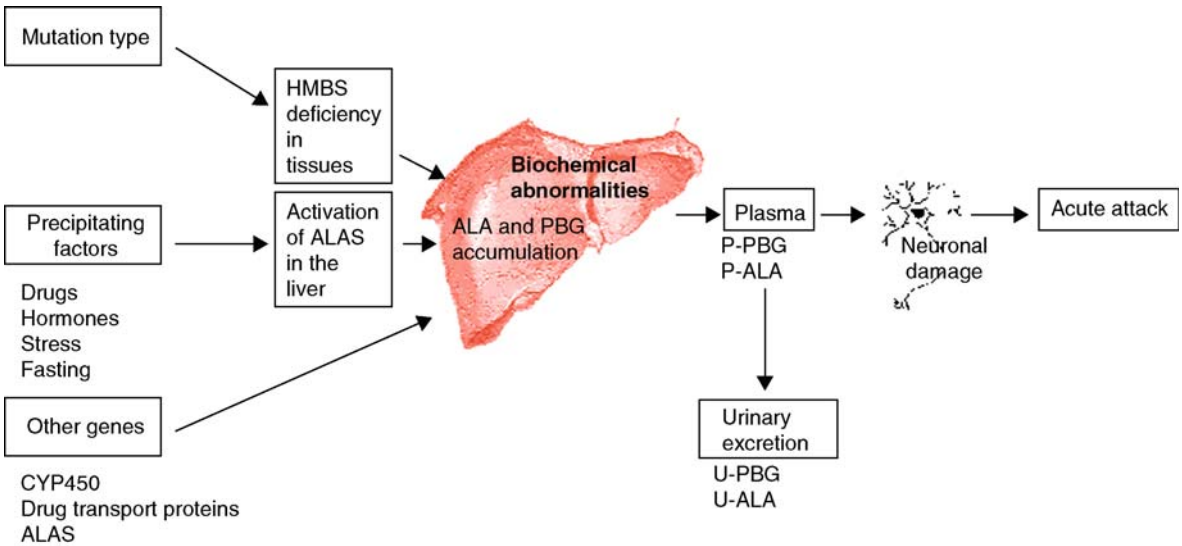
AIP has an autosomal dominant pattern of inheritance and penetrance is around 10–40% based on different patient data [1]. The overall prevalence is 1–10:100,000. The highest prevalence is reported from Northern Sweden (500–2,000:100,000) because of a founder effect. The symptoms appear after puberty except in very rare homozygous AIP, in which a progressive neurodegenerative disease manifests already in the early infancy [1].

## Genes

The HMBS gene is located at 11q23.3 and includes 15 exons. Two different mRNAs, one for erythroid and the other for non-erythroid tissues, are transcribed via two promoters and processed by alternative splicing [1]. More than 250 mutations in the HMBS gene (www.hgmd.cf.ac.uk/ac/gene.php?gene = HMBS) have been reported to cause AIP. Heterozygous patients have around 50% of the total HMBS activity measured in their erythrocytes, leucocytes, fibroblasts and hepatocytes, which is enough to maintain the normal demand for haem [1]. Of all AIP patients, 5–16% have a variant form of AIP; in which only non-erythroid isoform of HMBS is deficient due to the mutations in the housekeeping form of the enzyme. Clinical manifestations do not differ from the classic form, but the erythrocyte HMBS activity is normal [1,3].

## Molecular and Systemic Pathophysiology

The cytoplasmic HMBS catalyzes the head-to-tail condensation of four molecules by a series of deaminations to form the linear tetrapyrrol pre-uroporphyrinogen (hydroxymethylbilane) in which dipyrromethane acts as a cofactor. In AIP, the majority of the mutations cause a loss of function of HMBS based on in vitro studies and as a result, the enzyme activity is dramatically decreased when measured in the patients' cells [1]. A few mutations have been reported to cause a milder disease (lower penetrance and mortality and milder abnormalities in the porphyrin metabolism) [3]. This may be explained by the fact that these residues do not cause dramatic changes in the catalytic active site or in the stability of the polypeptide and have a higher residual activity.



**Porphyria, Acute Intermittent. Figure 1** Pathogenesis of an acute attack. HMBS, hydroxymethylbilane synthase; ALAS, aminolevulinic acid synthase; ALA, aminolevulinic acid; PBG, porphobilinogen.

Pathogenesis is similar with other acute porphyrias (see also ►Variegate porphyria and ►Hereditary coproporphyria): overproduction of potentially neurotoxic porphyrin precursors, aminolevulinic acid (ALA) and porphobilinogen (PBG) in the liver cause accumulation of porphyrins and their precursors in other tissues via circulation (Fig. 1) [2]. Whether intraneural synthesis of porphyrin precursors contributes to neurological manifestations of an acute attack remains controversial [2].

Accumulation of porphyrins and their precursors is initialized via activation of ALA synthase (ALAS), which is the first and rate-limiting enzyme in the haem biosynthesis. This induction results in symptoms only if an additional enzyme such as HMBS causing acute porphyria, is deficient [2]. ALAS in the liver (ALAS1) can be induced directly at transcriptional and translational levels by many drugs, chemicals and alcohol or indirectly by low glucose concentration and stress (Fig. 1) [1].

These factors may provoke an acute attack and on the other hand, ALAS1 can be inhibited via negative feedback mechanism using the end-product, haem [1]. In addition, glucose has been shown to inhibit ALAS1 indirectly via PCG-1α in vitro conditions. Thus, haem preparations and glucose infusions have been used for the treatment of acute attacks.

During an acute attack the symptoms can be explained by autonomic neuropathy, which manifest as pandysautonomia with predominantly vagal insufficiency (tachycardia, hypertension, constipation, bladder paresis and, probably, abdominal pain), acute encephalopathy (anxiety, euphoria, hallucinations, SIADH, seizures, unconsciousness) and mainly motor axonal peripheral neuropathy (diffuse muscle weakness, hyporeflexia and sensory loss) [2].

Manifestations of acute porphyria could be precipitated either by direct neurotoxicity of porphyrin precursors, which has been demonstrated in vitro, or by deficiency of neural haem-containing enzymes or both [2]. Increased formation of free radicals because of auto-oxidation of ALA and inhibition of $Na^+/K^+$ ATPase by ALA demonstrated in vitro could play a role in neuronal damage. High affinity of ALA to GABA and glutamate receptors could provoke seizures, since inhibitory mechanisms via these neurotransmitters are blocked [2]. Disruption of the blood-brain barrier, which could be demonstrated by reversible multifocal edema in the brain MRI in patients during an acute attack, could explain acute encephalopathy [4]. Currently, there is no evidence for abnormal activity of the haem-containing enzymes in the neural tissues in AIP.

## Diagnostic Principles

During an acute attack more than five-fold increase in urinary porphyrin precursors (PBG and ALA) is mandatory [1]. Plasma porphyrin emission spectrum should be positive in 615–620 nm and excludes variegate porphyria (624–627 nm). Normal or less than two-fold increase in fecal coproporphyrin with normal III/I isomer ratio (<1) may distinguish AIP from hereditary coproporphyria. Urinary porphyrins are usually also elevated and uroporphyrin levels may exceed those found in patients with porphyria cutanea tarda (see ►Porphyria cutanea tarda) [1].

During remission: increased levels of urinary porphyrin precursors have been found in 85% of patients with AIP [1]. Decreased activity of erythrocyte HMBS has been detected in 85% of the patients with AIP (normal in the variant form). Mutations in the HMBS gene have been identified in 95–99% of the cases. Mutation screening among family members is recommended [3].

## Therapeutic Principles

Hematine (Panhematine®, Ovation Pharmaceuticals, Inc.) or haemarginate (Normosang®, Orphan Europe) are used as a treatment for acute attacks [1]. The drug is administered usually for four consequent days or longer, if required in severe cases. Mild attacks can be treated with glucose infusions (>300 g/day) to avoid fasting.

Symptomatically opiates should be used for pain alleviation, β-blockers for tachycardia and hypertension, neuroleptics and benzodiazepines for vomiting and mental symptoms, and diazepam for seizures [1]. SIADH, which is relatively common during an acute attack, should be treated with water restriction, if S-Na is >125 mmol/L, or infusion of saline (<12 mmol/L/day) if S-Na ≤125 mmol/L or in unconscious patients or with seizures. Dehydration should be avoided especially in renal failure.

Precipitating factors such as certain drugs (www.drugs-porphyria.org/) and alcohol should be eliminated during an acute attack. Proper nutrition including parental nutrition, if necessary, should be provided, and infections should be treated promptly and properly [1].

[1]Maastricht University Center for Molecular Dermatology (MUCMD), University Medical Center Maastricht, Maastricht, The Netherlands
[2]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany

## Synonyms

Symptomatic porphyria; Acquired hepatic porphyria; Chemical porphyria; PCT

## Definition and Characteristics

The cutaneous findings include increased photosensitivity due to photosensitization by porphyrins and skin fragility as well as blistering, erosions, crusts, and miliae on the sun-exposed areas of the body. In addition, hyper-pigmentation, hypertrichosis, sclerodermoid plaques, and scarring alopecia can be observed. The clinical manifestation of PCT is usually precipitated by different triggering factors, among them alcohol, estrogens, polychlorinated hydrocarbons, hemodialysis in patients with renal failure, iron, and viral infections such as hepatitis C and HIV.

## Prevalence

PCT is the most frequent type of porphyria worldwide.

## Genes

PCT (OMIM 176100) results from a decreased catalytic activity of uroporphyrinogen decarboxylase (URO-D) (E.C. 4.1.1.37), the fifth enzyme in heme biosynthesis.

## Molecular and Systemic Pathophysiology

Uroporphyrinogen decarboxylase (URO-D) (E.C. 4.1.1.37) is localized in the cytosol and catalyzes the sequential oxidative decarboxylation of the four acetic acid side-chains of uroporphyrinogen to form the tetra carboxylic coproporphyrinogen. According to the major site of expression of URO-D, at least two types of PCT can be distinguished: A sporadic (acquired) variant, designated type I PCT, in which the enzymatic deficiency is exclusively expressed in the liver and a familial (hereditary) variant, designated type II PCT, in which the catalytic enzymatic defect is detected in all tissues. Currently, the ratio between type I and type II PCT is estimated to be approximately 3:1–4:1. Type II PCT is usually inherited as an autosomal dominant trait, displaying incomplete penetrance, since not all individuals carrying a mutation in the URO-D gene will develop the clinical phenotype. However, rare cases in which the genetic defect was inherited in a recessive fashion have also been described and these patients are referred to as suffering from hepatoerythropoietic porphyria (HEP).

## Diagnostic Principles

Besides the skin findings, the disease reveals a characteristic biochemical porphyrin excretion pattern with increase of uroporphyrin (type I isomers > type III isomers), 7-carboxyl porphyrins (type III isomers > type I isomers), and coproporphyrin in the urine and isocoproporphyrin in the feces. In heterozygotes suffering from type II PCT URO-D activity is decreased by approximately 50% in all cells and, thus, can be assessed by enzyme assays. The diagnosis of type II PCT can be confirmed by the detection of mutations in the URO-D gene on chromosome 1p34.

## Therapeutic Principles

Photoprotection; phlebotomy (500 ml of blood is removed at biweekly intervals until the hemoglobin decreases to approximately 10 g/dL; low-dose chloroquine therapy (125 mg twice weekly over 9–12 months).

Protocoproporphyria; South African genetic porphyria

## Definition and Characteristics

Variegate porphyria (VP) is an acute porphyria that results from the deficiency of the enzyme protoporphyrinogen oxidase (PPO), which catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX. VP has a variable presentation, with both photosensitivity and neurovisceral symptoms occurring separately or together. Photosensitivity and photodermatitis may develop, as in hereditary coproporphyria (HCP) and porphyria cutnea tarda (PCT), but does so at an earlier age than PCT. Patients may present with skin fragility, bullae, erosions or ulcers following mild trauma of light exposed skin, milia, hyper-pigmentation and hypertrichosis of sun exposed areas. Acute neuropsychiatric attacks occur, as in acute intermittent porphyria (AIP), HCP, or δ-amino levulinic acid (ALA) dehydratase porphyria with abdominal pain, vomiting, constipation, tachycardia, hypertension, psychiatric symptoms, and possible quadriplegia. The penetrance of neurovisceral symptoms is lower in VP than in AIP. All patients with VP and the genetic defect are at risk of developing neurovisceral crises, if exposed to alcohol or porphyrinogenic drugs. Hepatic involvement is usually mild, but patients are at increased risk for hepatocellular carcinoma.

## Prevalence

VP is very common in South Africans of Afrikaans descent, with a prevalence of about three in 1,000. In Finland the prevalence is about 1.3 per 100,000. It is much lower in other parts of the world.

## Genes

The gene for the enzyme protoporphyrinogen oxidase (PPOX) has been localized to chromosome 1q22. PPOX is 1431 bp long, has 13 exons and encodes a 477 amino-acid polypeptide. VP is usually inherited in an autosomal dominant pattern with a variable penetrance. 129 different mutations in the PPOX gene have been recorded so far (Cardiff; www.hgmd.cf.ac.uk).The R59W mutation, which is the most common, is seen in approximately 95% of South African cases of VP. The enzyme defect in other geographic regions is not dominated by the R59W mutation. The R59W mutation in PPOX gene creates a *Sty*1 endonuclease cut site, a combination of restriction enzyme and single strand conformation polymorphism (SSCP) analysis now allows a rapid diagnosis of VP in S. Africa.

Rarely, VP patients inherit a PPOX mutation from each parent. They have more severe disease, with onset in childhood but do not show any neurovisceral crises. Homozygosity for R59W has not been reported as yet and is presumed to be embryo lethal. Most patients with severe homozygous VP (HVP) are, in fact, compound heterozygotes, rather than true homozygotes.

The variable degree of clinical presentations could be explained by the high degree of heterogeneity of PPOX mutations and the types of mutations they carry (frame shift, missense, nonsense, and splice site). However, no clear genotypic-phenotypic correlations have been observed thus far.

## Molecular and Systemic Pathophysiology

PPO exists as a inner mitochondrial membrane-embedded flavoprotein, which is responsible for the penultimate step of heme biosynthesis. PPO leads to the removal of six hydrogen atoms from protoporphyrinogen IX to form protoporphyrin IX (Fig. 1: See the Heme Biosynthetic Pathway).

PPO activity is stimulated by glutathione and inhibited by hemin. VP usually results from a heterozygous deficiency of ∼50% PPO activity. Homozygotes or compound heterozygotes show more profound reduction in PPO activity (∼20–25% activity).

5-Amino levulinic acid synthase -1 (ALAS-1) is increased in the livers of VP patients. When hepatic ALAS-1 is induced, there is a marked overproduction of ALA and porphobilinogen (PBG). Porphobilinogen deaminase (PBGD) is inhibited by protoporphyrinogen (increased levels seen in VP), which leads to higher ALA and PBG levels. Protoporphyrinogen undergoes auto oxidation to protoporphyrin before being excreted into bile and feces.

## Diagnostic Principles

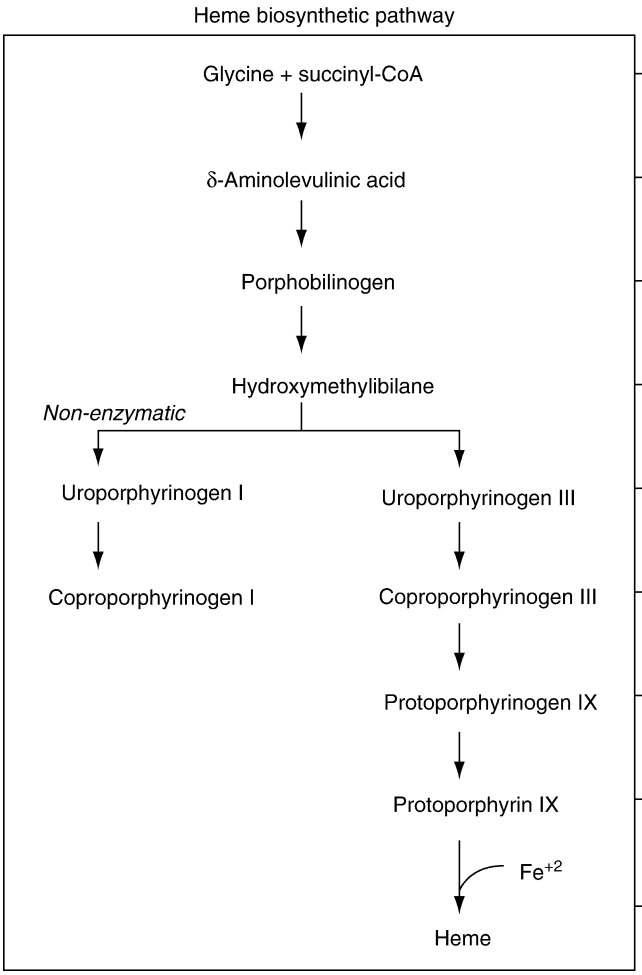
A good initial screening test is the total plasma porphyrin level along with fluorescence pattern analysis, if found to be elevated. In this test, the fluorescence emission spectrum of diluted plasma is measured. The exciting wavelength is the Soret band (400–410 nm). Uro- and copro-porphyrin, which accumulate in PCT or HCP, have a peak emission at 618 nm, whereas protoporphyrin, which accumulates in protoporphyria (PP), shows a peak at 636 nm. A protein-dicarboxyl porphyrin complex unique to VP has a peak at 626 nm. The latter is nearly always present in post-pubertal VP patients, and is the simplest and most reliable method for making a presumptive diagnosis of VP.

Urinary ALA and PBG are increased during an acute attack. The degree of elevation is usually lower than seen in AIP. Erythrocyte PBGD is usually low in AIP but normal in VP.

VP is characterized by increased fecal excretion of protoporphyrin IX and coproporphyrin III. The coproporphyrin III/I ratio permits distinction between VP and AIP. The ratio is >2 in VP but <2 in AIP.

## Therapeutic Principles

Therapy of the acute attacks is the same as for AIP. Prompt identification and discontinuation of



| Enzymes | Diseases |
|---|---|
| ALA Synthase | |
| ALA Dehydratase | ALA dehydratase deficiency |
| Porphobilinogen deaminase | Acute intermittent porphyria |
| Uroporphyrinogen III synthase (cosynthase) | Congentital erythropoietic porphyria |

offending drugs, chemicals and alcohol is important. Adequate attention to hydration and nutrition with at least 300 g/d carbohydrate intake is recommended. Intravenous heme, as heme arginate or hematin, is useful in the acute neurovisceral crises. Cutaneous symptoms are managed as in HCP with protective clothing (Solatene) and opaque sunscreens. Canthraxanthrin (a beta-carotene analog) may be helpful. In contrast to PCT, phlebotomy and antimalarials are not effective for management of VP or HCP. The prognosis for VP is generally good although rarely, acute neurovisceral attacks may be severe or life-threatening especially following ingestion of precipitating drugs. Because of the increased life long risk of development of hepatocellular carcinoma, consideration should be given to screening for this eventuality with repeated measures of serum alpha fetoprotein (AFP), AFP-L3, or des-gamma-carboxy-prothrombin (DCP) also known as PIVKA-II (every 6 m) and abdominal imaging (at least annually).

# Porphyric Neuropathy

Jeffrey C. Wagner, A. Gordon Smith
Department of Neurology, University of Utah School of Medicine, Salt Lake City, UT, USA

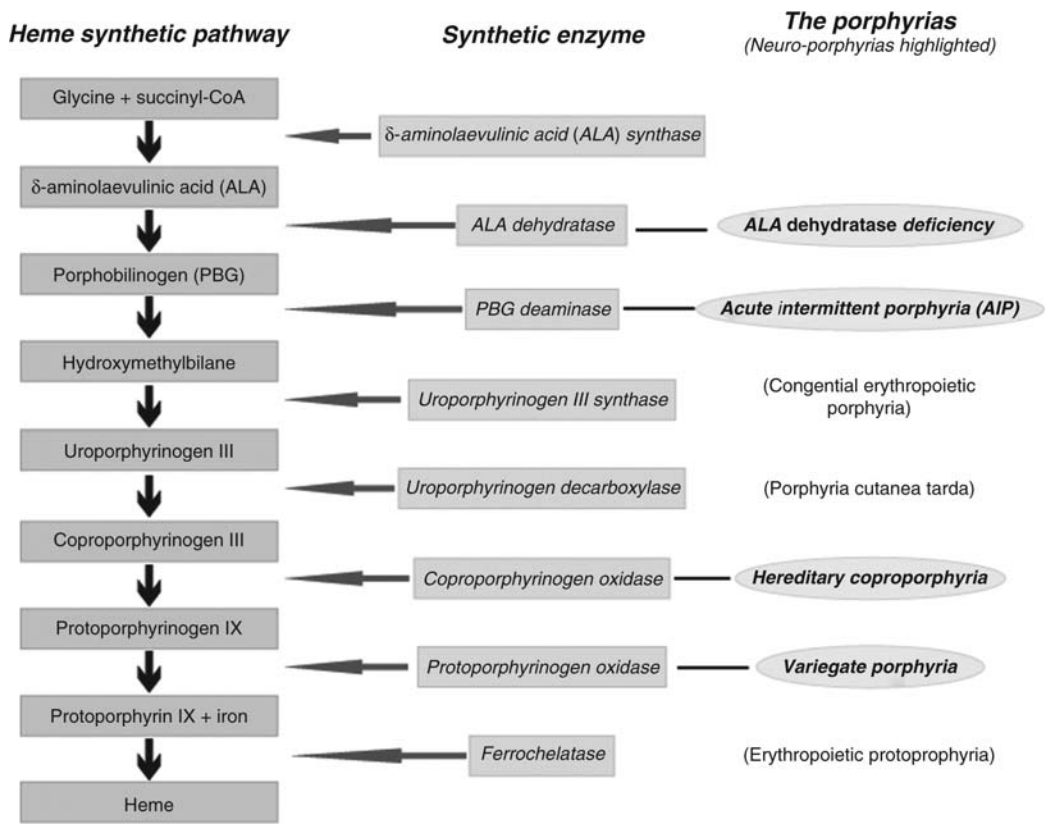
## Definition and Characteristics

Porphyria is derived from *porphuros*, Greek for purple. This refers to the purplish discoloration assumed by urine from some porphyric patients after exposure to light. There are seven porphyric syndromes which result from enzymatic defects in the heme biosynthesis pathway leading to accumulation of toxic heme precursors. (Fig. 1).

Classical acute porphyric attacks are associated with aminolevulinate dehydratase deficiency porphyria (ADDP), acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP). (Fig. 1) Attacks are characterized by abdominal pain often resulting in hospitalization accompanied by psychiatric and central nervous system symptoms [1–3]. These are followed in days to weeks by motor axonal neuropathy, often accompanied by autonomic dysfunction [2]. In severe or unrecognized cases, progression to confusion, seizures, coma and even death can occur.

ADDP is the only recessively inherited form, the only form that presents in infancy and is also the rarest [1]. AIP is the most common form, and is associated with a higher rate of recurrent attacks than other forms [2]. Hepatoma causes death in 10% of patients with AIP, and yearly liver ultrasounds with serum α-fetoprotein levels have been advised in patients over 50 years of age [3]. HCP is rare, and associated with photosensitivity in addition to attacks. Photosensitivity is also a feature of VP, which is rare except in South Africa, where founder effect likely resulted in increased prevalence [2].

Although rare, the combination of psychiatric, gastrointestinal, and characteristic neurologic features should raise the possibility of porphyria. Despite the distinctive clinical and electrodiagnostic features, many cases are mistaken for Guillain-Barré Syndrome. This can result in delayed treatment and increased long-term sequelae. Advances in enzyme analysis and genetic screening have made diagnosis more accurate between attacks.



**Porphyric Neuropathy. Figure 1** Heme biosynthesis pathway with enzymes in italics, porphyrias in boxes with acute (neuro-porphyrias) in bold.

## Prevalence

0.5–10:100,000 depending on the population (3:1,000 Caucasians in South Africa have VP).

## Genes

*ADDP*: aminolevulinate dehydratase gene (9q34), autosomal recessive.
*AIP*: hydroxymethylbilane synthase (porphobilinogen deaminase) gene (11q23.3), autosomal dominant.
*HCP*: coproporphyrinogen oxidase gene (3q12), autosomal dominant.
*VP*: protoporphyrinogen oxidase gene (1q22–23), autosomal dominant.

## Molecular and Systemic Pathophysiology

Heme is synthesized in all cells, but the vast majority occurs in erythroid and hepatic cells [1–3]. Heme is essential for production of myoglobin, hemoglobin and P450 cytochromes. Any factor that increases heme biosynthesis results in accumulation of precursors and can precipitate porphyric symptoms. Because P450 cytochromes contain heme, any substance that up regulates the P450 system can result in a porphyric attack. The most common precipitant of attacks are medications (Table 1), many of which induce P450 production [1,2,4,5].

Estrogen and progesterone also induce the P450 system and have been blamed for the higher incidence of attacks in women [3]. Fasting increases activity of δ-aminolevulinic acid (δ-ALA) synthase and is a recognized precipitant [1,2]. Interestingly, neuropathy associated with lead intoxication may be a result of disrupted heme biosynthesis [1,2].

**Porphyric Neuropathy. Table 1** Drugs that may precipitate acute porphyric attacks [1,2,4,5]

| Probably safe[a] | Unsafe |

| Acetaminophen | Alcohol |
| Aspirin | Barbiturates |
| Atropine | Carbamazepine |
| Diazepam | Chlorpropamide |
| Digoxin | Danazol |
| Glucocorticoids | Ergots |
| Insulin | Griseofulvin |
| Narcotic Analgesics | Halothane |
| Neostigmine | Meprobamate |
| Penicillin | P450 cytochrome inducing agents |
| Phenothiazines | Phenytoin |
| Propofol | Progestins |
| Propranolol | Succinamides |
| Serotonin Reuptake Inhibitors | Sulfonamides |
| Streptomycin | Valproic Acid |

[a]Choices regarding medication use in porphyric patients should be undertaken with caution, weighing potential risks and benefits and considering alternatives. The most up-to-date references should be consulted when possible.

ADDP, AID, HCP, and VP are also known as neuroporphyrias because they cause peripheral nerve injury during attacks [2]. Peripheral neuropathy is typically acute in onset and motor predominant [1,2]. Overall incidence has been estimated at 10–40% of patients [1]. Neuropathy becomes symptomatic within 75 days, and 80% of patients are symptomatic within 30 days of initial porphyric attack symptoms [1]. The classic distribution is proximal more than distal, upper more than lower extremities. A potential explanation for this pattern is that heme precursors may be taken up at axon terminals allowing retrograde transport to the cell body where toxic effects occur [1]. Therefore, nerves with shorter axons would be expected to suffer damage first. For the same reason, it is not surprising that when present, sensory symptoms are classically felt in a "bathing trunk" distribution, with decreased pin-prick over the trunk and thighs. Reflexes may be reduced or absent. Symptoms of autonomic dysfunction are often present, and usually begin with hypertension and tachycardia [3]. Cardiac arrhythmias can develop, and may precede cardiac arrest. Although most symptoms of a porphyric attack resolve quickly after initiating treatment, neuropathy recovers slowly, and deficits can accumulate with subsequent attacks [1]. Long-term deficits are more severe and persistent when treatment is delayed [1].

Nerve conduction studies typically show findings consistent with motor axonal neuropathy without evidence of demyelination [1,2]. Sensory responses are of normal or slightly reduced amplitude with normal latencies. Electromyography shows fibrillation potentials and positive sharp waves in proximal more than distal muscles.

## Diagnostic Principles

Diagnosis depends on identifying heme precursors in urine or feces. During an attack, urinary porphobilinogen should show 20–50 fold elevation compared with reference values in AIP, HCP, and VP [3]. In ADDP and lead toxicity, urinary δ-ALA will be elevated with normal urinary porphobilinogen. Diagnosis is more difficult between attacks, and may require measurement of enzyme activity or genetic testing.

## Therapeutic Principles

Treatment focuses on removing known precipitants of porphyric attacks, and avoiding new precipitants when managing symptoms of an attack [1–3]. As in Guillain-Barré Syndrome, cardiac monitoring may be

needed because of autonomic dysfunction. Adequate caloric intake is needed to suppress δ-ALA synthase activity. If vomiting limits oral intake, glucose infusions can be used. Although a randomized clinical trial of intravenous hematin for acute porphyria did not show significant benefit, it is still used by most treating clinicians because it decreases δ-ALA synthase activity [1–3].

# Portal Hypertension

Maria Mela, Ulrich Thalheimer, Dimitrios Samonakis, Andrew K. Burroughs
Department of Liver Transplantation and Hepatobiliary Surgery, Royal Free Hospital, London, UK

## Synonyms

PHT

## Definition and Characteristics

Portal hypertension (PHT) is defined as a free portal vein pressure in excess of the normal 5–10 mmHg. Depending on the site of increased resistance to portal flow, portal hypertension can be classified as: presinusoidal (intrahepatic and extrahepatic), sinusoidal and post-sinusoidal (intrahepatic and extrahepatic).

## Prevalence

Significant portal hypertension (hepatic venous pressure gradient, HVPG > 10 mmHg) is present in more than 60% of cirrhotics and 90% of portal hypertension cases in the western hemisphere are related to cirrhosis.

## Molecular and Systemic Pathophysiology

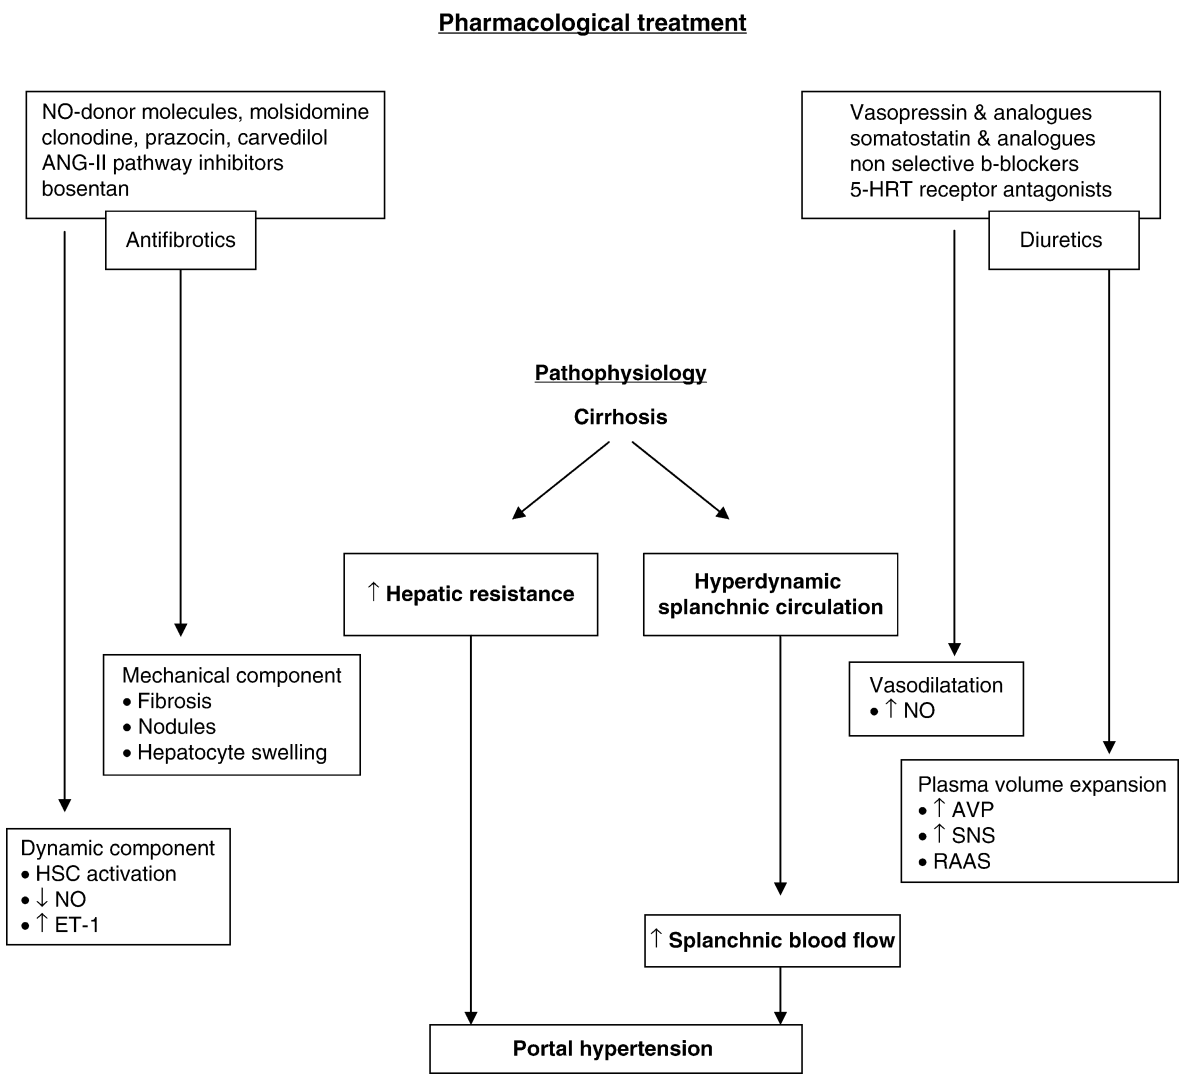
Portal pressure (P) is determined by the portal venous inflow (Q) and the vascular resistance (R) that opposes that flow: $P = Q \times R$ (Ohm's law). In the normal liver, intrahepatic resistance changes with variations in portal blood flow, thereby keeping portal pressure within normal limits. In hepatic cirrhosis however, intrahepatic resistance and splanchnic blood flow are increased. Therefore, portal hypertension is the result of a combination of decreased compliance and increased portal flow Fig. 1.

The major site of resistance is at the level of sinusoids. In cirrhotics, hepatocyte swelling, capillarization of the sinusoids (loss of fenestrations of endothelial cells) and accumulation of fibrillar extracellular matrix are evident. Moreover, distortion of the portal vein branches (pre-sinusoidal) and compression of the hepatic venules by cirrhotic nodules (post-sinusoidal), also contribute in the intrahepatic resistance to portal flow. Along with this "mechanical" increase in hepatic vascular resistance there is a "dynamic" factor which accounts for approximately 30% of the increased resistance. This is a reversible, vascular component closely associated with the function of transformed hepatic stellate cells (HSC) as myofibroblasts. Furthermore, nitric oxide (NO) and endothelins (ETs) are vasoactive compounds that play important role in modulating myofibroblast contractility, and their interplay is a determinant factor of local sinusoidal blood flow, especially in injured liver.

Systemic and splanchnic vasodilatation is an integral part of portal hypertension; the increased splanchnic flow accounts for the increased total blood volume and cardiac output as well as the decreased total vascular resistance with normal to low arterial pressure in cirrhotic patients. The mechanisms underlying the peripheral vasodilatation have not been fully defined but are thought to include increased levels of circulating vasodilators, increased endothelial synthesis of local vasodilators and decreased responsiveness to endogenous vasoconstrictors. Vasodilatory mediators that have been implicated include endothelins, nitric oxide, glucagon, prostacyclin and angiotensin II.

Expansion of plasma volume in another major factor in the development of hyperdynamic circulation. It is believed that dilatation of the systemic and splanchnic vessels leads to a decrease in central arterial blood volume. Subsequently there is a compensatory activation of the renin-angiotensin aldosterone (RAAS), sympathetic (SNS) and vasopressin (AVP) systems. Sodium and water retention then ensue resulting in plasma volume expansion.

Beyond a critical value of portal pressure, portosystemic collaterals form in order to decompress the portal system and minimize the portal hypertension. These collaterals represent the opening of embryonic channels or redistribution of flow in the existing veins. The vascular resistance of the collateral vessels, although lower than that of the obstructed portal system, is nevertheless higher than normal portal resistance. Therefore, even after their formation and in the extreme situation in which virtually all portal flow is diverted to



**Portal Hypertension. Figure 1** Treatment and pathophysiology of portal hypertension.

the systemic circulation, the portal pressure is not normalized. They are not passive conduits; in contrast, they respond reflexively and independently to various hemodynamic and pharmacological stimuli. Factors that modulate collateral resistance are expressed by Poiseuille's formula: $R = 8nl/\pi r^4$ where $n$ is the viscosity of blood, $r$ is the radius and $l$ is the length of the vessel. Under physiologic conditions, $n$ and $l$ are constants. Since resistance changes in proportion to the fourth power of the radius, small changes in vessel size produce large changes in pressure.

Transformed HSC, NO and ET, as already mentioned, play a major role in the pathogenesis of increased intrahepatic resistance and therefore of portal hypertension. Their interaction offers the rational for some of the therapeutic approaches currently used and many more under investigation. *HSC* are resident perisinusoidal mesenchymal cells with a microanatomical position in the sinusoids analogous to vasoregulatory pericytes [1]. They are in close contact with hepatocytes and sinusoid endothelial cells and when quiescent they play a key role in the metabolism of the retinoids. However, in chronic liver tissue damage, HSC as well as other extracellular matrix-producing cells undergo a process of activation from the quiescent "storing" phenotype to a "myofibroblast-like" phenotype. The presence of reiterated liver tissue damage leads to "perpetuation" of HSC activation which is essentially characterized by a definite shift toward phenotypical features favoring vasoactivity and fibrogenesis, cell proliferation, cell migration, increased extracellular matrix synthesis, release of cytokines and growth factors and increased cell contractility.

Several other contractile cell types may contribute to the contraction of the evolving scar tissue typical of cirrhotic liver. In particular, while activated HSC may be important at the edge and within cirrhotic nodules where sinusoids are capillaries, activated portal myofibroblasts and smooth muscle cells, derived from portal arterial vessels, are likely to strongly affect the neoformed vascular structures located in the inner part of fibrous septa.

Several vasoactive agents have been shown to be present in the microenvironment of the hepatic tissue undergoing fibrogenesis and to modulate HSC contractility. The role of NO and ET has been particularly highlighted. NO is an endothelium-derived relaxing factor. As shown by experiments in animal livers, incremental increases in blood flow and subsequent wall shear stress, leads to a flow-dependant increase in NO production serving to limit the increase in perfusion pressure. In the cirrhotic liver however, there is a deficit of NO in the intrahepatic microcirculation [2]. This reduction in endothelial NO, leads to a greater increase in perfusion pressure in response to incremental increases in flow and subsequent shear stress. By impairing flow further due to the mechanical compression, regenerative nodules and fibrosis, higher blood velocities are needed to maintain the flow, higher shear stress is induced and presumably inadequate NO is produced as a response. As a result, there is a greater relative reduction of sinusoidal diameter and increasing portal vascular resistance. In contrast to the impaired NO production in the intrahepatic circulation, splanchnic and systemic vascular NO production is increased [3]. The main enzymatic source for this vascular overproduction has been identified as the endothelial nitric oxide synthase (eNOS) and it appears to be upregulated as normal chronic adaptation of the endothelium in response to chronically elevated splanchnic blood flow in portal hypertension. The exact mechanisms of this manifestation are still unknown.

Endothelin-1 is a vasoactive 21-aminoacid peptide with potent and long lasting constrictor effects in the hepatic portal circulation at a very low concentration [4]. It is secreted by endothelial and other cell types and elicits its biological responses via the heptahelical $ET_A$ and $ET_B$ receptors, which trigger G-mediated receptors. $ET_A$ conveys mostly vasoconstriction and $ET_B$ conveys vasoconstriction and dilatation mediated by two receptor subtypes. Activated HSC express both $ET_A$ and $ET_B$ receptors; since endothelin is overproduced in liver injury (especially in cirrhotic patients with ascites), enhanced stellate cell contractility in this setting may lead to a perisinusoidal constriction and increased intrahepatic resistance. Concomitant contraction of the abundant vascular smooth muscle cells located in the portal venules caused by the same stimuli that contract HSCs also participates in the dynamic component of intrahepatic resistance.

## Diagnostic Principles

The presence of varices, variceal hemorrhage and/or ascites is indicative of the presence of clinically significant portal hypertension (HVPG > 10 mmHg). Duplex-Doppler ultrasonography (DDUS) is useful as an initial diagnostic study; nodular liver surface, splenomegaly, collateral circulation or ascites point towards the diagnosis of chronic liver disease and portal hypertension. Computed tomography is useful when US is inconclusive. It visualizes more accurately the portal vein and the collaterals. MRI angiography detects the presence of portosystemic collaterals and obstruction of portal venous vasculature but it is rarely required for the diagnosis of PHT. PHT is reliably confirmed with the measurement of portal pressure. Direct portal pressure measurement is no longer performed; it is invasive with a high risk of complications. The current practice is to measure the HVPG, which although an indirect measurement, correlates closely with the portal venous pressure in the majority of chronic liver diseases i.e. those with a predominant sinusoidal component. The HVPG value has been found to correspond to morbidity and mortality risks and it is considered to be useful in assessing the efficacy of the various therapeutic modalities. Endoscopic evaluation of gastroesophageal varices in cirrhotics, especially with significant PHT, is mandatory; their presence confirms the diagnosis of portal hypertension but their absence does not exclude it.

## Therapeutic Principles

The improved understanding of the pathophysiology of portal hypertension has provided the rationale for the use of pharmacological approaches to decrease the portal hypertension (Fig. 1). Currently most drugs are directed towards lowering portal blood flow but new drugs acting on the liver microcirculation are investigated. Endoscopic, radiological and surgical therapies are also part of the therapeutic spectrum of PHT.

### Pharmacological Agents

#### *Drugs that Modify Intrahepatic Resistance*

Possible treatments have focused on potentiation of vasodilatory signaling systems (NOcGMP) or inhibition of vasoconstrictive pathways (ET-1, ANG-II, sympathetic a-adrenergic).

*NO-donor molecules*: Nitrovasodilators (Isosorbide-5-mononitrate [ISMN], isosorbide dinitrate) degrade in the blood stream generating bioavailable NO. The NO diffuses directly to effector contractile cells inducing relaxation by cyclic-GMP. ISMN induces significant and sustained reduction in HVPG but it is associated with the development of partial tolerance. Moreover, it is suggested that the systemic vasodilatory action may exacerbate the pre-existing hyperdynamic circulation of

cirrhosis by augmenting venous capacitance and hypovolemia. This "underfilling" may have deleterious effects on long-term hepatic function and renal function. Aiming to increase the intrahepatic production of NO, portal injection of adenovirus coupled with the gene encoding endothelial NO has been reported. This approach enhances the expression of NO-synthase in liver cells and although still experimental and far from being clinically applicable, significantly reduced portal pressure for a short period. *Molsidomine*: While organic nitrates reduce portahepatic pressure, they lower arterial pressure and induce tolerance. Molsidomine, is a preferential venous dilator that like nitrates acts as a relaxant of vascular smooth muscle by increasing circulation of cGMP. It has little effect on arterial pressure in normal subjects and does not produce pharmacological tolerance. Molsidomine has been studied in a cirrhotics' population and found to cause significant and sustained reduction of WHVP (11%), HVPG (15%), and MAP (13.5%). Drugs acting on alpha-adrenergic receptors include prazosin and clonidine. Prazosin is an a-1-receptor blocker producing 18% reduction of HVPG by reducing intrahepatic resistance. It does not affect the cardiac index or the hepatic blood flow and has no effects on renal function and sodium handling. However it is accompanied by a significant fall in the mean arterial pressure. Clonidine is a centrally acting a-2-agonist that acts by reducing peripheral noradrenalin outflow and thus the sympathetic tone in patients with cirrhosis. It has similar to prazosin effects in portal and systemic hemodynamics. Carvedilol is a novel vasodilating non-selective b-blocker with intrinsic a-1 receptor antagonism and calcium channel antagonism. It has a potent portal hypotensive effect, maybe greater than propranolol and in low dose does not seem to have significant systemic effects. Inhibitors of the angiotensin-II (ANG-II) pathway: The actions of ANG-II include: enhancement of the adrenergic vasoconstrictor influence on the portal system, direct contractile influence on stellate cells and therefore increase in the hepatic sinusoidal resistance and, finally, sodium and fluid retention induced by stimulation of aldosterone secretion. Captopril, enalapril, losartan and irbesartan have all been studied in the treatment of portal hypertension. They have been reported to induce marginal or significant reduction in HVPG. However, they cause hypotension and reduce the GFR in patients with moderate liver failure. Therefore, ANG II receptor antagonists may prove to be useful in early cirrhosis for their antifibrotic potential (will be discussed later) but not in late cirrhosis due to their potential deleterious effects on renal function. In view of the increased levels of ET in cirrhotics and its vasoconstrictive action via $ET_A$ and $ET_B$ receptors, Bosentan, a mixed $ET_A$ and $ET_B$ receptor antagonist has been studied in portal hypertensive rats. Bosentan decreased significantly the portal pressure without affecting renal circulation. Similar compounds are currently undergoing to Phase I clinical trials.

*Antifibrotic agents*: Fibrosis remains the principal cause of increased vascular resistance in liver disease and activated HSC together with portal fibroblasts are the major source of the accelerated synthesis and deposition of the extracellular matrix (ECM). Moreover, the vasoactive compounds (ANG-II, ET, NO) play a major role in the injured liver not only by regulation of the intrahepatic blood flow but also by direct modulation of fibrogenesis. ANG-II elicits a marked dose-dependent cell contraction and proliferation in activated human HSC. These effects are totally blocked by losartan and reduced by nitric oxide donors or prostaglandin E2. However, while systemic infusion of ANG-II induces fibrosis in other organs (heart, kidney), no significant fibrotic response has been detected in the liver. HSC are also a major target of ET via type A and type B receptors. Selective $ET_A$ receptor blockade dramatically reduced collagen accumulation in animal experiments. Interestingly, modification of the microcirculation may well have a secondary effect on the fibrogenesis and therefore the interaction of vasoactive drugs/receptor antagonists-HSC-microcirculation-fibrogenesis becomes much more complex.

### Drugs that Decrease the Splanchnic Blood Flow

The decrease in blood flow is mainly achieved with the use of vasoconstrictors that may also cause an increase in the portocollateral resistance by passive collapse of the venous channels due to decreased intravascular volume.

*Vasopressin and its analogues*: Vasopressin through the pathway of phospholipase C, causes splanchnic arteriolar vasoconstriction and decreases portal tributary inflow with a resultant decline in portal pressure. Although hepatic arterial flow increases, total hepatic blood flow usually decreases. The side effects of vasopressin have been reduced with the use of an analogue, terlipressin; the active component is released in a slow manner at target sites. Somatostatin and its analogues: Somatostatin increases splanchnic vascular resistance mainly by inhibiting the release of vasodilatory peptides such as glucagon, vasoactive intestinal peptide and substance P. Therefore it reduces splanchnic and azygos blood flow and portal pressure. On the other hand, it has been reported that in the presence of endothelin-1, somatostatin as well as octreotide, exert a local vasoconstrictive effect on the collateral vessels of portal hypertensive rats. These mechanisms may also play a role in the arrest of hemorrhage, the principal indication for somatostatin use. A number of b-blockers have been studied but only the non-selective b-blockers propranolol and nadolol are currently in use. Propranolol reduces the HVPG by 10–33%. However, 30% of patients fail to

respond after chronic dosing. The fall in portal pressure is produced by a combination of reduced cardiac output ($b_1$ antagonism) and reduced splanchnic blood flow ($b_2$ antagonism). It consistently reduces azygous blood flow that implies reduction in collateral flow; this might be an important mechanism of action in reducing variceal bleeding.

*5-hydroxytryptamine (5-HT) receptor antagonists*: A serotonin mechanism has been reported to contribute to the hyperdynamic circulation of portal hypertension. Following several studies in portal hypertensive rats, single or chronic administration of ketanserin in humans showed significant reduction in HVPG (from 23% to 14.6%) as well as in MAP. The combination of *5HT*3 antagonists with propranolol reduced the HVPG in patients who did not initially responded to propranolol but this reduction was not sustained during follow up.

*Diuretics*: Most patients with portal hypertension have an expanded plasma volume, associated with a peripheral vasodilation. The use of antialdosteronic drugs aims at decreasing portal pressure through a decrease in blood volume. The administration of loop diuretics causes acute depletion of plasma volume, with a reduction of the porto-hepatic gradient, but this depletion is promptly followed by an increase in sodium retention. Chronic administration of spironolactone in patients with cirrhosis without ascites leads to a significant reduction of the HVPG. Moreover, it has been demonstrated that it reduces the esophageal variceal pressure, both as a single agent and in combination with propranolol in nonresponders to b-blockers.

## Endoscopic Therapy for Gastroesophageal Varices

*Sclerotherapy*: The goal of EST is to inject a sclerosant that subsequently results in variceal thrombosis and scarring. It is performed every 10–14 days until the varices are eradicated, which usually takes five or six sessions. Each EST session can cause local or systemic complications. Superficial ulcers resulting from tissue necrosis is the commonest (70% at 1 week) with stricture formation being the most significant long-term complication. After obliteration, varices tend to recur overtime in 50–70% of individuals. Such varices are at risk of bleeding, and surveillance endoscopy must be performed, initially at 6-month and later at 1-year intervals.

*Variceal obturation with tissue adhesives*: The tissue adhesives n-butyl-2-cyanoacrylate and isodutyl-2-cyanoacrylate have been used to treat esophageal and gastric varices. The adhesive is injected into the variceal lumen and within seconds of contact with blood it hardens forming a solid cast of the injected vessel. Mediastinitis, pulmonary embolism and cerebrovascular accidents have been reported following variceal obturation.

*Variceal band ligation*: EVL is highly effective in obliterating varices. An elastic band is used to strangulate the superficial varix, resulting in thrombosis, inflammation, necrosis and sloughing of the mucosa and mural scar formation up to, but not including, the muscularis propria. EVL is associated with fewer complications than sclerotherapy; superficial mucosal ulcers are common but the development of dysphagia from strictures is rare. Similarly to sclerotherapy, ligation is performed every 10–14 days until the varices are eradicated, which typically requires three or four sessions.

## Transjugular Intrahepatic Portosystemic Shunt (TIPS)

TIPS may stop variceal bleeding when traditional endoscopic methods have failed and can be used as a secondary prevention of variceal bleeding [5]. Intractable ascites, and probably hepatic hydrothorax are also indications for treatment with TIPS. The TIPS is a percutaneous intervention used to create a portosystemic shunt. The shunt is established directly inside the liver parenchyma by connecting a main portal branch with a large hepatic vein. The parenchymal tract is kept open by an expandable metallic stent. Depending on the diameter of the stent used to create the TIPS, different proportions of portal blood flow are diverted into the systemic circulation, reducing the portal hypertension. Right heart failure with elevated central venous pressures, severe hepatic failure and uncontrolled hepatic encephalopathy not precipitated by bleeding, constitute absolute contraindications for TIPS. Variceal bleeding, the commonest indication for TIPS, recurs in 21% at 2 years and shunt dysfunction (occlusion or significant stenosis) is almost always the cause. Unfortunately only a few stents remain well patent for years without any intervention; stenosis or occlusion rates reach 50% at 2 years. The decrease or even elimination of the portal flow to the liver may result in transient decrease in liver function but occasionally (1–3%) in progressive liver failure. New hepatic encephalopathy post-TIPS is of major concern and occurs in a range of 12–34%. A percentage of those patients appear to be resistant to medical therapy. New covered stents appear to result in less rebleeding, but these early results need validation

## Surgery

*Decompressive surgical shunts* are suitable for patients with preserved liver function who are non-compliant with medical or endoscopic therapy. They achieve overall rebleeding rate of 14% and survival rate of 86% but they may cause encephalopathy in 21% (severe in 3%). The portal blood flow-preserving procedures (selective shunts, devascularization procedures) achieve more favorable results (rebleeding 6%, postoperative encephalopathy 6%, operative mortality 3% and shunt obstruction 4%) and do not adversely affect the potential for future liver transplantation. Partial shunts (small diameter

portacaval H-graft shunt) have also been shown to have excellent long term survival in non-transplantation candidates with Child's A and B cirrhosis with refractory variceal bleeding (in elective or urgent clinical setting) but are associated with considerable encephalopathy. *Liver transplantation*: Uncontrolled variceal bleeding is one of the highest priority indications for liver transplantation. It is however an exceedingly rare option for the vast majority of patients, both because it is not commonly available and because of shortages and delays in organ procurement. The possibility of future transplantation limits the choice of surgical procedure to distal splenorenal shunt, mesocaval or intercaval interposition shunts and TIPS.

# Portal Vein Thrombosis

Maria Mela, Ulrich Thalheimer, Dimitrios Samonakis, Andrew K. Burroughs
Department of Liver Transplantation and Hepatobiliary Surgery, Royal Free Hospital, London, UK

## Synonyms

PVT

## Definition and Characteristics

Portal vein thrombosis (PVT) represents the commonest form of extrahepatic portal vein obstruction. The most frequent site of thrombosis is at the level of portal vein origin (90%).

## Prevalence

PVT constitutes about 7% of causes of PHT in adults. However, PVT is the main cause of portal hypertension in children. In non-cirrhotic patients, PVT is a relatively uncommon condition in Western countries (<5%) but accounts for up to 40% of cases of PHT in developing countries. The incidence of PVT varies according to the characteristics of the patients evaluated: 35% in patients with hepatic malignancy, 7–16% in cirrhotics, 22% in patients who had history of splenectomy.

## Molecular and Systemic Pathophysiology

PVT is not an all-or-none phenomenon and there are various degrees of PVT, from incomplete and segmental thrombosis to total obstruction of the splanchnic venous system. The site, extent and rapidity of formation of the thrombus determine the clinical consequences and the occurrence of the two most important complications of PVT: intestinal infarction and chronic portal hypertension.

Involvement of the mesenteric veins and venous arches has deleterious effects for the intestine. The mesenteric arches cease to function as collateral circulation to drain intestinal blood toward the adjacent patent territories and this, coupled with reflex arteriolar vasoconstriction result in ischemia and, if prolonged, intestinal infarction.

As regards the liver, occlusion of the portal vein that normally provides two-thirds of the hepatic blood flow does not usually produce an acute manifestation and the signs are absent or transient (at least in patients without cirrhosis). Apoptosis of the liver cells and increased mitotic activity in the well-perfused cells have been demonstrated but these changes are subtle. The explanation of the well-maintained liver function is due to the fact that thrombosis of the portal vein is followed by immediate vasodilation of the hepatic arterial bed. If there is no repermeation of the portal vein, multiple hepatopetal collateral vessels bypassing the thrombosed portion of the portal vein are formed within few days. These represent the cavernoma and form networks within the hepatoduodenal and hepatocolic ligaments, around the common bile duct and gall bladder and over the surface of the liver and terminate in middle-sized intrahepatic portal veins. As a result of these compensatory mechanisms the hepatic flow is maintained or minimally diminished. However, in order for the portal perfusion to be maintained through the collaterals, portal hypertension (presinusoidal type) develops. Patients with PVT have a hyperkinetic circulatory state characterized by increased blood volume, cardiac output and low systemic vascular resistance. The wedged hepatic venous pressure is normal and intrasplenic pressure is significantly elevated. The role of autonomic nervous dysfunction, as has recently been suggested, in the pathogenesis of the above mentioned circulatory changes is controversial.

Primary myeloproliferative disorders and inherited deficiencies in natural inhibitors of coagulation have most frequently been associated with PVT.

Concurrence of prothrombotic disorders is common and local precipitating factors (i.e. inflammatory lesions, injury of the portal venous system and cancer of abdominal organs) should be investigated when recent PVT is diagnosed, even in the presence of a systemic thrombophilic factor [1]. The increased incidence of PVT in patients with cirrhosis may be due to the thrombophilic tendency, decreased blood flow, periportal lymphagitis and fibrosis. At times PVT is idiopathic (8–15%).

## Diagnostic Principles

PVT is commonly a disease of young children. Suspicion of PVT should be present if there is a history of well-tolerated upper gastrointestinal bleeding in the absence of cirrhosis, splenomegaly and in the case of children, growth retardation and repeated infections. The liver function tests are essentially normal and the upper gastrointestinal endoscopy confirms the presence of varices. An accurate diagnosis can be made by duplex or color Doppler-ultrasound; it is 94–100% sensitive and 96% specific [2]. Although the contrast-enhanced CT scan is highly specific, it is less sensitive in detecting thrombus compared with ultrasonography (76 vs. 94%). Both of these can differentiate between recent and old thrombosis-which is essential for the management-in most cases. Angiography serves as both a diagnostic and therapeutic tool in the management of PVT. With the non-invasive technique of magnetic resonance angiography, it is possible to differentiate low-flow states from intraluminal thrombus.

## Therapeutic Principles

The management of patients with PVT is primarily the management of variceal bleeding. Patients with gastric or esophageal varices should receive pharmacological and/or endoscopic therapy for prevention of first or recurrent bleeding as recommended for cirrhotics with portal hypertension. Signs of intestinal infarction necessitate laparotomy, excision of any necrotic bowel and aggressive anticoagulation in cases of massive and extensive PVT; however, mortality remains as high as 76%. The treatment of the underlying disease, e.g. broad-spectrum antibiotics for sepsis, is of major importance.

As to the therapy of the thrombosis itself, no consensus exists. For symptomatic, noncavernomatous PVT the goal of the therapy is to reduce the portal pressure by increasing outflow via the creation of a shunt (but this depends on the extent of the thrombosis) or decreasing inflow (emobilization) and prevent further extension of the thrombus. Many centers prefer the transjugular intrahepatic portosystemic shunt (TIPS) with subsequent anticoagulation as a primary mode of therapy of PVT even in cirrhotic patients that are considered for liver transplantation at a later stage [3]. During the TIPS procedure the portal vein can be recanalized with the use of a combination of angioplasty, mechanical thrombectomy and stent placement. Case reports have described successful catheter directed or systemic thrombolysis for the resolution of the thrombus, but these techniques greatly magnify the already high risk of gastrointestinal hemorrhage and the infusion into the feeding artery is unpredictable because of preferential flow into collaterals. TIPS technical failures may be followed by transhepatic methods of shunt creation or arterial embolotherapy. Careful imaging of the PV is mandatory before the use of TIPS due to the high incidence of hepatoma in cirrhotic PVT patients.

In recent thrombosis, anticoagulation alone has been reported to achieve complete or partial repermeation in 80% of the patients, preventing ischemic intestinal injury in the short term and extrahepatic portal hypertension in the long term. Therefore, some investigators support 6-month anticoagulant therapy, or life long if an underlying thrombophilia has been demonstrated [4]. Time elapsed from the onset of symptoms and etiology of the thrombosis are probably important determinants of the therapy (TIPS and/or anticoagulation) and outcome.

If PVT remains unrecognized and is left untreated symptoms resolve, collateral vessels develop and cavernous transformation of the portal vein and portal hypertension ensue. In this setting the role of anticoagulant therapy is controversial. In retrospective studies, anticoagulant therapy increased neither the risk nor the severity of gastrointestinal bleeding. Moreover it prevented extension and recurrent thrombosis in the portal system. However, indiscriminate use of anticoagulation in chronic portal thrombosis is not advocated. Recurrent GI bleeding from ruptured esophageal varices may be a recurrent manifestation and thus anticoagulation may stand the risk of being deleterious rather than beneficial. Patients with documented or strongly suspected thrombophilia (personal or familial history of recurrent thrombosis) who can be predicted to be at low risk of bleeding (age <50 years, small or absent esophageal varices and no potentially hemorrhagic extrasplanchnic lesions) could be offered permanent anticoagulant therapy. Hepatosplenic embolotherapy has also been suggested for cavernomatous PVT. Once considered a contraindication to liver transplantation, the presence of PVT alone does not preclude patients from undergoing transplant, although a more complex surgery is required and they have more postoperative complications and higher mortality rates [5].

## Postgastrectomy Syndrome

Yogesh M. Shastri, Jürgen M. Stein
Department of Medicine I, ZAFES, J. W. Goethe-University Hospital, Frankfurt, Germany

### Synonyms

Dumping syndrome; Afferent loop syndrome; Efferent loop syndrome; Postgastrectomy malabsorption and anemia; Primary gastric remnant cancer

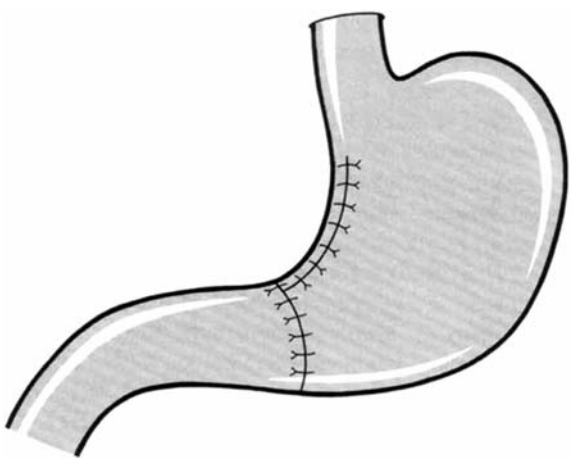
### Definition and Characteristics

Postgastrectomy syndrome is a group of disorders following the surgical removal of the stomach (Figs. 1 and 2). It includes Dumping syndrome (early: symptoms presenting within 10–30 min after eating; late: symptoms occurring within 1–3 h after eating), afferent loop syndrome (characterized by partial/total obstruction of limb of jejunum after Bilroth II, which causes a rapid increase in pressure in afferent loop due to continuing pancreatic and biliary secretion), efferent loop syndrome (obstruction of the efferent jejunal loop after gastric

resection or simple gastroenterostomy), postgastrectomy malabsorption (fat malabsorption), postgastrectomy anemia (due to iron and vitamin deficiency), postgastrectomy bone disease (osteomalacia), and primary gastric remnant cancer (appearance of tumor at least 5 years after primary gastric surgery for a histologically proven benign disease).

## Prevalence

About 25–50% of patients after gastric surgery develop some manifestations of dumping, with 5–10% having clinically significant symptoms, and 1–5% manifest severe disabling symptoms. Incidence and severity of symptoms are directly related to the extent and type of the surgery performed. It is less frequent with Bilroth I than II resection. The majority of patients have early dumping and approximately 25% of these present with late dumping. Dumping is a desired side effect after bariatric surgery and is seen in up to 75% of patients. Afferent loop syndrome is more common than efferent loop syndrome, and both may occur days to years after surgery. Fat malabsorption has an incidence between 60 and 70%, and is more common in Bilroth II; fortunately, in majority of the patients it is mild and chemical rather than clinical. Postgastrectomy anemia has been reported in 3–63% of patients, and incidence increases with time. Subclinical osteomalacia is more common than frank osteomalacia with an incidence of 15–22%. Patients undergoing gastrectomy have twofold increased risk of cancer 15 years after resection. The risk increases with time and is 4–7 times in males as that of females.



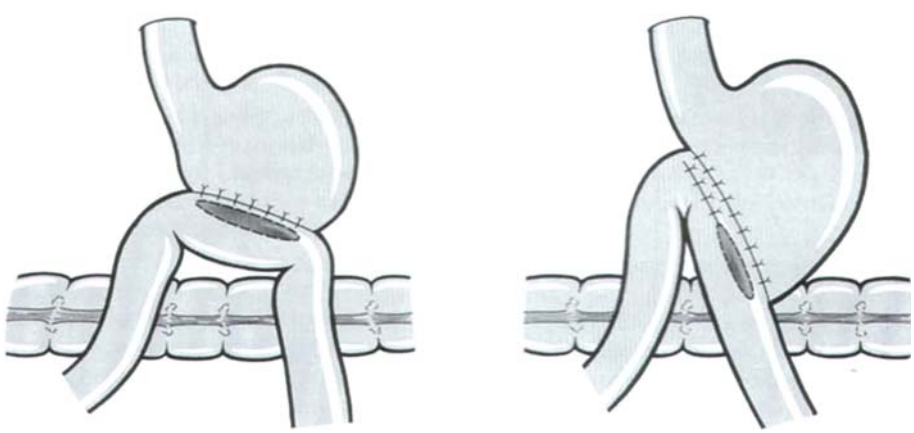
**Postgastrectomy Syndrome. Figure 1** Bilroth I gastroduodenostomy.

## Molecular and Systemic Pathophysiology

Early *dumping syndrome* results from accelerated gastric emptying of hyperosmolar contents from stomach into small bowel, which leads to fluid shift into intestinal lumen and release of vasoactive amines in the gut lumen. Late dumping syndrome is due to hypoglycemia following an exaggerated insulin release induced by rapid passage of carbohydrate into small bowel. Dumping syndrome is associated with vasomotor symptoms (palpitation, fatigue, faintness, syncope, diaphoresis, headache, flushing, sancope, pallor, etc.) and gastrointestinal symptoms (nausea, epigastric fullness, eructations, vomiting, abdominal cramps, borborygmi, bloating, etc.)

*Afferent loop syndrome* can be acute or chronic. Main pathogenic factors include internal hernia, kinking, adhesions, or anastomotic stenosis. There occurs intermittent distention of duodenum, proximal jejunum leading to epigastric/abdominal fullness, and pain. Sudden emptying of the intestinal loop into the gastric remnant results in bilious vomiting with relief of symptoms.

*Efferent loop syndrome* results from internal hernia, scarred stenosis, and adhesions. It manifests as abdominal cramps, around the umbilicus and large voluminous bilious vomit admixed with food.



**Postgastrectomy Syndrome. Figure 2** Bilroth II antecolic gastrojejunostomy.

*Postgastrectomy malabsorption* is usually fat malabsorption (fecal fat >6 g/day). Protein and carbohydrate malabsorption is not clinically significant. Various causes for its occurrence are rapid emptying, stasis and bacterial overgrowth, rapid intestinal transit, poor mixing with bile and pancreatic secretions, pancreatico-cibal asynchrasy.

*Postgastrectomy anemia* is due to iron deficiency (more frequent) and vitamin deficiency, which may coexist. Pathogenesis is attributed to decreased intake, decreased bioavailability, impaired absorption, increased blood loss, lack of intrinsic factor, decrease of gastric acid, bacterial ingestion, and conversion of vitamin $B_{12}$.

*Postgastrectomy bone disease* is due to poor intake, malabsorption of vitamin D, steatorrhea, formation of calcium soaps, and duodenal bypass.

## Diagnostic Principles

*Dumping syndrome*: Diagnosis is mostly clinical by Sigstad's diagnostic scoring system based on symptoms of dumping values; a provocation test with 50 gm of glucose after 10 h of fasting would produce sign and symptoms of dumping, high plasma glucose levels within 60 min of provocative test, and reduced plasma glucose levels 60–180 min later, as well as positive hydrogen breath test after glucose ingestion.

*Afferent loop syndrome*: Diagnosis is mainly clinical and is supplemented by endoscopy, hepatobiliary scintigraphy, CT scan, or MRI.

*Efferent loop syndrome*: is diagnosed with upper GI series.

*Postgastrectomy malabsorption*: is evident from fecal fat >6 g/day.

*Postgastrectomy anemia*: is apparent from blood count, and further diagnosis is directed to iron and vitamins.

*Postgastrectomy bone disease*: is evident from radiographs and analysis of mineral metabolism.

*Primary gastric remnant cancer*: Diagnosis rests on endoscopy.

## Therapeutic Principles

*Dumping syndrome*: Treatment should be almost exclusively dietary. No fluid of any kind during meals; avoid concentrated sweets such as sugar, jelly, pudding, cakes, and also milk and milk products; plan 6–8 meals/day; eat slowly and if possible lie down for 20 min following meal; diet low in simple carbohydrates and high in proteins; starch and glycogen should replace disaccharides and free sugar. Pharmacologic therapy may be required by about 3–5%, who will have persistent dumping symptoms despite changes in diet and who will need some other treatment. Most commonly used drugs are tolbutamide, propranolol (to reduce vasomotor symptoms), serotonin antagonists – cyproheptadine and methysergide maleate, prednisolone and verapamil. Acarbose is a potent alpha glycoside hydrolase inhibitor, which significantly reduces the postprandial rise of insulin by delaying digestion of carbohydrate – useful in late dumping, dose limiting side effects include diarrhea and flatulence. Octreotide acts mainly by inhibiting the release of insulin and other gut-derived hormones, and also decreases the rate of gastric emptying. Dosage is 25–50 µg, 2–3 times/day, 15–30 min before meals. A recent review comparing 7 randomized controlled trials involving 65 patients did prove its efficacy conclusively in patients with severe dumping syndrome. Common side effects are diarrhea and injection aversion. Most patients improve with time, but corrective surgery should be considered if medical and dietary treatment fails in a trial of minimum 1 year. Surgery includes stoma revision, pyloric reconstruction, conversion of Bilroth II to I anastomosis, jejunal interpositions, and the most effective is Roux-en-Y gastrojejunostomy; it is easier to perform and has fewer long-term complications.

*Afferent loop syndrome*: Management is surgical and includes a Roux-en-Y anastomosis, conversion of Bilroth II to I, or jejunostomy between the afferent and the efferent loops to decompress the obstruction.

*Efferent loop syndrome*: Treatment is surgical with second antecolic gastroenterostomy above the first with an enterostomy.

*Postgastrectomy malabsorption*: Treatments include frequent small meals, pancreatic enzymes, and antibiotics, and if it does not work then finally conversion to Bilroth I or jejunal interposition.

*Postgastrectomy anemia*: Treatment is iron and vitamin supplementation.

*Postgastrectomy bone disease*: Vitamin D administration with calcium should result in symptomatic, biochemical, radiological, and histological improvement with in 3–6 months.

*Primary gastric remnant cancer*: The only therapy is surgical resection, though most are unresectable at presentation. The prognosis is dismal.

## Synonyms

PTSD

## Definition and Characteristics

An anxiety disorder persisting in some individuals following an experience of intense fear or helplessness in response to a traumatic event that posed a threat of death or injury to self or others. It is defined according to the duration and intensity of clinical symptoms when these cause functional impairment or subjective distress. Symptoms fall into three clusters including reexperiencing the event (recollections, nightmares, flashbacks, and distress or physiological reactivity to reminders of the event); avoidance of trauma-related stimuli (efforts to avoid trauma-related thoughts, talks, activities, places, or people, or inability to recall aspects of the trauma) with numbing of general responsiveness (diminished interest, social withdrawal, restricted effect or foreshortened sense of future); and increased arousal (difficulties with sleep, concentration, anger outbursts, hypervigilance, and exaggerated startle response) (DSM IV-TR). Persistence of symptoms for over a month from the traumatic event defines acute PTSD and that for over 3 months chronic PTSD.

## Prevalence

U.S. national comorbidity survey rates for life time PTSD prevalence are estimated at 6.8% of the general population [1], with a 3.5% rate of current (12 months) PTSD, and a higher risk for women exposed to trauma. War-related PTSD rates are estimated at one of five of Vietnam era veterans exposed to combat [2]. About 40% of those affected develop a long-term debilitating course with little response to treatment. Chronic PTSD is noted for elevated comorbid rates of depression, nicotine, alcohol and other substance abuse, and other anxiety disorders.

## Genes

The etiology is complex and multifactorial, whereby trauma exposure may trigger underlying genetic vulnerability. Vietnam era twin data show modest heritability in the range of 30% for combat-related PTSD, with both additive and specific genetic contribution for PTSD and comorbid disorders including other anxiety disorders, nicotine, alcohol, and other substance use disorders among trauma survivors. While PTSD might be seen as a typical outcome of gene–environment interaction, the actual underlying genes are unknown.

A number of small effect candidate genes have been implicated with risk for PTSD, but there are currently no replicated gene association findings [3].

## Molecular and Systemic Pathophysiology

The pathophysiology is unknown. Altered physiological endocrine neurochemical immune and gene transcriptional reactivity, as well as functional and structural brain correlates, have all been implicated, but most have not produced consistent findings, and none can be regarded as valid specific markers for PTSD. Cross-sectional studies comparing endophenotypes among Vietnam combat veterans with and without chronic PTSD, and their identical cotwins not exposed to combat, report an acquired attribute of increased startle response, and several predisposing familial factors such as neurological soft signs, diminished hippocampal volume, and the presence of abnormal cavum septum pellucidum [4]. An altered immune response to stress, as well as a differential global gene expression signature in white blood cells, have been described in trauma survivors who develop chronic PTSD, providing preliminary evidence suggesting a general reduction in transcriptional reactivity following trauma may be an underlying feature [5].

## Diagnostic Principles

PTSD diagnosis is based on clinical observation and reported typical enduring symptoms (as above) that are the cause for subjective distress and functional impairment. There are currently no known molecular genetic markers to assist diagnosis.

## Therapeutic Principles

Antidepressants and structured psychological interventions (e.g., cognitive behavioral therapy) alleviate symptoms and subjective distress in subjects with chronic PTSD, and are currently investigated for their effectiveness in preventing the occurrence of chronic PTSD. Preliminary therapeutic studies of glucocorticoids and beta adrenergic receptors blocking agents yielded conflicting results.

# Postural Tachycardia Syndrome

Giris Jacob, David Robertson
Recanati Autonomic Dysfunction Center, Rambam Medical Center, Haifa Israel and the Autonomic Dysfunction Center, Vanderbilt University, Nashville, TN, USA

## Synonyms

Idiopathic orthostatic tachycardia; Orthostatic intolerance; POTS

## Definition and Characteristics

Chronic symptoms suggestive of inadequate cerebral perfusion and sympathetic activation with standing, such as lightheadedness, visual changes, pre-syncope and frank syncope, chest discomfort, fatigue, anxiety, nausea and diaphoresis in the absence of significant orthostatic hypotension. The hallmark of the syndrome is the remarkable increase in heart rate ≥30 beats per min that occurs on the assumption of the upright posture [1].

## Prevalence

The exact prevalence is unknown, but it primarily affects young women (~1:500) with a female to male ratio of about 5:1.

## Genes

One mutation has been identified so far, detected in twins in the norepinephrine transporter (NET) gene on chromosome 16q. This mutation results in the exchange of alanine for proline (Ala457Pro) [2].

## Molecular and Systemic Pathophysiology

Many heterogeneous pathophysiologies underlie POTS. Low blood volume, with and without low plasma renin activity, is found in many patients with POTS [3]. Indeed, correction of this hypovolemia with intravenous saline significantly attenuates the tachycardia as well as almost all of the aforementioned symptoms. A neuropathic form of POTS, resulting from partial or patchy sympathetic denervation was recently described. Because of disordered norepinephrine release in a setting of hypovolemia, orthostatic stress may cause pooling of blood in the abdomen and legs and consequently decrease venous return, which results in tachycardia and cerebral hypoperfusion [4]. In addition, a disturbance in the buffering control of the cardiovascular system is common in patients with POTS. The exact nature of this baroreflex failure and whether it is central or peripheral remains to be explored.

Other pathophysiologies and etiologies have been described, including the first specific genetic defect, described by Shannon et al. [2] in identical female twins with typical POTS. The aforementioned mutation causes a less than 2% functionality of the norepinephrine transporter as compared to the wild type leading ultimately to POTS [4]. Some patients with POTS have autoantibodies directed against the $\alpha_3$ subunit of the $N_N$-nicotinic receptor [5].

## Diagnostic Principles

The occurrence of chronic frequent orthostatic symptoms for more than 6 months, heart rate of greater than 30 beats per min after 10 min of standing without significant drop in blood pressure, and absence of acute or chronic illnesses affecting the autonomic nervous system.

## Therapeutic Principles

The treatment for patients with POTS remains challenging. The use of non-pharmacological tools aiming to increase blood volume and venous return is an

important approach. By encouraging exercise and lower extremity muscle strengthening, a high water and salt diet and in some patients fitted stocking has been effective. A pharmacological approach should be reserved for moderate to severe forms of POTS. This approach includes the use of low doses of β-adrenoreceptor antagonists to attenuate the tachycardia. The α1-adrenoreceptor agonist (i.e. midodrine) seems to be helpful in some patients. Also fludrocortisone is used to increase plasma volume.

### Synonyms

Prader-Labhart-Willi syndrome; PWS

### Definition and Characteristics

Prader-Willi syndrome (PWS) is characterized by hypotonia, hypomentality, hypogonadism, and obesity, and is referred to as the $H_3O$ syndrome [1]. Profound infantile hypotonia contributes to feeding difficulties, failure to thrive, and developmental delay [2]. Affected individuals have an increased percentage of body fat and a reduced lean body mass [2]. Other manifestations include microdontia, enamel hypoplasia, high-arched

palate, narrow forehead, almond-shaped eyes, small-appearing mouth with thin upper lips, down-turned corners of the mouth, small hands and feet, short stature, scoliosis, kyphosis, and characteristic behavioral problems such as temper tantrums, tendency to be argumentative, oppositional, rigid, manipulative, possessive, and stubborn behavior, compulsive snacking, and compulsive skin-picking (Fig. 1) [3,4].

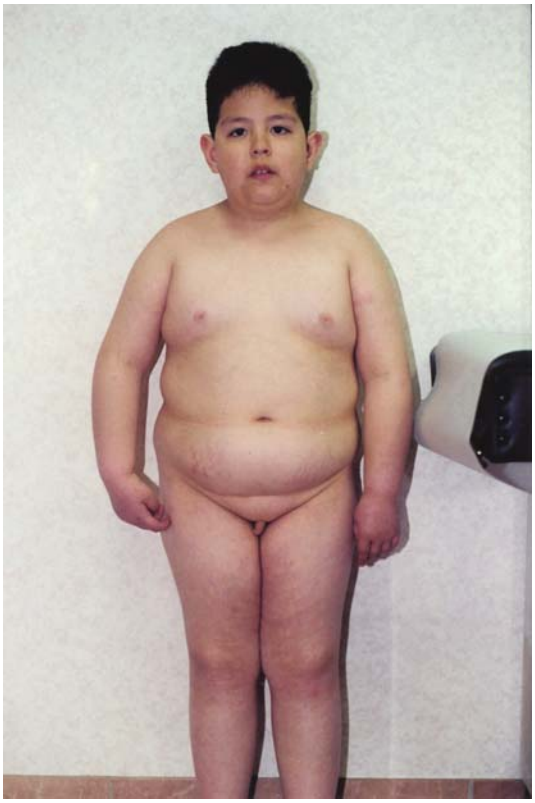
Potential complications include dental caries, pubertal delay, type 2 diabetes mellitus, hypertension, atherosclerosis, joint contracture, osteoporosis, glomerulosclerosis, myeloid leukemia, and development of a Pickwickian or obesity-hypoventilation syndrome [3].

## Prevalence

Current data suggest a prevalence of one in 10,000 to 15,000 [5]. Both sexes are equally affected [5]. All races are affected.

## Genes

Prader-Willi syndrome results from inactivity of the paternal copies of the imprinted ribonucleoprotein N gene (SNRPN), the necdin gene, and other genes on15f [11].



**Prader-Willi Syndrome. Figure 1** A 9-year-old boy with Prader-Willi syndrome. Note the narrowing of the temples, almond-shaped eyes, obesity, and hypogonadism.

## Molecular and Systemic Pathophysiology

Approximately 70% of cases are due to a paternal deletion of chromosome 15q11–q13, 25% are due to maternal uniparental disomy (presence of two maternal homologous), and <5% are due to paternal imprinting defects such as failure to maintain activation of the 15q11–q13 region of the paternal chromosome or to translocation at the PWS locus [4]. Hypothalamic dysfunction accounts for many of the features of PWS. Both serum growth hormone and insulin-like growth factor-1 levels are low in children with PWS.

## Diagnostic Principles

There are published consensus clinical criteria for the diagnosis of PWS [4,5]. Nevertheless, DNA testing with fluorescent in situ hybridization or methylation analysis has become the standard because the DNA testing allows an earlier diagnosis and is essential for genetic counseling [5].

## Therapeutic Principles

The management should be individualized, and should involve a multi-disciplinary team, which includes a dietitian, occupational therapist, speech and language pathologist, social worker, school teacher, physicians of various specialties, and the family. A healthy diet that avoids excess consumption of calories and a structured program of daily physical activity is important. Medical treatment consists of the prevention and treatment of obesity and the management of general health and medical problems as they arise. Growth hormone therapy instituted early in life can accelerate growth and increase the final height, normalize the lean body mass adjusted for height, delay fatty tissue accumulation, and accelerate motor development [4].

►Preauricular Sinus

# Preauricular Sinus

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Preauricular pit; Preauricular tract; Preauricular fistula; Preauricular cyst

## Definition and Characteristics

A preauricular sinus presents as a small blind-ended opening in the external ear, usually located at or near the anterior limb of the ascending helix [1]. Rarely, the opening is found at the superoposterior edge of the helix, the tragus or the lobule [2]. The visible pit may represent the full extent of the deformity or it may represent the opening of a sinus tract that can vary in length, branch, follow a tortuous course, and have a cystic component [2]. The sinus tract often connects to the perichondrium of the auricular cartilage and is usually lateral, superior, and posterior to the facial nerve and parotid gland [3]. Preauricular sinuses are more frequent on the right side and are bilateral in 25–50% of cases [3]. Majority of cases are asymptomatic. At times, a preauricular sinus may become infected, presenting with redness and swelling of the surrounding tissue and a purulent discharge (Fig. 1).

The preauricular sinus has been described as part of a number of syndromes, notably branchio-oto-renal syndrome [1,3]. Other syndromes include branchio-otic, branchio-oto-ureteral, branchio-oto-costal, branchio-oculo-facial, Waardenburg, and trisomy 22 [2,3].

**Preauricular Sinus. Figure 1** A 2-year-old child with left preauricular sinusitis, presenting with redness and swelling in the preauricular area.

## Prevalence

Preauricular sinuses occur in approximately 0.1–1% of whites, 4–5% of blacks, and up to 10% of orientals [1]. The sex ratio is equal. Most cases are sporadic.

## Genes

Bilateral cases are more likely to be inherited [2]. When the condition is inherited, the pattern is of incomplete autosomal dominance with reduced penetrance and variable expression [2]. The gene locus has been mapped to chromosome 8q11.1–q13.3 [2]. The branchio-oto-renal syndrome is caused by mutations in the EYAI gene.

## Molecular and Systemic Pathophysiology

Embryologically, the six auditory hillocks, derived from the caudal border of the first branchial arch and the cephalic border of the second branchial arch, unite to form the external ear. Defective fusion of one or more of the six auricular hillocks results in the formation of a preauricular sinus [1].

## Diagnostic Principles

The diagnosis is mainly clinical and usually clear-cut. When the condition is complicated by abscess formation, it may simulate a furuncle or an infected sebaceous cyst. A thorough clinical evaluation is necessary to look for associated anomalies. Renal ultrasonography should be considered in patients with preauricular sinuses accompanied by one or more of the following: another malformation or dysmorphic feature, a family history of deafness and auricular or renal malformation, and a maternal history of gestational diabetes mellitus [4].

## Therapeutic Principles

No treatment is necessary unless the sinus is infected. Antimicrobial therapy is indicated for the treatment

of preauricular sinusitis, and incision and drainage for a preauricular abscess. Once infection occurs, the risk of recurrence is high. At this point, the sinus tract should be surgically excised, as recurrent infections may cause fibrosis around the sinus making complete excision more difficult. Incomplete resection is the main factor in recurrence. To aid complete resection of the sinus tract, pre-operative sonography, pre-operative sinograms and intra-operative methylene blue injection and the use of a lacrimal probe have been used [2]. Recurrence occurs in 9–42% of patients [3]. Recurrence rates are influenced by the surgical technique used, experience of the surgeon, the number of infections, severity of the infection, and previous surgery [5].

### Synonyms

Pregnancy-induced hypertension with proteinuria

### Definition and Characteristics

Pre-eclampsia (PE) is diagnosed in the presence of hypertension (i.e. blood pressure ≥140/90 mmHg after 20th week of gestation in previously normotensive women) accompanied by proteinuria (≥300 mg in 24-h urine sample) [1].

PE is unique to human pregnancy and a leading cause of maternal and perinatal morbidity and mortality worldwide. Risk factors for PE are nulliparity, a family or own history of PE, pre-existing diabetes or increased body mass index, multiple pregnancy, maternal age > 40, ≥10 years since the last pregnancy, renal disease, hypertension or raised blood pressure at booking and chronic autoimmune disease. Other risk factors are thrambophilias, insulin resistance in concert with obesity and in the developing world malnutrition is also considered. The clinical symptoms (e.g. edema, headache, visual changes, mid epigastric or right upper quadrant pain, nausea, vomiting, oliguria or shortness of breath) differ in prevalence and severity. The most common form of PE manifests as late-onset (>34 weeks) and a slowly progressing disease without any subjective symptoms or related pathology. Early onset of PE (i.e. <34 weeks) is more often severe causing maternal and fetal morbidity with increased risk for growth restriction (IUGR), fetal asphyxia and placental abruption. This form of PE, especially if recurrent in subsequent pregnancies, may include impairment in liver and kidney functions, coagulation and central nervous system and be related to maternal chronic diseases such as thrombophilia and renal diseases [1]. Current epidemiological evidence implies that women with history of PE are even at increased risk to develop hypertension, coronary and cerebro-vascular disease in later life. In addition, IUGR can "program" the new-born to develop metabolic syndrome and thereby cardiovascular disease [2].

### Prevalence

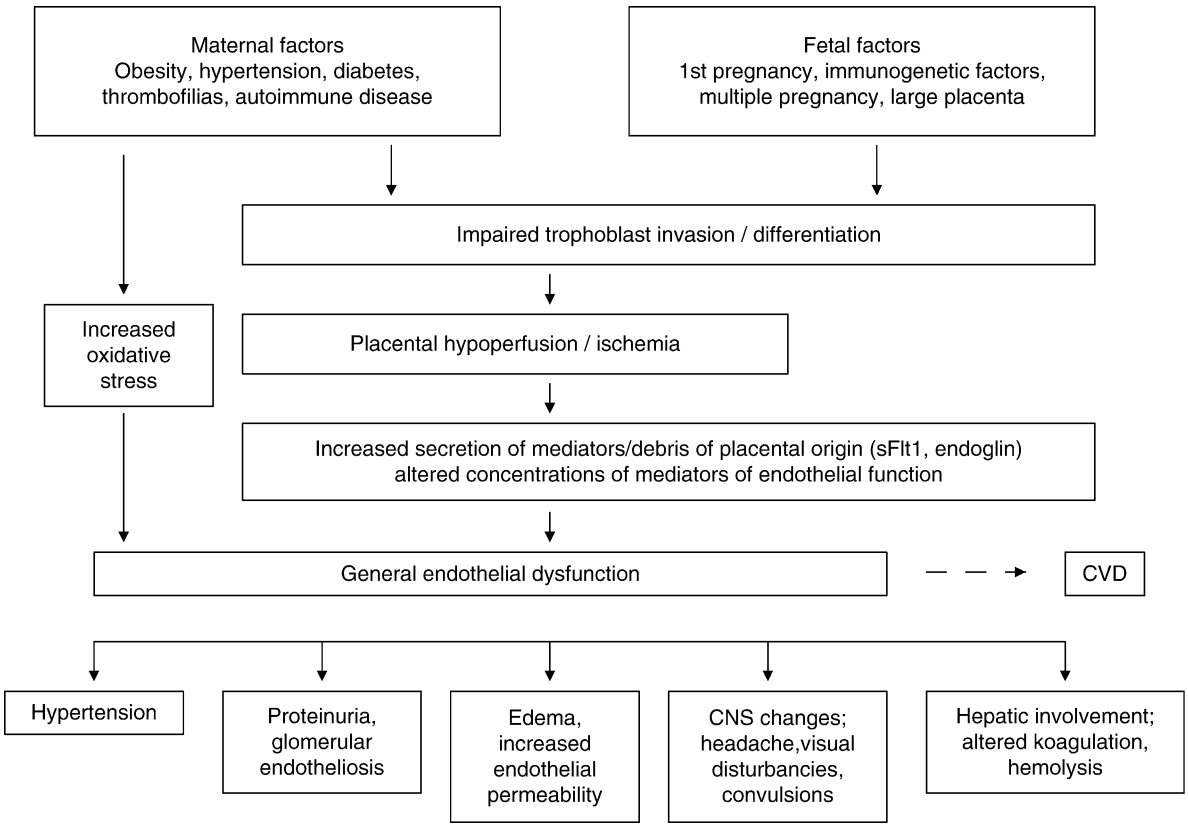
The prevalence is up to 7% in all pregnancies in the Western world but is up to three times higher in the developing countries [1].

## Genes

There is a familial predisposition to preeclampsia; first degree relatives (mother, sisters) have a fourfold increased risk for PE, however the mode of inheritance is unclear. It is unlikely that a single susceptibility gene accounts for genetic predisposition; over 50 candidate genes have been reported encoding elements of renin-angiotensin system, thrombophilias, placentation, vascular remodeling and genes involved in oxidative stress and endothelial cell dysfunction [3].

## Molecular and Systemic Pathophysiology

The etiology remains elusive. The first phase is considered to be the sub-optimal placentation due to a poor cytotrophoblast invasion and failure of maternal spiral arteries to undergo subsequent remodeling process to form maximally dilated low resistance vascular system. Additionally, spiral arteries show often acute atherosis (necrosis, fibrin deposits, foam cells) thickening the vascular wall. Resulting reduced uteroplacental blood flow and placental ischemia leads to the release of placental factor/s with detrimental effects upon the maternal vascular endothelium. The strongest candidate is the soluble form of vascular endothelial growth factor receptor, fms-like tyrosine kinase (sFlt) that also targets placental growth factor. As result, endothelial and placental (trophoblast) growth will be stunted, leading to PE. In addition, soluble endoglin seems to cooperate with sFlt to induce endothelial malfunction. The poor placentation does not always result in PE; combination with maternal susceptibility (e.g. diabetes, hypertension, microvascular disease) increases the risk. PE could also be caused by an exaggerated maternal inflammatory response towards the presence of trophoblast debris. The second phase is a widespread endothelial dysfunction characterized by extensive vascular permeability and vasoconstriction



**Pre-Eclampsia. Figure 1** Hypothetic pathophysiology of pre-eclampsia (PE). Maternal and/or fetal factors contribute to the abnormal placentation characterized by impaired trophoblast invasion and differentiation, phase 1 in PE. Resulting reduced placental perfusion together with ischemia activates the release of placental debris and/or mediators affecting endothelial function directly or indirectly. Pre-existing maternal factors may have a direct effect on endothelial function, e.g. via increased oxidative stress, increasing the risk for severe PE. Generalized endothelial dysfunction (phase 2) precedes the clinical features like hypertension, edema, proteinuria, symptoms from CNS or hepatic involvement. Women with previous PE have increased risk for CVD which may be mediated by endothelial dysfunction. *sFlt1* fms-like tyrosine kinase 1, *CNS* central nervous system; *CVD* cardiovascular disease.

leading to an inadequate hemodynamic adaptation to pregnancy and development of clinical manifestations. Markers of endothelial dysfunction are elevated during PE, including vascular cellular adhesion molecule-1, intercellular adhesion molecule-1, E-selectin, endothelin-1 and cellular fibronectin. Women with PE are more likely to have impaired uterine artery doppler waveforms, reduced flow-mediated dilation of the brachial artery and functional abnormalities in small arteries ex vivo.

Higher levels of cytokines such as tumor necrosis factor alpha, interferon gamma, interleukin-6, interleukin-1, and C-reactive protein will result in a pro-inflammatory and pro-thrombotic phenotype. Subsequent activation of endothelial cells leads to expression of adhesion molecules and production chemo-attractants for leukocyte recruitment and infiltration enhancing the inflammation. Hypoxic placenta will suffer oxidative stress and increased oxidative markers (e.g. F2-isoprostanes, malondialdehyde) are apparent. Disequilibrium between antioxidant defenses and production of reactive oxygen species favors the latter. Free radicals per se are detrimental to endothelial cells through lipid peroxidation of membranes and oxidation of lipoproteins. Reactive oxygen species may also activate pro-inflammatory transcription factors such as NF-kappaB, which controls the expression of adhesion molecules and inflammatory factors. These proinflammatory factors are mostly attributed to pregnancy but their levels can be exaggerated due to maternal constitutional factors such as obesity and tendency towards the metabolic syndrome [1,4,5] (Fig. 1).

## Therapeutic Principles

Delivery is the definitive cure for PE, when there are persistent severe symptoms, multiorgan dysfunction, severe intrauterine growth restriction, suspected abruption placentae, or non-reassuring fetal status. Meanwhile, the therapy is directed to stabilization of blood pressure with antihypertensive medication and rest. If needed magnesium sulfate is given to prevent convulsions. Mild, late-onset disease needs regular observation and controls in maternity unit and an induction of labor, if needed. There is currently no single test for effective prediction of PE [1]. The mechanisms of pre-eclampsia may open new modalities towards primary prevention of later cardiovascular morbidity in women with previous PE [2].

# Preexcitation Syndrome

Radosław Lenarczyk, Oskar Kowalski, Zbigniew Kalarus
First Department of Cardiology, Silesian Medical School, Silesian Center for Heart Disease, Zabrze, Poland

## Synonyms

Wolff-Parkinson-White syndrome; WPW

## Definition and Characteristics

Congenital syndrome in which the ventricular muscle is excited electrically earlier than it would occur if the impulse was conducted to the ventricles only through the physiological atrioventricular conduction system. Preexcitation syndrome (PS) results from the developmental defect of the atrioventricular electrical insulation of the heart, in the most common form due to a persistence of abnormal muscular connection – the accessory pathway (AP) bridging electrically either left or right atrium to the ventricle (atrioventricular AP, formerly called Kent fibers). Atrioventricular APs with the ability to conduct the impulse anterogradely – from atria to ventricles (overt preexcitation) produce a specific electrocardiographic pattern of ventricular preexcitation – a short PQ interval, widened QRS complexes with a slurring in an initial part (delta wave), and changes in ST-T segment. The presence of AP is a substrate for atrioventricular reentry tachycardia (AVRT), which is the main feature of PS. In the majority of patients, this arrhythmia, usually presenting as narrow-QRS tachycardia, manifesting clinically as paroxysmal palpitations. In some patients, AVRT can cause presyncope, syncope, exacerbation of coronary insufficiency, or heart failure. The term WPW syndrome refers to the presence of electrocardiographic signs of preexcitation and the symptomatic tachycardia. In patients with the permanent form of AVRT, tachycardia-induced cardiomyopathy can develop. Patients with PS have a higher incidence of atrial fibrillation (prevalence of 11–40:100) than the general population.

This arrhythmia can be life threatening in PS, as it can result in extremely fast ventricular rates that initiate ventricular fibrillation (an estimated incidence of sudden deaths in PS is about 0.6%/year). The reasons for higher incidence of atrial fibrillation in PS population are not clear, but may be due to the presence of AP itself, specific features of AVRT seen in some patients, or primary atrial pathology [1].

## Prevalence

With an incidence of 15–31/10,000, PS is the second most common cause of paroxysmal supraventricular arrhythmia in the Western countries.

## Genes

In the vast majority of patients with otherwise structurally normal hearts WPW is a sporadic disease, without an obvious underlying genetic factor. In some cases, isolated WPW can be familiar (3.4%) and the pattern of inheritance appears to be autosomal dominant [2]. However, in these cases no disease-linked genes have been identified. Patients with familiar WPW are more likely to have multiple APs and appear to be at higher risk of sudden death. In rare cases, PS can accompany other cardiac or multi-organ genetic diseases. These include Ebstein's anomaly (6–30% of patients), familiar hypertrophic cardiomyopathy, Pompe disease, Danon disease, tuberous sclerosis, and Leber's hereditary optic neuropathy. However, no clear association between particular genes or mutations and the persistence of AP has been found in any of these entities. The only syndrome in which such association was found is the rare autosomal-dominant syndrome characterized by WPW, progressive disease of the cardiac conduction system, and hypertrophic cardiomyopathy. The syndrome is caused by mutation in PRKAG2 encoding the gamma-2 subunit of the AMP-activated serine/threonine kinase (AMPK). The gene contains 16 exons, >280 kb of DNA and is located on the 7q3 chromosome [3,4]. Apart from the historically first identified missense mutation (R302Q), at least five other disease-causing mutations have been described so far [5]. AMPK is a trimeric protein, which is composed of three units: a catalytic alpha subunit (63kDa), a noncatalytic beta subunit (30kDa), and a noncatalytic regulatory gamma subunit (37–63kDa). Each of units consists of multiple subunits (α1, α 2, β1, β2, γ1, γ2, and γ3) coded by different genes.

## Molecular and Systemic Pathophysiology

AMPK is activated in the states of the metabolic stress by an upstream AMPK kinase (which phosphotylates the α subunit) and by AMP. Beta unit regulates AMPK activity and beta unit localization, and gamma unit regulates binding affinity for AMP. Activation of AMPK in response to high cellular energetic demand regulates various ATP-consuming and ATP-generating pathways, decreasing the use of ATP for nonessential functions and stimulating ATP-producing pathways. The activated enzyme regulates lipid metabolism (inhibiting HMGCoA reductase, acetyl-CoA carboxylase, glycerophosphate acyltransferase, activating malonyl-CoA decarboxylase), increases the glucose uptake by skeletal, cardiac muscle, and adipocytes, activates 6-phosphorofructoso-2-kinase and glycolysis in cardiac muscle, inhibits protein, cholesterol, and fatty acids synthesis, and activates endothelial nitric synthase and ion channels activity. AMPK regulates genes transcription, using transcription factor HNF-4α and transcriptional co-activator p300 as substrates. The molecular mechanisms responsible for the abnormal development of atrioventricular rings in the hearts of patients with the mutant AMPK remain unknown. The effects of PRKAG2 mutation on AMPK activity is controversial (some authors report increased, while others report decreased, activity of the kinase), and distinct, time-related effect of different mutations on AMPK is possible. The phenotypic expression of the various mutations is however virtually identical, leading to intracellular glycogen accumulation (possibly due to elevated glucose uptake) with resultant specific cardiac histopathology: enlarged myocytes with vacuoles containing amylopectin, a insoluble glycogen derivative. Glycogen accumulation is a hypothetic factor responsible for AP persistence (similarly to Pompe or Danon disease); however, the exact pathomechanism of this process is unknown. Two hypotheses are considered: embryonic connections between atria and ventricles that normally regress due to atrioventricular rings development, persist in subjects with mutant AMPK, or glycogen deposits activate silent accessory pathways.

## Diagnostic Principles

In patients with overt PS standard ECG can be used to assess AP location. An invasive electrophysiological study is a "gold standard" in patients with symptomatic narrow QRS tachycardia, as it allows determining the type and exact localization of accessory connection. In patients with coexisting ventricular hypertrophy and conduction disturbances, genetic screening may be advisable to detect PRKAG2 mutation.

## Therapeutic Principles

Acute treatment of AVRT – vagal maneuvers, intravenous adenosine (nondihydropyridine calcium-channel antagonist if adenosine contraindicated), intravenous procainamide if wide-QRS arrhythmia, direct-current cardioversion, or adenosine if unstable hemodynamically.

Recurrent AVRT – radiofrequency current ablation is a first line therapy in symptomatic patients and in

asymptomatic high-risk occupations (competitive athletes, pilots, bus drivers, etc). Long-term therapy with flecainide, propafenone, amiodarone, or a beta-blocking agent can be used in patients who do not wish to undergo catheter ablation.

# Pregnancy-induced Hypertension with Proteinuria

►Pre-Eclampsia

# Premature Complexes, Atrial and Ventricular

Dan Wichterle
2nd Department of Internal Medicine, 1st Medical School, Charles University, Prague, Czech Republic

## Synonyms

Atrial/ventricular premature complexes/contractions/beats; APCs; VPCs

## Definition and Characteristics

Atrial/ventricular premature complexes (APCs, VPCs) are due to deranged impulse formation caused by enhanced normal (or abnormal) automaticity or triggered activity in latent (subsidiary) pacemaker cells in atria, coronary sinus, pulmonary veins, AV junction, His-Purkinje system, and ventricles.

## Prevalence

Both atrial and ventricular premature complexes can be found on 24-h Holter monitoring in over 60% of normal adults and in up to 80% of patients with structural heart disease.

## Molecular and Systemic Pathophysiology

Abnormal automaticity governed by $K^+$ and long-lasting $Ca^+$ currents can rise from cells that have reduced maximum diastolic potentials (>−50 mV). Automaticity at membrane potentials <−70 mV may be due to hyperpolarization-activated (pacemaker) current. Electrotonic effects from surrounding normally polarized or more depolarized myocardium influence the development of automaticity.

Triggered activity is pacemaker activity that results from a preceding impulse or series of impulses. It is initiated by afterdepolarizations – depolarizing oscillations in membrane voltage induced by one or more action potentials.

Afterdepolarizations are due to a variety of conditions:

(1) Excessive $Ca^{2+}$ accumulation in the sarcoplasmic reticulum during action potential prolongation, spontaneous sarcoplasmic reticulum $Ca^{2+}$ release, and subsequent activation of $Ca^{2+}$-dependent $Cl^-$ currents or the electrogenic $Na^{2+}/Ca^{2+}$ exchanger current.
(2) Spatial dispersion of repolarization due to electrophysiological distinctions among epicardial, midmyocardial, and endocardial myocytes with different density and/or properties of ionic channels (transient outward $K^+$ current, slow delayed $K^+$ rectifier current, late $Na^+$ current, and inward $Na^+/Ca^+$ exchanger current).
(3) Sympathetic stimulation.

These depolarizations can occur before (phases 2 and 3) or after full repolarization (phase 4), and are best termed early (EADs) and delayed afterdepolarization (DADs), respectively.EADs may be responsible for ventricular arrhythmias during bradycardia, hypokalemia, or other situations such as the acquired and congenital forms of the long QT syndrome.DADs most likely play a causative role in arrhythmogenesis in the failing hearts. This triggered activity was also observed in pulmonary veins, during digitalis intoxication, and in acute infarction and/or reperfusion.

## Diagnostic Principles

APCs are recognized on ECG as early P waves with morphology that differs from the sinus P wave. After early APCs conduction, delay may be observed and very early may even be blocked in the atrioventricular node. Most commonly, an APC enters and resets the sinus node, so that the postextrasystolic pause is less than fully compensatory. The QRS complex following most APCs is normal, although early APCs may be followed by aberrantly conducted QRS complexes due to the premature complex falling within the relative refractory period of the His-Purkinje system.

VPCs are recognized by wide (usually >0.14 s), bizarre QRS complexes that are not preceded by P waves. When they arise in the specialized conduction system, they may be <0.12 s in duration. Most commonly, VPCs are not conducted retrogradely to the atrium to reset the sinoatrial node. Thus, they result in a fully compensatory pause. VPCs may also manifest retrograde conduction to atrium and cause inverted P waves in inferior leads and less than compensatory pause.

## Therapeutic Principles

Most APCs are asymptomatic, and treatment is not required. When they cause palpitations or trigger paroxysmal supraventricular tachycardias, treatment may be useful. Factors that precipitate APCs, such as alcohol, tobacco, or adrenergic stimulants, should be identified and eliminated. In their absence, mild sedation or use of a beta blocker may be tried.

Isolated asymptomatic VPCs in the absence of cardiac disease, regardless of configuration and frequency, need no treatment. Beta blockers may be successful in managing symptomatic VPCs. For other antiarrhythmic agents, proarrhythmia risk-to-benefit ratio should be considered, especially in patients with structural heart disease. In them, frequent VPCs are associated with an increased risk of cardiac death. However, the relationship of abolition of ventricular ectopy to the reduction of fatal events has never been established.

Catheter ablation strategies may be used for the treatment of highly symptomatic and drug-resistant patients.

# Premature Thelarche

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

The cardinal feature of premature thelarche is breast development that occurs without additional signs of sexual maturation in children younger than 8 years [1]. The condition most often manifests between the first and third years of life, and the enlargement may involve only one breast or one breast more than the other (Fig. 1) [1].

No significant changes of the nipples or areolae occur. Enlarged breast tissue may be tender, but usually the tenderness is transient. The vulva, labia majora, labia minora, and vagina remain infantile in appearance [1]. Pubic hair and axillary hair do not develop. Body habitus is child-like and does not show mature contours. Growth and osseous maturation are normal, and the child generally is of normal height and weight [1]. Menarche occurs at the usual age, and the patterns of adolescent sexual development and function are normal.

## Prevalence

The incidence has been estimated to be 21:100,000 person/year [2].

## Genes

Activating mutations in the Gsα and FSH receptor genes are not a major cause of premature thelarche whereas polymorphisms of the FSH receptor are common [3]. Activating mutations of GNASI gene are responsible for some cases of premature thelarche [4].

## Molecular and Systemic Pathophysiology

Premature thelarche may be the result of an "overactivation" of the hypothalamic-pituitary-gonadal axis in early childhood secondary to altered sensitivity to steroids of the hypothalamic receptors controlling sexual maturation with temporary FSH–stimulated increases of ovarian estrogen secretion [5]. Increased sensitivity of breast tissue to estrogen is another possible cause. A relationship between neonatal mammary hyperplasia and premature thelarche has been suggested since some children with premature thelarche have had hyperplasia of the breast tissue in the neonatal period [5]. Premature thelarche may result from exposure to exogenous estrogens, either indirectly

**Premature Thelarche. Figure 1** An 18-month old child with premature thelarche.

through the nursing mother, or directly through estrogen-containing foods, drugs, or cosmetics. Although the occurrence is usually sporadic, a number of familial cases have been described [5].

## Diagnostic Principles

Premature thelarche must be differentiated from neonatal hyperplasia of the breast, which can occur in either sex and generally subsides spontaneously within a few weeks or months, although in some cases, the hyperplasia of the breast may persist [5]. Premature thelarche must also be differentiated from adiposal breast tissue in obese children, neurofibroma of the chest wall, precocious puberty, or pseudoprecocious puberty [5]. The latter may be caused by an ovarian or feminizing adrenal tumor. Malignant tumors of the breast are extremely rare in children. The diagnosis is usually a clinical one. Provided the growth is normal and there are no other signs of sexual maturation, laboratory studies are not necessary. In suspicious cases, serum estradial and skeletal age should be obtained. In premature thelarche, the serum estradial level is within the normal range for prepubertal girls and the skeletal age is normal [5].

## Therapeutic Principles

Premature thelarche is a benign condition and no therapy is necessary. Since enlargement of breasts may be the first sign of pseudoprecocious or of true puberty, a prolonged period of observation with monitoring of other pubertal events and linear growth is indicated in all instances.

# Premature Ventricular Contractions

►Extrasystoles

# Premenstrual Dysphoric Disorder

Jamie Maguire, Istvan Mody
Departments of Neurology and Physiology, The University of California, Los Angeles, CA, USA

## Synonyms

PMDD

## Definition and Characteristics

Premenstrual dysphoric disorder (PMDD) is a mood disorder characterized by anxiety, anger, irritability, moodiness and depressive symptoms, which occur cyclically during the late luteal phase of the menstrual cycle. PMDD differs from premenstrual syndrome (PMS) in symptom severity; PMDD patients exhibit increased symptom severity and dominant psychiatric symptoms. The symptoms of PMDD are similar to those of major depressive disorder (MDD) with the difference that in PMDD symptom manifestation is cyclical, related to the onset of menses. PMDD is recognized as a clinical mood disorder in the appendix of the Diagnostic and Statistical Manual of Mental Disorders, the American Psychiatric Association DSM-IV-TR and by the Food and Drug Administration (FDA), but has not as yet been listed as a separate disorder in the World Health Organization's International Classification of Diseases.

## Prevalence

The prevalence of PMDD is approximately 2–8% of women in their reproductive years [1]. Despite such a high prevalence, the World Health Organization (WHO) does not include PMDD or PMS in the comprehensive report regarding the economic burden of mental health disorders. However, studies show an increased number of sick days in women with PMS/PMDD and a self-reported decrease in productivity. During the reproductive age of women (14–51 years, a conservative estimate), an average of 1,400 workdays/person are estimated to be lost due to PMS/PMDD, corresponding to 3.84 years of disability (DALY). In the United States alone this would add up to 14,492,465 DALYs, resulting in a significant economic burden [1]. In addition to the loss of productivity, health care costs for the treatment of PMDD-associated symptoms such as depression and headaches, also add to the economic impact of the disease [1].

## Genes

Evidence from family and twin studies suggests a genetic contribution to the etiology of PMDD. However, to date, no genes associated with PMDD have been identified.

## Molecular and Systemic Pathophysiology

The cause of PMDD has not been definitively established, but several theories exist. Due to the depressive mood symptoms in PMDD and the beneficial effects of selective serotonin reuptake inhibitors (SSRIs), one theory suggests that PMDD is due to a deficit in serotonin. Evidence supporting this hypothesis includes the correlation of self-rated mood symptoms in women with PMDD with decreased levels of serotonin. However, further studies have not found any abnormality in serotonergic function in affected women [2].

Symptom manifestation in menstrual cycle linked psychiatric and neurological disorders has been attributed to changes in hormone levels over the menstrual cycle; accordingly, suppression of ovulation ameliorates symptoms. However, there is no consistent evidence of changes in ovarian steroid concentrations or of their metabolites between patients with PMS/PMDD and controls. Instead, it has been suggested that women with PMS/PMDD differ in brain sensitivity to neurosteroids. Consistent with this hypothesis, PMS/PMDD patients are less sensitive to neurosteroids, ethanol and benzodiazepines.

The GABAergic system has been implicated in the pathogenesis of menstrual cycle linked disorders due to the fact that neurosteroids act directly on $GABA_A$Rs. Neurosteroids preferentially act on δ subunit containing $GABA_A$ receptors and in particular, on the tonic inhibition mediated by these receptors. Studies in animals have shown an ovarian cycle linked fluctuation of δ subunit containing $GABA_A$ receptors expressed on the surface of neurons and it has been suggested that a deficiency in the cyclical receptor expression may underlie the disease. Interestingly, pharmacologically increasing ambient GABA levels with inhibitors of GABA uptake, which preferentially increases tonic inhibition mediated by extra-synaptic δ subunit-containing $GABA_A$Rs is therapeutic in the treatment of anxiety disorders.

## Diagnostic Principles

PMDD is characterized by a variety of mood, somatic and behavioral symptoms that occur during the late luteal phase of a woman's menstrual cycle, which may be difficult to interpret or diagnose. The American Psychiatric Association established diagnostic criteria for the diagnosis of PMDD, which require prospective symptom ratings, a complete family and personal history of mental disorders and medical diseases and a thorough physical examination. Despite the defined diagnostic criteria, many women with debilitating premenstrual disorders go undiagnosed.

## Therapeutic Principles

The complex symptom presentation of patients with PMDD has led to the use of many different types of treatment strategies for the disease. Unfortunately, none of these treatment strategies has proven effective in all women with PMDD. Treatments include non-pharmacological strategies, such as exercise, dietary changes, dietary supplements and psychotherapy. Current evidence suggests that the accepted pharmacological

treatments for PMDD have similar overall efficacy. However, less than 60% of women with PMDD are responsive to traditional pharmacological treatment. This is partially due to the fact that current treatments for PMDD rely on therapies for major depressive disorders rather than specifically for the treatment of PMDD, which most probably has a very distinct pathology.

Present pharmacological treatment of PMDD focuses on SSRIs, GABAergic agonists and oral contraceptives. The Food and Drug Administration (FDA) has approved several SSRIs for the treatment of PMDD despite the fact that there seems to be no deficit in serotonergic function in patients with PMDD [2]. SSRIs are typically used to treat the symptoms of irritability and anxiety in patients with PMDD. GABAergic mechanisms are much more likely to be involved, but there are few experimental studies on the subject. GABAergic agonists have been proven to be efficacious for the treatment of anxiety and anxious/depressive symptoms in affected women.

In addition, it is known that suppression of ovulation ameliorates symptoms in PMDD. There have been controversial results in the use of oral contraceptives in the treatment of PMDD, but the novel progestin drospirenone has proven effective in reducing premenstrual symptoms in many women [3].

### Synonyms

Camurati-Engelmann disease; CED

### Definition and Characteristics

Autosomal dominant bone dysplasia characterized by symmetrical hyperostosis of the long bones.

### Prevalence

Estimated to be <1/1,000,000. Until now, a few hundred cases have been described worldwide.

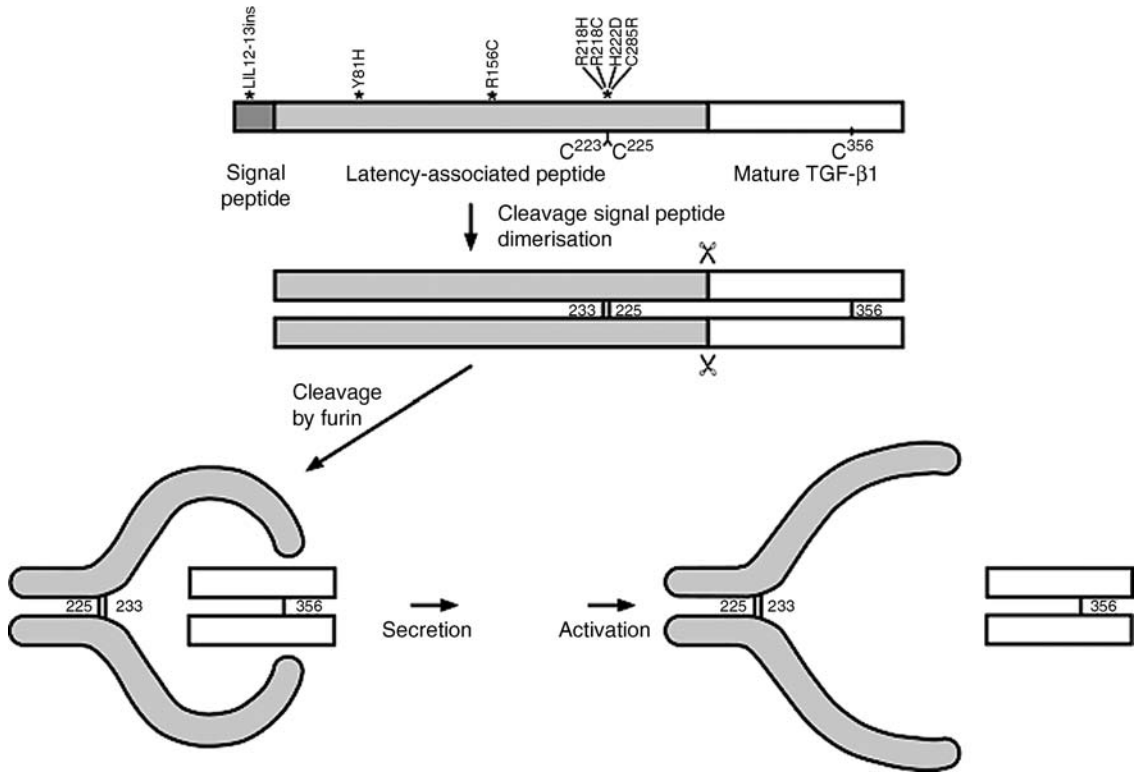
### Genes

TGFB1, located on the chromosomal region 19q13.2, coding for transforming growth factor-β1 (TGF-β1).

### Molecular and Systemic Pathophysiology

TGF-β1 is an ubiquitous growth factor implicated in diverse functions. It is produced in an inactive form, in which the aminoterminal domain (the so-called latency-associated peptide or LAP) shields the receptor binding epitopes on the carboxyterminal part, the mature peptide. After activation, the mature peptide can bind to its receptor and induce a signaling cascade. In this way, TGF-β1 regulates the transcription of numerous genes.

In the bone, TGF-β1 has an important role in coupling bone resorption by osteoclasts to new bone formation by osteoblasts. On the one hand, it stimulates chemotaxis, proliferation, and differentiation of osteoblast precursors in vitro and enhances bone formation in vivo. On the other hand, formation of osteoclasts is inhibited. Since TGF-β1 is activated in the acidic environment created by resorbing osteoclasts, it prevents further bone resorption and stimulates bone formation.



**Progressive Diaphyseal Dysplasia. Figure 1** Processing and activation of TGF-β1. Asterisks indicate the mutations identified in Camurati-Engelmann disease.

The mutations that cause CED are located in the signal peptide and latency-associated peptide of TGF-β1 (Fig. 1) and have been shown to influence either secretion or activation of the mutant protein. In both cases, this results in an overinduction of the signal transduction pathway. In view of the functions of TGF-β1 in bone, an overactivity of TGF-β1 is likely to inhibit bone resorption, while enhancing bone formation. This is in line with the typical radiographic pattern seen in CED patients: cortical thickening due to periosteal apposition of bone by the osteoblasts with concomitant narrowing of the medullary cavity due to the impaired functioning of the osteoclasts.

## Diagnostic Principles

CED patients suffer from bone pain, are often tired, show reduced muscle mass and subcutaneous fat, and have a typical waddling gait. Auditory and visual impairment and exophthalmos can occur. Radiographs show a bilateral symmetrical affection of the long bones. In the diaphyses, a modeling defect can be seen with cortices that are increased in thickness and partly or completely obliterated marrow cavities. The metaphyses can be affected as well, but the epiphyses never are. The long bones are affected in a certain order: tibia, femur, fibula, humerus, ulna, radius. In about 50% of the cases, sclerosis can be seen at the skull base [4]. Scintigraphy is positive for sites of active bone remodeling. There are no general biochemical abnormalities. Detection of a mutation in the TGFB1 gene can confirm the diagnosis.

## Therapeutic Principles

No gene therapy is currently available. Patients benefit from treatment with corticosteroids such as prednisone and deflazacort, which can alleviate bone pain and fatigue, but do not alter the radiographic signs. Reaming of the medullary cavity can also be performed, but as the disease progresses, obliteration can recur.

## Progressive Supranuclear Palsy

Hans-Jürgen Gdynia, Albert C. Ludolph
Department of Neurology, University of Ulm, Ulm, Germany

### Synonyms

Steele-Richardson-Olzewski syndrome; PSP; PSNP

### Definition and Characteristics

Progressive supranuclear palsy (PSP, PSNP) is a slowly progressive neurodegenerative disorder mainly characterized by an akinetic-rigid syndrome, slowing or inability to generate voluntary saccadic eye movements and frontal dementia. Additional symptoms are sleep disturbances, emotional or personality changes such as irritability, occasional angry outbursts, intellectual losses, apathy and difficulty with abstract reasoning. The first symptom of PSP is usually unsteadiness and falling, the most characteristic aspect is gaze palsy. PSP is the second most frequent cause of degenerative parkinsonism [1]. In a recent study, two distinct clinical phenotypes of PSP have been described. Richardson's syndrome is characterized by early onset of postural instability and falls, supranuclear vertical gaze palsy and cognitive dysfunction. PSP-parkinsonism (PSP-P) is characterized by asymmetric onset, tremor and a moderate initial therapeutic response to levodopa [2].

### Prevalence

PSP is estimated to affect about 4–6/100,000 persons, or about 5–6% of persons thought to have parkinsonism. The incidence in the age range 50–99 is 5.3/100,000.

### Genes

One gene and one locus have been linked to PSP, but these are only abnormal in a minority of the patients. PSNP1 can be caused by mutations in the MAPT gene on 17q21.1 (MIM 601104). For autosomal dominantly inherited PSNP2, a locus on chromosome 1q31.1 has been described (MIM 609454).

### Molecular and Systemic Pathophysiology

The clinical symptoms of PSP are caused by progressive damage to neurons in midbrain, basal ganglia (especially internal globus pallidus), subthalamic nuclei and the dentate nucleus of the cerebellum. The cerebral cortex is also affected and decreased metabolism of cerebral glucose correlates with dementia in PSP. Neuropathologically, the disease is characterized by midbrain atrophy, neuronal loss and neurofibrillary tangles in the basal ganglia, diencephalon and brainstem. The substantia nigra, subthalamic nucleus and pontine base are typically involved as well as the ventral anterior and lateral thalamic nuclei.

Until recently, either a virus or toxins in the environment were suspected to be one cause of PSP. Genetic studies suggest that some cases of PSP are associated with variations in the tau gene. Tau is a microtubule-binding protein that is normally abundant in neurons. In typical PSP, pathological tau is composed of aggregate four-repeat (E10+) forms that accumulate in cells and glia in the brain. An association between PSP and a dinucleotide polymorphic repeat between exons 9 and 10 of the microtubule-associated tau gene (MAPT) have been demonstrated. This association was confirmed by other studies; an overrepresentation of the

most common allele (a0) and genotype (a0a0) was reported. Furthermore two extended haplotypes that cover the human tau gene have been described (H1 and H2) and it has been shown that the most common haplotype H1 was significantly overrepresented in patients with PSP, extending the earlier reports of the association between the intronic dinucleotide polymorphism a0. Another haplotype is designated HapA, characterized by a homozygous polymorphism in the 5-prime splice site untranslated region of exon 1, two missense mutations in exon 4A and a nonsense mutation in the 5-prime splice site of exon 8. Furthermore, a mutation in a highly conserved position in exon 1 of the MAPT gene has been described in a few cases of PSP [3]. Additionally it was suggested that the Q7R polymorphism of the saitohin gene, which is located within intron 9 of the MAP gene, is associated with PSP. In contrast to the variations in the MAPT gene (PSNP1) on 17q21.1, the gene for PSNP2 on 1q31.1 has not been identified yet [4].

### Diagnostic Principles

PSP is mainly a clinical diagnosis; the hallmarks of the disease are an akinetic-rigid syndrome, gaze palsy, falls and frontal dementia. In cerebral MRI, the superior cerebellar peduncle is smaller in PSP than in controls, on average 20% [5]. The ratio of area of midbrain to the pons on sagittal MRI has been reported to be an accurate method of diagnosis, as the midbrain is smaller in PSP.

### Therapeutic Principles

There is currently no curative medication for PSP; reducing the symptoms is currently the main goal of treatment. Anti-parkinsonian drugs such as levodopa are mildly helpful in a minority of persons with PSP. On the other hand, numerous supportive treatments are known and essential. Eye care is important, i.e. patients should have good lighting, as well as astigmatic correction in spectacles and should avoid bifocals and progressive lenses. Blepharospasm and apraxia of eyelid opening can be treated with botulinum toxin. Due to the akinetic-rigid syndrome and the risk of severe falls, patients should be provided with a wheelchair. Furthermore, psychological support should be supplied; caregivers and patients should be counseled regarding the natural history of the disease. Advance directions should be used.

## Propionic Acidemia

James V. Leonard
Clinical and Molecular Genetics Unit, Institute of Child Health, University College London, London, UK

### Synonyms

Propionyl CoA carboxylase deficiency (formerly ketotic hyperglycinemia)

### Definition and Characteristics

Propionic acidemia is caused by a defect in propionyl CoA carboxylase, a mitochondrial enzyme. It is an autosomal recessive disorder, characterized particularly by episodic acute encephalopathy, psychomotor retardation and feeding difficulties [1].

### Prevalence

There are no accurate details of the prevalence but it is less than 1 in 50,000 in most countries. It appears to be more common in Middle East.

## Genes

Two complementation groups recognized that correspond to the two genes (PCCA and PCCB) encoding polypeptides in the multimeric mature enzyme, α and β These form a hexamer of the protomers $(\alpha\beta)_6$. Biotin, the co-enzyme, is bound to the α subunit.

## Molecular and Systemic Pathophysiology

Propionate and propionyl CoA are formed from several sources and are normally converted to succinate, entering the citric acid cycle. As a result of the defect in propionyl CoA carboxylase, there is accumulation of propionyl CoA, which may be metabolized via many pathways and the production of many metabolites including methylcitrate and propionyl glycine. There is wide variation in the phenotype of this disorder. It may present in the neonatal period or later during childhood. Those who present in the neonatal period usually do so with a progressive encephalopathy, which starts with poor feeding, vomiting and lethargy and progresses to coma and apnoea. Many neurological signs have been observed including seizures, alterations in tone and myoclonus. In infancy this condition often presents with failure to thrive, poor feeding and developmental delay. Older patients may present with psychomotor retardation and episodic acidosis. Additional neurological features are common including stroke-like episodes and movement disorders. The clinical course is one of recurrent episodes of decompensation with acidosis and encephalopathy, often precipitated by infections. Marrow suppression is common during acute illness being responsible for pancytopenia. Other complications include pancreatitis and cardiomyopathy [2].

A wide variety of mutations in either gene may be responsible for much of the clinical heterogeneity [3].

## Diagnostic Principles

Routine investigations may show a metabolic acidosis (increased anion gap), with or without ketosis, hypoglycemia and hyperammonemia. Plasma glycine and propionylcarnitine are often increased but neither of these is specific. The diagnosis is usually made on the basis of urine organic acids, which may contain a large number of compounds. The most common are methylcitrate, 3-hydroxypropionate, propionylglycine and tiglylglycine. Methylmalonic acid is not present. The diagnosis is confirmed by enzyme studies in culture skin fibroblasts measuring propionate incorporation into protein or propionyl CoA carboxylase activity. The diagnosis can also be made by mutation analysis.

## Therapeutic Principles

The mainstay of treatment is high low protein that may incorporate an aminoacid supplement omitting propiogenic aminoacids (valine, isoleucine, methionine and threonine).The value of these is unclear [4]. Carnitine is given in doses of 100–300 mg/kg/d in divided doses. Metronidazole and other antibacterial agents are used to reduce propionate production from the gut, but the optimum dose and duration of treatment are not known. Growth hormone increases growth velocity in short children but does not improve metabolic control.

The diet must meet the requirements of vitamins, minerals and all other nutrients. Maintenance of a good nutritional state is very important and as feeding difficulties are common, tube feeding by naso-gastric or gastrostomy tube is frequently necessary. Continuous overnight feeds are often useful. There is increasing evidence that liver transplantation is beneficial [5]. Gene therapy is currently not an option.

## Protein C Deficiency

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

### Synonyms

Deficiency of protein C

### Definition and Characteristics

Protein C defiency (PC) is a vitamin K-dependent serine protease zymogen. It is primarily produced by the liver. PC is composed of a 250-amino acid heavy chain and a 155-amino acid light chain, bound by a disulfide bond. It is activated by the endothelial thrombomodulin–thrombin complex, exposing a catalytic site that cleaves and inactivates factors Va and VIIIa. This protease action is supported by the cofactor free protein S.

### Prevalence

Population estimate of PC deficiency is 1/300 [1]. In consecutive patients with first venous thrombosis this number is 3–5%. Heterozygous PC deficiency is associated with an increased risk of venous thrombosis of about tenfold as compared with non-carriers in high-risk populations.

### Genes

Usually autosomal dominant. Heterozygous deficiency is associated with an increased risk of venous thrombosis; homozygous deficiency is extremely rare and associated with a severe clinical phenotype comparable to homozygous protein C deficiency, of purpura fulminans.

*Gene Map Locus*: 2q13-q14. The PC gene spans about 10–kb genomic DNA, nine exons.

### Molecular and Systemic Pathophysiology

PC deficiency is classified on the basis of plasma levels into:

- Type I: low plasma levels of PC.
- Type II: qualitative deficiency characterized by decreased activity and normal PC antigen levels.

Gene defect analysis revealed a highly heterogeneous basis, and database of defects is recorded; the last published update recorded 161 mutations, mostly missense mutations [2]. Griffin first noted type I PC deficiency in a young patient with recurrent thrombophlebitis complicated by pulmonary embolism [3]. Since then, numerous family-associated cases of PC deficiency have been linked with an increased risk of venous thromboembolism. The thrombotic risk is due to a diminished inhibitory potential on intrinsic coagulation activity resulting in an increased rate of thrombin generation that upon significant clinical challenge precipitates thrombosis. Acquired deficiencies of PC may occur in conditions associated with disseminated intravascular coagulation (DIC) such as in severe sepsis. A particular example is meningococcal sepsis that is associated with purpura fulminans because of a combination of depletion of PC due to DIC and a diminished endothelial cofactor function in the activation of PC [4] The latter condition mimics the very rare cases of homozygous PC deficiency. Other rare causes of acquired PC deficiency are during warfarin treatment in heterozygous PC-deficient individuals when PC levels may drop relatively low as compared with procoagulant proteins resulting in a procoagulant state and warfarin-associated skin necrosis due to microvascular thrombosis; other acquired causes are the very rare formation of autoantibodies, and the use of valproic acid.

*Clinical Features*: Risk of venous thromboembolism is increased with an estimated 5–10-fold in patients with a heterozygous deficiency. PC deficiency has also been associated with thrombosis at unusual sites including mesenteric and portal veins, renal vein, cerebral venous system. There is no correlation with arterial thrombosis, except in exceptional cases such as young individuals.

### Diagnostic Principles

Initial testing of PC is by an amidolytic assay, also in the presence of a lupus anticoagulant. PC antigen assays may be warranted for distinguishing type I and II PC deficiency. In case of suspected deficiency the tests

should be confirmed and acquired causes should be ruled out. PC testing should preferably not be done during an acute event because acquired lower PC values may be due to temporary depletion, and in case of warfarin treatment only after a sufficient time interval following drug cessation [5].

### Therapeutic Principles

In individuals with a congenital PC deficiency adequate thrombosis prophylaxis is warranted in high risk for thrombosis conditions such as following surgery. In specific situations such as pregnancy, the use of low molecular weight heparin prophylaxis throughout pregnancy and postpartum is presently indicated. In case of rare homozygous PC deficiency the use of PC concentrate can be employed. An activated recombinant PC preparation has been registered for use in patients with severe sepsis, but the etiology is not primarily based on PC deficiency.

## Protein-losing Enteropathy

Karel Geboes[1], Gert Van Assche[2]
[1]Department of Pathology, University Hospital Leuven, Leuven, Belgium
[2]Division of Gastroenterology, University Hospital Leuven, Leuven, Belgium

### Synonyms

Protein-losing enteropathy (refers to diseases in which protein loss relates to the small bowel. Protein-losing gastroenteropathy (PLG) encompasses the entire gastrointestinal tract (GI)); PLE

### Definition and Characteristics

In normal subjects 10% of plasma protein loss occurs through saliva and GI secretions. After protein digestion, amino acids are resorbed distally and synthesis compensates for the loss. In patients with PLG, protein leakage, independent of molecular weight, exceeds protein synthesis, resulting in hypo-proteinemia, edema, and in some cases, pleural and pericardial effusions. Proteins with rapid catabolic turnover (e.g. insulin) are less affected than longer-lived albumin, fibrinogen and most immunoglobulins. PLG is not a disease but rather a syndrome with a variety of underlying diseases and mechanisms (Table 1).

Common features are reduced serum concentrations of albumin, gamma globulins, fibrinogen and ceruloplasmin. Hypoproteinemia can be associated with fat and carbohydrate malabsorption and fat-soluble vitamin deficiencies. Changes in clotting factors are not significant and there is no propensity to infection except for cases with depletion of lymphocytes [1].

### Genes

From clinical observations it appears that PLE Occurs when multiple environmental insults collide and overwhelm predisposing genetic insufficiencies rather than being the result of one or multiple gene defects. This multi hit cascade hypothesis is illustrated by patients with the Fontan surgery in which PLE may be a late event and by patients with a congenital disorder of glycosylation (CDG) CDG is caused by mutations in genes needed for the biosynthesis of the lipid linked oligosaccharide precursors of N-linked oligosaccharide chains. PLE occurs only in these patients during stressful bouts of gastroenteritis.

### Molecular and Systemic Pathophysiology

The pathogenesis is not fully understood. Several mechanisms have been proposed: increased venous

and/or lymphatic pressure; dilated lymphatic vessels leaking proteins; increased microvascular permeability; loss of heparan sulphate (HS); widening of tight junctions (TJ); mucosal injury with inflammation and an effect of IFN-γ and TNF-α (Table 2).

Chronically elevated superior vena caval pressures would impede lymph drainage into the thoracic duct. Combined with increased inferior vena caval and portal vein pressures, this could cause intestinal congestion and leakage of proteins. Relieving central venous pressure by treating the underlying cardiac disease can help

to treat PLG, but not all cases have good clinical response. Furthermore, increased venous pressure does not necessarily induce PLG. Similar data are observed after Fontan surgery, performed for palliative treatment of complex congenital heart defects. Episodic or prolonged PLG is a feared but rare complication in spite of surgically improved hemodynamics [2].

A relation with autoimmunity and increased capillary permeability due to activated immune deposits has been suggested as an alternative mechanism but data are limited.

At the molecular level, "Heparan Sulphate" and increased intestinal levels of IFN-γ and elevated systemic concentration of TNF-α have been associated with PLG. Enterocyte HS deficiency causes severe congenital PLE within the first weeks of life. Routine histology of intestinal biopsy specimens is unremarkable but immunohistochemistry reveals loss of HS [3,4]. Heparan sulphate proteoglycans comprise a core protein to which heparan sulphate glycosaminoglycan chains are attached. They are classified into several families based on their core protein structure. Glypicans and Syndecans are cell surface components. Perlecans are secreted in the extracellular matrix. All three families are evolutionarily conserved. They are expressed at the basolateral surfaces of the epithelial cells in the normal human large and small intestine and associated with important cell functions, including cell growth, migration, adhesion and signaling pathways such as the transforming growth factor-β pathway. They can interact with external proteins like cytokines, growth factors, and pathogens such as viruses. The cytoplasmic portion of the core protein connects with the cytoskeleton. In vitro studies confirm that removal of HS, more specifically of the sulphate groups and uronic acid causes protein leakage. In vivo, absence or loss of HS has been described in post-Fontan patients and in reparative epithelium from inflammatory bowel disease patients presenting with PLG. The etiology of the loss of HS is unclear. A defective synthesis of precursors (congenital disorder of glycosylation – CDG) has been identified as well as formation of autoantibodies to vascular heparan sulphate proteoglycan (lupus erythematosus). Loss of HS can also be explained by the high turnover rate of intestinal epithelial cells, which increases during inflammation and infections.

Transient PLG is reported in patients with or without Fontan surgery in association with Helicobacter pylori, Clostridium difficile and Cytomegalovirus infections. The association between PLG and infections/inflammation is partly explained by increase of IFN-γ and TNF-α. IFN-γ and TNF-α decrease epithelial barrier function through a disorganization of the TJ. TNF-α acts through NF-κB-mediated activation of myosin light-chain kinase promoter resulting in increased myosin light-chain kinase protein expression and activity with contraction of perijunctional actin-myosin filaments and alterations of TJ protein localization and opening of the intestinal TJ barrier [5]. Treatment with antibodies directed against TNF−α restores the gut barrier in Crohn's disease. In in vitro studies, TNF-α increases protein leakage more than does loss of HS. These effects are synergistic, possibly because cell-associated HS interferes with TNF-α-receptor binding or TNF-α-induced signaling pathways.

## Diagnostic Principles

Clinical suspicion of PLG is usually raised by low serum levels of specific proteins such as albumin. Alpha1-antitrypsin clearance can be used as a diagnostic tool but recovery of injected and isotope labeled albumin ($^{51}$Cr or $^{125}$I) is a more specific test.

## Therapeutic Principles

Optimal treatment consists of optimization of nutritional status to improve protein synthesis and treatment of the underlying disease to prevent intestinal protein loss including surgery for constrictive pericarditis or congenital heart diseases or for Crohn's disease. Gene therapy and specific pharmacological therapies (anti-TNF-α treatment?) are not available (yet).

## Synonyms

Deficiency of protein S alpha

## Definition and Characteristics

The mature PS molecule is a vitamin K-dependent plasma glycoprotein of 635 amino acids. It is primarily produced by the liver. Its main function is as a cofactor in the protein C anticoagulant mechanism. PS occurs in two forms in plasma, i.e., a free, functionally active form and an inactive form bound to C4b-binding protein. Free PS is a cofactor for the proteolytic degradation of factors Va and VIIIa by activated protein C. In addition, PS has a protein C-independent anticoagulant activity. Protein S deficiency (PS).

## Prevalence

Population estimates of PS deficiency range between 0.03 and 0.13% [1]. Heterozygous PS deficiency is associated with an increased risk of venous thrombosis of about tenfold as compared with non-carriers in high-risk populations.

## Genes

Usually autosomal dominant. Heterozygous deficiency is associated with an increased risk of venous thrombosis; homozygous deficiency is extremely rare and associated with a severe clinical phenotype comparable to homozygous protein C deficiency, of purpura fulminans [1].

*Gene Map Locus*: 3p11.1-q11.2. This region contains two PS genes, PROS1 and PROS2. PROS1 is the active gene and spans 80-kb genomic DNA, 15 exons. PROS2 is a pseudogene.

## Molecular and Systemic Pathophysiology

PS deficiency is classified on the basis of plasma PS levels into:

- Type I: low plasma levels of both total and free PS.
- Type II: qualitative deficiency characterized by decreased activity and normal total and free PS antigen levels.
- Type III: normal levels of total PS and low levels of free PS.

Gene defect analysis revealed a highly heterogeneous basis; a database of defects is recorded, the last published update recorded 131 mutations in 203 PS-deficient analyzed families [2]. Majority is type I and III, only seven cases of type II have been recorded.

Partial protein S deficiency was first observed in six unrelated individuals with severe recurrent thrombosis [3]. Deficiency of the free form of PS is the main determinant of the associated risk of thrombosis, by reduced inhibitory capacity against the intrinsic route of coagulation. The result is increased thrombin generation that upon significant clinical challenge induces thrombosis. The main effect is on venous thromboembolism, but associations with arterial thrombosis have been reported. Acquired deficiencies of PS may occur in acute phase conditions due to increased levels of C4b-binding protein. Both total and free PS may be influenced by age, sex, and hormonal status.

*Clinical Features*: Risk of venous thromboembolism is increased with an estimated fivefold in patients with a heterozygous deficiency, while mortality is not increased [1]. In one study, the cumulative risk of venous thrombosis was 50% at the age of 45 years [4].

## Diagnostic Principles

Plasma PS can be measured by immunological and functional methods. Determination of free PS is important, but this depends on effective precipitation of the PS-C4b-binding protein complex, which has been notoriously difficult due to a low reproducibility [4]. Recent recommendations suggest initial testing with either a functional or an immunological assay for free PS. The results from functional assays should be interpreted with caution and if abnormal always be confirmed by immunological assay. Total PS assays are not indicated unless for establishing the type of PS deficiency [4].

## Therapeutic Principles

In individuals with a congenital PS deficiency, adequate thrombosis prophylaxis is warranted in high risk for thrombosis conditions such as following surgery. In specific situations such as pregnancy, the use of low molecular weight heparin prophylaxis throughout pregnancy and postpartum is presently indicated. Replacement therapy is not available.

## Synonyms

Macro-albuminuria

## Definition and Characteristics

Proteinuria is defined by the presence of protein in the urine exceeding 300 mg/24 h (normal excretion: 80 ± 24 mg/24 h). Proteinuria may be an isolated finding, but it can be accompanied by other renal symptoms like hematuria, impaired renal function, and hypertension. If protein excretion exceeds 3.5 g/24 h and serum albumin is below 30 g/l, the condition is called nephrotic syndrome. In kidney disease, proteinuria is a strong predictor of progressive deterioration of renal function and development of end-stage renal failure. Furthermore, it is an independent risk marker for cardiovascular disease.

## Prevalence

In the general population of randomly selected individuals, the prevalence of proteinuria >0.3 g/l in the PREVEND cohort of 8,592 individuals was 0.6% [1].

## Genes

In recent years, several genetic defects have been identified in patients with glomerular diseases characterized by proteinuria [2]. The major gene defects identified so far are listed in Table 1. Gene defects of extracellular matrix proteins localized in the glomerular basement membrane (GBM), like type IV collagen and laminin, lead to an abnormal ultrastructure of the GBM over time causing an increased permeability and thus leading to proteinuria and finally in some patients to end-stage renal failure. Gene defects of proteins localized in the podocyte lead to malfunction of the slit diaphragm (nephrin, podocin) or an abnormal podocyte architecture due to dysregulation of the actin cytoskeleton (WT1, α-actinin 4, TRPC 6, LMX1B). Both conditions lead to podocyte foot process effacement, proteinuria, and focal segmental glomerulosclerosis. Depending on the mutation, the abnormalities can become manifest either very early (directly after birth) or late in adulthood.

## Molecular and Systemic Pathophysiology

Proteinuria can be the result of four different pathophysiological mechanisms: (i) glomerular proteinuria, (ii) tubular proteinuria, (iii) overflow proteinuria, and (iv) tissue proteinuria [3].

*Glomerular proteinuria* results from abnormalities at the glomerular filtration barrier. As a result, proteins enter the glomerular filtrate and when tubular reabsorptive capacity of proteins is exceeded, they can be detected in the urine. The glomerular capillary filter consists of three layers: fenestrated endothelial cells, the GBM, and podocytes (visceral epithelial cells). Tracer studies with differently charged molecules with increasing molecular radii have indicated that the permeability of the glomerular capillary filter has two major characteristics: a charge-dependent permeability (cationic molecules filtrate better than neutral charged molecules, which have a better filtration than anionic molecules) and a size-dependent permeability (filtration progressively declines with greater molecular radii). In addition, glomerular permeability is determined by the slit diaphragm, which interconnects adjacent podocyte foot processes. The charge-dependent permeability is probably determined by the GBM and the size-dependent permeability by the GBM and the slit diaphragm. Disturbance of the charge-dependent permeability leads to a preferential loss of anionic molecules (i.e., albumin), which is called selective proteinuria, while defects in the size-dependent permeability leads to loss of all plasma proteins (non-selective proteinuria). The negatively charged sulfate and carboxylic groups of the polysaccharide heparan sulfate (HS) are thought to play an important role in the charge-dependent permeability properties of the GBM (Steno hypothesis), since in several kidney diseases proteinuria has been associated with decreased HS levels in the GBM. However, a number of recent animal studies, which are listed in Table 2, question the primary role of HS in glomerular filtration, as direct or indirect interference with HS does not result in (acute)

**Proteinuria. Table 1** Genetic causes of proteinuria

proteinuria. For instance, enzymatic cleavage of in mice with overexpression of mammalian heparanase, knockout of the enzyme involved in HS biosynthesis (EXT1), and knockout of several HS-bearing (domains of) core proteins (agrin, perlecan, collagen XVIII) did not directly result in proteinuria [4]. There are some indications that negatively charged neuraminic acid in the endothelial glycocalyx and/or at the podocyte cell surface is an important determinant for the charge-dependent permeability properties of the glomerular filter.

*Tubular proteinuria* results from either a defective reabsorption of proteins by proximal tubular cells or an overflow of the reabsorptive capacity of these cells. The first condition is characterized by urinary excretion of low molecular weight proteins like α1- and β2-microglobulins, which because of their small molecular radius can freely permeate through the glomerular

**Proteinuria. Table 2** Experimental animal model studies with a reduction in GBM negative charges: mechanisms and renal phenotype

| Animal model | Mechanisms | Renal phenotype |
|---|---|---|
| Heparanase-overexpressing mice | Enzymatic cleavage of HS[a] | Only a twofold increase in proteinuria |
| Podocyte-specific EXT1 knockout mice | Depletion of HS-copolymerase (enzyme involved in HS polymerization) | Minor proteinuria |
| Podocyte-specific agrin knockout mice | Depletion of agrin (major HS-bearing core protein in the GBM) | No abnormalities |
| Perlecan exon 3 knockout mice | Depletion of the HS-bearing N-terminal domain I of perlecan (minor HS-bearing core protein in the GBM) | No abnormalities, twofold increases in proteinuria accompanied by endothelial cell and podocyte abnormalities after extreme albumin overload |
| Collagen XVIII knockout mice | Depletion of collagen XVIII (minor HS-bearing core protein in the GBM) | No abnormalities |

[a]HS = heparan sulfate.

filter. Decreased resorptive capacity can be hereditary (i.e., Fanconi's syndrome) or acquired tubular defects (i.e., tubulo-interstitial nephritis). Tubular proteinuria in general does not exceed 1.5 g/24 h. Tubular proteinuria can also be caused by glomerular proteinuria, in which the resorption of the larger-sized proteins induces toxic effects in the tubular cells, which damages reabsorption. In this combined glomerular and tubular proteinuria, both low and high molecular weight proteins are detected in the urine.

*Overflow proteinuria* is the result of an increased glomerular filtration of low molecular weight proteins circulating in excess, like free hemoglobin, myoglobin, or free light chains of immunoglobulins. The increased delivery to proximal tubular cells can be toxic leading to secondary excretion of microglobulins.

*Tissue proteinuria* can result from inflammatory or neoplastic conditions in the urinary tract, resulting in weeping of proteins by the abnormal tissue.

## Diagnostic Principles

For routine screening paper strips can be used which show a color change of a dye. This gives a semi-quantitative scoring of the urinary concentration of proteins. The lower limit of detection is 200 mg albumin/l. These dipsticks are relative insensitive for globulins and do not detect light chains. For a quantitative analysis, several colorimetric or turbidometric methods are available, which detect albumin and globulins equally and have a lower limit of detection (50 mg/l). For the specific detection of certain excreted proteins (i.e., α1- or β2-microglobulin, κ or λ light chains, myoglobulin), immunochemical methods are available by using specific antibodies in either ELISA, immunofixation, or immunonephelometry. Since proteinuria is very often accompanied by hematuria, the presence of red blood cells in the urine should also be investigated, e.g., by using a dipstick test. If positive, it should be confirmed by analysis of the urinary sediment, which allows detection of dysmorphic red blood cells and/or erythrocyte casts. For a proper diagnosis of the disease, a renal biopsy is very often mandatory to enable histological analysis.

## Therapeutic Principles

A number of glomerular and tubulointerstitial diseases respond to immunosuppressive therapy using drugs like corticosteroids, cyclophosphamide, azathioprine, mycophenolate mofetil, anti-CD20, and other biologicals. Proteinuria can also be reduced by treatment with compounds that reduce the intraglomerular pressure. This can be accomplished on the one hand by vasoconstriction of the pre-glomerular arteriole (e.g., by non-steroidal anti-inflammatory drugs (NSAIDs)), and on the other hand by vasodilatation of the post-glomerular arteriole (e.g., by angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor 1 (AT1) antagonists). Since proteinuria itself induces a series of events leading to tubulointerstitial fibrosis, reduction of proteinuria is a powerful therapeutic option to retard or prevent progressive decline of renal function. Therefore, patients should receive treatment with ACE inhibitors and/or AT1 receptor blockers in combination with low dietary salt and/or thiazide diuretics to reduce proteinuria as much as possible [5]. This should be combined with eventually additional antihypertensive drugs to a target blood pressure <130/80 mmHg.

A number of heparin (highly sulfated HS)-based drugs, called heparinoids, have been shown to ameliorate proteinuria. However, the exact mechanism of the renoprotective effect has not yet been elucidated.

# Prothrombin G20210A Mutation, Elevated Prothrombin Level, and Arterial Thrombosis

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Hyperprothrombinemia [F2, 20210G-A]

## Definition and Characteristics

Prothrombin is a vitamin K-dependent serine protease zymogen primarily produced by the liver. In plasma it is the precursor zymogen of thrombin that is formed after activation of prothrombin by activated factor X. In vitro, the concentration of prothrombin is an important determinant of the rate of thrombin generation [1]. The prothrombin G20210A mutation is associated with increased plasma levels of prothrombin, i.e., in wildtype 20210GG this is 1.05 U/ml, in heterozygous G202100A carriers on average 1.32 U/ml, and in homozygous 20210 AA individuals 1.70 U/ml [2]. The mechanism has not been fully characterized but the variant has a more effective poly (A) site, leading to increased mRNA and protein expression [3,4].

## Prevalence

In Europe, the prevalence of the mutation is 2.0% overall (95% CI 1.4–2.6%). It is rare in African Americans, Asians, and native Americans. This prevalence is on average 1–2-fold increased in patients with arterial vascular disease.

## Genes

The prothrombin gene spans >21-kb genomic DNA and contains 14 exons.

Elevated prothrombin plasma levels are associated with a G to A transition at base pair 20210 in the 3′ untranslated region of the prothrombin gene.

*Gene Map Locus*: 11p11-q12.

## Molecular and Systemic Pathophysiology

The G20210A mutation is generally documented by PCR analysis. Alternatively, automated fluorescence, invader assay, or multiplex PCR-based assays can be utilized for genotyping. Determination of the prothrombin concentration by clotting assay is cheap but nonspecific for the prothrombin mutation due to a wide range in normal values [2].

The main consequence of the G20210A mutation is an increase in prothrombin concentration, which is the most likely cause of the thrombotic risk. This assumption is based on both genetic linkage data between a quantitative locus for prothrombin plasma concentration and the G20210A mutation on the one hand, and the lack of other mutations linked to prothrombin levels on the other hand [2]. The association between changes in prothrombin concentrations and thrombin generation provides the likely pathophysiological mechanism.

*Clinical Features*: The presence of the G20210A mutation provides a modest risk factor for myocardial infarction (OR 1.28, 95% CI 0.94–1.73) and ischemic stroke (OR 1.30, 95% CI 0.91−1.87) [5]. Pooling data from all studies the risk remained modest at OR 1.32, 95% CI 1.03−1.69) in a total number of 16,945 individuals analyzed [5]. However, in patients <55 years of age the OR was somewhat stronger at OR 1.66, 95% CI 1.13–2.46).

## Diagnostic Principles

In accordance with the molecular mechanism, genotyping is the only suitable assay. Prothrombin levels give additional information. Presently, determination of the G20210A mutation is part of the most routine thrombophilia test panels.

## Therapeutic Principles

Prothrombin concentrations and activity are lowered by vitamin K antagonists. Prothrombin conversion to thrombin, and thrombin itself is being inhibited by

anticoagulants including heparin and low molecular weight heparin (by its anti-factor Xa effect), while specific thrombin inhibitors like hirudin and ximelagatran bind and neutralize thrombin.

In Europe, the prevalence of the mutation is 2.0% overall (95% CI 1.4–2.6%). It is rare in African Americans, Asians, and native Americans. In patients with VTE the prevalence is 4–8%.

## Genes

The gene spans >21 kb genomic DNA and contains 14 exons. Elevated prothrombin plasma levels are associated with a G to A transition at base pair 20210 in the 3′ untranslated region of the prothrombin gene.

*Gene Map Locus*: 11p11-q12.

## Molecular and Systemic Pathophysiology

The G20210A mutation is generally documented by PCR analysis. Alternatively, automated fluorescence, invader assay, or multiplex PCR-based assays can be utilized for genotyping. Determination of the prothrombin concentration by clotting assay is cheap but nonspecific for the prothrombin mutation due to a wide range in normal values [2].

The main consequence of the G20210A mutation is an increase in prothrombin concentration, which is the most likely cause of the thrombotic risk. This assumption is based on both genetic linkage data between a quantitative locus for prothrombin plasma concentration and the G20210A mutation on the one hand, and the lack of other mutations linked to prothrombin levels on the other hand [2]. The association between changes in prothrombin concentrations and thrombin generation provides the likely pathophysiological mechanism.

*Clinical Features*: The presence of the G20210A mutation increases the risk of venous thromboembolism 2–3-fold [4]. In combination with other risk factors including factor V Leiden mutation, this risk increases substantially. In combination with oral contraceptives or pregnancy the risk of VTE increases about 15-fold [2].

## Diagnostic Principles

In accordance with the molecular mechanism, genotyping is the only suitable assay. Prothrombin levels give additional information. Presently, determination of the G20210A mutation is part of the most routine thrombophilia test panels.

## Therapeutic Principles

Prothrombin concentrations and activity are lowered by vitamin K antagonists. Prothrombin conversion to thrombin, and thrombin itself is being inhibited by anticoagulants including heparin and low molecular

weight heparin (by its anti-factor Xa effect), while specific thrombin inhibitors like hirudin and ximelagatran bind and neutralize thrombin.

Jorge Frank[1], Thomas Schwarz[2]
[1]Maastricht University Center for Molecular Dermatology (MUCMD), University Medical Center Maastricht, Maastricht, The Netherlands
[2]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany

## Synonyms

Erythrohepatic porphyria; Protoporphyria; EPP

## Definition and Characteristics

Erythropoietic protoporphyria begins early in life. The main clinical manifestation is protoporphyrin (PP)-sensitized cutaneous photosensitivity, including burning, stinging, pruritus and pain associated with edema, erythema, and urticarial lesions within a few minutes after exposure to sunlight. Severe liver disease with terminal hepatic failure has been reported in approximately 5% of patients.

## Prevalence

The exact incidence and prevalence of EPP is unknown.

## Genes

EPP (OMIM 177000) results from an inherited partial deficiency of ferrochelatase (FC) (E.C. 4.99.1.1; heme synthase; protoheme-ferrolyase).

## Molecular and Systemic Pathophysiology

Ferrochelatase (FC) (E.C. 4.99.1.1; heme synthase; protoheme-ferrolyase) is localized at the inner mitochondrial membrane and catalyzes incorporation of iron into PP to form heme. Until recently, the disease was believed to be inherited in an autosomal dominant fashion with incomplete penetrance. However, these data were not in accordance with several reports indicating that individuals with clinically overt disease revealed a reduction of FC activity in bone marrow, reticulocytes, lymphocytes, liver and cultured skin fibroblasts of 20–40% of normal, which is much lower than expected in an autosomal dominant disorder. Recently, it was demonstrated that the penetrance of EPP is modulated by the expression of wildtype FC indicating that the cutaneous symptoms in clinically overt disease are caused by a FC mutation in *cis* inherited from one parent associated with co-inheritance of an intronic single nucleotide polymorphism (SNP), IVS3–48T/C, inherited in *trans* from the other parent. This polymorphism modulates the use of a constitutive aberrant acceptor splice site. Subsequently, the aberrantly spliced mRNA is degraded by nonsense-mediated mRNA decay and leads to an additional FC deficiency necessary for phenotypic expression.

## Diagnostic Principles

Besides onset of the clinical symptoms in early childhood the diagnosis of EPP is based on the detection of elevated free PP in the red blood cells and/or feces.

## Therapeutic Principles

Photoprotection with topical sunscreens is usually of low benefit, if at all; orally administered beta-carotene (60–180 mg per day) has been found helpful in preventing or minimizing the symptoms of skin photosensitivity.

# Pruritic Urticarial Papules and Plaques of Pregnancy

Christina M. Ambros-Rudolph
Department of Dermatology, Medical University of Graz, Graz, Austria

## Synonyms

Toxemic rash of pregnancy; Late-onset prurigo of pregnancy; Toxic erythema of pregnancy; Polymorphic eruption of pregnancy; PUPPP

## Definition and Characteristics

Pruritic urticarial papules and plaques of pregnancy (PUPPP) is a common benign inflammatory dermatosis specific to pregnancy. It most often involves primigravidae at late term and tends not to recur in subsequent pregnancies. The eruption usually starts in the last trimester (85%), most commonly between 36 and 39 weeks gestation, or within days after delivery (15%) [1]. Earlier occurrence is very rare. Pruritic erythematous edematous papules and plaques appear almost invariably first in the striae distensae of the lower abdomen. Sparing of the periumbilical region is typical. The lesions quickly become generalized involving also other parts of the body such as the buttocks, thighs, lateral parts of the trunk, and arms. Facial involvement is rare as is the involvement of palms and soles; however, if the latter are affected, they may mimic scabies or pompholyx-like lesions. While pruritic and urticarial papules and plaques are the presenting features in almost all patients, about half develop more polymorphic features as the disease evolves. These include widespread, non-urticated erythema, target lesions, tiny vesicles, and eczematous changes (Fig. 1).

Both, mother and fetus, do well and there is no cutaneous involvement in the newborn. The eruption resolves over 4–6 weeks, independent of delivery.

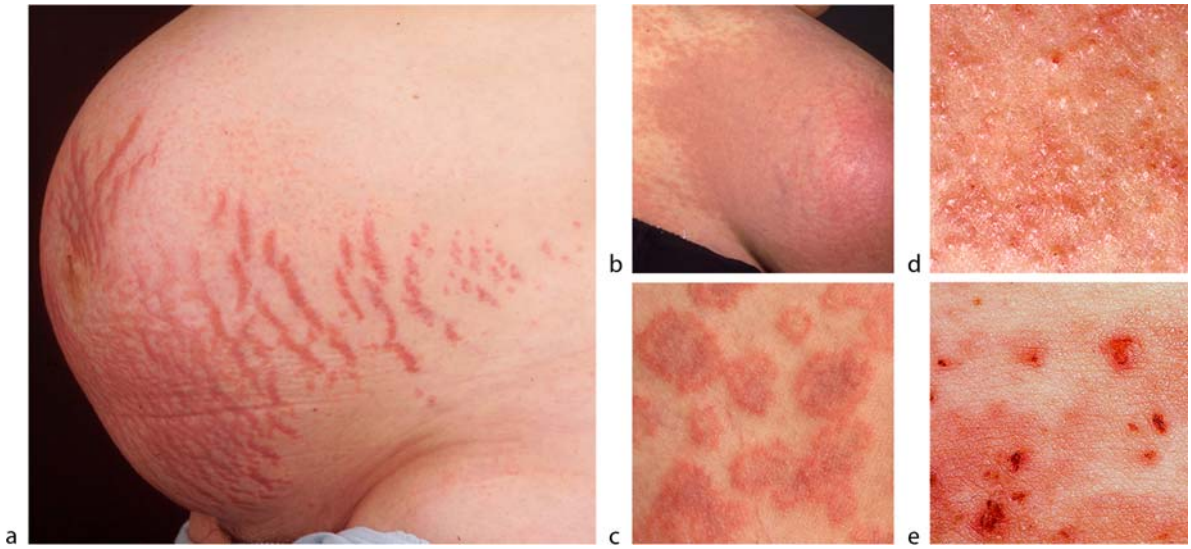
The most important differential diagnosis to rule out is pemphigoid gestationis which tends to appear earlier, does not favor the striae, shows common involvement of the umbilical region, and, most importantly, has characteristic immunofluorescence findings. Other common diagnoses to exclude are atopic eruption of pregnancy, scabies, drug eruptions, and erythema multiforme [2]. On occasion, allergic contact dermatitis caused by over-the-counter remedies for striae may mimic PUPPP.

## Prevalence

1:120–160 pregnancies.

## Molecular and Systemic Pathophysiology

The etiology of PUPPP is yet unrevealed. There is no autoimmune background and the frequency of human leukocyte antigens in women with PUPPP is normal. A hormonal basis for this eruption has been explored by some authors [3], but no consistent abnormal finding has been reported. Multiple gestation pregnancies and excessive maternal weight gain are established risk factors [1]. The striking association of skin lesions to striae distensae observed mainly in primigravidae at late term has favored rapid, late abdominal wall distension with consecutive damage to connective tissue as key aspect in the development of PUPPP. It has been postulated that exposure of otherwise hidden or inert antigens within collagen could possibly elicit an



**Pruritic Urticarial Papules and Plaques of Pregnancy. Figure 1** PUPPP and its variable morphology. (a) Typical presentation of PUPPP with pruritic erythematous papules around prominent urticated striae in a primigravida at late term. (b) As the disease evolves, about half of patients develop more polymorphic features including widespread non-urticated erythema, (c) target lesions, (d) tiny vesicles, and (e) eczematous changes.

allergic-type reaction, resulting in the initial appearance of the eruption within striae. Generalization of the eruption could result from cross reactivity to collagen in otherwise normal-appearing skin thus promoting the inflammatory response; immune tolerance in subsequent pregnancies could prevent recurrence. Whether peripheral microchimerism in pregnancy with deposition of fetal DNA in maternal skin may also play a role in triggering the inflammatory process, as suggested by a recent study [4], remains speculative.

## Diagnostic Principles

Histopathologic examination of lesional skin reveals a spectrum of non-specific findings, including a mild to moderate, superficial and mid-dermal, perivascular, lymphohistiocytic infiltrate, with frequent eosinophils. Spongiosis and marked papillary dermal edema may appear as microvesiculation clinically. Epidermal changes include akanthosis, hyperkeratosis and/or parakeratosis and are usually more pronounced in older lesions. Direct immunofluorescence examination shows no relevant abnormalities and is characteristically negative for linear C3 and immunoglobulin G deposition along the dermo-epidermal junction, the hallmark finding of pemphigoid gestationis. Indirect immunofluorescence is always negative and laboratory findings are normal.

## Therapeutic Principles

The disease is self-limiting without serious sequelae for mother or child and usually requires only symptomatic treatment. Basic therapy should consist of oil baths and/or emollients; antipruritic additives such as menthol, polidocanol, or urea (up to 10%) may be useful and are safe in pregnancy. In most cases topical treatment with moderately potent corticosteroids (e.g. methylprednisolone aceponat, momethasone fuorat, clobetasone butyrate 0.05%, or hydrocortisone butyrate 0.1%) either singly or combined with oral antihistamines suffice to control symptoms. During the first trimester, the older and best tested sedating first-generation antihistamines such as pheniramine, diphenhydramine and dimethindene are preferred. Later-on, if a non-sedating agent is required, loratadine and cetirizine may also be used safely. More severe cases of PUPPP may profit from a short course of systemic corticosteroids. A tapering dose of oral prednisolone, 30 mg daily for 5–10 days, should be sufficient and is considered safe.

## Pseudohermaphroditism, Female

Valéria Lamounier-Zepter
Medical Clinic III, University of Dresden, Dresden, Germany

### Definition and Characteristics

Abnormal female genital differentiation with the expected gonads (ovaries) and normal sex chromosomes.

### Prevalence

21-Hydroxylase deficiency: 1 in 14,554 live births. 11β-hydroxylase deficiency: 1 in 100,000 live births.

### Genes

CYP21B (chromosome band 6p21.3); CYP11B (chromosome band 8q21–q22); 3β-HSD (chromosome band 1p13); CYP19 (chromosome band 15q21); GR gene (chromosome band 5q31).

### Molecular and Systemic Pathophysiology

Female pseudohermaphroditism is mainly caused by syndromes of congenital adrenal hyperplasia. Adrenal enzyme defects – 21-hydroxylase deficiency (P450c21), 11β-hydroxylase deficiency (P450c11), 3β-hydroxysteroid dehydrogenase (3β-HSD) deficiency – result in decreased cortisol secretion. The inefficient cortisol synthesis leads to increases of pituitary adrenocorticotropic hormone (ACTH) secretion and consequent oversecretion of androgens. The prenatal exposure of excessive androgens induces virilization of the female external genitalia [1].

Cytochrome P450 aromatase (CYP19) is required for the conversion of androgens to estrogens. Mutations in the CYP19 gene results in an inactive protein with consequently disturbed estrogen productions and overproduction of androgens [2].

Female pseudohermaphroditism has also been described in a case of homozygous inactivating mutation of glucocorticoid receptor (GR) gene, with glucocorticoid resistance, which leads to excess ACTH secretion with resultant androgen and mineralocorticoid excess [3].

### Diagnostic Principles

Karyotyping and hormonal investigation: The postnatal diagnosis of 21-hydroxylase deficiency is confirmed by 17-hydroxyprogesterone measurements after intravenous administration of ACTH. The 11β-hydroxylase deficiency is diagnosed by the measurement of elevated basal or ACTH-stimulated 11-deoxycortisol levels in serum. The 3β-HSD deficiency is indicated by elevated serum levels of 17-hydroxypregnenolone and DHEA before and after ACTH stimulation [4].

Prenatal diagnosis can be performed by genetic analysis of mutations on CYP21B, CYP11B, 3β-HSD, and CYP19 genes.

### Therapeutic Principles

In adrenocortical insufficiency or glucocorticoid receptor defect, the administration of glucocorticoids corrects the (relative) lack of glucocorticoids and thus prevents further virilization. Early prenatal treatment may prevent virilization. Further therapeutic options include antiandrogens and surgical correction of clitoris and vagina.

# Pseudohypoaldosteronism, Autosomal Dominant

Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, IA, USA

## Synonyms

Pseudohypoaldosteronism type-1; PHA-1

## Definition and Characteristics

It is a rare disorder that is characterized by renal resistance to aldosterone with salt wasting, hyperkalemia, and metabolic acidosis. Inactivating mutations in one copy of the mineralocorticoid receptor gene (MLR) cause this form of PHA1 (OMIM-177735) [1].

## Prevalence

Rare disease.

## Genes

Mineralocorticoid receptor gene (MLR) NR3C2, gene map locus 4q31.1, inheritance autosomal dominant or sporadic.

## Molecular and Systemic Pathophysiology

Aldosterone acting via the MLR stimulates $Na^+$ transport in the connecting tubule (CNT) and the collecting duct. Inactivation of one copy of MLR leads to diminished $Na^+$ reabsorption in the distal nephron with resulting urinary $Na^+$ loss and hypotension [2,3]. The failure to transport $Na^+$ directly leads to inhibition of apical membrane $K^+$ and $H^+$ secretion from the principal and α-intercalated cells of the collecting duct and account for the hyperkalemia and acidosis. The abnormality in $Na^+$ reabsorption and $K^+$ handling tends to diminish with time. The improvement in salt wasting with increasing age is not well understood and suggests that in early childhood there is a critical dependence on a full complement of functional MR.

## Diagnostic Principles

The disease classically presents with lethargy, failure to thrive, inadequate growth, vomiting, feeding difficulties and volume depletion within the first week of life. The clinical characteristics of PHA-I are those of hypoaldosteronism, i.e., low blood pressures, hyponatremia, hyperkalemic metabolic acidosis, hyperreninemia, and renal salt wasting. Compared to autosomal recessive PHA-1, it is a milder disorder that is limited to renal manifestations. Occasionally, PHA1 can present during pregnancy with polyhydramnios. However, the disease classically presents with lethargy, failure to thrive, inadequate growth, vomiting, feeding difficulties and volume depletion within the first week of life. The infants manifest hypotension with hyperkalemia, hyponatremia and metabolic acidosis. An elevated plasma renin activity and high serum and urine aldosterone levels will be invariably found. The trans-tubular $K^+$ gradient is expected to be $< 5$ in the presence of hyperkalemia reflecting aldosterone resistance. $Na^+$ concentrations in the urine, sweat and saliva will be high reflecting the loss of ENaC-mediated $Na^+$ transport in these sites. Diagnosis is made by demonstrating inappropriately high urinary $Na^+$ losses in the presence of hyponatremia, decreased trns-tubular $K^+$ gradient in the presence of hyperkalemia, and increased levels of aldosterone and renin.

## Therapeutic Principles

Therapy consists of fluid and Na+ supplementation with ion exchange resin therapy with requirements being higher early in infancy and tending to diminish over time. Sodium chloride supplementation is followed by significant clinical improvement and correction of electrolyte abnormalities. Children with this

form of PHA1 usually outgrow the syndrome, and in later life, NaCl supplementation and resin therapy may not be required.

Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, IA, USA

## Synonyms

Pseudohypoaldosteronism type-1; PHA-1

## Definition and Characteristics

It is a rare condition that is characterized by hypotension from severe urinary salt wasting presenting in the neonatal period with weight loss, vomiting, dehydration, and occasionally respiratory distress. This form of PHA1 (OMIM 264350) is a consequence of loss-of function mutations in any of the three subunits of the amiloride sensitive epithelial sodium channel (ENaC).

## Prevalence

Rare disease.

## Genes

Mutation in either alpha subunit (SCNN1A), the beta subunit (SCNN1B), or the gamma subunit (SCNN1G) of the epithelial sodium channel (ENaC) that map to 12p13, 16p13–p12 and 16p13–p12(1). Inheritance is autosomal recessive or sporadic.

## Molecular and Systemic Pathophysiology

ENaC, comprised of three homologous units (α, β, γ) is expressed in the apical membrane of epithelial cells of the connecting tubule (CNT) and collecting duct of the kidney and in airways, alveoli, sweat glands and the distal colon (2–p4). The fundamental abnormality in this form of PHA-I is that inactivating mutations in both copies of the α, β or γ ENaC subunits result in defective sodium transport in the distal nephron with resulting volume depletion, hyperkalemia and metabolic acidosis beginning in early infancy. Elevated plasma renin and aldosterone levels in these children are the result of sustained volume depletion. Children with the disorder may also have pulmonary manifestations with increased airway secretions, chronic cough and recurrent respiratory infections.

## Diagnostic Principles

It is characterized biochemically by hyponatremia, severe hyperkalemia, metabolic acidosis and renal salt wasting, and raised plasma renin and aldosterone concentrations. Sweat and salivary sodium concentrations are also elevated. Urinary $Na^+$ is inappropriately elevated in the presence of volume depletion and there is decreased urinary potassium excretion with a normal GFR and normal adrenal function.

## Therapeutic Principles

Infants typically present early in life with severe symptoms and the disease has been associated with a reported high mortality. Emergent treatment of the volume depletion and hyponatremia requires parenteral saline repletion and the management of hyperkalemia includes the use of ion-exchange resins and in some cases, temporary dialysis. In the long term children can be managed with large doses of oral NaCl together with chronic ion-exchange resin therapy for those with resistant hyperkalemia. Patients may require oxygen for episodes of dyspnea and cyanosis associated with excess respiratory tract secretions or lung infections.

# Pseudohypoaldosteronism Type I, Autosomal Recessive and Dominant Forms

Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, IA, USA

## Synonyms

PHA1, autosomal recessive; Systemic PHA1 (OMIM #264350); PHA1, autosomal dominant; Renal limited PHA1 (OMIM #177735); PHA1, autosomal recessive and dominant forms

## Definition and Characteristics

PHA1 is a disorder characterized by severe renal salt wasting associated with hyponatremia, hyperkalemia and metabolic acidosis that begins early in life. Autosomal recessive PHA1 is not limited to the kidney and there is elevated sweat and salivary electrolytes that may contribute to the salt wasting. Pulmonary manifestations may appear in the older child with increased airway secretions, chronic cough and recurrent respiratory infections. Autosomal dominant PHA1 has no pulmonary phenotype and symptoms typically remit with age [1].

## Prevalence

The majority of reported cases of autosomal recessive PHA1 have occurred in consanguineous kindred and the true prevalence of the disease in the general population is unknown. Autosomal dominant PHA1 is another rare cause of salt wasting in infancy.

## Genes

Loss of function mutations in both copies of one of three different genes causes the recessive form of PHA1 [2]. These genes, SCNN1A, SCNN1B and SCNN1G are subunits of the epithelial sodium channel, α, β and γ that map to 12p13, 16p13-p12 and 16p13-p12 [3,4]. Inactivating heterozygous mutations in the mineralocorticoid receptor (MLR) on 4q31.1 cause autosomal dominant or sporadic PHA1 [5].

## Molecular and Systemic Pathophysiology

$Na^+$ absorption from the tubular lumen into the (CNT) and collecting duct of the kidney occurs through the epithelial $Na^+$ channel (ENaC) and contributes to the reabsorption of 2–5% of the filtered $Na^+$ load. Aldosterone acting via the MLR stimulates $Na^+$ transport in the CNT and the collecting duct. Loss of function mutations in ENaC subunits or inactivation of one copy of MLR leads to failure of $Na^+$ reabsorption in the distal nephron with resulting urinary $Na^+$ loss and hypotension. The failure to transport $Na^+$ directly leads to inhibition of apical membrane $K^+$ and $H^+$ secretion from the principal and α-intercalated cells of the collecting duct and account for the hyperkalemia and acidosis.

In autosomal recessive but not dominant PHA1 there is also a reduction in $Na^+$ transport in the alveolar and airway epithelia which leads to increased airway secretions that manifests as a runny nose with a chronic cough. $Na^+$ transport is inhibited in sweat and salivary glands resulting in high sweat and salivary gland electrolytes.

## Diagnostic Principles

Occasionally, PHA1 can present during pregnancy with polyhydramnios. However, the disease classically presents with lethargy, failure to thrive, inadequate growth, vomiting, feeding difficulties and volume depletion within the first week of life. The infants manifest hypotension with hyperkalemia, hyponatremia and metabolic acidosis. An elevated plasma renin activity and high serum and urine aldosterone levels will be invariably found. The trans-tubular $K^+$ gradient is expected to be <5 in the presence of hyperkalemia reflecting aldosterone resistance. $Na^+$ concentrations in the urine, sweat and saliva will be high reflecting the loss of ENaC-mediated $Na^+$ transport in these sites. Once stabilized, infants and children with the disorder generally respond to large doses of oral NaCl. However these children are prone to recurrent salt depletion crises.

## Therapeutic Principles

Infants typically present early in life with severe and life-threatening symptoms and the disease has been associated with a reported high mortality. Emergent treatment of the volume depletion and hyponatremia

requires parenteral saline repletion and the management of hyperkalemia includes the use of ion exchange resins and in some cases temporary dialysis. These patients do not respond to exogenous mineralocorticoids which is consistent with the pathophysiology. In the long term children can be managed with large doses of oral NaCl together with chronic ion exchange resin therapy for those with resistant hyperkalemia. These children are prone to recurrent salt depletion crises that may require frequent hospitalizations. In autosomal dominant PHA1 children usually outgrow the syndrome and in later life salt supplementation and resin therapy may not be required.

# Pseudohypoaldosteronism Type II

Christian A. Koch
Division of Endocrinology, Diabetes and Metabolism, University of Mississippi Medical Center, Jackson, MS, USA

## Synonyms

Gordon's syndrome

## Definition and Characteristics

Hyperkalemia and hypertension, normal glomerular filtration rate, suppressed plasma renin activity, normal or elevated aldosterone levels, hyperchloremia, and reduced bicarbonate. The reduced renal secretion of potassium makes this condition look like an aldosterone-deficient state ("Pseudohypoaldosteronism") see [1].

## Prevalence

Unknown, since patients are underdiagnosed. There are only a few families diagnosed with this condition, predominantly in Australia (Gordon and coworkers) and also in the U.S. (Lifton and coworkers). It is estimated that Gordon's syndrome also affects a significant amount of individuals with low plasma renin "essential" hypertension who respond well to thiazide diuretic therapy [2–4].

## Genes

Autosomal dominantly inherited disorder with possible genes mapped to chromosomes 1, 12, and 17, and recently identified mutations in WNK kinases WNK1 and WNK4 on chromosomes 12 and 17, respectively.

## Molecular and Systemic Pathophysiology

Hypertension in these patients may develop by increased renal salt reabsorption, the concomitant hyperkalemia by reduced renal K excretion despite normal glomerular filtration and aldosterone secretion. These features are chloride-dependent: infusion of sodium chloride instead of sodium bicarbonate corrects the abnormalities as does the administration of thiazide diuretics which inhibit salt reabsorption in the distal nephron. Gordon and coworkers found that all features could be reversed by very strict dietary salt restriction.

*Etiology*: Abnormalities such as (activating) mutations in the amiloride-sensitive sodium channel of the distal renal tubule [2–4].

## Diagnostic Principles

Hyperkalemia and hypertension, normal glomerular filtration rate, suppressed plasma renin activity, normal or elevated aldosterone levels, hyperchloremia, and reduced bicarbonate. Mutation analysis of WNK1 and WNK4.

## Therapeutic Principles

Severe dietary salt restriction; antihypertensives with preferably use of thiazide diuretics.

# Pseudohypoparathyroidism Type 1A

Lee S. Weinstein
Metabolic Diseases Branch, National Institute of Diabetes, Digestive, and Kidney Diseases, National Institutes of Health, Bethesda, MD, USA

## Synonyms

Albright hereditary osteodystrophy; AHO; Pseudopseudohypoparathyroidism; PHP 1A

## Definition and Characteristics

AHO is a congenital syndrome characterized by the presence of short stature, rounded face, brachydactyly, subcutaneous ossifications, and, in some cases, neurobehavioral deficits [1,2]. Pseudohypoparathyroidism type 1A (PHP1A) is the co-occurrence of AHO, obesity and resistance to parathyroid hormone (PTH), thyrotropin (TSH), and gonadotropins (the latter especially in females). Some relatives of PHP1A patients have AHO alone, a condition also referred to as pseudopseudohypoparathyroidism (PPHP). PHP1B is a condition characterized by PTH resistance in the absence of AHO. Progressive osseous heteroplasia (POH) is characterized by more severe platelike subcutaneous ossifications which invade into the deeper soft tissues.

## Prevalence

One study estimated the prevalence of pseudohypoparathyroidism in Japan to be about 3–4 per million.

## Genes

GNAS coding for the stimulatory G protein α-subunit (Gsα) on chromosome 20q13.

## Molecular and Systemic Pathophysiology

Gsα is the stimulatory G protein α-subunit which is required for the intracellular cyclic AMP response to hormones and other extracellular signals in most tissues [1]. AHO is generally associated with heterozygous Gsα null mutations and presumably results from Gsα haploinsufficiency in many tissues, including bone. Patients who inherit these mutations maternally also develop hormone resistance and obesity (PHP1A) while those that inherit the same mutations paternally do not (PPHP). This is due to the fact that Gsα is maternally imprinted in several tissues, including renal proximal tubules, thyroid, and gonads, which are the sites of action of PTH, TSH, and gonadotropins, respectively. All three of these hormones signal through Gsα, and therefore mutation of the active maternal allele leads to hormone resistance due to low expression of Gsα in these tissues. PTH resistance in the kidney leads to hypocalcemia and hyperphosphatemia due to increased phosphate reabsorption and reduced synthesis of 1, 25 dihydroxyvitamin D in the renal proximal tubules. Some patients with Gsα null mutations develop POH. PHP1B is caused by a *GNAS* imprinting defect that leads to loss of maternal-specific imprinting (DNA methylation) within the "exon 1A" region of the gene [3]. This presumably leads to loss of Gsα expression in renal proximal tubules, resulting in PTH resistance, but does not affect Gsα expression in most other tissues (which presumably explains why these patients do not develop AHO).

## Diagnostic Principles

AHO is usually diagnosed clinically based upon the development of the characteristic features, although individually many of the features are not specific. All patients suspected of having AHO should be tested for the presence of hormone resistance to determine whether PHP1A is the correct diagnosis. In the absence of hormone resistance, the diagnosis of PPHP should not be made unless there is a clearcut family history of PHP1A or a Gsα defect has been identified. The co-occurrence of brachydactyly and subcutaneous ossifications is relatively specific for AHO. PTH resistance is characterized by high serum PTH levels associated with hyperphosphatemia, and usually hypocalcemia, in the absence of vitamin D deficiency. A reduced urinary cyclic AMP response to PTH analog is the gold-standard, although the analog is presently not commercially available. TSH resistance presents as mild to moderately elevated serum TSH levels in the presence

of low or low normal free thyroxine (T4) levels. Women with gonadotropin resistance develop ovulatory and/or fertility problems. The diagnosis can be confirmed by biochemical tests demonstrating Gsα deficiency in erythrocyte membranes or genetic tests demonstrating Gsα mutations. PHP1B is diagnosed by the presence of PTH resistance in the absence of AHO, and can be confirmed by Southern blot analysis demonstrating the presence of a GNAS methylation defect. This test is only presently available in research laboratories.

### Therapeutic Principles

PTH resistance is generally managed with oral calcium supplements and vitamin D analogs to normalize serum calcium and PTH (if possible) without producing hypercalciuria. TSH resistance is treated with oral levothyroxine to normalize TSH. Gonadotropin resistance in women can be managed with oral contraceptives. There is no specific therapies to manage the somatic and neurological abnormalities which characterize the AHO phenotype.

## Pseudohypoparathyroidism Type Ib

Caroline Silve
Unité Inserm, Faculté de Médicine Xavier Bichat, Paris, France

### Synonyms

PHP 1b

### Definition and Characteristics

Pseudohypoparathyroidism type I b (PHP-Ib) is characterized by hypocalcemia and hyperphosphatemia associated with isolated renal resistance to parathyroid hormone (PTH). Patients with PHP-Ib, in contrast to patients with PHP-Ia, do not present the set of somatic features of Albright hereditary osteodystrophy (AHO) nor signs of resistance to other hormones that act through the stimulation of adenylate cyclase.

### Prevalence

PHP-Ib prevalence is unknown, PHP prevalence has been reported to be approximately 3°/°° in one study.

### Genes

Gs alpha protein gene locus GNAS1, which maps to the chromosome 20q13 region.

### Molecular and Systemic Pathophysiology

PTH is a main regulator of renal phosphate reabsorption and 1 alpha hydroxylase activity in the renal proximal tubule. PTH acts by binding to its receptor (PTHR1), which belongs to the class B family of seven putative transmembrane domain G protein-coupled receptors. Most PTH biological actions are attributed to the stimulation of cAMP production following the coupling of the receptor to adenylate cyclase by the stimulatory protein Gs. The Gs alpha gene, GNAS1, is located in a domain, which is imprinted in a tissue specific manner and is regulated by alternate splicing. Gs alpha is biallelically expressed in most tissues, but only the maternal Gs alpha allele is expressed in the renal proximal tubule. Thus, a defect is Gs alpha maternal allele expression would result in the resistance of the renal proximal tubule to PTH. A loss of methylation at a differentially methylated region of GNAS1, the exon A/B, and a biallelic expression of A/B transcripts have been shown in all sporadic and familial PHP-Ib cases. Therefore, a defect is postulated in a regulatory element located more than 50 kb upstream of exon A/B in PHPIb pathogenesis.

### Diagnostic Principles

Hypocalcemia, hyperphosphatemia, low 1,25 dihydoxyvitamin D levels in the presence of high circulating PTH concentrations and normal renal function. Absence of dysmorphy. Autosomal dominant PHP-Ib develop only in offspring of affected or unaffected obligate carriers. Patients with PHP-Ib (and a) show neither a phosphaturic response nor a nephrogenous cyclic AMP response to the administration of exogenous PTH.

### Therapeutic Principles

There is no curative treatment for PHP Ib; symptomatic treatment with calcium and calcitriol reduces hypocalcemia.

# Pseudo-Obstruction

►Intestinal Obstruction, Functional

# Pseudopseudohypoparathyroidism

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

PPHP

## Definition and Characteristics

Patients with pseudopseudohypoparathyroidism (PPHP) have the typical features of Albright hereditary osteodystrophy (AHO) without parathyroid hormone (PTH) resistance [1]. The characteristic phenotype is short stature, moon face, obesity, brachydactyly, mental retardation, lenticular cataracts, ectopic calcification or ossification, and dental hypoplasia. Brachydactyly is the most specific feature occurring in AHO. The most commonly shortened metacarpal is the fourth metacarpal which occurs in approximately 65% of patients with PPHP [1]. Metastatic calcification in patients with PPHP commonly affects the subcutaneous tissues and basal ganglia. In contrast to patients with pseudohypoparathyroidism (PHP), patients with PPHP have normal serum calcium, phosphate, and PTH levels.

## Prevalence

PPHP is a rare disorder; the prevalence of which is not known.

## Genes

PPHP is inherited as an autosomal dominant disorder [2]. PPHP is caused by heterozygous inactivating mutations in GNAS which contains 13 exons encoding the Gsα and is located at 20q13. As Gsα is paternally imprinted (silenced) in specific target tissues, mutation on the maternally derived allele leads to PHP-Ia or PHP-Ic while a paternally derived mutation leads to PPHP [2]. As such, PPHP, PHP-Ia, and PHP-Ic often occur in the same kindred.

## Molecular and Systemic Pathophysiology

The molecular basis for PPHP is a defect in the $G_s$ protein. Each heterotrimeric $G_s$ protein has a specific α subunit which binds guanine nucleotide and interacts with specific receptors and effectors. The $G_s$ protein mediates the activation of adenyl cyclase by several peptide hormones to produce cAMP [3]. cAMP then activates protein kinase; the physiological consequences of which vary according to the cell type. The reduction in $G_s$ protein explains the reduced responsiveness of target organs to the respective hormones. AHO phenotype is caused by resistance to PTH-related peptides [3].

## Diagnostic Principles

PPHP has to be distinguished from PHP. PHP is a heterogeneous disease characterized by end-organ resistance to PTH and classified as types Ia, Ib, Ic and II according to the phenotype, underlying pathogenesis, and biochemical abnormalities (Table 1) [3,4].

Patients with 2q37 deletion may have an AHO phenotype but no PTH resistance [5]. Genetic studies are often necessary to establish the diagnosis. Other differential diagnosis includes acrodysostosis, Turner

**Pseudopseudohypoparathyroidism. Table 1** Classification of pseudohypoparathyroidism and pseudopseudohypoparathyroidism

| | PPH-P | PHP-Ia | PHP-Ib | PHP-Ic | PHP-II |
|---|---|---|---|---|---|
| AHO phenotype | + | + | – | + | – |
| Response to PTH | | | | | |
| Urinary cAMP | N | ↓ | ↓ | ↓ | N |
| Urinary phosphate | N | ↓ | ↓ | ↓ | ↓ |
| Serum calcium | N | ↓ or (rarely) N | ↓ | ↓ | ↓ |

# Pseudotruncus

►Pulmonary Atresia

# Pseudoxanthoma Elasticum

Jouni Uitto, Qiujie Jiang
Department of Dermatology and Cutaneous Biology, Jefferson Medical Collage, Philadelphia, PA, USA

## Synonyms

Grönblad-Strandberg syndrome; PXE

## Definition and Characteristics

Pseudoxanthoma elasticum (PXE) is a multi-system disorder affecting connective tissues primarily in the skin, eyes and the cardiovascular system [1]. The characteristic pathologic lesion displays dystrophic mineralization of connective tissues, primarily the elastic fibers which are pleiomorphic and appear fragmented. The characteristic cutaneous findings are yellowish papules which tend to coalesce into larger plagues of inelastic skin in the predilection sites, i.e., the lateral neck, axillae, and antecubital fossae. The cutaneous lesions are progressive and can lead to extensive involvement manifesting with loose, sagging and inelastic skin. The cutaneous findings are primarily of cosmetic concern, however, they often signify clinical involvement of the eyes and the cardiovascular system, with considerable morbidity and even mortality. The ocular findings consist of angioid streaks which result from breaks in the calcified elastic lamina of the Bruch's membrane, derived from the retina and the choroid plexus. These fractures lead to breakage of blood vessels and neovascularization from choriocapillaries, and subsequent leakage of newly formed vessels can lead to hemorrhage and scarring, with progressive loss of visual acuity, and rarely, legal blindness. In the vascular connective tissue system, mineralization affects primarily mid-sized arteries, and progressive mineralization of the elastic media and intima leads to formation of plagues, which manifest with intermittent claudication, loss of peripheral pulses, hypertension and angina, and rarely myocardial infarction at relatively early age.

PXE demonstrates considerable both intra- and interfamilial phenotypic heterogeneity, and the severity can be highly variable. In some families, certain organ systems, such as skin, eyes or the cardiovascular system, are more severely affected.

PXE is exclusively an autosomal recessive disease, and occurrence of the disease in two subsequent generations reflects in many cases pseudodominance due to consanguinity in the family [2].

## Prevalence

The precise prevalence of the disease is not known, but estimates vary from 1:25,000 to 1:100,000. Even the lower number may be an underestimate, as milder cases often go undiagnosed.

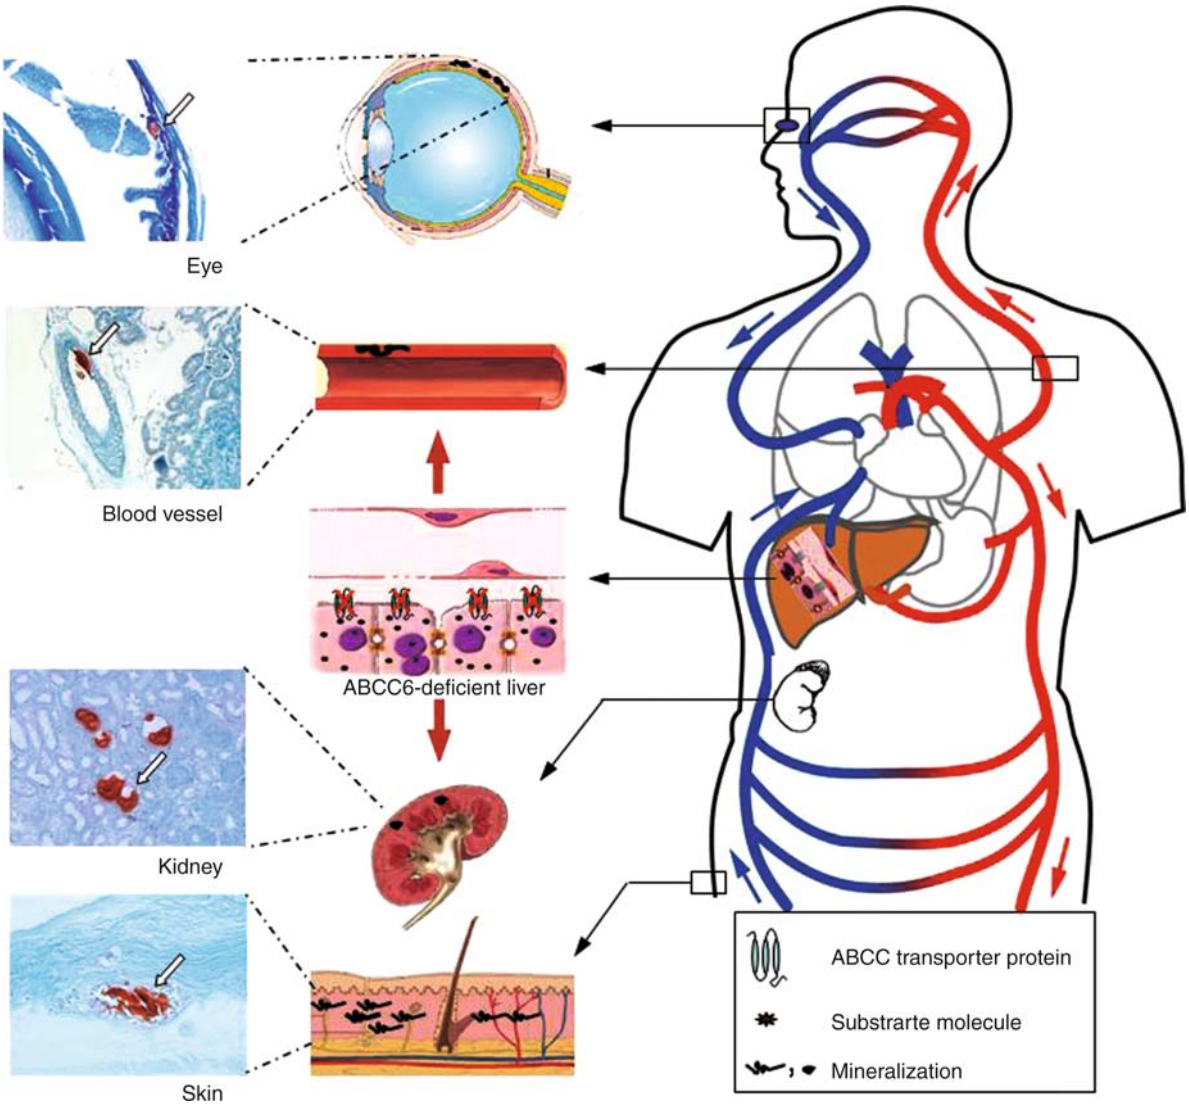
## Genes

The classic forms of PXE are due to loss-of-function mutations in the ABCC6 gene, member of the ATP-binding cassette protein family of genes, expressed primarily in the liver, to a lesser extent in the proximal tubules of kidneys, and at low level, if at all, in tissues affected in PXE. PXE-like cutaneous changes have been encountered in a number of other heritable conditions, including β-thalassemia and in patients with multiple coagulation factor deficiency (caused by mutations in the GGCX gene) [3]. Rare, acquired forms of PXE are associated with topical exposure to mineral-containing chemicals and as a sequela of long term ingestion of D-penicillamine [1].

## Molecular and Systemic Pathophysiology

Well over 200 distinct mutations in the ABCC6 gene have been encountered in families with PXE – these

include premature termination codon, missense and splicing mutations, as well as small insertions and deletions or large deletions which in some cases eliminate the entire gene [4]. The missense mutations frequently affect the two nucleotide binding fold domains, required for the binding and hydrolysis of ATP to allow this protein to serve as a transmembrane transporter. However, the precise function and the physiologic ligands in vivo of this transporter are currently unknown. The ABCC6 protein (also known as multi-drug resistance associated protein 6, MRP6) is expressed primarily in the basolateral side of the plasma membrane of hepatocytes. It has been postulated that in physiologic situations, this transporter removes toxic substances from the liver to circulation (Fig. 1).



**Pseudoxanthoma Elasticum. Figure 1** Representation of pseudoxanthoma elasticum (PXE) as a generalized, multiorgan disease inherited in an autosomal recessive fashion. PXE is caused by mutations in the *ABCC6* gene, which encodes multidrug resistance-associated protein 6 (MRP6), primarily expressed in the liver. This protein is postulated to serve as an efflux pump on the basolateral surface of hepatocytes transporting substrate molecules from the intracellular milieu to blood. In the absence of MRP6 transporter activity in the liver (red Xs, middle panels), the blood levels of currently uncharacterized metabolites may change, and this process leads to ectopic mineralization of connective tissue in a number of organs, including the retina of the eye, the blood vessel walls, the kidney tubules, and the dermis of the skin (middle panel). The mineralization process can be visualized by specific stains, such as Alizarin red, as shown in the left panels (*open arrows*) in the corresponding tissues from an *Abcc6*$^{-/-}$ mouse, which recapitulates the genetic, histopathologic, and ultrastructural features of human PXE (Adapted from Uitto J (2007), J Invest Dermatol 127:507–510).

In the absence of ABCC6 transporter activity, such critical molecules are deficient or absent in circulation, and it has been postulated that these molecules are required to prevent ectopic mineralization of peripheral tissues under normal homeostatic conditions. Potential candidate molecules include fetuin-A, ankylosis protein, osteocalcin and matrix gla protein – the latter requires γ-glutamyl carboxylation for activation [5].

## Diagnostic Principles

PXE is a heritable disorder, but the age of onset is delayed and the clinical diagnosis based on skin and/or ocular findings is usually made in early teens or adolescence but in some cases the clinical diagnosis is not made until in late adulthood. The diagnosis is confirmed by histopathology of the lesional skin, which demonstrates the presence of pleiomorphic elastic structures with extensive mineralization, as visualized by special stains (Verhoeff-van Giesson for elastin; von Kossa or Alizarin red for calcium). Demonstration of ABCC6 mutations can be used for confirmation of the diagnosis as well as for pre-symptomatic diagnosis in families with history of PXE.

## Therapeutic Principles

There is no specific treatment for PXE. The primary prevention of ocular complications, the most feared consequences of the disease, consists of protection from trauma particularly to the head, since head trauma can result in excessive bleeding to the eyes and retinal detachment. Ophthalmologic care includes annual eye examination. Laser photocoagulation has been suggested to be effective, but its long-term efficacy is compromised by high recurrence rate (~65%). Macular translocation is an experimental approach, the efficacy of which is currently unknown. Treatment of hypercholesterolemia and hypertension is recommended as necessary, and cessation of smoking is essential in alleviating signs of peripheral vasculopathy. Cosmetic surgery can alleviate esthetic problems associated with cutaneous findings.

# PSNP

►Progressive Supranuclear Palsy

# Psoriasis

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Definition and Characteristics

Plaque psoriasis or psoriasis vulgaris, the most common variant, is characterized by sharply demarcated erythematous plaques with adherent silvery micaceous scales (Fig. 1) [1]. Removal of the scales results in fine punctate bleeding, which is referred to as the Auspitz sign. The lesions are usually symmetrically distributed and pruritic. Typical sites include the knees, elbows, and lower back. Involvement of the scalp, face, and the intertriginous and diaper areas is more common in infants and young children. Mucosal involvement is unusual. Other variants include guttate psoriasis, pustular psoriasis, erythrodermic psoriasis, and flexural psoriasis. Seronegative inflammatory arthritis develops in about 5 to 20% of patients [2]. Psoriatic arthritis can precede, coincide with, or follow the development of the skin lesions. Most patients eventually develop nail involvement. Nail involvement precedes the skin lesions in approximately 4% of patients [3]. Nail involvement includes pitting, discoloration, onycholysis, or onychodystrophy [2]. Complications of psoriasis include an increased risk of non-melanoma skin cancer and emotional distress in more severely affected individuals [3].

## Prevalence

Estimates of prevalence range from 1 to 2% [2]. Approximately 25% of patients develop the disease before 20 years of age. Both sexes are affected equally.

**Psoriasis. Figure 1** Plaque psoriasis presenting on the back.

The condition is more common in Caucasian individuals than in black or Asian individuals [4]. The prevalence is greatest in northern, colder climates, and the disease is more severe in the colder months [1]. A family history of psoriasis in a first-degree relative is present in about 30% of patients with childhood-onset psoriasis [1]. The concordance rate in monozygotic twins is approximately 70%, compared with 20% in dizygotic twins [2].

## Genes

Psoriasis is associated with various histocompatibility antigens, especially HLA-Cw6. Psoriasis susceptibility loci within the major histocompatibility complexes have been mapped to several chromosomes.

## Molecular and Systemic Pathophysiology

Psoriasis is characterized by hyperproliferation of epidermal keratinocytes and hyperkeratosis as well as a lymphocytic infiltration that consists mainly of T lymphocytes. Activation of T lymphocytes, migration of T lymphocytes to the skin, and T lymphocyte-mediated production of cytokines such as interferon gamma, interleukin-2, and tumor necrosis factor alpha is important in the pathogenesis [4,5]. Interferon gamma inhibits apoptosis of keratinocytes, interleukin-2 stimulates growth of T lymphocytes and tumor necrosis factor alpha increases proliferation of proinflammatory cytokines and adhesion molecules [5]. The adhesion molecules further stimulate T lymphocytes to produce cytokines [3]. Predisposing factors include the use of chloroquine, withdrawal of corticosteroid in a susceptible individual, emotional stress, alcohol or tobacco consumption, trauma (Köebner phenomenon), hypocalcaemia, xerosis, and sunburn. Streptococcal infection can precipitate guttate psoriasis via a mechanism that involves activation of $CD4^+$ T cells by a superantigen.

## Diagnostic Principles

Psoriasis is a clinical diagnosis. In infancy and early childhood, psoriasis should be differentiated from seborrhoeic dermatitis and nummular eczema. In older individuals the condition should be differentiated from pityriasis rubra pilaris and pityriasis lichenoides chronica. In patients with guttate psoriasis, culture from the throat or perianal area, and measurement of the serum antistreptolysin O titer should be considered.

## Therapeutic Principles

Precipitating and exacerbating factors should be minimized or avoided. Optimal skin care requires constant attention to hydration and lubrication, and efforts to minimize itching. Topical medications such as corticosteroids, calcipotriene, retinoids, or immunomodulators such as tacrolimus and pimecrolimus are commonly prescribed as initial therapy. Narrow band UVB phototherapy or photochemotherapy psoralen UVA (PUVA), either alone or in combination with other topical remedies, should be considered for widespread or severe psoriasis [4]. Systemic treatment is usually reserved for severe and generalized forms of psoriasis that are resistant to other therapies. Combination, sequential, or rotational systemic therapy, with methotrexate, acitretin, or cyclosporine, can achieve additive or synergistic efficacy at lower dosages and with less risk of adverse events [4]. Newer medications such as alefacept, efalizumab, etanercept, and infliximab, which block molecular steps in the pathogenesis, have less potential for side effects but are more expensive.

## Pubertal Gynecomastia

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Definition and Characteristics

Pubertal gynecomastia is defined as a benign proliferation of glandular tissue of the breast in males at the time of puberty, resulting in a concentric enlargement of one or both breasts [1,2]. The affected adolescent is otherwise healthy. The condition is usually bilateral but may affect one breast more than the other. Breast enlargement is often so minor that it may remain unrecognized unless specifically sought for by palpation. However, breast enlargement can be quite significant and simulate early stages of female breast development (Fig. 1) [1].

Secondary sexual characteristics such as pubic hair development and testicular enlargement are characteristically present for at least six months prior to the onset of the gynecomastia [2]. Puberty gynecomastia is usually asymptomatic; only occasionally does it cause discomfort or, rarely, pain.

### Prevalence

Pubertal gynecomastia has an onset between 10 and 12 years of age. It has a peak occurrence between 13 and 14 years of age when approximately 40% of boys are affected.

### Molecular and Systemic Pathophysiology

The breast enlargement associated with pubertal gynecomastia is believed to result from a short-lived increase in plasma estrogens. Aromatization occurs within the breast tissue. Aromatase is the key enzyme for estrogen biosynthesis [2]. Circulating estrogens are derived mainly from adrenal androgens, the production of which is increased in early adolescence. Boys with pubertal gynecomastia tend to have an absolute increase in the production of estradiol relative to testosterone. There is also increased sensitivity of the breast tissue to estrogens [1]. As puberty progresses, testosterone becomes the dominant hormone and this would cause the male breast tissue to regress.

### Diagnostic Principles

Gynecomastia should be differentiated from accumulation of adipose tissue in the mammary region (lipomastia) in obese boys [2]. In gynecomastia, a mobile, rubbery, discrete, subareolar disk-like plaque of breast tissue can be felt, whereas no disk-like plaque can be felt in lipomastia [2,3]. It is important to differentiate gynecomastia from lipoma, neurofibroma, and carcinoma of the breast.

**Pubertal Gynecomastia. Figure 1** A 14-year-old boy with pubertal gynecomastia.

Pubertal gynecomastia should also be differentiated from pathological causes of gynecomastia which may result from medications (e.g., digitalis, spironolactone, methyldopa, isoniazid, domperidone), hypogonadism (e.g., anorchia, Klinefelter syndrome, androgen resistance syndrome), adrenal disorders (isolated adrenocorticotropic hormone deficiency, feminizing adrenal tumors), hepatic disorders (e.g., cirrhosis, hepatoma), thyroid disorders (hypothyroidism, hyperthyroidism), chronic renal failure, cystic fibrosis, hermaphroditism, and malnutrition [1,3]. Gynecomastia may also be inherited as an autosomal dominant or X-linked recessive disorder due to the mutation of the P450 aromatase gene [1,3]. The initial evaluation should include a careful history and a physical examination. Laboratory tests should be selected based on clinical findings and may include serum estradial, testosterone, dihydroepiandrosterone sulfate, LH, FSH and HCG, liver function tests, renal function tests, thyroid function tests, and karyotyping.

## Therapeutic Principles

Treatment consists mainly of reassuring the patient that the condition is benign and transient. Spontaneous resolution occurs in about 75% of boys within 2 years and 90% of boys within 3 years [3]. Medications such as raloxifene and tamoxifen may be used to treat severe pubertal gynecomastia [4,5]. Reduction mammoplasty should be considered for those cases that fail to respond to medical treatment and causing sufficient psychological disturbance and embarrassment to interfere with the patient's social life.

# Pulmonary Actinomycosis

Orhan Yildiz[1], Uner Kayabas[2]
[1]Department of Infectious Diseases, Faculty of Medicine, Erciyes University, Kayseri, Turkey
[2]Department of Infectious Diseases, Faculty of Medicine, Inonu University, Malatya, Turkey

## Synonyms

Thoracic actinomycosis

## Definition and Characteristics

The pulmonary form of actinomycosis is a rare chronic suppurative pulmonary or endobronchial infection caused mainly by actinomyces israelii, a gram-positive anaerobic organism. It is frequently observed as a secondary and localized infection often with lung involvement, especially in residual cavities or bronchiectasis. They may form an abscess and sinus tract formation and cause purulent discharge with yellowish sulfur granules. It classically involves cervicofacial (50–60%), abdomino-pelvic (20%), pulmonary (15%), and mixed organs (10%) including brain, cutaneous, ophthalmic, cardiac, genitourinary, and disseminated [1,2]. The diagnosis of pulmonary actinomycosis is often not made until relatively late in the course. The usual presentation is an indolent, slowly progressive pneumonia with fever, weight loss, cough, sputum, and chest pain [2]. The symptoms and the clinical and radiological signs mimic malignancy or tuberculosis. The presence of an air bronchogram within a mass lesion and one or more small cavities should suggest the possibility of a non-neoplastic process, such as actinomycosis. There may be hemoptysis, hilar adenopathy, mediastinal, and cardiac involvement.

## Prevalence

Actinomycosis is a rare infection occurring in 1 out of 300,000 people per year. The presentation of pulmonary actinomycosis has also changed. It now appears less aggressive in nature compared with the pre-antibiotic era [2]. These changes in both the disease's presentation and its incidence may be the result of improvements in oral hygiene, and in the early initiation of treatment when pulmonary infection is suspected. The peak incidence of disease is reported to be in the mid-decades. Male: female ratio is approximately 3:1. A higher incidence of pulmonary actinomycosis has also been reported in patients with underlying respiratory disorders, such as emphysema, chronic bronchitis, and bronchiectasis, and in alcoholics, but the series was small [1,2].

## Molecular and Systemic Pathophysiology

Actinomyces spp. are higher prokaryotic bacteria belonging to the family actinomyceataceae. Actinomycosis is caused mainly by actinomyces israelii. Additional species that are established but less common causes of actinomycosis include a. naeslundii/viscosus complex, a. odontolyticus, a. meyeri, and a. gerencseriae. Depending on the site of infection, most actinomycotic infections are polymicrobial in nature [1,2].

Members of the genus actinomyces are predominant primary colonizers of the oral cavity and play an important role in initiating plaque development. Bacterial

fimbriae have been shown to play an important role in the interaction between bacteria and host cells or among bacterial cells. Further genetic analysis of the various enzyme activities detected from strains of actinomyces should allow for an assessment of the role of these components in microbial ecology, and their contribution to the overall success of actinomyces spp. as a primary colonizer and a key player in oral health and disease [3].

A vital step in the development of actinomycosis is the disruption of the mucosal barrier, allowing the organisms to invade. Poor oral hygiene and associated dental disease may increase the risk. Pulmonary actinomycosis most likely starts when oropharyngeal secretions are aspirated into a minor bronchus, causing atelectasis and pneumonitis. Once established, the initial acute inflammation is followed by the characteristic chronic, indolent phase that generates local necrosis and fibrosis and commonly cavitates. Histopathology reveals an acute inflammation surrounded by fibrosing granulation tissue. Such material contains "sulfur granules," colonies of organisms forming an amorphous center surrounded by a rosette of clubbed filaments; these usually contain associated organisms, including actinobacillus actinomycetemcomitans, haemophilus, and fusobacterium spp. Actinomycosis is not clearly associated with the immunocompromised state [1,2].

## Diagnostic Principles

Actinomycosis is very difficult to diagnose because its appearance varies from similarities with bronchogenic carcinoma to fungal infections, lung abscesses, and pneumonitis-like tuberculosis infections. The diagnosis is rarely suspected except for patients with the classic presentation of a penetrating chest infection with pleural involvement (pleural effusions, empyema, and pleural thickening) and a chest wall mass or draining sinus [2,4]. Occasional cases are detected with cytologic examination showing sulfur granules. Actinomyces israelii is a bacterium that may be normally found in the oral flora, and so it is difficult to determine whether the cultured organism is pathogenic or not. Fine-needle aspiration or transbronchial biopsy and CT- or ultrasound-guided aspirations or biopsies are successfully used to obtain clinical material for diagnosis [4]. In many cases, the diagnosis is made histologically after resection for a suspected neoplasm. Any material obtained should be cultured under anaerobic conditions. The agents of actinomycosis are non-spore-forming rods (except for a. meyeri). Growth usually appears within 5–7 days, but primary isolation may take up to 2–4 weeks. The diagnosis therefore requires a combination of several factors, including a positive culture and demonstration of sulfur granules in purulent matter from infected tissue, correlation with the clinical and radiological features, and the response to antibiotic treatment.

## Therapeutic Principles

Untreated, pulmonary actinomycosis is ultimately fatal, whereas early treatment can prevent the late complications of extensive disease and result in cure rates of over 90%. The rationale for the use of penicillin in actinomycosis is based more on extensive successful clinical experience over the last 50 years than on randomized control trials. Although therapy should be individualized, 18–24 million units of intravenous penicillin per day are given initially for 2–6 weeks, followed by oral therapy with penicillin or amoxicillin for 6–12 months. Recently, several investigators have treated extensive thoracic actinomycosis with relatively brief courses of therapy [5]. Tetracyclines, erythromycin, chloramphenicol, and clindamycin are suitable alternatives. The role of surgery is often controversial. Some have reported impressive results with antibiotic treatment alone in patients with extensive disease. Even though surgical drainage of abscess and empyema as well as excision of sinus tracts are often helpful, appropriate antibiotic coverage should be performed soon after the operation to prevent possible complications or spread of the disease. Percutaneous drainage of abscesses in combination with medical therapy is another option.

# Pulmonary Alveolar Phospholipoproteinosis

►Pulmonary Alveolar Proteinosis

# Pulmonary Alveolar Proteinosis

Richard G. Hegele
Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada

## Synonyms

Alveolar proteinosis; Alveolar lipoproteinosis; Alveolar phospholipidosis; Pulmonary alveolar lipoproteinosis; Pulmonary alveolar phospholipoproteinosis; PAP

## Definition and Characteristics

Abnormal intraalveolar surfactant accumulation with minimal pulmonary interstitial inflammation or fibrosis [1]. Variable natural history, from spontaneous resolution to death. Three sub-types recognized: acquired PAP; congenital PAP; secondary PAP.

## Prevalence

Reported prevalence of 3.7 cases per million population.

## Genes

*Acquired PAP*: No genes definitively reported for humans. PAP-like disease occurs in granulocyte-macrophage colony stimulating factor (GM-CSF) and GM-CSF receptor $\beta_c$ subunit knock-out mice. The human GM-CSF receptor $\beta_c$ subunit gene is located on chromosome 22q11.2.

*Congenital PAP*: Homozygous frame-shift mutation (121ins2) in exon 4 of surfactant protein (SP)-B gene (chromosome 2) is best described; other mutations in SP-B, SP-C and in GM-CSF receptor $\beta_c$ genes have been reported.

*Secondary PAP*: Mutation in y + L amino acid transporter-1 gene reported in cases of lysinuric protein intolerance.

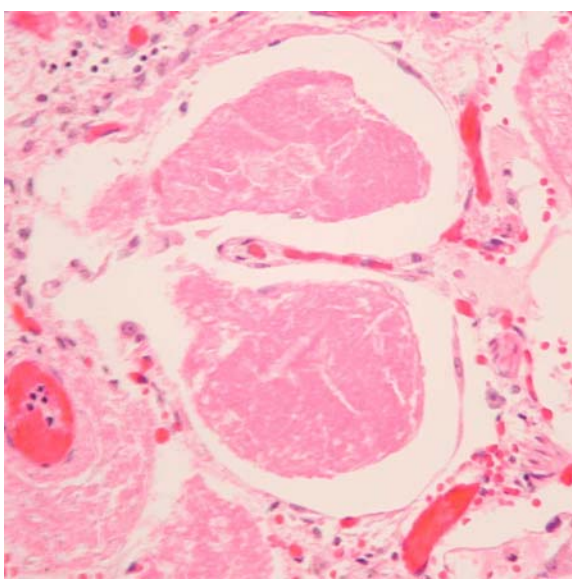
## Molecular and Systemic Pathophysiology

In Acquired PAP, production of neutralizing antibodies to GM-CSF results in inhibition of activity of endogenous GM-CSF, and is manifested by impaired catabolic activity of pulmonary surfactant by alveolar macrophages [2].

In congenital PAP, functional GM-CSF deficiency occurs via decreased binding of endogenous GM-CSF to mutant GM-CSF receptor $\beta_c$, or by a novel truncated form of $\beta_c$ lacking a transmembrane domain and acting as a soluble inhibitory receptor. Alternatively, a frame-shift mutation in the SP-B gene leads to an unstable SP-B mRNA, decreased SP-B protein levels and secondary disturbances in SP-C processing. In secondary PAP, underlying causes include inhalation of various dusts, fibers and metals; congenital and acquired immunodeficiency states (including iatrogenic immunosuppression); malignancies and hematopoietic disorders. The specific gene defect for lysinuric protein intolerance (see above) is associated with defective membrane transport of dibasic amino acids. Secondary PAP is believed to be related to an absolute deficiency and/or functional impairment in surfactant clearance by alveolar macrophages. Proteomic analysis of bronchoalveolar lavage fluid from PAP patients reveals multiple SP-A isomers, confirming a high surfactant content [3]. GM-CSF appears to be crucial for the differentiation of alveolar macrophages (but not other tissue macrophages) and this may explain why organ involvement by PAP is limited to the lung [4].

## Diagnostic Principles

Acquired PAP usually presents as progressive dyspnea, with minimally productive cough or fatigue, weight loss, low-grade fever, and frequently a normal physical examination. Congenital PAP and Secondary PAP can have a more fulminant presentation of respiratory distress. Pulmonary function testing classically reveals a restrictive defect, with a disproportionate reduction in diffusing capacity relative to vital capacity. Plain chest radiography characteristically shows a combination of patchy alveolar and interstitial disease, while high resolution computed tomography of the chest shows a "crazy paving" pattern related to airspace disease and thickening of interlobular septa [5]. Examination of fluid recovered by bronchoalveolar lavage (BAL) is classically "milky" and microscopically reveals a combination of granular, acellular proteinaceous material (Fig. 1). The



**Pulmonary Alveolar Proteinosis.**
**Figure 1** Photomicrograph of BAL fluid specimen from a patient with acquired PAP. Note granular, acellular material within the alveolar spaces (hematoxylin and eosin stain).

P

proteinaceous material may be associated with "foamy" alveolar macrophages that have intracytoplasmic, periodic acid-Schiff (PAS)-positive inclusions.

### Therapeutic Principles

Therapeutic lung lavage, often repeated, is a mainstay of treatment, together with therapy of any associated condition (e.g., infection). Pharmacological therapy with GM-CSF is also used with good response in up to one half of cases, and appears to be partially effective even in patients with Acquired PAP whose disease is characterized by production of neutralizing anti-GM-CSF antibodies. There are sporadic case reports describing other pharmacological therapy (e.g., ambroxol) in PAP but the general efficacy and effectiveness of these agents remain unproven.

## Pulmonary Alvolear Lipoproteinosis

►Pulmonary Alveolar Proteinosis

## Pulmonary Anthrax

Jean-Nicolas Tournier
Département de Biologie des Agents Transmisibles, Centre de Recherches du Service de Santé des Armées, Unité Interactions Hôte-Pathogène, La Tronche, France

### Synonyms

Inhalational anthrax; Respiratory anthrax; Anthrax pneumonia; Wool-sorter's disease; Blackbane (medieval term)

### Definition and Characteristics

Pulmonary anthrax is an infectious disease caused by the inhalation of bacillus anthracis spores. B. anthracis is an aerobic, Gram-positive, spore-forming, non-motile bacillus species [1]. Following infection, the bacilli proliferate, producing their main virulence factors: a capsule and two toxins (edema toxin [ET] and lethal toxin [LT]). Anthrax meningitis is a common complication of pulmonary anthrax. The 50% lethal dose in humans has been estimated at 40,000 spores.

Spore inhalation is followed by a period of incubation ranging from 1 to 10 days (range of 4–6 days for the US outbreak in 2001), but infection may occur up to 43 days after spore inhalation (Sverdlosk outbreak, 1979). The clinical presentation of anthrax comprises two stages. In the first stage, patients report atypical flu-like signs including fever, chills, cough, headache, chest pain, weakness, myalgia, gastrointestinal complaints (nausea, vomiting, diarrhea and abdominal pain). This first stage may last up to 4 days. The second stage of the disease develops abruptly, with acute respiratory distress, hypoxemia, cyanosis and hypotension, rapidly progressing to death. Anthrax pneumonia is a misleading term, because neither pneumonitis nor bronchitis is observed, even though the lung is the site of entry.

### Prevalence

The incidence of naturally acquired pulmonary anthrax is extremely low. A recent analysis of published anthrax cases for the 1900–2005 period identified 71 reported cases of natural pulmonary anthrax [2]. We should also add to these cases the report of two outbreaks of pulmonary anthrax, one related to accidental release from a biological weapons facility in 1979, at Sverdlosk in the former USSR (at least 66 cases), and the other due to a bioterrorism attack in 2001 in the USA (11 cases).

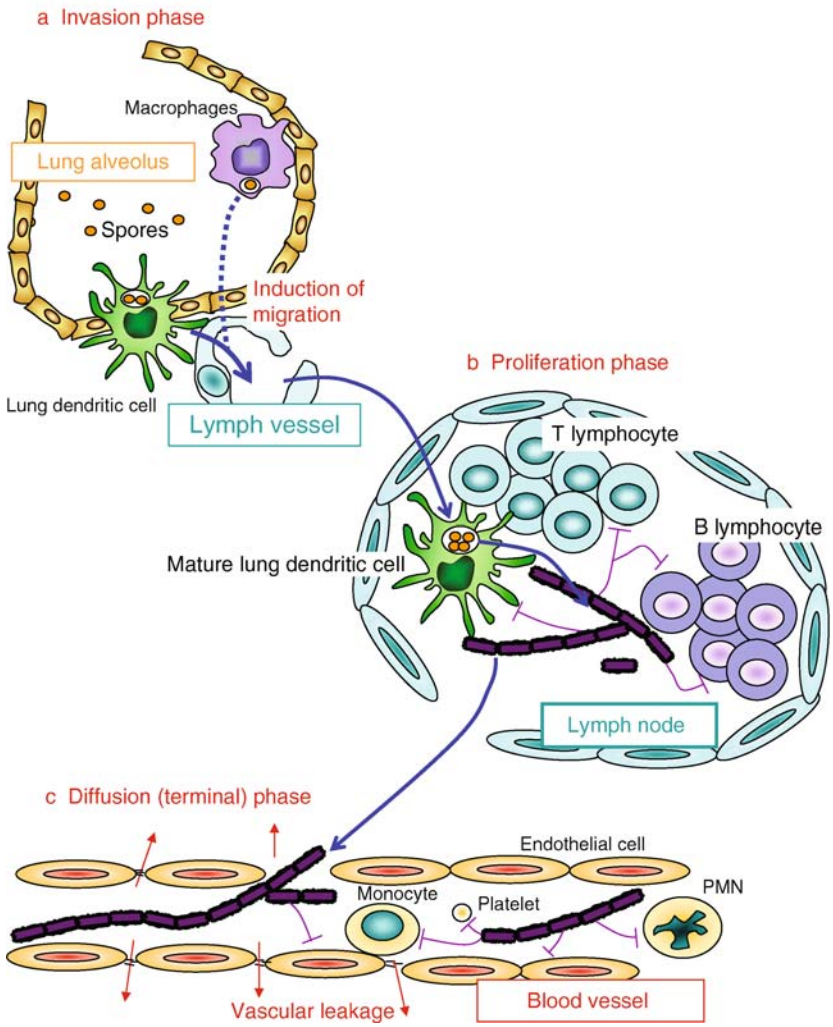
### Genes

No genetic predisposition to inhalational anthrax has been identified, although susceptibility to infection may be variable in mouse strains. Genetic susceptibility to LT-induced cell death has been associated with the NALP1B locus in mice.

B. anthracis contains a chromosome and two extrachromosomal elements: pXO1 and pXO2. The 5,227,293 base pairs (bp) of the B. anthracis chromosome, the 181,677 bp of pXO1 and the 94,829 bp of pXO2 have been yet sequenced [3]. The chromosome bears 5,508 open reading frames (ORF), whereas pXO1 and pXO2 bear 217 and 113 ORFs, respectively.

### Molecular and Systemic Pathophysiology

The spores, which are the infectious form of the pathogen, are first captured by pulmonary phagocytes (Fig. 1) [4].



**Pulmonary Anthrax. Figure 1** Current model of pulmonary anthrax pathophysiology. (a) *Invasion phase:* Lung phagocytes present in the alveolus (i.e. alveolar macrophages and lung dendritic cells) efficiently take up spores by phagocytosis. Lung dendritic cells then migrate to the draining thoracic lymph nodes (TLN). (b) *Proliferation phase:* Bacilli efficiently escape from the phagosome by unknown mechanisms and proliferate in the TLN. Toxin secretion has local effects, impairing dendritic cell, T- and B-cell functions and paralyzing the immune system. (c) *Diffusion (terminal) phase:* The high bacterial load results in the production of large amounts of toxins, which diffuse over long distances in the blood and have a wide range of deleterious effects on endothelial cells, inducing vascular leakage and the inhibition of monocyte and polymorphonuclear neutrophil (PMN) functions. *Blue arrows:* pathway of pathogen cell migration; *purple arrows:* effect of toxins on cellular targets; *red arrows:* vascular leakage.

Alveolar macrophages were thought to act as a "Trojan horse" for spores, but recent data have demonstrated that lung dendritic cells (DC) may also play an important role because they continually sample the contents of the alveoli, efficiently taking up anthrax spores by phagocytosis, migrating to the thoracic lymph nodes (TLN) and reprogramming chemokine receptor expression.

By the time the pulmonary phagocytes arrive in the TLN, some germinating spores in the phagosomes have already developed into bacilli and proliferated, as shown by previous studies of macrophages *in vitro*. The exact mechanisms of escape from the phagosome, leading to extracellular proliferation, remain unknown, but the capsule may be involved in this crucial step. Several studies have shown that LT impairs antigen presentation by inhibiting the expression of costimulatory molecules by DCs, T-cell activation and B-cell proliferation, impairing both cellular and humoral responses.

In the last phase of disease progression, the bacilli proliferate in long chains in the bloodstream and may cause secondary meningitis. As a result, large amounts of LT and ET are released into the blood. LT causes major endothelial barrier disruption. These modifications, together with LT-induced apoptosis, increase the permeability of the capillary wall, leading to the cardiovascular distress observed in patients in the late phase of infection. Mice injected with ET rapidly develop hypotension and bradycardia, associated with focal necrosis and lesions in many tissues. Finally, both LT and ET induce major pathological damage and cardiovascular collapse following their administration, accounting for clinical shock and distress, leading ultimately to death.

### Diagnostic Principles

The presence of abnormalities on either chest X rays or computed tomography (CT) scans is important for diagnostic presumption in the context of an outbreak [5]. The isolation of Gram-positive, encapsulated, non-motile bacilli from the blood is a crucial step towards diagnosis and should precede antibiotic treatment. The bacterial load is usually very high and bacilli may be observed on Gram staining of the blood, as reported in the 2001 outbreak. Blood cultures may also grow very rapidly, within 6 h. b. anthracis isolation should be followed by an assessment of the antibiotic susceptibility of the bacillus. b. anthracis isolation should be confirmed by national and/or international reference laboratories.

### Therapeutic Principles

The key to effective treatment is the rapid initiation of antibiotic treatment and supportive care, including intravascular volume repletion, vasopressor treatment and ventilatory support, as required. Pleural effusion drainage may be necessary. Ciprofloxacin and doxycycline, administered intravenously, are the most frequently recommended antibiotics. Both proved effective during the 2001 outbreak. In the near future, anti-toxin recombinant antibody and/or toxin inhibitors may become useful adjuvant therapies for use with antibiotics.

## Pulmonary Arterial Hypertension

►Pulmonary Hypertension

## Pulmonary Arterio-venous Fistula

Ahmet Mesrur Halefoğlu
Department of Radiology, Şişli Etfal Training and Research Hospital, Şişli, İstanbul, Turkey

### Synonyms

Arteriovenous malformation/pulmonary; PAVF; PAVM

### Definition and Characteristics

Pulmonary arteriovenous fistula or malformation (PAVF or PAVM), a direct communication between the pulmonary artery and vein without an intervening capillary bed, is a rare vascular anomaly [1]. It may be acquired or congenital. Most congenital arteriovenous fistulas are associated with hereditary hemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome. Acquired pulmonary arterio-venous fistulas are very rare and underlying pathologic processes include trauma, infection (actinomycosis and schistosomiasis), long-standing hepatic cirrhosis, mitral stenosis, metastatic carcinoma and systemic amyloidosis. PAVF occurs twice as often in women as in men but there is a male predominance in newborns. Around 10% of cases of PAVF are identified in infancy or childhood, followed by a gradual increase in the incidence through the fifth and sixth decades. Approximately 70% of PAVF cases are associated with HHT.

Conversely, approximately 15–35% of persons with HHT have PAVF. Nearly 53–70% of PAVFs are found in the lower lobes [2]. Approximately 70% of patients have unilateral disease, 36% have multiple lesions and 50% of those with multiple lesions have bilateral disease. Although most patients are asymptomatic, it is well known that PAVFs can cause dyspnea from a right-to-left shunt, bleeding or result in hemoptysis and hemothorax. Because of paradoxical cerebral emboli, various central nervous system complications have been described, including stroke and brain abscess [1]. The classical triad of exertional dyspnea, cyanosis and clubbing is found in 30% of adults. PAVF can be classified either simple or complex. 80–90% of PAVFs are of the simple type – defined as those with a single feeding segmental artery and a single draining vein. The rest are complex, with two or more feeding arteries or draining veins.

## Prevalence

They occur with an incidence of 2–3 per 100,000 population. Depending on the geographic population studied, HHT has been found to occur with an incidence between 1/39,216 and 1/2,351.

## Genes

Although primarily described in patients with HHT, these genetic abnormalities may also be present in patients without HHT. Genetic mapping in the last few years led to discovery that HHT can be categorized into 2 linkage groups: HHT1 has been linked to band 9q33, and HHT2 has been linked to 12q13. The involved gene encodes endoglin, a membrane glycoprotein on endothelial cells that binds transforming growth factor [3]. A third and rare variant of HHT not linked to chromosome 9 or 12 has been reported: its major manifestation is hepatic involvement. Also, a third locus for HHT has been reported at band 3p22, where the transforming growth factor (TGF)-β2 receptor gene is located. The HHT1 gene is associated with higher incidence of PAVM, epistaxis, mucocutaneous telangiectasia and cerebrovascular malformations.

## Molecular and Systemic Pathophysiology

The genetic mutations at the two major loci are recognized. Endoglin is identified as the gene product for HHT1 on band 9q33. Approximately 16 mutations of the endoglin gene are reported. The mechanisms for gene mutation causing HHT1 include a dominant negative effect; a 2-hit model; and most likely, haploinsufficiency. The second locus for HHT has been mapped to 12q. The mutation in 12q may be in the β-glycan gene or in activin receptor-like kinase 1 (ALK-1). ALK-1 can bind either activin or TGFβ in the presence of their respective type 2 receptors. At least 12 mutations of the ALK-1 gene have been identified. The mechanisms of mutation appear to be similar to HHT1 mutations and include the dominant negative mechanism, the 2-hit model, and haploinsufficiency. The HHT2 gene is not predominantly associated with PAVM and cerebral AVMs.

Endoglin and ALK-1 bind TGFβ, which is implicated in angiogenesis. PAVM likely develops as a result of interplay of various factors among diverse cells and matrix during vascular insults. Changes in endoglin and activin receptorlike kinase (ALK) might cause endothelial cells to respond abnormally to TGFβ during the process of vascular remodeling, resulting in the formation of AVM.

The exact pathogeneses of PAVM is unknown. Some investigators have hypothesized that the cause is a defect in terminal arterial loops which allows dilatation of thin-walled capillary sacs. Others have argued that PAVM are the result of incomplete resorption of the vascular septae that separate the arterial and venous plexuses which normally anastomose during fetal development. It has also been suggested that multiple small PAVM develop as a result of failure of capillary development during fetal growth. The large saccular PAVM develop by means of progressive dilatation of the smaller plexus, leading to the formation of tortuous loops and multiloculated sacs. With time, the intervening vascular walls may rupture, resulting in the formation of a single large saccular PAVM.

## Diagnostic Principles

Shunt fraction measurement, contrast echocardiography, and radionuclide perfusion lung scanning are useful methods for diagnosis of PAVM.

Imaging methods that are used in the diagnosis of PAVM are available.

The chest x-ray is abnormal in 98% of patients and is the most common clue to the anomaly. A peripheral density connected to the hilum by vascular markings is the most characteristic finding.

Currently, spiral computed tomography (CT) offers the least invasive and least expensive method to establish the presence of PAVFs. The number and size of the fistulas can be determined by obtaining appropriate imaging data, and afferent and efferent vessels can be displayed. Spiral CT with contiguous images and overlapping reconstructions is more sensitive than angiography for detecting and displaying the vascular connections of PAVF. Furthermore, additional application of surfaced rendered three-dimensional reconstruction from thin spiral CT data reveals angiogram-like images of PAVFs (Fig. 1).

Although physical examination, auscultation findings, laboratory tests, chest radiography and CT are important diagnostic tools in the differential diagnosis

**Pulmonary Arterio-venous Fistula. Figure 1** CT angiogram showing PAVFs in the middle and lower lobes of the lung.

of PAVFs, magnetic resonance imaging (MRI) together with angiography, has a distinctive role in the non-invasive diagnosis of this entity by demonstrating the architecture of the vessels [4].

Despite advances in the techniques mentioned, contrast pulmonary angiography remains the gold standard in the diagnosis of PAVF, and is usually necessary if resectional or obliterative therapy is being considered. Thus, angiography is now performed primarily for the treatment, not diagnosis of PAVFs.

## Therapeutic Principles

The primary objectives of therapy are to eliminate or reduce the right-to-left shunt and to prevent and treat complications. Because untreated lesions are associated with 11% mortality and 26% morbidity, most patients with PAVFs should be treated.

The recent trend in the management of PAVFs is to consider the treatment when the feeding arteries are more than 3 mm in diameter, even if the patient is asymptomatic, because feeding arteries of this size have been associated with paradox embolization and neurologic complications [5].

For the past decade, the standard therapy for most PAVFs has been angiographic intervention. The fact that it is less invasive than surgery and can be repeated easily are two major advantages. Two methods can be used: occlusion balloons and metallic coils. In experienced hands, it those procedures are safe and effective and reduce the risk of paradoxical embolization.

Although surgical excision has the benefit of offering definitive therapy for a solitary PAVF, it is more invasive than embolotherapy. Surgical treatment either conservative lung resection or lung transplantation may have to be considered in candidates with multiple PAVFs or those with failed transcatheter embolotherapy.

# Pulmonary Atresia

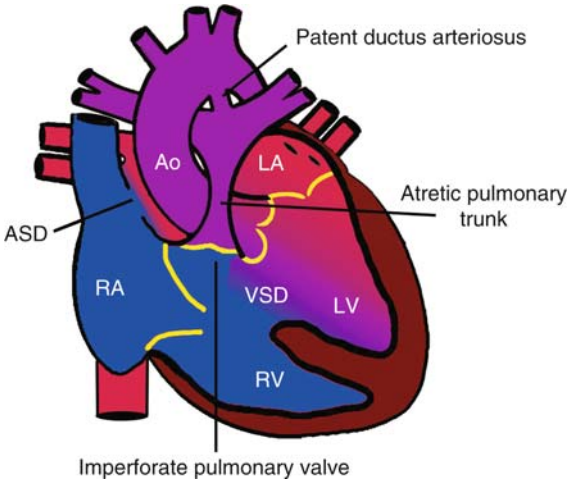
Mary Redmond Hutson, Margaret L. Kirby
Department of Pediatrics, NPRI, Duke University, Durham, NC, USA

## Synonyms

Pulmonary atresia with ventricular septal defect; PA-VSD; Tetralogy of Fallot with pulmonary atresia; TOF; Pseudotruncus; Truncus arterious type 4; Pulmonary atresia with intact ventricular septum; PA/IVS; PAIVS; Membranous pulmonary atresia

## Definition and Characteristics

Pulmonary atresia (PA) is a severe narrowing or complete obstruction of the pulmonary valve (Fig. 1). This may involve the pulmonary semilunar valve only, or narrowed valve orifice combined with infundibular atresia, or the narrowing can extend into entire pulmonary vascular tree [1]. PA often is accompanied by collateral vessels that shunt blood from the systemic to pulmonary circuit. The atretic pulmonary outlet can occur with or without a ventricular septal defect (VSD). If the ventricular septum is intact (PA/IVS), the tricuspid valve is often poorly developed and the right ventricle is hypoplastic with anomalous coronary artery patterning [1]. In pulmonary atresia with VSD (PA-VSD), the



**Pulmonary Atresia. Figure 1** Pulmonary atresia with VSD.

pulmonary semilunar valve and the subpulmonary infundibulum is undersized. PA-VSD is often characterized as a variant of tetralogy of Fallot (TOF). The aorta is shifted to the right and either overrides the ventricular septum or arises completely from the right ventricle. This has also been called pseudotruncus because, for practical purposes, there is a single outflow vessel arising from the ventricles [1]. Both forms of pulmonary atresia are often accompanied by a patent foramen ovale or secundum type atrial septal defect.

## Prevalence

Overall incidence is low with PA/IVS occurring in 1–3% of all congenital heart defects and PA-VSD in 2.5–3.5% of patients with congenital heart defects.

## Genes

In humans, few single-gene defects have been linked to pulmonary atresia. Broadly, the two forms of PA with or without an intact ventricular septum can be attributed to different stages of cardiogenesis [4]. PA/IVS with the defect limited to an imperforate pulmonary valve (i.e. relatively normal right ventricle) would occur relatively late in development and involve defects in valvulogenesis. This would include defects in epithelial to mesenchymal transformation and/or remodeling of the valve. Van Meirop suggested that in PA/IVS, cardiac development is normal through septation with the defect occurring later perhaps due to prenatal inflammation. However, PA/IVS with hypoplastic right ventricle and tricuspid valve suggests a problem in the growth and differentiation of the precursors of the right ventricle. PA-VSD is due to abnormal development of the precursors of the conotruncal myocardium and arterial pole smooth muscle. At 3 weeks of embryonic development, the heart is an endothelial tube ensheathed by a thin myocardial layer. The heart tube continues to lengthen producing a looped heart tube. This lengthening is essential for proper positioning of the outflow and inflow in order to establish correctly aligned pulmonary and systemic circuits. The lengthening of the heart tube is accomplished by the addition of the myocardium and smooth muscle produced from the field of cardiac progenitors in the pharynx called the secondary heart field [3]. Failure of these precursors to lengthen the heart tube leads to failure of the outflow vessels to align properly with the ventricles. In chick, surgical ablation of the secondary heart field results in pulmonary atresia with VSD [5]. PA-VSD, similar to the severe form of TOF, has been linked to a microdeletion of human chromosome 22q11 (DiGeorge syndrome) and is frequently seen in patients with other types of conotruncal defects [2]. The transcription factor, Tbx1, is located in the deleted region and deletion of Tbx1 in mice recapitulates the DiGeorge phenotype [3]. A mutation or microdeletion in Jagged 1, a Notch ligand expressed in the developing heart is associated with human Allagile syndrome which includes tetralogy of Fallot with pulmonary atresia [3].

## Molecular and Systemic Pathophysiology

PA/IVS is a cyanotic heart defect that presents soon after birth necessitating that the fetal circulation pattern be maintained until surgical intervention [1]. Because the entire right ventricle is underdeveloped, blood from the right atrium moves to the left atrium through an atrial septal defect where saturated and desaturated blood mixes. The blood is pumped from the left ventricle, out the aorta and shunted to the pulmonary vascular tree through a patent ductus arteriosus (PDA). Normally the ductus arteriosus closes within the first day after birth. Thus if the ductus arteriosus narrows or closes, blood flow to the lungs is reduced to critically low levels resulting in severe cyanosis. Medications must be given to keep the PDA from closing [1].

PA-VSD type defects also present with cyanosis in the neonatal period due to the paucity of pulmonary blood flow. The degree of cyanosis depends on the extent of pulmonary atresia, maintaining a patent ductus arteriosus and the presence of systemic to pulmonary collateral vessels (Fig. 1).

## Diagnostic Principles

Echocardiography and cardiac catheterization are used to diagnose the pulmonary atresia, extent of right ventricular hypoplasia, position of the VSD, and to identify real pulmonary arteries and/or any collateral vessels.

### Therapeutic Principles

Surgical repair is required within the first weeks of life to increase blood flow to the lungs [1]. Palliative surgery involves placing a shunt between the aorta and the pulmonary artery to increase blood flow to the lungs. When the defect is limited to the pulmonary valve, the valve can be perforated to restore pulmonary blood flow. In a complete repair, the ultimate goal is to restore biventricular function, which would entail patching an ASD and/or VSD, and creating continuity between the RV and the pulmonary outlet, which may not be possible if the right ventricle, pulmonary trunk or pulmonary arteries are very small. In PA/IVS with severe tricuspid and right ventricular hypoplasia, a Fontan (univentricular) procedure or heart transplant may be the only option [1].

### Synonyms

Chlamydia pneumoniae infection

### Definition and Characteristics

Chlamydia pneumoniae is an intracellular parasite with a unique developmental cycle in which two functionally and morphologically distinct cell types are recognized. The infectious cell type, which is specialized for extracellular survival and transmission, is termed the elementary body (EB). The intracellular, vegetative, cell type is called the reticulate body (RB). The developmental cycle is initiated by endocytosis of an EB by an eukaryotic host cell. Chlamydiae remain within an intracellular vacuole, termed an inclusion, for their entire developmental cycle. By 8 h post infection, EBs begin to reorganize and differentiate into RBs, which then begin to multiply by binary fission. RBs undergo logarithmic division by binary fission and subsequently redifferentiate into EBs. These infectious EBs are released by host cell lysis at 60–84 h post-infection and initiate a new cycle of replication [1].

### Prevalence

The second to fourth (6–22%) leading pathogen of community-acquired pneumonia.

### Molecular and Systemic Pathophysiology

Chlamydia pneumoniae is an important cause of acute respiratory illnesses, including pneumonia, bronchitis, pharyngitis, and sinusitis. chlamydia pneumoniae is transmitted by a respiratory route and has an incubation period of about 2–4 weeks. There is a direct association between chlamydia pneumoniae infection and other clinical manifestations such as acute exacerbations of

COPD and asthma. Infection with Chlamydia pneumoniae elicits a local immunological response that is potentially relevant to asthma. This includes the production of proinflammatory cytokines (tumor necrosis factor-α, interleukin-1β, and interleukin-6), neutrophil chemotaxis, and the inhibition of cellular apoptosis [2]. Moreover, chlamydia pneumoniae not only infects airway epithelial and mononuclear cells, but also smooth-muscle cells, resulting in the secretion of significant amounts of both interleukin-6 and basic fibroblast growth factor. Collectively, the data suggest that chlamydia pneumoniae might interact with and perpetuate airway inflammation, leading to an increase in both symptoms and severity of asthma.

The common findings of chlamydia pneumoniae pneumonia on radiographs are alveolar opacities with a unilateral distribution; however, these are nonspecific. Clinical findings, results of routine blood examinations, and chest radiographs do not distinguish chlamydia pneumoniae pneumonia from other atypical pneumonias.

The pulmonary CT findings consist mainly of ground-glass attenuation (GGA), acinar pattern (defined as a lobular unit consolidation or GGA), and consolidation (Fig. 1) [3].

Acinar patterns are more common than other atypical pneumonias such as Mycoplasma pneumoniae pneumonia. As well, CT findings of thickening of the bronchial wall and centrilobular nodules are significantly less frequent in chlamydia pneumoniae than in Mycoplasma pneumoniae. Mediastinal and/or hilar lymph node enlargement and pleural effusions are observed in 5% and 30%, respectively.

The typical pathologic changes arise primarily from the respiratory bronchiole and then spread centrifugally to the adjacent alveoli, but changes never arise from the distal portion of the alveolar duct, atria, or alveoli, resulting in pneumonia that is anatomically lobular [4]. These observations seem to account for the predominant CT findings of GGA, consolidation, and acinar patterns.

Chlamydia pneumoniae is associated with a wide range of chronic diseases characterized by local and/or systemic inflammatory responses. More importantly, there is growing evidence of an association of this pathogen with atherosclerosis.

Stimulation of host cells by IFN-r inhibits growth of chlamydia pneumoniae primarily by induction of indoleamine 2,3-dioxygene activity, which deprives the organism of tryptophan. INF-r can lead to the formation of a persistent state of chlamydia pneumoniae in vitro, a phenomenon that is characterized by the formation of pleomorphic reticular bodies (RBs) that are maintained in a viable state. Features of chlamydia pneumoniae persistence induced by INF-r include downregulation of important antigens, such as 60-kDa cystein-rich outer membrane complex protein B (OmcB/Omp2), chlamydial lipopolysaccharide, and expression of genes related to cell division (ftsK and ftsW). By contrast, levels of chlamydial heat shock protein 60 (cHSP60) remain unaltered. cHSP60 is implicated in the induction of deleterious immune responses and has been found to colocalize with infiltrating macrophages in atheroma lesions. cHSP might stimulate, enhance, and maintain innate immune and inflammatory responses and contribute to atherogenesis [5].

**Pulmonary Chlamydia Infection.**
**Figure 1** A 78-year-old woman with chlamydia pneumoniae pneumonia. High-resolution CT scan at the level of the right lower lobe shows an acinar pattern on a background of ground-glass attenuation. Consolidation and interlobular septal thickening are also present.

## Diagnostic Principles

Diagnosis of chlamydia pneumoniae pneumonia is confirmed by microimmunofluorescence (MIF) testing with at least a fourfold titer rise for IgG and fourfold or greater rises for IgM antibody titers.

## Therapeutic Principles

In patients infected with chlamydia pneumoniae pneumonia, treatment with β-lactam antibiotics is not effective because chlamydia pneumoniae pneumonia is an intracellular pathogen. However, it is susceptible to antibiotics that interfere with protein or DNA synthesis, such as tetracyclines, macrolides, and quinolones.

# Pulmonary Congestion

►Pulmonary Edema

# Pulmonary Edema

Timothy M. Moore, Mary I. Townsley
[1]Department of Internal Medicine, University of South Alabama College of Medicine, Mobile, AL, USA
[2]Department of Physiology and the Center for Lung Biology, University of South Alabama College of Medicine, Mobile, AL, USA

## Synonyms

Pulmonary congestion; Lung water

## Definition and Characteristics

Pulmonary edema is defined as increased extravascular lung water, caused by a rate of fluid extravasation from the pulmonary vasculature into the interstitium and alveoli of the lungs which exceeds the rate of fluid clearance by lymphatic drainage and/or alveolar fluid reabsorption. Pulmonary edema is not a single disease entity, but a clinical outcome of cardiogenic or noncardiogenic origin. Cardiogenic pulmonary edema (CPE), resulting from pulmonary hypertension secondary to cardiac dysfunction, is more common. Noncardiogenic pulmonary edema (NCPE) results from acute lung inflammation and/or direct endothelial injury, and occurs despite normal pulmonary vascular pressures.

## Prevalence

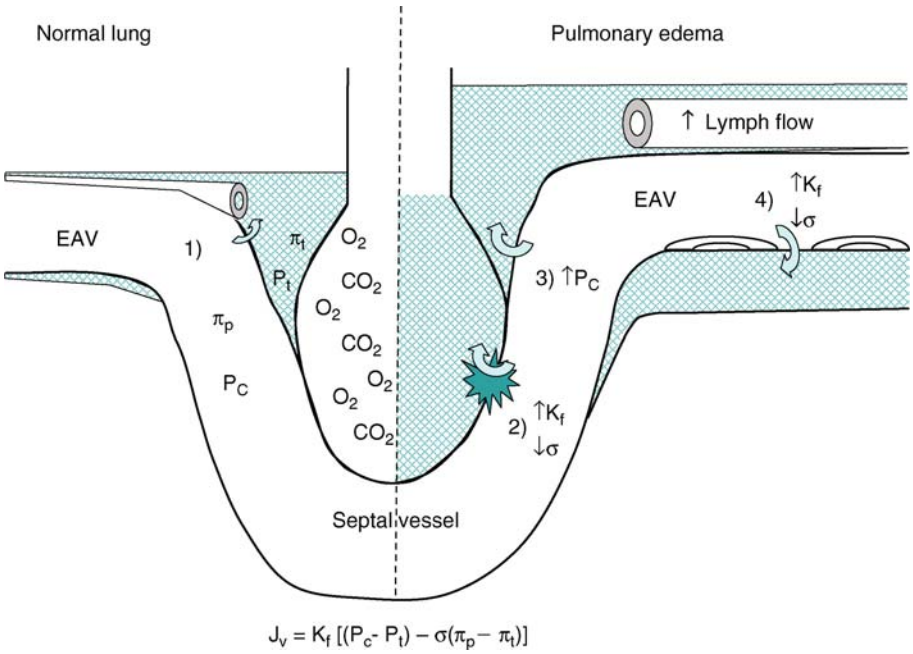
Defining prevalence for pulmonary edema is difficult as it is not a single disease entity. Chronic congestive heart failure, as one example of a disease which could potentially lead to CPE, is quite common, with nearly 400,000 cases newly identified each year. However, CPE is not a requisite finding in this patient population due to adaptive mechanisms in lung [1]. Acute lung injury or adult respiratory distress syndrome, which results from NCPE, has been better characterized. In the United States, the incidence of acute lung injury is ~ 86 cases per 100,000 person-years [2].

## Genes

The genetic basis for pulmonary edema is unclear, although susceptibility to acute lung injury may have a genetic component [2]. The responses of pulmonary endothelial cells to inflammation involve activation of specific transient receptor potential (TRP) $Ca^{2+}$ permeant cation channels. Of the six known mammalian TRP subfamilies, TRPC (canonical) and TRPV (vanilloid) channels have been implicated. TRP channels are differentially distributed in the lung vasculature. (TRPC1 = 3q22-q24; TRPC4 = 13q13.1-13q13.2; TRPV4 = 12q24.1).

## Molecular and Systemic Pathophysiology

The endothelial barrier in the alveolar septal compartment is ~20 times "tighter" than that provided by endothelium in extra-alveolar vessels, evidence for phenotypic heterogeneity [3,4]. This tight barrier limits pressure-induced fluid extravasation into the septal compartment and protects the lung against alveolar flooding. Other edema safety factors, including increased interstitial pressure, decreased interstitial protein concentration, and increased lymph flow, maintain homeostasis until left atrial pressure exceeds 25 mmHg. Pathologic pulmonary edema results when (i) the net hydrostatic force exerted across the normal lung endothelial barrier is chronically increased (CPE) and the safety factors are overwhelmed, or (ii) the endothelial barrier itself becomes compromised (NCPE). While CPE is rather homogenously distributed, disruption of the lung endothelial barrier in acute lung injury is heterogenous. Agonists activating TRPC1/TRPC4



**Pulmonary Edema. Figure 1** Fluid balance in extra-alveolar and alveolar vessels under normal conditions (left) and during CPE or NCPE (right). $J_v$ = net fluid flux; $K_f$ = filtration coefficient; $P_c$ = microvascular hydrostatic pressure; $P_t$ = tissue hydrostatic pressure; σ = plasma protein reflection coefficient; and $\pi_p$ and $\pi_t$ = plasma and tissue oncotic pressures, respectively. (i) Basal homeostasis: The "tightness" of the alveolar segment protects against increases in $P_c$ up to 25–33 mmHg. Fluid extravasation occurs primarily in extra-alveolar vessels (EAV). Lymphatics easily drain fluid and protein. (ii) NCPE and hypoxemia result from frank alveolar-capillary membrane injury or activation of TRPV4 channels in septal endothelium. Active solute transport in alveolar epithelial promotes fluid reabsorption from alveoli. In the face of a disrupted endothelial barrier, alveolar fluid reabsorption is insufficient to prevent alveolar flooding. (iii) CPE 2° to elevated $P_c$ causes interstitial edema, vascular cuffing, and increased lymphatic activity. Total lung compliance is impaired, thereby increasing work of breathing. Alveolar flooding occurs when safety factors are exhausted. (iv) NCPE 2° to gap formation in EAV endothelium. Activation of endothelial TRPC1/TRPC4 channels promotes fluid and protein extravasation into perivascular cuffs. Because the alveolar-capillary membrane remains intact, alveolar fluid transport mechanisms can effectively limit alveolar flooding.

channels lead to gap formation in extra-alveolar vessel endothelium and edema accumulation in cuffs surrounding extra-alveolar vessels and airways. In contrast, activation of TRPV4 channels leads to specific disruption of endothelium in the alveolar septal compartment to cause alveolar flooding [5] (Fig. 1).

## Diagnostic Principles

Lung water can be assessed by a number of methods, including thermal-dye double-indicator dilution, quantitative computed tomography, and magnetic resonance imaging. Gravimetric measurements can also be applied experimentally. However, the clinical diagnosis of pulmonary edema is typically based on history, physical exam, and chest radiograph. Oxygenation tends to be negatively correlated with severity of pulmonary edema. Elevated B-type natriuretic peptide in the setting of respiratory distress helps diagnose CPE [6].

## Therapeutic Principles

For treatment of CPE, treatment of the underlying cardiac dysfunction is indispensable. Diuretic therapy and supplemental oxygen are employed. Morphine sulfate can also reduce pulmonary venous congestion. Decompensated patients may require endotracheal intubation and mechanical ventilation. NCPE requires careful supportive ventilation strategies to minimize barotraumas and diuretics are ineffective until vascular leak sites are repaired. There are currently no effective pharmacological therapies to treat NCPE, nor any which specifically target implicated TRP channels.

# Pulmonary Embolism

Maria-T. Krauth, Ingrid Pabinger
Division of Hematology and Hemostaseology, Department of Internal Medicine I, Medical University Vienna, Vienna, Austria

## Synonyms

Venous thromboembolism; VTE

## Definition and Characteristics

Acute occlusion of one or more pulmonary arteries by thrombotic material (emboli) originating from the deep venous system, in 95% of cases from the lower extremities.

## Prevalence

The incidence of venous thromboembolism (VTE) in the total population has been estimated to be approximately 70–113 cases/100,000/year, 25–50% of these cases present with symptomatic pulmonary embolism (PE). The incidence increases considerably with age, specifically after 60–70 years of age. Usually the incidence derived from autopsy studies is higher than the incidence from clinical studies. Whereas incidence data found in autopsy studies might overestimate the incidence of symptomatic PE, clinical data most probably underestimate the true incidence due to undiagnosed cases in the population.

## Genes

Genetic predisposition for VTE includes inherited hypercoagulability (e.g., deficiency of antithrombin, protein C or protein S, factor V Leiden mutation, and prothrombin G20210A variation).

## Molecular and Systemic Pathophysiology

Pulmonary embolism (PE) reflects a disease that ranges from incidental, clinically unimportant thromboembolism to massive embolism with, in worst case, sudden death. Hypercoagulability leads to the formation of a thrombus in the deep veins most often of the legs or pelvis, which may suddenly dislodge and embolize into the pulmonary arteries, causing potentially serious consequences. The pathophysiological effects are increased pulmonary vascular resistance due to obstruction and release of vasoactive agents. The subsequent increase in alveolar dead space and redistribution of blood flow (which creates areas of ventilation–perfusion mismatch) impair gas exchange. Additionally, stimulation of irritant receptors causes alveolar hyperventilation. The reflectory bronchoconstriction augments airway resistance, and lung edema or hemorrhage decreases pulmonary compliance. As a result, right ventricular afterload increases and tension rises in the right ventricular wall and may lead to dilatation, dysfunction, and ischemia of the right ventricle, thus reducing cardiac output. All in all, progressive right-heart failure and the subsequently reduced forward cardiac output are the main causes of death from acute PE.

The hemodynamic response to PE is related to the size and number of emboli as well as to the patient's pre/co-existing cardiopulmonary status. Pulmonary emboli can be detected in approximately 50% of patients with documented DVT, while asymptomatic thrombosis of the leg veins has been observed in approximately 70% of patients with confirmed symptomatic PE. Thrombi located in deep veins behind or proximal to the knee are more likely to result in clinically significant and fatal PE than clots distal to the popliteal vein. An explanation to that finding may be the fact that the size of a thrombus depends on the respective vessel size that are usually larger at the proximal deep leg/pelvic veins.

*Risk Factors*: Venous thromboembolism (VTE) is a multifactorial disease influenced by many different factors, including genetic, environmental, and drug-related influences. VTE can occur in individuals without any identifiable risk factors, but most often one or more of such factors are present in a patient who develops clinically apparent VTE. First, the risk to develop VTE is enhanced by inherited or acquired hypercoagulability (e.g., deficiency of antithrombin, protein C or protein S, factor V Leiden mutation and prothrombin G20210A variation, antiphospholipid antibodies). Patients with such an identifiable endogenous "thrombophilic" risk factor often remain asymptomatic until they are exposed to an additional risk factor. Environmental risk factors strongly associated with VTE/PE include major surgery, trauma, use of oral contraceptives/hormone replacement therapy, or pregnancy. Cancer and medical illnesses that require inpatient treatment (e.g., sepsis, congestive heart failure, stroke, myocardial infarction) increase the risk as does prior VTE or a family history of VTE. Risk factors for PE are listed below:

*Endogenous and environmental*:

- Increasing age
- Obesity
- Use of oral contraceptives/hormone replacement therapy
- Pregnancy and delivery
- Long-haul air travel

*Surgery and trauma*:

- Major general surgery, especially cancer patients
- Orthopedic (especially hip and knee replacement) surgery
- Gynecological/urological/neurosurgery
- Major trauma
- Trauma of the lower extremity, especially fractures

*Thrombophilia*:

- Deficiency of antithrombin III, protein C or protein S
- Factor V Leiden and prothrombin G20210A variation
- Hyperhomocysteinemia
- Elevated levels of Factor VIII, IX, or XI
- Antiphospholipid antibodies (lupus anticoagulant, anti-beta-2-glycoprotein I antibodies)

*Medical and other illnesses*:

- Previous PE or DVT
- Cancer (especially during chemotherapy)
- Congestive heart failure
- COPD
- Metabolic syndrome
- Inflammatory bowel disease
- Antipsychotic drug use
- Chronic in-dwelling central venous catheters
- Stroke, limb paresis
- Varicose veins

## Diagnostic Principles

Symptoms indicative of PE are often non-specific; PE may even occur without clinical symptoms (asymptomatic PE). PE is to be considered when symptoms of deep vein thrombosis are present. Dyspnea is the most frequent symptom, and tachypnea the most frequent sign of clinically apparent PE. Other symptoms include tachycardia, pleuritic and/or substernal chest pain, cough, and hemoptysis. If massive PE is present, patients may present with hypoxemia, hypotension, syncope, and cyanosis.

For optimum diagnostic accuracy, symptoms, and signs should be combined with laboratory tests: chest radiography and ECG have limited diagnostic value (they are often normal in patients with PE) but may show signs of right heart strain (right bundle branch block, S1Q3 findings, inverted T waves). Arterial blood gas values may indicate hypoxemia; laboratory testing reveals elevated D-dimer levels.

The 'gold standard' diagnostic test for the diagnosis of PE has been pulmonary angiography. However, this is an invasive and expensive procedure and depends on the presence of experienced staff. A non-invasive alternative is spiral computed tomography of the chest with the use of contrast medium or ventilation/perfusion lung scanning. Transthoracic echocardiography is useful in critically ill patients suspected of having pulmonary embolism and can help to identify right ventricular pressure overload indicative of PE, as well as myocardial infarction, dissection of the aorta, or pericardial tamponade, all of which may mimic pulmonary embolism. By venous ultrasonography deep vein thrombosis can be visualized; however, absence of thrombotic material does not exclude PE.

## Therapeutic Principles

The key to appropriate therapy is risk stratification. Low-risk patients (vast majority of patients) have an excellent prognosis with anticoagulation alone, while high-risk patients might benefit from thrombolysis or embolectomy in addition to anticoagulation. These are patients with massive pulmonary embolism and cardiogenic shock or overt hemodynamic instability. Rapid clot resolution accelerates reduction in pulmonary vascular obstruction and can improve pulmonary perfusion, hemodynamics, and gas exchange. Patients with massive PE, who are in cardiogenic shock, are at high risk for death with conventional anticoagulation and should be treated with thrombolytic agents unless it is absolutely contraindicated (active internal or recent intracranial bleeding).

Heparin is the basis for the treatment of acute PE. It accelerates the action of antithrombin, thereby preventing an additional thrombus from forming and permitting endogenous fibrinolysis to dissolve some of the clots. In the absence of overt contraindications such as active gastrointestinal hemorrhage, patients with a moderate or high clinical likelihood of pulmonary embolism should receive intensive anticoagulation with heparin during the diagnostic workup.

Unfractionated heparin (UFH) requires frequent laboratory monitoring and dose adjustments (therapeutic range 1.0–1.5-fold prolongation). Weight-adjusted doses of subcutaneous low molecular weight heparins (LMWHs) have been shown to be as safe and effective as UFH in treating PE since they have an excellent bioavailability and a longer half-life, allowing a once or twice daily subcutaneous injection without anticoagulation monitoring.

Although the insertion of retrievable inferior vena cava filters can usually prevent major pulmonary embolism, filters appear to offer no advantage in patients with proximal deep venous thrombosis with free-floating thrombi. However, an inferior vena caval filter is warranted in patients with pulmonary embolism in the presence of

active hemorrhage or recurrent pulmonary embolism despite adequate anticoagulation.

Vitamin K antagonists can be safely started in parallel to therapeutic anticoagulation with UFH or LMWH. In general, the target international normalized ratio (INR) is 2.0–3.0. The optimal duration of anticoagulation after PE remains uncertain. A treatment period of 6 months prevents more recurrences than a period of 6 weeks among patients with a first episode of PE. An indefinite (lifelong) anticoagulation should be considered in patients with recurrent pulmonary embolism and in those in whom a high risk of recurrence is suggested, such as in those with a deficiency of antithrombin, combined genetic defects or presence of antiphospholipid-antibodies. In cancer patients, treatment with LMWH over a period of 3–6 months is superior to vitamin K antagonists.

# Pulmonary Fibrosis

Manfred Ballmann
Department of Pediatric Pneumology and Neonatology, Medical School Hannover, Hannover, Germany

## Synonyms

Idiopathic pulmonary fibrosis; IPF; Cryptogenic fibrosing alveolitis

## Definition and Characteristics

IPF is defined as a specific form of chronic fibrosing interstitial pneumonia limited to the lung and associated with the histological appearance of usual interstitial pneumonia (UIP) on surgical (thoracoscopic or open) lung biopsy [1]. The etiology is unknown. It is the most common (60%) form of idiopathic intestinal pneumonias.

Diagnosis is made mainly in elderly men (mean age at diagnosis 68 years). Clinically, it is characterized by a gradual onset, unproductive cough, exertional dyspnoea, and on physical examination crackles and clubbing. Lung function test show restriction (reduced FVC) and impaired gas exchange ($D_{LCO}$). Typical HRTC patterns are honeycombing and patchy reticular abnormalities located predominantly in the lower lobes. The clinical course is as a continuous decline of pulmonary function with the possibility of acute exacerbations. Some risk factors had been identified (smoking, chronic aspiration, anti-depressant drugs, metal, and wood dust). Prognosis is poor with a median mortality of 3 years.

## Prevalence

The prevalence of IPF in different series ranges from 6 to 20 per 100,000 persons with a higher prevalence in men. In persons older than 75 years, the prevalence may exceed 175 per 100,000. In the subgroup of familial IPF, prevalence is reported from the United Kingdom with 1.3 per $10^6$.

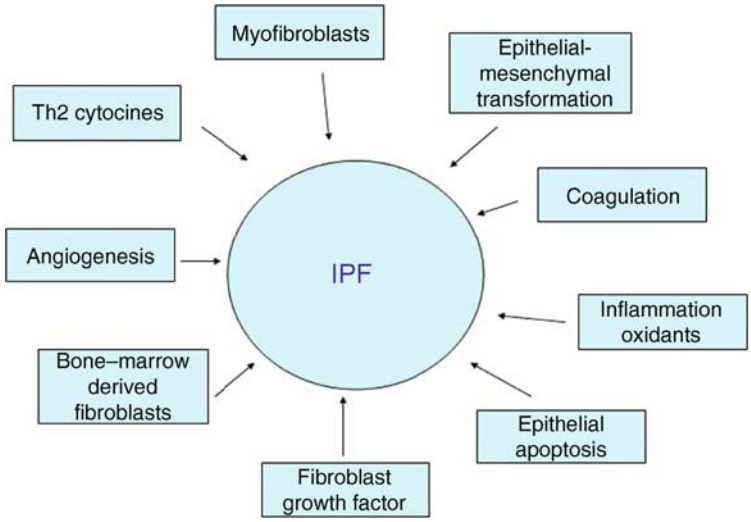
## Genes

In IPF, genetic associations are shown to genes involved in epithelial cell injury and abnormal wound healing. This includes genes encoding tumor necrosis factor (TNF; −308 adenine) and interleukin-1 receptor antagonist (+2018 thymidine). Additional association with disease severity and progression (interleukin-6/TNF receptor II and transforming growth factor-*b*1, TGFB1; +869 cytosine) were reported. Very recently, gene expression signatures were identified that differentiated between hypersensitivity pneumonitis (HP) and IPF. The HP gene expression signature was enriched for genes that are functionally associated with inflammation, T-cell activation, and immune responses, whereas the IPF signature was characterized by the expression of tissue remodeling, epithelial, and myofibroblast genes [2].

## Molecular and Systemic Pathophysiology

Former “inflammatory fibrosis” hypothesis seems now no longer valid. In the last decade, there is a growing body of evidence, suggesting that IPF is not as much a chronic inflammatory disease but a disorder associated with impaired wound healing and injury repair.

The current “epithelial/fibroblastic” hypothesis suggests that IPF results from multiple episodes of epithelial cell activation from exogenous and endogenous stimuli. These stimuli are not yet defined.



**Pulmonary Fibrosis. Figure 1** Events related to IPF pathogenesis (adapted from [4]).

Disruption of the alveolar epithelium is the result of repeated injury. Consequently, activated epithelial cells initiate a complex process including migration, proliferation, and activation of mesenchymal cells [3]. These events result in the formation of fibroblastic/myofibroblastic foci mirroring abnormal wound repair. Fibroblasts are key players in the pathogenesis of IPF. Nevertheless, their origin is still unclear, and there is evidence that not only intrapulmonary but also circulating stem cells derived from extrapulmonary progenitor cells participate in the process of repair and remodeling.

Additionally impaired communication between epithelial and mesenchymal cells is involved in the disturbed repair process. Events related to IPF pathogenesis are shown schematically in Fig. 1.

## Diagnostic Principles

If there is any suspicion of IPF based on history, physical examination, lung function tests, or chest X-ray a HRCT is indicated. If the HRCT presents patterns typical for UIP and clinical work-up is clearly compatible with the diagnosis of IPF, a surgical lung biopsy is not needed.

In the absence of surgical lung biopsy, the presence of all four of the major (i) exclusion of other known causes of ILD, (ii) abnormal pulmonary function studies that include evidence of restriction (reduced VC, often with an increased FEV1/FVC ratio) and impaired gas exchange [increased P(A–a)O2, decreased PaO2 with rest or exercise or decreased DLCO], (iii) bibasilar reticular abnormalities with minimal ground glass opacities on HRCT scans and (iv) transbronchial lung biopsy or BAL showing no features to support an alternative diagnosis) diagnostic criteria as well as at least 3 of the 4 minor ((i) age >50 years, (ii) insidious onset of otherwise unexplained dyspnoea on exertion, (iii) duration of illness >3 months and (iv) bibasilar, inspiratory crackles) criteria increases the likelihood of a correct clinical diagnosis of IPF in the immunocompetent adult.

In all other cases, surgical lung biopsy is needed to differentiate UIP from other patho-histological entities (e.g., idiopathic pulmonary fibrosis, familial pulmonary fibrosis, connective tissue disease, chronic hypersensitivity pneumonitis, radiation pneumonitis, or asbestosis).

## Therapeutic Principles

Up to now there is no good evidence to support the routine use of any specific therapy in the management of IPF [3]. For many years, immunosuppressants, especially corticosteroids, were used alone or in combination with immunomodulatory or antifibrotic agents, e.g., azathioprine, cyclophosphamide, and colchicine.

With changes in the understanding of the pathophysiology of IPF as predominantly a disease of fibroproliferation and not inflammation, new therapeutic options were tested [5]. The aim is to interrupt the molecular events that are involved in the perpetuation of the fibrotic process in IPF. Up to now, interventional studies demonstrated no clear advantage related to meaningful primary outcome parameters in the treatment groups.

In IPF, reference for evaluation of lung transplantation should be considered with initial diagnosis and hypoxemia, pulmonary hypertension and cor pulmonale should be treated in the meantime.

# Pulmonary Hemosiderosis, Idiopathic

Richard G. Hegele
Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada

## Synonyms

Ceelen-Montaldo disease; IPH

## Definition and Characteristics

Intermittent, diffuse alveolar hemorrhage, with cough, dyspnea, hemoptysis, diffuse pulmonary infiltration and anemia, typically occurring in children [1].

## Prevalence

Exteremely rare. Seventeen patients documented in children's hospital Los Angeles by retrospective chart review over a 26-year period. Twenty-three patients reported in a Turkish study over a 15-year period [2]. Has been described in association with celiac disease (Lane-Hamilton syndrome) [3].

## Genes

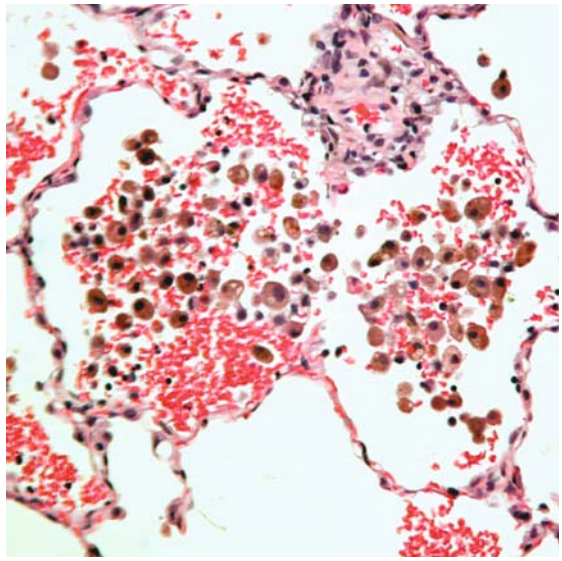
Unknown. Has been described in brothers, in a mother and son, and in children of consanguineous parents.

## Molecular and Systemic Pathophysiology

Poorly understood. In contrast to other pulmonary hemorrhage syndromes, no specific features to suggest an immunologically-mediated process is evident.

## Diagnostic Principles

High index of suspicion is warranted in a symptomatic child who has hypochromic, microcytic anemia. High resolution computed tomography of the chest is considered a useful diagnostic modality [4]. Open lung biopsy specimen (Fig. 1) reveals histological features of hemosiderin-laden macrophages and free, extravasated erythrocytes, and small amounts of fibrin. Results of other investigations for other pulmonary hemorrhage syndromes (e.g., c-ANCA; anti-glomerular basement membrane antibodies) are negative.



**Pulmonary Hemosiderosis, Idiopathic.**
**Figure 1** Photomicrograph of open lung biopsy specimen from a patient with IPH. Note hemosiderin-laden macrophages (golden-brown cytoplasm) and free erythrocytes within the alveolar spaces, in the absence of inflammatory changes to alveolar capillaries (hematoxylin and eosin stain).

## Therapeutic Principles

Despite lack of definitive immunological basis, treatment with corticosteroids +/− other immunosuppressive agents is often given [1,2]. Long-term survival is possible but patients may develop autoimmune-type disorders. Disease may recur in lung allografts after transplantation [5].

# Pulmonary Hypertension

Terence K. Trow[1], Vallerie V. McLaughlin[2]
[1]Pulmonary Hypertension Center, Yale University School of Medicine, New Haven, CT, USA
[2]Pulmonary Hypertension Program, University of Michigan Health System, Ann Arbor, MI, USA

## Synonyms

Familial pulmonary arterial hypertension; FPAH; Idiopathic pulmonary hypertension; IPAH

## Definition and Characteristics

The abnormal elevation of mean pulmonary arterial pressures above 25 mm of mercury (mmHg) at rest and 30 mmHg during exercise when pulmonary wedge pressures are ≤15 mmHg [1]. Can be the end result of a variety of environmental factors in the genetically predisposed. The familial form is inherited as an autosomal dominant disease with incomplete penetrance. An increased female to male ratio (2.7:1) has been noted as has genetic anticipation (i.e. onset of disease at an earlier age in successive generations).

## Prevalence

Unknown. When strictly FPAH and IPAH are examined, estimates are 1–2 cases per million [1].

## Genes

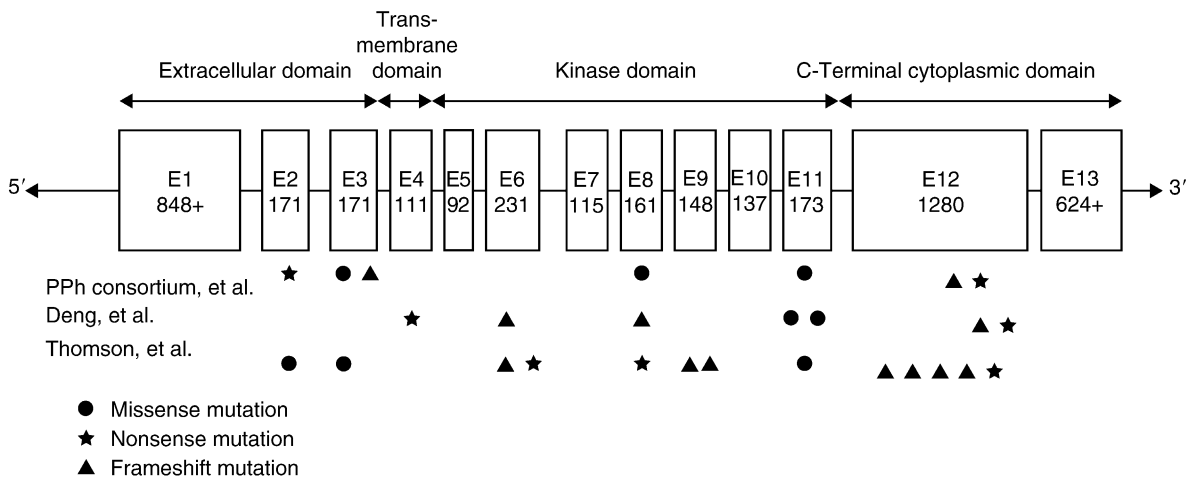
Multiple mutations in the bone morphogenetic receptor II protein (BMPR2) have been shown to cause both the familial and sporadic forms, which codes for a receptor in the transforming growth factor beta (TGF-beta) superfamily. It is located on chromosome 2 at q33, is comprised of 13 exons, 4,000 base pairs, and codes for 1,038 amino acids. Twelve of 13 exons have had mutations described (Fig. 1).

More recent work suggests mutations at a second gene locus at q31-32 [2]. Another less frequent anomaly in the activin receptor-like 1 (ALK 1) gene can also lead to PAH. ALK1 is likewise a receptor in the TGF-beta superfamily, implicating altered TGF-beta signaling as central to development of the disease [2].

## Molecular and Systemic Pathophysiology

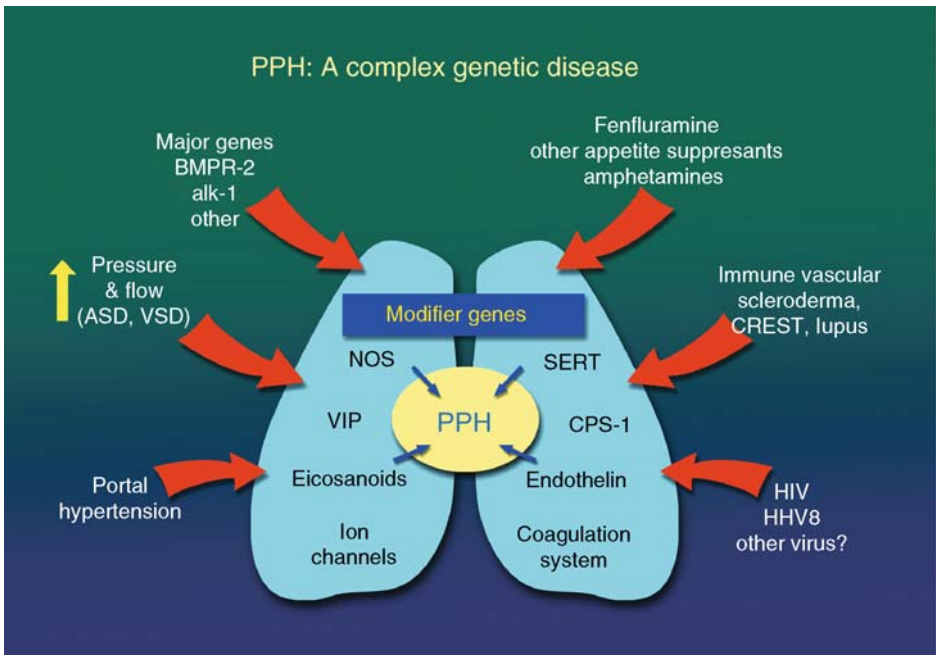
The expression of the pulmonary arterial hypertension phenotype is complex and incompletely understood (see Fig. 2).

Compelling data implicates alterations in TGF-beta signaling, but the precise molecular mechanisms remain obscure. Furthermore, while mutations in the BMPR2 gene can be demonstrated in 75% of FPAH patients or their family members, only 15–20% of these patients demonstrate the phenotype [2]. It is likely that additional environmental factors and/or modifier gene



**Pulmonary Hypertension. Figure 1** Range of mutations. Shown from left the right mutations so far identified in exons 1–3 (extracellular domain involved in dimerization with BMPR1), exon 4 (transmembrane domain), exons 5–11 (kinase domains involved in phosphorylation of SMAD proteins), and exon 12–13 (cytoplasmic tail domains). Reprinted with permission from [2].

P



**Pulmonary Hypertension. Figure 2** Primary pulmonary hypertension can be induced in susceptible individuals by a number of conditions or stimuli. These elicit a response modulated by genetic susceptibility. Listed are some genes with functional polymorphisms known to influence vascular function. Knowledge regarding these modifier genes is in its infancy. Reprinted with permission from Newman et al. (2005) The future of genetics in pulmonary hypertension. Adv Pulm Hypertens 4(1):30–31.

defects are important in determining who develops PAH. Candidate genes include those for voltage-gated $K^+$ channels, vasointestinal peptide, serotonin transport proteins, prostacylin synthase, nitric oxide synthase, serine elastase, angiotensin converting enzyme, and endothelin 1 [2]. In non-familial cases, dysregulated expression of angiopoietin-1 with downstream suppression of bone morphogenetic protein I (BMPR1), a necessary partner in homodimer formation with BMPR2, has been proposed as an alternate mechanism of altered TGB-beta signaling [3].

Regardless of the interplay of these factors, patients with PAH share in common reduced levels of prostacyclin and nitric oxide, and elevated levels of serotonin and endothelin 1. This results in not only an imbalance in vasoconstrictor tone but also messages that promote smooth muscle and endothelial cell overgrowth. The end result is an arteriopathy characterized by neointimal proliferation, medial wall thickening, and plexigenic lesions. In situ microthrombi add to the restriction of blood flow through these abnormal vessels.

## Diagnostic Principles

Suspecting the disorder can be a challenge given nonspecificity of symptoms. A family history of PAH may prompt screening, even in the asymptomatic. Signs associated with comorbid conditions should be sought including Raynaud's phenomenon, snoring, witnessed apneas, orthopnea, and paroxysmal nocturnal dyspnea. A history of human immunodeficiency virus risk factors, prior pulmonary embolism, and use of appetite suppressants should be explored. Physical exam findings of an accentuated pulmonary component to the second heart sound, palpable left parasternal lift, cyanosis, digital clubbing, nail-fold capillary abnormalities, and the presence of telangiectasias may be helpful clues. An electrocardiogram will reveal right ventricular hypertrophy and right axis deviation in 87% and 79% of IPAH patients respectively. Chest radiography may reveal enlarged pulmonary arteries, as well as pruning of the vascular markings. Doppler echocardiography with contrast should be done in all suspected cases to assess for shunts or left ventricular systolic and diastolic dysfunction. Pulmonary artery systolic pressures can be estimated by echocardiography, but right heart catheterization (RHC) is needed to establish the diagnosis and assess for vasodilator response. All patients with confirmed PAH should undergo ventilation/perfusion scanning to exclude chronic thromboembolic disease (CTED) [4].

## Therapeutic Principles

In severe cases intravenous (IV) epoprostenol administration via continuous infusion is the treatment of

choice. Trepostinil has also recently been approved for IV administration. In less advanced disease, a variety of medical options exist for therapy including oral endothelin 1 blockade (e.g. bosentan and ambrisentan), oral inhibitors of phosphodiesterase-5 which secondarily boost cyclic GMP levels (e.g. sildenafil), inhaled iloprost, subcutaneous prostanoid administration (e.g. trepostinil), and oral prostanoid therapy (e.g. beraprost). Selection of therapy depends on individual patient comorbities and preference. A small subset of PAH patients can benefit from high dose calcium channel blocker use and are defined by their vasodilator response during RHC. Warfarin, supplemental oxygen, diuretics, and digoxin remain helpful adjuncts. Surgical thromboendarterectomy in patients with CTED should be offered to appropriate candidates. Patients with New York Heart Association Class III and IV disease should be referred to a transplant center for early evaluation for possible lung transplantation in anticipation of failure to respond to medical therapy [5].

# Pulmonary Lymphangioleiomyomatosis

Richard G. Hegele
Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada

## Synonyms

Pulmonary lymphangiomyomatosis; LAM

## Definition and Characteristics

A disorder that occurs almost exclusively in premenopausal women, in which lymphatics and blood vessels are surrounded by smooth muscle proliferation, clinically characterized by progressive dyspnea, cough, chest pain, hemoptysis, pneumothorax and chylous pleural effusions, culminating in progressive airflow obstruction, leading to respiratory failure and cor pulmonale [1].

## Prevalence

Reported prevalence of approximately one case per million population in Europe and the United States. There are rare case reports of LAM occurring in men [2]. Can occur sporadically and has been described in the setting of tuberous sclerosis.

## Genes

Autosomal dominant inheritance, with some cases possibly involving loss of heterozygosity for tuberous sclerosis complex (TSC)2 gene on chromosome 16p13 [3].

## Molecular and Systemic Pathophysiology

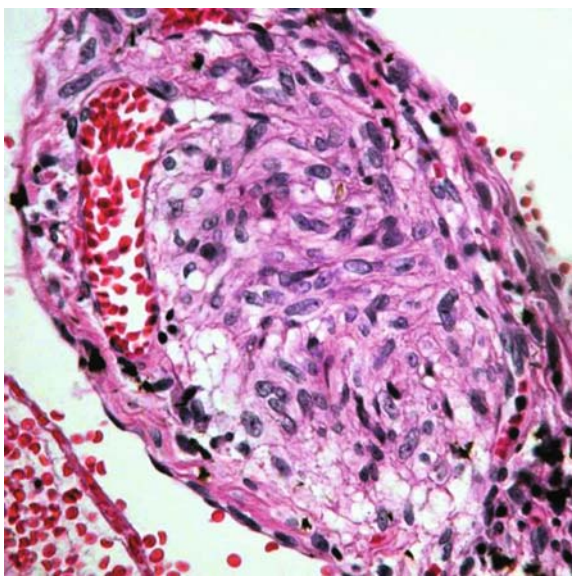
Believed to involve abnormal activity of tuberin, the product of TSC2, a tumor suppressor gene that normally forms a functional heterodimer with hamartin (the product of the TSC1 gene), resulting in inhibition of at least two kinases that are important regulators of cell proliferation, protein kinase B (PKB)/Akt and p70 S6 ribosomal kinase (S6K) [1,3,4]. In LAM, somatic mutations of TSC2 could result in less effective hamartin-tuberin interactions, with resultant enhanced PKB/Akt and/or S6K activity. Alternatively, interactions between 14-3-3beta and structurally normal tuberin, either through overexpression of 14-3-3beta or via creation of a new 14-3-3 binding site on tuberin that is phosphorylated from effects of the p38 and MK2 kinase cascade, is associated with compromised ability of the tuberin-hamartin complex to reduce S6K phosphorylation. Hormonal effects of estrogen on enhancing cellular proliferation in LAM are well described but molecular pathophysiological mechanisms remain uncertain: one possibility is that estrogen can increase the ratio of bcl-2 (apoptosis suppressor) to Bax (pro-apoptotic homologue) in affected smooth muscle cells. Other autocrine, paracrine or circulating molecules (e.g., basic fibroblast growth factor, platelet derived growth factor) might increase the expression of various transcription factors to result in smooth muscle cell proliferation: such mechanisms are possibly relevant to the recurrence of disease in the lungs of patients who undergo lung transplantation with allografts obtained from male donors.

## Diagnostic Principles

Given that clinical features are often non-specific, there may be up to several years' delay between onset of symptoms and diagnosis. In a minority of patients, the presence of other aspects of TSC (e.g., renal angiomyolipoma) is helpful. Pulmonary function tests can show a combination of obstructive and restrictive changes. High resolution computed tomography of the chest shows characteristic thin-walled cystic lesions. Histopathology shows expansion of the lung interstitial space by spindle-shaped cells with blunt-ended, "cigar-shaped" nucleic, characteristic of smooth muscle differentiation (Fig. 1). LAM cells to show positive immunostaining with HMB-45 antibody (originally developed as a marker for the diagnosis of malignant melanoma). Despite its usefulness as a marker of LAM cells, it is unclear whether the HMB-45 antigen is relevant to the pathogenesis of LAM.

## Therapeutic Principles

In addition to supportive treatment for airflow obstruction, pleural effusions and pneumothoraces, hormonal therapy (anti-estrogen, progesterone hormonal therapy, oophorectomy and tamoxifen) has been used, although not in controlled trials. Rapamycin has been touted as a possible therapy. Lung transplantation is indicated in end-stage disease, although recurrences in allografts have been described [5]. Pregnancy may exacerbate disease, although there are numerous reports of successful, uncomplicated pregnancies in women who have LAM. Evaluation for stigmata of TSC, including renal angiomyolipoma (found in ~50% of women with LAM), is warranted.



**Pulmonary Lymphangioleiomyomatosis.**
**Figure 1** Photomicrograph of lung biopsy specimen from a patient with LAM. Note the presence of interstitial spindle cells with cigar-shaped nuclei, typical of smooth muscle. (Hematoxylin and eosin stain).

# Pulmonary Nocardiosis

Atteyet-Alla Fetouh Yassin
Institute of Medical Microbiology, Immunology and Parasitology, Friedrich-Wilhelms-University, Bonn, Germany

## Definition and Characteristics

The etiological term nocardiosis refers to diseases caused by members of the bacterial genus nocardia. Pulmonary nocardiosis results from inhalation or aspiration of nocardial cells into the lungs leading to primary infection that may either remain localized or may disseminate by way of the blood stream or lymphatics to other parts of the body. In approximately 30% of cases, dissemination to the brain and central nervous system does occur.

There is no specific clinical presentation that is diagnostic for pulmonary nocardiosis, and the disease

has often been misdiagnosed as pyogenic infection or tuberculosis. Signs such as persistent cough, malaise, chest or abdominal pain, dyspnea, fever, and anorexia are usually present. Cavitation and spread into the pleural space are common.

## Prevalence

Nocardia infections are exogenous, i.e., caused by organisms not part of the indigenous human microflora. Despite the ubiquitous presence of the organisms in soil, the prevalence of these organisms within the environment appears to differ for each geographic location depending upon factors such as mean daily temperature, humidity, moisture, and soil composition. It is not possible to state with any certainty the prevalence of infections caused by nocardiae because there has been no active national or international surveillance effort to ascertain the incidence of the disease. However, there is general agreement that recognition of increased numbers of human infections has occurred in the world since 1960.

## Molecular and Systemic Pathophysiology

In pulmonary nocardiosis, nocardia enters the host by way of inhalation. The primary mechanisms of eliminating these bacteria from the lungs are by ciliary activity of the bronchial epithelium and by phagocytosis of alveolar macrophages. The initial events, therefore, must involve the interaction of nocardia with alveolar macrophages. The ability of nocardia to inhibit or modify phagocytosis and to grow within phagocytic cells relates to their virulence. The mechanism of this inhibition is controlled by components associated with the bacterial cell surface. Nocardiae have a complex cell envelope composed of several classes of free and bound lipids, peptides, and polysaccharides. Some of these compounds such as "cord factor" (trehalose-6,6′-dimycolate) and sulfolipids (also containing trehalose esters) are toxic and are able to induce pathology within the host. Cord factor induces multiple responses in the host, including granulomatous inflammation and adjuvanticity protection. Sulfolipids participate in pathogenesis by the specific inhibition of phagosome–lysosome fusion during ingestion of the nocardial cells by macrophages. Since the lysosomes cannot fuse, the degradative enzymes cannot be discharged into the phagosome containing the nocardia. This apparently has a major effect on the macrophage's ability to kill or inhibit nocardia, and might permit the bacterial cell to grow within the phagocyte.

## Diagnostic Principles

Multiple sputum specimens should be collected from patients with pulmonary disease, because the slow growth of nocardia and the presence of contaminating organisms make recovery unreliable. Nocardiae grow on most laboratory media such as blood agar and brain heart infusion agar and occasionally grow on media used for the isolation of mycobacteria (e.g., Middlebrook synthetic agar and Löwenstein-Jensen medium) and can survive the usual *N*-acetylcysteine digestion procedure that is done on sputum or bronchial washings for isolation of mycobacteria. The culture should be incubated for 1 week to reliably detect nocardia species in culture. Nocardiae are aerobic, gram positive and slightly acid fast bacteria. The morphology of colonies varies from dry to waxy and hard or rough, with a velvety surface caused by rudimentary to abundant aerial mycelia. Colony coloration varies from chalky white, tan, buff, or yellow to orange and after 1–2 weeks incubation the colonies attain a size of 5–10 mm.

In order to reach a successful identification of all nocardial species, it is suggested to use combinations of phenotypic and genotypic characterization methods. Phenotypic tests include mycolic acids analysis with thin-layer chromatography and conventional biochemical tests that include hydrolysis tests of adenine, casein, elastin, esculin, guanine, tyrosine, testosterone, xanthine, hypoxanthine, and urea. Besides these decomposition tests, assimilation of organic compounds on minimal media, such as the AUX medium described by Yassin and coworker in 1995, may also be used.

Sequencing of the 16S rRNA gene has been used successfully to identify the nocardiae to the species level. When full-length sequences (±1,400 nucleotides) are analyzed, 16S rRNA gene sequencing is considered a reliable tool for species identification in the genus nocardia. Sequences are compared with those of the type strains deposited in the GenBank database. However, GenBank database should be used with caution since 16S rRNA gene sequences of many nocardia species are not included in public databases, taxonomic changes are not often applied to public databases, and many faulty entries are found in publicly accessible databases.

## Therapeutic Principles

Treatment of pulmonary nocardia infections continues to be difficult. Antimicrobial agents of various classes have been reported either to possess significant in vitro activity against nocardia sp. in laboratory studies or to have been proven successful in limited clinical case studies. Primary agents that have been used successfully are amikacin, imipenem, minocycline, and linezolid. Combination therapy with a sulfa-containing agent and one of the primary agents has been recommended for serious, systemic disease. Despite considerable enthusiasm about treatment with the trimethoprim–sulfamethoxazole combination, there have been many reports of treatment failures and relapses, and trimethoprim–sulfamethoxazole

is not effective against many nocardia isolates. The use of amikacin in combination with imipenem has been suggested for serious infections. These agents work well but their application is limited by high cost and significant toxicity. In addition, the emergence of resistance to imipenem is a cause of concern as no other antibiotics with bactericidal activity were found for such resistant strains. Other potentially efficacious drugs include the extended-spectrum cephalosporins, amoxicillin-clavulanate, newer macrolides, other aminoglycosides, and the fluoroquinolones. However, apart from amoxicillin-clavulanic acid, none of these compounds is sufficiently active against Nocardia farcinica. The duration of therapy is uncertain, but it should be protracted because of the occurrence of considerable numbers of relapses after shorter courses of therapy. As far as imipinem/amikacin is concerned, infections due to susceptible nocardia strain can completely be cured within 4–6 weeks applying the following doses: imipinem 4.0 g/day = 1.0 g i.v. 6 hourly; amikacin 1.0 g/day = 500.0 mg 12 hourly.

# Pulmonary Regurgitation

Anselm Uebing, Michael A. Gatzoulis
Adult Congenital Heart Disease Unit, Royal Brompton and Harefield NHS Trust, London, UK

## Synonyms

Pulmonary valve regurgitation; Pulmonary valve insufficiency; Pulmonary valve incompetence

## Definition and Characteristics

Backflow of blood from the pulmonary artery into the right ventricle owing to imperfect functioning of the pulmonary valve.

## Prevalence

Pulmonary regurgitation is not usually found as an isolated cardiac lesion although most normal individuals have trivial pulmonary regurgitation. Pulmonary regurgitation is a common complication after therapeutic relief of pulmonary stenosis or following repair of tetralogy of Fallot. The absence of the pulmonary valve (absent pulmonary valve syndrome) is an uncommon congenital anomaly usually associated with tetralogy of Fallot.

## Genes

A microdeletion of chromosome 22q11 is present in 15% of patients with tetralogy of Fallot with or without absence of the pulmonary valve.

## Molecular and Systemic Pathophysiology

Pulmonary regurgitation is better tolerated than aortic regurgitation. The low resistance of the pulmonary vascular bed allows systolic blood flow through the pulmonary microvessels to the pulmonary veins resulting in a limitation of diastolic backflow from the pulmonary artery to the right ventricle [1].

Pulmonary regurgitation leads to right ventricular enlargement and dysfunction dependent on degree and duration of backward flow into the right ventricle. Right ventricular enlargement and dysfunction in turn cause tricuspid regurgitation and are associated with electrical conduction abnormalities (visible on electrocardiogram as prolonged QRS duration) and an increased risk of arrhythmias and sudden cardiac death [2].

## Diagnostic Principles

The diagnosis of pulmonary regurgitation can be made by clinical examination. An early diastolic decrescendo murmur audible on auscultation in the third left intercostal space signifies pulmonary regurgitation, and a palpable right ventricular impulse indicates associated right ventricular enlargement. Symptoms of right heart failure like elevated jugular venous pressure, liver enlargement, and peripheral edema are rare but present if right ventricular dysfunction developed as the result of pulmonary regurgitation.

An electrocardiogram may show prolongation of the QRS duration especially in patients previously operated for tetralogy of Fallot. Chest X-ray characteristically shows dilatation of the pulmonary trunk and the central pulmonary arteries and enlargement of the cardiac silhouette. Evaluation of the pulmonary valve and the presence and severity of pulmonary regurgitation can be performed by echocardiography using Doppler techniques. Cardiovascular magnetic resonance imaging has become the gold standard for evaluation of pulmonary regurgitation. Measurement of systolic and diastolic blood flow through the pulmonary valve can be

quantified by blood flow velocity mapping allowing for calculation of the amount of backflow from the pulmonary artery into the right ventricle (i.e., pulmonary regurgitant fraction) [3].

### Therapeutic Principles

Pulmonary valve function should be restored before irreversible right ventricular dysfunction and heart failure ensues [4]. Gene therapy, pharmacological as well as dietary therapies are not available.

If a patient with pulmonary regurgitation presents with heart failure diuretics, angiotensin-converting enzyme inhibitors and beta blockers have a role prior to surgical treatment.

Surgical pulmonary valve replacement using bioprosthetic valves is usually required to restore pulmonary valve competence in patients with significant pulmonary regurgitation. For selected patients, percutaneous implantation of bovine valve of jugular veins mounted in a stent in the position of the pulmonary valve may be feasible [5].

## Pulmonary Stenosis

Helena M. Gardiner
Institute of Reproductive and Developmental Biology, Faculty of Medicine, Imperial College, Queen Charlotte's and Chelsea Hospital, London, UK

### Synonyms

Pulmonary valve dysplasia

### Definition and Characteristics

Variable abnormality confined to either the pulmonary valve (which may be mono- or bicuspid) or may involve muscular overgrowth of the right ventricular outflow tract and/or supravalvar stenosis. It may be detected in the fetus by ultrasound and postnatally by the variable presence of cyanosis (depending on severity), a valvar click, a single second heart sound and a systolic murmur in the upper left intercostal spaces radiating widely posteriorly.

Pulmonary stenosis may be isolated but is also a prominent feature of syndromes (Noonan, Alagille, Williams-Beuren and Leopard among others), or may be described in association with congenital nephrotic syndrome or deafness.

### Prevalence

Isolated valve involvement is reported in about 5% of fetal and postnatal cardiac series.

### Genes

Commonest associations include:

1. Noonan syndrome gene map locus 12q24.1
2. Williams-Beuren syndrome gene map locus 7q11.2
3. Alagille syndrome gene map locus 20p12

### Molecular and Systemic Pathophysiology

1. One form of Noonan syndrome maps to 12q24.1 and is due to mutations in PTPN11 in about half the patients studied. This gene encodes the nonreceptor protein tyrosine phosphatase SHP2, which contains two Src homology-2 (SH2) domains [1].

2. Williams-Beuren syndrome is a contiguous gene syndrome most often caused by hemizygous deletion of a 1.5-Mb interval encompassing at least 17 genes at 7q11.23 with mutations in the elastin gene [2], LIM kinase-1 and haploinsufficiency of the RFC2 gene. Other genes implicated include hemizygosity for the LIMK1, haploinsufficiency of CYLN2, with GTF2IRD1 and GTF2I thought responsible for the main aspects of Williams-Beuren syndrome.
3. Alagille syndrome is caused by mutation in the Jagged-1 gene (JAG1) [3] which encodes a ligand for NOTCH1. Alagille syndrome is one of the major forms of chronic liver disease in childhood with severe morbidity and a mortality of 10–20%. Autosomal dominant inheritance was confirmed by linkage studies [4] with penetrance of 94% and 15% sporadic cases. Affected parents had posterior embryotoxon and at least one other major syndromic feature suggesting that systematic screening of parents for the clinical features of Alagille syndrome should improve the accuracy of genetic counseling.

## Diagnostic Principles

The clinical signs of Pulmonary valve stenosis are supported by echocardiographic findings. The pulmonary valve may be doming but the leaflets thin or there may be valvar dysplasia with thickening of the valve leaflets. There is variable right ventricular hypertrophy and muscular overgrowth of the right ventricular outflow tract. Supravalvar pulmonary stenosis is characterised by pronounced "waisting" of the supravalvar pulmonary trunk.

1. Noonan syndrome has an estimated incidence of one in 1,000–2,500 live births [1]. It is an autosomal dominant dysmorphic syndrome characterized by hypertelorism, a downward eyeslant, and low-set posteriorly rotated ears. Other features include short stature, a short neck with webbing or redundancy of skin, cardiac anomalies, epicanthic folds, deafness, motor delay, and a bleeding diathesis.
2. Williams syndrome is an autosomal dominant disorder including supravalvular aortic stenosis, multiple peripheral pulmonary arterial stenoses, hypertension, elfin face, mental deficiency, short stature and a characteristic dental malformation, and infantile hypercalcemia. It has a frequency of about 1:10,000 live births.
3. Alagille syndrome is characterised by neonatal jaundice due to a reduction in intrahepatic bile ducts. The histologic diagnosis may be difficult or impossible in infancy and so the early diagnosis depends on the clinical features. These include posterior embryotoxon and retinal pigmentary changes in the eye, pulmonary valve stenosis and/or peripheral pulmonary arterial stenosis in the cardiovascular syndrome, abnormal "butterfly" vertebrae and a decrease in the interpediculate distance in the lumbar spine with varying degrees of foreshortening in the fingers. There are characteristic facies including a broad forehead, pointed mandible and bulbous tip of the nose. Neurological involvement includes absent deep tendon reflexes and poor school performance.

## Therapeutic Principles

Pulmonary stenosis is treated according to symptoms (cyanosis and breathlessness) using either interventional balloon dilatation or surgery when the valve is severely dysplastic (such as in Noonan syndrome). In syndromic cases such as Alagille's syndrome multiple peripheral stenoses may be suspected echocardiographically and should be confirmed using angiography but are difficult to treat. There is no gene therapy yet available for this syndrome but growth-restricted children with Alagille syndrome are insensitive to growth hormone and may benefit from IGF-I treatment.

### Synonyms

Pulmonic stenosis with interatrial communication; Triologie de Fallot

### Definition and Characteristics

When pulmonary stenosis (PS) and atrial septal defect (ASD) occur together, the interatrial shunt could be patent foramen ovale, ostium secundum ASD, or ASDs of the ostium primum or sinus venous variety. Obstruction to the right ventricle (RV) outflow is usually caused by stenosis of the pulmonic valve (PV) and less commonly of the pulmorary artery (PA) and its branches. When a true ASD is present, coexisting PS is almost always valvular. In PV stenosis with intact ventricular septum, the coexisting right to left shunt (RTLS) is usually via a patent foramen ovale (PFO) rather than a true ASD. In patients with significant PV stenosis and RTLS through a PFO, clinical features include exertional syncope, chest pain, central cyanosis, erythema of fingers and toes, clubbing of digits, underdevelopment, moon face, a sustained and strong RV impulse, and a systolic pulmonic murmur maximal in the second left intercostal space. The murmur usually radiates upward and to the left, and has a long duration extending beyond the aortic component of the second sound. In patients with large ASD and mild to moderate PS, clinical features include normal systemic arterial pulse, normal jugular venous pressure with normal and equal A and V waves, systolic thrill at the pulmonic area, hyperdynamic RV impulse, ejection pulmonic systolic murmur, fixed wide split of the second sound, and the occurrence of the fourth heart sound. PS occurs in 40% of patients with the Noonan syndrome. ASD occurs in about a third of Noonan patients, and is usually in association with PS.

### Prevalence

The combination of ASD and PS is very uncommon except in the Noonan syndrome, which occurs in 1 to 1,000 to 2,500 life births [1].

### Genes

PS and ASD can coexist in Noonan syndrome, which is an autosomal dominant disorder secondary to mutations in two genes: PTPN 11, KRAS [1]. Approximately 50% of Noonan patients have mutations in the PTPN11, which encodes SHP-2, a tyrosine phosphatase containing Src homology 2 (SH2) domain that participates in signal transduction pathways involving the RAS-mitogen activated protein kinase. Missense mutations in KRAS, which encodes two isoforms of the RAS family of protein, account for only 2% of Noonan syndrome cases.

### Molecular and Systemic Pathophysiology

The pathophysiology of PS in association with ASD depends upon the degree of obstruction of RV outflow, the distensibility of the hypertrophied RV and the size of the interatrial communication. Patients can be classified into two subclasses: patients with severe PV stenosis and small RTLS via PFO; and patients with a large left to right shunt (LTRS) via a large ASD and mild to moderate obstruction to RV outflow. In severe

PS with PFO, the right and left ventricular pressure behave independently, systolic pressure in the RV exceeds the systemic level. Strong right atrial contraction, which gives rise to a large A wave, distends the hypertrophied RV. Eventually when the right ventricle fails, a big V wave develops. The main factor that determines the extent of RTLS is more from an elevated RV diastolic pressure rather than an elevated right atrial pressure. Stretching of the right atrium may contribute to the enlargement of the PFO leading to more interatrial flow. As the interatrial shunt flow increases, the pulmonary flow reciprocally falls. Eventually with the RV failure, the systolic output decreases despite entry of the right atrial blood into the left side of the heart. On the other hand, a nonrestricted ASD with mild to moderate PS resembles uncomplicated ASD because of a relatively distensible RV can accept a significant LTRS flow.

### Diagnostic Principles

In severe PS with PFO, the electrocardiogram shows an enlarged right atrium, right axis deviation, early R/S progression in the right precordial leads. Chest X-ray reveals oligaemic lung fields, prominent pulmonary trunk. Echocardiogram confirms PV stenosis and a stretched PFO. In contrast, in large ASD with mild to moderate PS, the electrocardiogram reveals RV hypertrophy; the chest x-ray reveals increased pulmonary arterial blood flow, a dilated pulmonary trunk and RV. Echocardiogram confirms a large ASD, dilated right atrium and RV, paradoxical ventricular septal motion, doming and stenosis of the PV.

### Therapeutic Principles

In patients with symptomatic PS and PFO, when the transpulmonic valve gradient exceeds 50 mmHg, balloon valvuloplasty is the initial treatment of choice for the majority of patients. In severe PS and dysplastic PV or recurrent PS after balloon valvuloplasty, surgical intervention is required [2]. In patients with a large ASD and mild to moderate PS, the indication for intervention is when the ratio of pulmonary to systolic cardiac output is greater than 1.5, or when there is evidence of RV volume overload, and heart failure [3]. Combined procedure of catheter–based balloon pulmonary valvuloplasty and ASD closure with Amplatzer Septal Occluder can be performed [4]. Surgery is indicated if the above fails or is not feasible.

## Pulmonary Vaso-occlusive Disease

►Pulmonary Veno-occlusive Disease

## Pulmonary Vein Stenosis

Lourdes Prieto
Department of Congenital Heart Disease, Cleveland Clinic Foundation, Cleveland, OH, USA

### Synonyms

PVS

### Definition and Characteristics

Pulmonary vein stenosis (PVS) is a narrowing of one or more pulmonary veins that may be congenital, post-surgical or acquired. Anatomically it can manifest as either a discrete stenosis, a longer segment narrowing at the junction of the pulmonary vein with the left atrium, or diffuse hypoplasia of the entire pulmonary vein including the intrapulmonary branches. About half of the patients with congenital PVS have other cardiac abnormalities. Post-surgical PVS occurs in about 10% of patients who undergo corrective surgery for anomalous pulmonary venous drainage (TAPVR). This cardiac malformation results from failure of the developing left atrium to connect to the common pulmonary venous plexus, such that one or all of the pulmonary veins drain abnormally into the right atrium or into one of the systemic veins. Surgery to connect the veins to the left atrium can result in stenosis due to excessive scarring at the anastomotic site. In some cases PVS is already present in the anomalous veins even before surgery.

PVS can be acquired in adulthood due to extrinsic compression of one or more pulmonary veins most commonly seen in fibrosing mediastinitis, sarcoidosis or neoplasm. In the last decade adult-onset acquired PVS has appeared as a complication of radiofrequency (RF) ablation to treat atrial fibrillation.

The clinical presentation of PVS depends on the number of stenotic veins and the severity of the narrowing. Children who have more than two stenotic veins often present in infancy and have a progressive course characterized by respiratory distress, sometimes with pulmonary edema, recurrent pneumonia and pulmonary hypertension. Mortality is high in untreated patients, and treatment is not always successful. Patients with acquired PVS (most often adults) with at least two stenotic veins present with shortness of breath, and sometimes cough, hemoptysis or pleuritic chest pain. Some adult patients with only one stenotic vein are also symptomatic but to a lesser degree. Resting pulmonary hypertension and concomitant right heart failure occur when at least three pulmonary veins are involved. Depending on the underlying mechanism, mortality in adult-onset acquired PVS can be low with adequate intervention.

## Prevalence

Congenital PVS occurs in <1% of patients with congenital heart disease. TAPVR makes up 0.5–2% of all congenital cardiac lesions, and PVS occurs in about 10% of these patients after surgery. Acquired PVS due to extrinsic processes is quite rare. PVS due to RF ablation is currently reported to occur in about 1% of patients undergoing this procedure.

## Genes

No specific genes associated with congenital PVS have been identified.

Patients with right atrial isomerism have up to a 90% incidence of TAPVR, and PVS occurs in about 30% of these. In mouse models the transcriptional modulator Cited2 is required for normal establishment of the left-right axis, acting upstream of Nodal, Lefty2 and Pitx2 in the lateral mesoderm, and of Lefty1 in the presumptive floor plate [1]. Right atrial isomerism is one of the left-right-patterning defects. In both, humans and mice, double heterozygous mutations in Nodal and HNF3ß genes have been shown to cause left-right malformations [2].

Abnormalities of pulmonary venous drainage are also seen more frequently in Turner syndrome (45, X) [3]. Familial Scimitar syndrome has also been described, consisting of total or partial anomalous venous drainage of the right pulmonary veins to the inferior vena cava, right lung hypoplasia and pulmonary sequestration.

Acquired PVS can result from sarcoidosis, and recently a candidate gene, BTNL2 in the MHC II region on chromosome 6, has been mapped. BTNL2, a member of the B7 family of costimulatory molecules, likely functions to down-regulate T-cell activation [4]. A BTNL2 single-nucleotide polymorphism associated with sarcoidosis is predicted to result in a truncated nonfunctioning protein.

## Molecular and Systemic Pathophysiology

Congenital PVS is thought to result from abnormal incorporation of the common pulmonary vein into the left atrium. Pathologic specimens reveal proliferative "myofibroblastic" cells which have characteristics of both myocytes and fibroblasts. A neoproliferative process involving this cell type has been postulated to explain the rapid progression of PVS. Proliferation of these cells may also explain the exaggerated response to injury that can lead to stenosis after surgery or RF ablation.

## Diagnostic Principles

PVS should be in the differential diagnosis of an infant presenting with respiratory distress or chronic respiratory symptoms of unclear etiology. PVS should also be sought in any patient with pulmonary hypertension. In children the diagnosis can almost always be made by echocardiography. Significant stenosis is characterized by pulmonary venous flow turbulence on color Doppler, along with a monophosic pattern or flow velocities >1.6 m/s.

In adults acoustic windows are often inadequate to make the diagnosis of PVS by echocardiography. Both MRI and multi-detector CT allow excellent visualization of the pulmonary veins, with CT having the highest spatial resolution. Still severely stenotic veins may not be visible by MRI or CT. Angiography is the gold standard and provides the most exact detail of pulmonary vein anatomy (Fig. 1).

Each pulmonary vein can be visualized either by injecting contrast via a catheter wedged in the pulmonary artery, or by selective angiography in each pulmonary vein after crossing the atrial septum.

## Therapeutic Principles

Both surgical and percutaneous treatment of PVS in children have been plagued by high recurrence rates. A recently described surgical technique known as sutureless marsupialization attempts to avoid the response to injury caused by direct stitching of the pulmonary veins by attaching the pericardium around the cut edges of the stenotic veins to the left atrium. Balloon dilation (including cutting balloons) usually results in immediate improvement, but repeat procedures are nearly always necessary. Restenosis is also nearly universal after stent angioplasty in children. Children with pulmonary vein hypoplasia extending into the intrapulmonary branches cannot be treated with these methods. Antiproliferative treatment with chemotherapy has been attempted with very mixed

**Pulmonary Vein Stenosis. Figure 1** Pulmonary artery wedge angiography in a patient whose left superior pulmonary vein appeared completely occluded by multi-detector CT. There is a trickle of flow entering the left atrium.

results, and lung transplantation remains the only option for these patients.

Patients with PVS due to extrinsic compression are treated with stent angioplasty with varying success, and long-term outcome has not been well studied.

Adults with post ablation PVS have been nearly universally treated with percutaneous techniques [5]. High recurrence rates have also been observed with balloon dilation and with relatively small stents. High long-term patency rates (≥80%) have been achieved with stents ≥8–10 mm in diameter. The size of the stent is dictated by the size of the normal vessel beyond the stenosis, and therefore early referral for intervention may improve outcome by minimizing vessel atrophy.

# Pulmonary Veno-occlusive Disease

Larry Latson
Department of Pediatric Cardiology, Cleveland Clinic Foundation, Cleveland, OH, USA

## Synonyms

Pulmonary vaso-occlusive disease; Pulmonary capillary hemangiomatosis; Primary pulmonary hypertension with venous or capillary involvement; PVOD

## Definition and Characteristics

Pulmonary veno-occlusive disease (PVOD) is a rare cause of pulmonary hypertension. It is considered to be a form of primary pulmonary hypertension which preferentially affects the post capillary pulmonary vasculature – i.e. small intra-parenchymal pulmonary veins. The term does not refer to congenital or acquired stenosis of the large, major extra-parenchymal branches of the pulmonary veins. The clinical and pathologic findings of PVOD have been seen in association with a wide range of conditions including viruses, collagen vascular diseases, hematologic malignancies, bone marrow transplantation, radiation therapy and chemotherapy [1]. Most cases, however, do not appear to have these associated conditions. PVOD has been seen in siblings in a small number of families, but most cases appear to be sporadic. The majority of patients present as young adults, but rare cases in children and elderly patients have been described [2]. The typical clinical presentation is very similar to that of primary pulmonary hypertension. Patients generally complain of shortness of breath with exercise, dyspnea, decreased exercise tolerance and eventually symptoms of right-sided heart failure. Non-invasive imaging (CT/MRI, ventilation-perfusion scans) and cardiac catheterization are used to confirm the presence of pulmonary hypertension and the absence of causes of secondary pulmonary hypertension (such as mitral stenosis, stenosis of the major pulmonary veins, pulmonary embolic disease, left to right shunts from congenital heart disease, and left ventricular failure). Clinical features that increase the likelihood of PVOD being the cause of pulmonary hypertension include the presence of rales and clubbing on clinical examination, severe reduction in diffusion capacity on pulmonary function testing, chest x-ray findings of reticular interstitial infiltrates, pleural effusions and septal lines, and CT findings of smooth interlobular septal thickening and multifocal ground glass opacities [2]. If definitive diagnosis is required, an open lung biopsy and examination of microscopic sections is considered to be the "gold

standard." The disease tends to be relatively rapidly progressive, and fewer than 20% of newly diagnosed patients are expected to be alive and well 5 years after diagnosis without treatment (Fig. 1).

## Prevalence

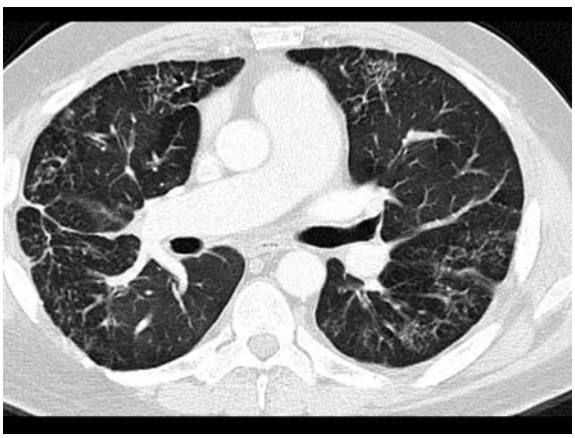
PVOD is a very rare condition. There have been fewer than 300 confirmed cases reported since diagnostic criteria were established. Fewer than 10% of patients with pulmonary hypertension have PVOD.

## Genes

PVOD has been reported to occur in several siblings. A single case report suggests that a mutation in bone morphogenetic protein receptor II (BMPR II), a member of the transforming growth factor-beta receptor family, may be one cause of PVOD [3].

## Molecular and Systemic Pathophysiology

Current opinion is that there is likely to be some inciting event that primarily affects the small pulmonary veins. The event may be environmental, infectious, or a genetic abnormality. This inciting event first leads to abnormal endothelial proliferation in the small pulmonary veins. Eccentric intimal fibrosis, occlusion, and re-canalization of veins, are seen as the disease progresses. These changes are more frequently seen in patients with PVOD than in patients with pulmonary hypertension secondary to mitral stenosis or fibrosing mediastinitis. Pulmonary capillary hemangiomatosis (abnormal proliferation of pulmonary capillaries) appears to most likely be a secondary angio-proliferative process [4]. Patients with significant disease also manifest changes in small pulmonary arteries. It can be difficult to differentiate PVOD from primary pulmonary hypertension due to disease of the small pulmonary arteries in some cases. Both forms of pulmonary hypertension may have changes in arteries and veins, but the changes in the arteries are less severe than those in the veins in patients with PVOD. Pulmonary venous obstruction eventually leads to pulmonary vascular congestion and pulmonary edema. The appearance on chest radiographs and CT images noted above are consistent with the primary level of obstruction at the pulmonary vein rather than the pulmonary artery level. With increasing pulmonary artery pressures, patients may develop an inability to increase cardiac output and the pulmonary edema may cause severe dyspnea. Late cardiac decompensation and sudden death are not uncommon.



**Pulmonary Veno-occlusive Disease. Figure 1** Axial CT image in lung windows shows mild, smooth interlobular septal thickening and centrilobular nodules with associated ground glass attenuation. A prominent main pulmonary artery segment can also be seen (figure courtesy of Tan-Lucien H. Mohammed, M.D., FCCP).

## Diagnostic Principles

Definitive diagnosis is by microscopic examination of multiple lung fragments from open lung biopsy. Inter- or intra-lobular veins showing eccentric or concentric narrowing or occlusion by cellular or collagenous fibrosis or recanalization is seen. Pulmonary veins are generally distinguished from pulmonary arteries on the basis of position and structure. Pulmonary veins are usually found at the edge of acini or midway between two arteries and pulmonary veins typically have a single elastic lamina instead of two or more laminae in pulmonary arteries.

## Therapeutic Principles

No specific effective treatment has been found for treatment of PVOD. A small number of patients have responded to vaso-dilators such as PGI2 or calcium channel blockers. These responses have tended to be temporary, however. In addition, patients have developed fulminate pulmonary edema with the use of calcium channel blockers or prostacycline [2]. Immunosuppressive and anti-inflammatory agents have been used in a small number of patients, but do not appear promising. The only proven effective therapy has been lung transplantation.

## Synonyms

PAF; Bradbury-Eggleston syndrome; Idiopathic orthostatic hypotension

## Definition and Characteristics

Adult-onset idiopathic neurodegenerative disorder affecting the peripheral autonomic nervous system. In the older literature, it is likely that many patients considered to have this disease actually suffered from some other autonomic neuropathy. The presence of alpha-synuclein containing neuronal cytoplasmic inclusion, termed Lewy bodies, allows further categorization as a Lewy body-type alpha-synucleinopathy, along with Parkinson's disease (PD), diffuse lewy body disease (DLBD) or multiple system atrophy (MSA).

## Prevalence

Probably less than 1:10,000. Slightly more prevalent in males than females.

## Genes

None yet known.

## Molecular and Systemic Pathophysiology

Neurodegenerative changes in afferent postganglionic sympathetic nerves resulting in a loss of catecholaminergic signaling. Inclusion bodies containing alpha-synuclein (αSYN), i.e., Lewy bodies, have been identified in neurons of the substantia nigra, locus ceruleus, thoracolumbar and sacral spinal cord, sympathetic ganglia and pre- and postganglionic sympathetic and parasympathetic nerves of persons with PAF [1].

Alpha-synuclein is the major fibrillar component of Lewy bodies and abnormal deposits of the protein were originally identified in plaques from the brains of persons with Alzheimer's disease. Since then, missense mutations in the gene have been linked to early-onset familial PD. Lewy bodies are also found in the brains of patients with PAF, although the severity of the lesions are much more profound in peripheral structures. It is unknown whether accumulation of αSYN is the cause of, or merely a byproduct of, neurodegenerative changes seen in PD, DLBD, MSA, and PAF. By definition, PAF is a disease affecting peripheral autonomic nerves with no central involvement. Because αSYN is located primarily in the brain, the utility of investigating this synuclein subtype in relation to PAF is debatable. Instead, gamma-synuclein may be more appropriately linked to peripheral neurodegeneration, since it is found in greater quantities in the peripheral nervous system, including sympathetic neurons. For example, in gracile axonal dystrophy (gad) mice, which do not express ubiquitin carboxyl-terminal hydrolase L1 (UCH-L1), accumulation of gamma-SYN resulted in axonal spheroid formation and peripheral neurodegeneration [2]. Spheroids are eosinophilic Lewy body-like lesions, differing from Lewy bodies in composition and locus, and both are associated with neurodegeneration. These results suggest that other types of synucleins and their interactions with members of the ubiquitination pathway may have a greater impact on peripheral nerve survival and be more relevant in determining the pathogenesis of PAF.

Most important, however, while several transgenic mouse models of alpha-, beta- and gamma-synucleinopathies have been used to investigate the neurodegeneration associated with other forms of orthostatic hypotension, none have yet investigated how such gene

manipulations may affect autonomic regulation of hemodynamics. Numerous investigations have revealed key mechanisms in nerve damage such as oxidative stress mediated by neurotoxins, posttranscriptional modifications associated with phosphorylation, glycosylation and ubiquitination, and interactions with other molecules that promote or block aggregation [3]. However, with regard to mouse models of PAF and other neurodegenerative diseases with autonomic involvement, it will be necessary to determine the effect of similar genetic mutations on parameters such as blood pressure regulation, catecholamine levels, and adrenergic receptor sensitivity.

## Diagnostic Principles

Disease onset is slow and progressive, usually occurring in midlife to old age, and intermittent periods of stability are common. Dysautonomia may not be recognized until daily activities are significantly affected. Urologic symptoms may precede hypotension and are sometimes the trigger for clinical evaluation. Patients often present with hesitancy, urgency or incontinence, with additional complaints of erectile or ejaculatory dysfunction in men. PAF is suspected on presentation of orthostatic hypotension, without an increase in heart rate. However, after meals, blood pressure commonly falls more than 40 mm Hg. Multiple orthostatic measurements may be necessary and patients are encouraged to document blood pressure, particularly on rising from sleep, after food consumption or exercise, and with exposure to extreme heat. Normal sympathetic and parasympathetic responses to dizziness such as nausea, pallor, or perspiration are often absent. Symptoms gradually worsen and deconditioning is common, thus exacerbating the condition and increasing susceptibility to secondary events.

A definitive diagnosis of PAF may take more than 5 years, necessitating diligent clinical observation and testing for signs of central nervous system neurodegeneration. There should be no sign of cerebellar, striatal, pyramidal or extrapyramidal dysfunction, which are indicators of PD or MSA. CNS involvement may sometimes be determined with magnetic resonance imaging or positron emission tomography, although clinical differentiation of PAF and MSA is usually possible. In contrast to MSA or PD, supine plasma norepinephrine levels are abnormally low and do not increase appropriately with upright posture. PAF patients exhibit decreased or absent sinus arrhythmia and a lack of blood pressure increase during phase IV of the Valsalva maneuver, as well as in response to the cold pressor or Stroop test. A supersensitivity to adrenergic receptor agonists may be detected as an exaggerated increase in blood pressure with infusion of norepinephrine, isoproterenol or tyramine, or an attenuated vasodepressor response to clonidine in comparison to MSA [4]. A dramatic drop in blood pressure following consumption of a measured amount of food is typical of PAF and MSA. Ingestion of water is often pressor. Finally, postmortem identification of Lewy bodies in the brainstem and pre- and postganglionic autonomic neurons supports the diagnosis of PAF.

## Therapeutic Principles

In cases of mild to moderate hypotension, patient education and nonpharmacologic interventions are usually sufficient, including support stocking, abdominal binders, increased salt intake, and drinking water prior to rising and before meal. Later, fludrocortisone and short-acting pressor agents may become necessary. Administration of midodrine, hydrocortisone, yohimbine, or the synthetic amino acid L-threo-3,4-dihydroxyphenyslerine (L-DOPS) has also proven beneficial in maintaining orthostatic pressure [5].

# Pure Cutaneous Histiocytosis

►Langerhans' Cell Histiocytosis

# Purine Nucleoside Phosphorylase Deficiency

Lynette D. Fairbanks, H. Anne Simmonds
Purine Research Unit, Guy's Hospital, London, UK

## Synonyms

PNP deficiency

## Definition and Characteristics

Autosomal recessive defect involving an enzyme normally a vital link in the "inosinate cycle" of the purine salvage pathway (Fig. 1) leading to a combination of neurological and immunological deficits. Enzyme-deficient patients have in effect a double defect, since the next step in the inosinate cycle involving hypoxanthine phosphoribosyltransferase (HPRT: dotted lines) is unable to operate through absence of substrate.

## Prevalence

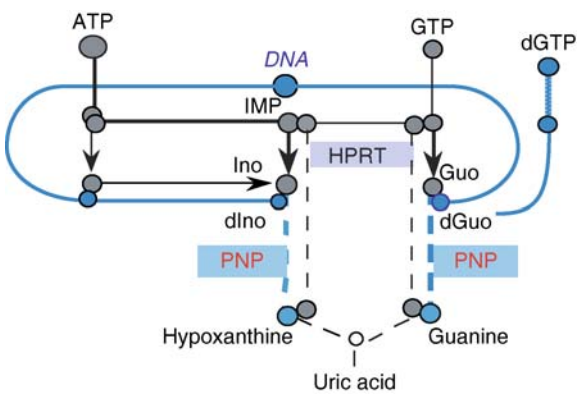
Rare. About 60 cases reported from many countries including Saudi Arabia, Pakistan, Barbados and Japan [1,2]. Thus not confined to any specific ethnic group. More frequent in consanguineous kindreds. Accounts for only 4% of patients with inherited immunodeficiencies [1]

## Genes

Locus on long arm of chromosome 14 (14q13.1). Molecular basis reported in 12 patients, mainly point mutations. Autosomal recessive inheritance confirmed by both parents being heterozygous for the same mutation [1, 2].

## Molecular and Systemic Pathophysiology

PNP catalyses the degradation of inosine (Ino), guanosine (Guo) and their deoxy analogues to the corresponding bases. Although a reversible reaction, degradation is favored because intracellular phosphate levels exceed those of ribose- or deoxyribose-1-phosphate. PNP is a housekeeping gene, expressed in all tissues, with highest activity in erythrocytes and kidney.



**Purine Nucleoside Phosphorylase Deficiency.**
**Figure 1** Role of PNP in degrading (d)-inosine and (d)-guanosine) to uric acid, which is replaced by these four nucleosides in PNP deficiency.

Symptoms are generally first noted in early infancy as developmental delay with spastic diplegia or tetraplegia (70%) with a history of recurrent infections, especially otitis media [1]. Some present with autoimmune hemolytic anaemia or idiopathic thrombocytopenia purpura and, unrecognized, have succumbed to non-irradiated blood or platelet transfusions [3]. Cellular immunodeficiency is attributed to dGTP accumulation catalyzed by deoxycytidine kinase or a specific kinase in thymocytes but not B cells, with inhibition of ribonucleotide reductase and DNA synthesis. Thymocyte dGTP accumulation (as for dATP in ADA deficiency) could lead to apoptosis and T-cell depletion [4]. Kinases for the three other nucleosides do not exist in human cells. Some residual T-helper cell function explains the initially relatively normal B cell function in many patients. Abnormalities of humoral immunity may develop subsequently.

## Diagnostic Principles

A low to absent plasma urate in the presence of the above symptoms is highly suggestive of PNP deficiency, but is not axiomatic. Some cases with appropriate symptoms but plasma urate within the low normal range due to tissue-specific variation in enzyme expression were not investigated for PNP initially. T-cell numbers and mitogen responses are markedly reduced, but B-cell function is preserved initially. Urate is replaced by inosine and guanosine in the ratio of ca. 4:1 in urine and plasma with lesser amounts of deoxyinosine and deoxyguanosine (ca 2:1). Preferential accumulation/excretion of inosine confirms the normal extensive hypoxanthine recycling relative to guanine by HPRT (Fig. 1), total purine excretion being increased two- to fourfold on a creatinine basis as a result. Confirmation by enzyme assay is essential, but will be difficult if treatment has necessitated a prior blood transfusion. dGTP (normally undetectable) is present in erythrocytes and NAD is elevated. Pitfalls include the finding of significant uric acid in the urine due to bacterial infection. Measurement of both plasma and urine uric acid is essential.

## Therapeutic Principles

Many modalities tried originally (red cell transfusion and various metabolic protocols) were unsuccessful. Patients invariably died before the age of 20 [1]. Of the first 33 cases, only two survive. Subsequent success of bone marrow transplantation depends on early recognition. Some have succumbed while awaiting a suitable donor. Haploidentical transplantation has a better success rate. Transplantation corrects the immunodeficiency but fails to reverse the neurological deficits [5]. Prenatal detection has been performed in both the first and second trimester.

# Purpura Rheumatica

►Purpura Schoenlein-Henoch

# Purpura Schoenlein-Henoch

Martina Brunner, Christos C. Zouboulis
Departments of Dermatology, Venerology, Allergology and Immunology, Dessau Medical Center, Dessau, Germany

## Synonyms

Purpura rheumatica; Leucocytoclastic angiitis (vasculitis allergica, anaphylactoid purpura)

## Definition and Characteristics

Acute IgA-dominant immune complex necrotizing leukocytoclastic vasculitis of the capillaries and the postcapillary venules [1]. The disease is characterized by purpuric papules primarily at the lower extremities as well as involvement of gut (50–80%; with nausea, vomiting, cramping, hematemesis, melena, gut invagination, and perforation), kidneys (50%; with hematuria, proteinuria, glomerulonephritis), scrotal and testicular hemorrhage (20% of the boys), CNS and pulmonary involvement (uncommon), and is often associated with arthralgias (60%). Generally benign and self-limited; resolution occurs over 4–6 weeks. Recurrences occur in approximately 30% of the cases. In 5% with diffuse glomerulonephritis leading to chronic renal disease.

## Prevalence

Purpura Schoenlein-Henoch is a frequent form of leucocytoclastic angiitis. It mostly occurs in children (4–11 years, peak 5 years; male:female, 2:1) with an incidence of 13.5–18 per 100,000. Young adults (male: female, 1:2) can also be involved with a more severe course. It frequently occurs 2–3 weeks after streptococcal infections of the respiration tract but also after other type of infections (75%).

## Genes

No gene association has been identified. The role of HLA alleles is unclear, associations can be suspected because of the simultaneous appearance of the disease in identical twins [2]. Increased occurrence of HLA-B35 and cytokine polymorphisms, especially of the interleukin-5 gene, has been reported and an association of interleukin-1 receptor antagonist gene polymorphism as well as deletion polymorphism of the angiotensin converting enzyme gene with kidney involvement was identified. Familial complement component 2 deficiency in patients with purpura Schoenlein-Henoch has also been described.

## Molecular and Systemic Pathophysiology

It is assumed that an unknown antigen stimulant triggers an increased IgA synthesis, which leads to the initiation of vessel involvement. Several cytokines, such as transforming growth factor-β, tumor necrosis factor-α, and interleukins are involved in the inflammatory process.

## Diagnostic Principles

*ACR diagnostic criteria for Purpura Schoenlein-Henoch (1990)*: (i) not thrombocytopenic palpable purpura, (ii) beginning of the illness at an age of less than 20 years, (iii) intestinal angina: diffuse stomach pain with deterioration after the meals or intestine ischemia with hemorrhagic diarrhea, (iv) histology of leukocytoclastic vasculitis (two or more positive criteria: 87.1% sensitivity, 87.7% specificity) [1,2].

*Characteristic histology*: Perivascular mixed neutrophilic and lymphocytic infiltrate, interstitial neutrophils, nuclear dust, and erythrocyte extravasates, fibrin deposits at the vessel walls. In the immune histology IgA deposits at the walls of the upper dermal vessels are detected.

## Therapeutic Principles

Treatment regimens are discussed controversially but in case of a decision for a systemic treatment corticosteroids are the regimen of choice. In kidney involvement glucocorticosteroids (1–2 mg/kg/day) have to be administered. Treatment with dapsone (1–2 mg/kg/day) is recommended in patients with recurrent course or no response to corticosteroids [3]. Dapsone has antioxidative effects and can suppress the production of free radicals in neutrophils. In addition, it impedes prostaglandin D2

production and synthesis of IgG and IgA antibodies as well as the IgA–neutrophil interactions. Alternative regimens with cyclosporine A [4], azathioprine, high-dose intravenous immune globulins [5], anticoagulants, factor XIII infusions as well as leukapheresis or plasmapheresis have been reported as a second line therapy or at a severe kidney involvement.

[2]Bone Research Programme, School of Medicine and Dentistry, Institute of Medical Sciences, Foresterhill, Aberdeen, UK

### Synonyms

Occasionally confused with autosomal recessive types of osteopetrosis

### Definition and Characteristics

Autosomal recessive cysteine proteinase defect leading to dysfunctional osteoclasts and resulting in increased bone density and a range of dysmorphic features including reduced statue and loss of distal phalanges.

### Prevalence

Very rare; around 150 cases reported in the literature.

## Genes

CTSK on 1q21 encodes the Cathepsin K gene, a member of the papain family cysteine proteinases highly expressed in musculoskeletal tissue and with a particularly high expression in osteoclasts, the bone resorbing cells.

## Molecular and Systemic Pathophysiology

Cathepsin K (CTSK) is a 329 amino acid protein with high homology to cathepsin S and L. Unlike the latter, CTSK is expressed at high levels in osteoclasts, where the enzyme (EC 3.4.22.38) acts as a lysosomal protease and is involved in cleavage of collagen, as well as other substrates, including non-collagenous matrix proteins. The enzyme is synthesized as a prepropeptide with a 15 amino acid signal sequence and a 99 residue pro piece. The mature enzyme has an optimal pH of 6.1 and is active within lysosomes in the osteoclasts, and secreted in the subosteoclastic resorption space to allow extracellular matrix degradation. The involvement of a defective cysteine proteinase in this disease was suggested after electron microscopical examination of bone biopsies of patients [1]. In these biopsies large areas of dematerialized bone were seen underneath normally polarized osteoclasts which were filled with vacuoles containing undigested collagen. A similar picture was obtained when mouse bone was treated in vitro with inhibitors of cysteine proteinases. Gelb and coworkers identified mutations in CTSK as the cause of pycnodysostosis [2]. To date over ten different mutations have been reported in patients, leading to varying degrees of reduction in enzyme activity [3,4]. In many cases the mutated enzyme shows no activity, due to truncations or protein degradation, in other cases reduced activity is seen. CTSK null mice have been engineered and they show some, but not all, characteristics of the human disease. Organic bone matrix degradation by osteoclasts in long bones is impaired, but in the skull no resorption defects are seen, suggesting that in the mouse other cysteine proteinases and/or metalloproteinases may take over the role of CTSK. The dysmorphic features seen in human patients, especially the facial abnormalities are not reproduced in the mouse models. The realization that CTSK has such an important and, in humans, non-redundant role in degradation of collagen in bone has led to the development of CTSK inhibitors as potential new anti-resorptive therapeutic agents.

## Diagnostic Principles

Increased bone density on X-ray combined with short statue, craniofacial abnormalities such as an abnormally enlarged skull and persistence of fontanel(s), hypoplastic middle face, maxillary hypoplasia, retention of deciduous teeth, delayed and/or ectopic eruption of permanent teeth, hypoplastic clavicles, and short clubbed fingers with hypoplastic or absent terminal phalanges. Patients are prone to frequent bone fractures due to unusually brittle bone, which generally heal normally.

## Therapeutic Principles

No specific treatment exists. Diagnosis is important to help prevent fractures. The dental abnormalities and malocclusion deserve attention and may require surgical intervention.

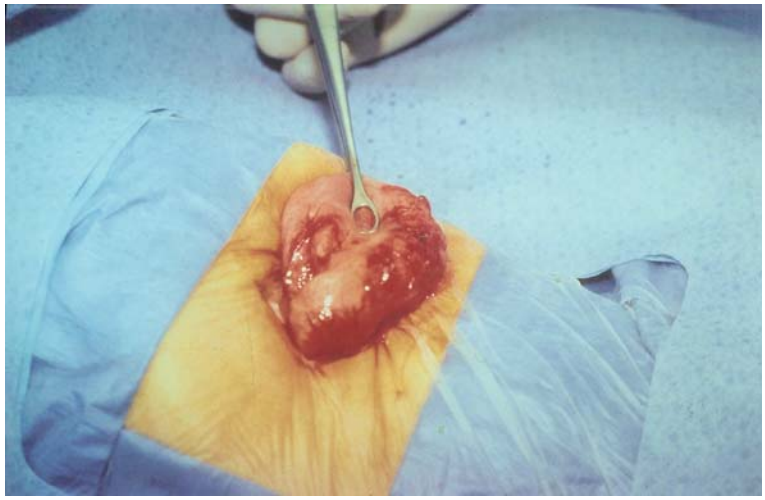
# Pyloric Stenosis

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

The hallmark of pyloric stenosis is progressive, non-bilious projectile vomiting that typically begins when the infant is about 3 weeks old [1]. The child is characteristically eager to feed immediately after vomiting. Occasionally, there may be blood in the vomitus as a result of gastritis or esophagitis. The infant fails to gain or actually loses weight. Approximately 2–5% of infants have unconjugated hyperbilirubinemia as a result of glucuronyl transferase deficiency secondary to caloric deprivation. Physical examination is best accomplished when the infant's stomach is empty and the infant is resting quietly. Peristaltic waves that progress across the upper abdomen from left to right during feedings may be visible [1]. A pyloric, olive-shaped mass that may be palpable in the right epigastrium is pathognomonic [1] (Fig. 1). As many as 7% of infants with pyloric stenosis have associated malformations, such as esophageal atresia, intestinal



**Pyloric Stenosis. Figure 1** Intraoperative finding of an elongated and thickened pylorus simulating an olive in a 3-week-old infant with pyloric stenosis.

malrotation, inguinal hernia, cryptorchidism, or obstructive uropathy. Pyloric stenosis is also associated with syndromes such as Smith-Lemli-Opitz syndrome.

## Prevalence

Pyloric stenosis occurs in approximately 3 of every 1,000 live births and is four times more common in boys [1]. Pyloric stenosis is relatively uncommon in African American and Asian infants [1].

## Molecular and Systemic Pathophysiology

Pyloric stenosis is due to a narrowing of the pyloric canal caused by hypertrophy of the pyloric musculature. Decreased nitric oxide synthetase activity, elevated prostaglandin and gastrin levels have been observed in the pyloric muscle and the serum of infants with pyloric stenosis [2]. Prostaglandin and gastrin can stimulate muscle hypertrophy and increase the intensity of pyloric contraction. Both genetic and environmental factors play a role in the pathophysiology. Consistently higher rates among boys and Caucasian infants, familial occurrence, and coexistence with congenital malformations and clinical syndromes suggest a genetic basis of the disorder. Exposure to erythromycin either prenatally or in the first few weeks of life is associated with an increased risk [3]. It has been hypothesized that erythromycin interacts with motilin receptors, inducing strong gastric and pyloric bulb contractions and resulting in hypertrophy of the pyloric musculature [3].

## Diagnostic Principles

The differential diagnosis for non-bilious emesis includes overfeeding, gastroesophageal reflux, milk allergy, pylorospasm, salt-wasting adrenogenital syndrome, increased intracranial pressure, congenital metabolic dysfunction, prepyloric antral web, and gastric duplication [1]. In the absence of a palpable pyloric mass, abdominal ultrasonography is the diagnostic test of choice. The most commonly used criteria for a positive ultrasonographic study include pyloric muscle thickness greater than 4 mm and pyloric channel length greater than 14 mm [1]. Because these measurements are age dependent, pyloric muscle thickness greater than 3 mm is diagnostic for pyloric stenosis in infants younger than 30 days [1]. If ultrasonography proves non-diagnostic, an upper GI tract barium study is recommended. The classic radiographic contrast findings include a single string sign or double railroad track sign and delayed gastric emptying [1].

## Therapeutic Principles

Pyloric stenosis may be complicated by dehydration and hypochloraemic metabolic alkalosis. The urinary pH is high initially, but eventually drops as the severe potassium depletion leaves only hydrogen ions to exchange with sodium ions in the distal renal tubules; this results in paradoxic aciduria. Fluid and electrolyte disturbances must be corrected with intravenous solutions before surgical intervention. Pyloromyotomy, the surgical procedure of choice, can be performed through a short transverse or periumbilical incision or laparoscopically. The surgeon splits the underlying pyloric mass without cutting the mucosa and closes the incision. Intravenous atropine therapy has a success rate of 75–87% [2,4]. The disadvantages of intravenous atropine therapy are the length of hospital stay required

and the necessity of continuing oral atropine medication after discharge [4]. As such, intravenous atropine therapy is not recommended in settings where the standard surgical procedure is readily available [2].

# Pyoderma

►Impetigo

# Pyoderma Gangrenosum

Peter Von Den Driesch
Department of Dermatology and Allergology, Center for Skin Diseases, Stuttgart Clinic, Stuttgart, Germany

## Definition and Characteristics

The term pyoderma gangrenosum describes an entity with the occurrence of chronic ulcerating lesions without obvious tendency of healing. Histologically, intraepidermal neutrophils and a dermal neutrophil-rich inflammation with more or less vasculitis are characteristic. Not rarely, these findings may even be unspecific. By direct immunofluorescence, deposits of IgG, IgM, C3, and especially IgA can be found in about 70% of the patients. The disease may unilesional or, more acute, multilesional. Clinical subtypes include a superficial granulomatous, a bullous very acute, and a pustular variant. In about 60%, the disease is associated with other conditions such as chronic autoimmune bowel disease, chronic rheumatoid arthritis, paraproteinemia, or hemoproliferative diseases [1,2].

## Prevalence

There are presently no population-based data available.

## Genes

A disease locus for familiar acne, pyoderma gangrenosum, and pyogenic arthritis was mapped to chromosome 15q [3].

## Molecular and Systemic Pathophysiology

In contrast to other neutrophilic diseases, main pathological feature in pyoderma gangrenosum is the ulcerating neutrophil-rich cell infiltration of the upper dermis *with* evidence for vasculitis in the *upper* dermis. The preferred localization of the disease on the lower legs, and the findings of direct immunofluorescence are additional hints for the pathogenetic relevance of vasculitis in pyoderma gangrenosum. As suggested in other neutrophilic diseases, the presence of a neutrophil-activating local cytokine milieu involving interleukin-8 and TNF-alpha is additionally likely. Perivascular lymphocytes are present in many cases; their pathogenic relevance remains unclear at the moment [2–4].

## Diagnostic Principles

*Major criteria*: (i) Occurrence of a primary sterile, chronic ulceration(s), typically with vialaceous undermined borders (ii) Exclusion of relevant differential diagnoses (e.g., pyoderma, ulcerations based on arterial or venous vessel diseases, and ulceration based on a classical leucocytoclastic vasculitis)

*Minor criteria*: (i) Histology from the border of the ulceration: neutrophil-rich infiltration of the dermis with signs for vasculitis and deposits of immunoglobulins and/or complement factors on the vessels. (ii) Presence of a relevant associated disease, e.g., chronic autoimmune bowel disease, chronic rheumatoid arthritis, paraproteinemia, or hemoproliferative disease. (iii) Response to treatment with systemic immunosuppressive therapy, little or no response to conventional external ulcer therapy.

Both major and at least two minor criteria are needed for diagnosis [2].

## Therapeutic Principles

The occurrence of pyoderma gangrenosum is associated with other conditions in about 60% of the patients. Treatment of the latter is thus recommended. Systemic administration of corticosteroids, colchicine, dapsone, cyclosporin A, or mycophenolate mofetil should be considered as first choice treatment. Increasing evidence points to intravenous immunoglobulins as important additional treatment option. Topical treatment with calcineurin inhibitors is of additional effect. Biological TNF-alpha blocking drugs such as eternacept or infliximab should be discussed only in rare severe relapsing cases and the occurrence of pyoderma gangrenosum along such a treatment for other reasons is reported. In 50%, pyoderma gangrenosum is chronic

and needs a long-lasting treatment. In these cases combination regiments are strongly recommended [2,4].

# Pyrexia

►Fever

# Pyridoxine Deficiency

Roland Bitsch
Institute of Nutrition, Friedrich-Schiller-University Jena, Jena, Germany

## Synonyms

Vitamin $B_6$ deficiency

## Definition and Characteristics

Depressions and confusions as early signs, seborrhoic dermatitis in the nasolabial fold and near the eyes, frequently combined with glossitis, epileptiform convulsions, and irritability, peripheral neuropathias, microcytic or sideroblastic anemia, hyperoxaluria with idiopathic nephrolithiasis.

## Prevalence

Vitamin $B_6$-deficient diet, chronic treatment with antagonistic drugs, such as the tuberculostatic isoniazid, chemotherapeutics such as, e.g., cycloserine and penicillamine and some anticonvulsiva.

## Genes

Amino acid (AA) decarboxylases (L-glutamate decarboxylase), AA lyases (kynureninase) and synthases (δ-aminolevulinic acid synthase), AA transferases (serin-palmitoyltransferase), Δ6-linoleic acid desaturase.

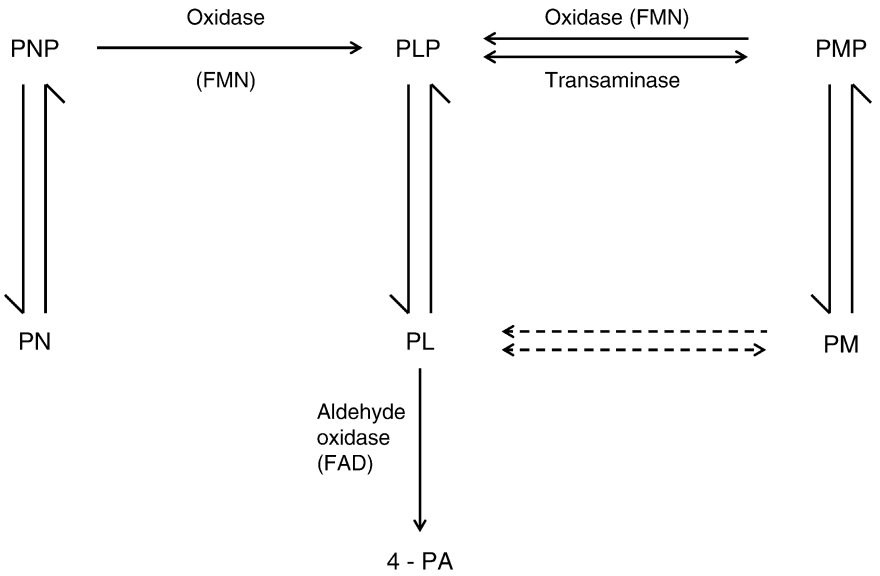
## Molecular and Systemic Pathophysiology

Owing to its ubiquitous occurrence in animal and plant products frank clinical deficiency symptoms of nutritive origin exist very rarely. If any, those are connected with other vitamin B deficiencies, such as riboflavin deprivation because of its interrelationship with the pyridoxine metabolism (see Fig. 1).

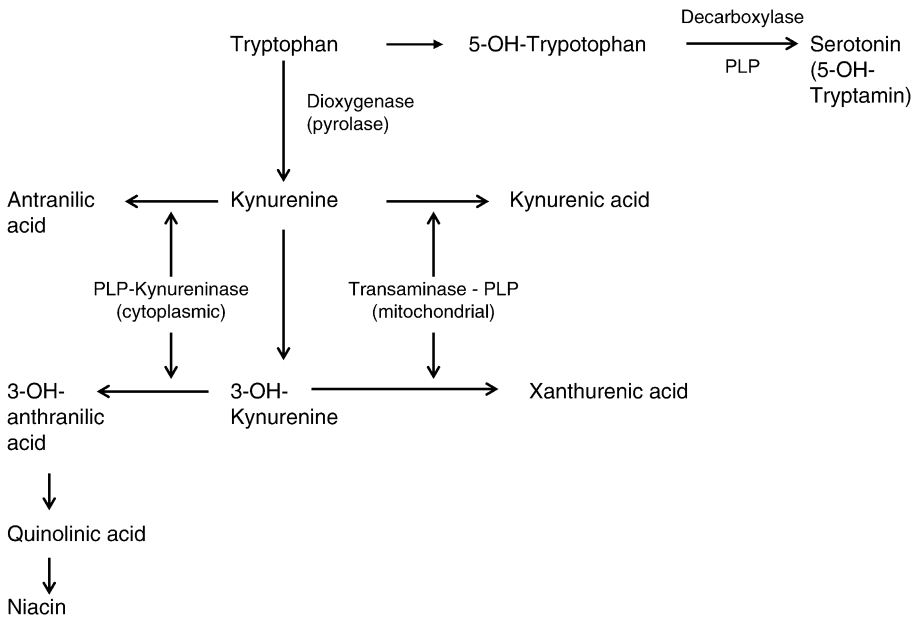
The development of seborrhoic dermatitis was observed in man and animal. Early symptoms in rats appear in the peripheral body region (tail and paws), proceeding slowly to the middle part of the body. This characteristic occurrence, named acrodynia, resembles deficiency symptoms of essential fatty acids and points out the possible pyridoxine-dependent disturbance of the linoleic acid metabolism. Subsequent studies demonstrated alterations in fatty acid levels in the cerebellum and cerebrum and a disturbed myelination interfering with a decrease in cerebral sphingolipids in progenies of dams fed a vitamin $B_6$-deficient diet [1,2].

In man, the skin is red and rough in the nasolabial folds and on the chin, and greasy scales are visible near the nose, mouth, and eyes. In 1953 it was demonstrated that skin lesions appeared after 2–3 weeks on a low vitamin $B_6$ diet combined with desoxypyridoxine administration as synthetic vitamin antagonist. The lesions disappeared after vitamin $B_6$ administration [1,2].

Symptoms of epileptiform convulsive seizures and nervous irritability were, likewise, 50 years ago observed in young babies fed a commercially canned, liquid-milk formula. At 4 weeks of age the babies became irritable and showed a stiffening of the body and convulsive seizures followed. After i.m. administration of 100 mg pyridoxine hydrochloride the seizures disappeared. It could be shown that the vitamin had been destroyed in the formula milk by heat during the canning process. These first occurring epileptiform convulsions due to $B_6$ deprivation reflect the relevance of PLP-dependent enzymes in the formation and metabolism of neurotransmitters. The $B_6$ deprivation seems to be more dramatic in infants owing to their incomplete brain function than in adults. When adults were nourished on a high protein diet devoid of vitamin $B_6$, abnormal EEGs had been observed. The EEG was normalized, on the other hand, after adding $B_6$ to the high protein diet in a relation of at least 1 μg $B_6$ per 100 g protein. In young rats made deficient during the development of the central nervous



**Pyridoxine Deficiency. Figure 1** Pyridoxine metabolism.



**Pyridoxine Deficiency. Figure 2** Tryptophan metabolism.

system the most significant feature of $B_6$ deficiency was the decrease of serotonin and GABA levels in various brain areas [1,2].

Peripheral neuropathies with and without seborrhoic lesions were observed in adults on a vitamin $B_6$-restricted diet. Besides depressions and insomnia, apathia, enhanced irritability, and paresthesias with reflex abnormalities developed. After tryptophan loading, the urinary excretion of xanthurenic acid and other tryptophan metabolites increased and the volunteers exhibited depressed PLP plasma levels (Fig. 2) [1,2].

Severe deficiency of vitamin $B_6$ in animals can lead to hypochromic microcytic anemia due to the role of PLP as coenzyme of the δ-aminolevulinic acid synthetase, which is a key enzyme of the heme biosynthesis. In humans, several cases of pyridoxine

responsive sideroblastic anemia with marked poikilocytosis and anisocytosis had been described, too [3].

A further consequence of $B_6$ deficiency may be an enhanced renal excretion of oxalic acid with tendency to nephrolithiasis. This deficiency symptom is, however, mostly restricted to a hereditary defect of the PLP-dependent alanine-glyoxylate-aminotransferase, whereby the main metabolic decomposition of glyoxylic acid is blocked and oxalic acid increases besides glycolic and glyoxylic acid [4].

The carpal tunnel syndrome, a neurological disorder of the nervus medianus, resulting in painful adduction rotation of thumbs at metacarpophalangeal joint, paresthesis, and pain in hands and morning stiffness of fingers, had occasionally been related to vitamin $B_6$ deficiency. The pyridoxine doses administered in patients (50–200 mg/day) over longer periods exceed, however, the physiological demand by far, the neurological symptoms improved only in part of the patients. More recently, no indications of $B_6$ deficiency in patients with this disorder could be found in placebo-controlled studies [1].

## Diagnostic Principles

The above-mentioned overt clinical deficiency symptoms should be verified by biochemical status criteria to avoid misinterpretation. An unequivocal $B_6$ deficiency exists with plasma or serum PLP levels below 20 nmol/l, urinary 4-PA excreti on below 128 nmol/nmol creatinine, and an AC value of the EAST activity above 2.05 [5].

## Therapeutic Principles

Dosages and duration of treatment depend on the deficiency degree and the clinical response to the therapeutic approach. Oral doses of 150–300 mg pyridoxine hydrochloride daily should be given for the repletion of body stores followed by improvement of the dietary $B_6$ supply. In severe deficiency, 50–200 mg pyridoxine hydrochloride should be administered i.m. or i.v. initially. Chronic administration of more than 500 mg pyridoxine for therapeutic purposes should be handled with caution (see ►Pyridoxine excess) [1,2].

# Pyridoxine Excess

Roland Bitsch
Institute of Nutrition, Friedrich-Schiller-University Jena, Jena, Germany

## Synonyms

Vitamin $B_6$ intoxication

## Definition and Characteristics

Peripheral sensory neuropathy with atactic disorders of gait, reflex disorders, impairment of palpatory, vibration and temperature sensation, and lack of action potentials of sensory nerves have been observed. In newborns, cases of convulsive seizures had been reported in the past.

## Prevalence

Therapeutic overdosage of pyridoxine supplements.

## Genes

Modulation of glutamate decarboxylase and aromatic L-amino acid decarboxylase genes, producing serotonin and GABA neurotransmitters.

## Molecular and Systemic Pathophysiology

Due to the unsaturable absorption from the intestinal tract therapeutical doses of pyridoxine far above the physiological requirement may be harmful. No adverse effects could be observed with high intake of vitamin $B_6$ from food sources. Megadoses of vitamin $B_6$ have been used in the past for various diseases of mental origin or metabolic or hormonal disturbances. These include autism, Down syndrome and other behavioral disorders, Parkinson disease, schizophrenia, premenstrual syndrome, carpal tunnel syndrome, rheumatoid and cartilage diseases, etc. The principal toxicity of concern observed with excessive intakes of vitamin $B_6$ is neuronal damage, and sensory and motor effects [1–3].

In 1954, the first case report of vitamin $B_6$ toxicity in a newborn was given. This case involved treatment of a

woman with 50 mg pyridoxine three or four times a week during her mid-pregnancy. The newborn exhibited pyridoxine-related convulsive seizures. No other reports that confirm the association between maternal pyridoxine intake and thereby conditioned convulsive disorders were communicated [2,4].

Toxic side effects in adults after long-term intake of pyridoxine megadoses were first observed in 1983. Six females and four males who had taken daily doses between 2 and 6 g pyridoxine hydrochloride for periods from 4 months up to 40 months prescribed by orthomolecular therapeutics for self-medication or for treatment of premenstrual edema developed the above-mentioned neuronal symptoms. Morphological examination revealed a non-specific axonal degeneration of large and small myelinated fibers in peripheral sensory nerves. Discontinuation of pyridoxine resulted in complete recovery in the course of 6 months. In the following, other cases were described involving subepidermal vesicular dermatosis in addition to the neuropathy [3,4].

The underlying mechanism of the neuropathy due to $B_6$ overdoses is debated. An important aspect is the duration of intake prior to the development of symptoms. Neurotoxicity has been reported only after prolonged periods of treatment with high doses. The vitamin itself is rapidly eliminated and the molecular mechanism to explain the delay between exposure and the development of adverse effects has to be elucidated. It had been suggested that pyridoxine-related neurotoxicity may occur when the capacity of the liver to phosphorylate pyridoxine to the active PLP is exceeded resulting in high circulating pyridoxal levels. This aspect may explain that neuropathies were not reported in women who received between 80 and 200 mg pyridoxine daily for treatment of premenstrual syndrome for less than 12 months [1,4].

From animal experiments with high $B_6$ doses of 150 mg pyridoxine/kg body weight/day for more than 100 days the neuropathological changes had been correlated to changes in electrophysiological and functional tests. The somatosensory maximum nerve conduction velocity was reduced and changes included lesions in the dorsal spinal column, dorsal spinal roots, and ganglia and in the sensory spinal trigeminal roots. Peripheral nerves exhibited demyelination, missing axons, and misformed Schwann cells. With the aid of positron emission tomography (PET), an increased rate constant for the formation of serotonin from its precursor 5-hydroxy-L-tryptophan (5-HTP) in the brain of Rhesus monkeys could be observed after i.v. pretreatment with pyridoxine [5].

In contrast to the intestinal uptake, the transport of pyridoxine across the blood–brain barrier is saturable and it has been speculated that the peripheral sensory neuropathy reflects the vulnerability of the neurons of the dorsal root ganglia because of the absence of the blood–brain barrier, thus protecting neurons within the central nervous system from excessive circulating pyridoxine levels [1,2].

Other adverse effects of high pyridoxine intake were single cases of erythema following exposure to UVA irradiation after intake of 200 mg or impaired memorization after intake of 500 mg pyridoxine/day.

The majority of case reports in humans indicate that adverse neurological effects are detected after doses above 500 mg pyridoxine/day, equivalent to about 8 mg $B_6$/kg body weight/day. From data including long-term treatment of patients with diabetic neuropathy as well as with carpal tunnel syndrome for up to 5 years a mean safety dose of 200 mg was established as NOAEL. Generally, the conclusion has been accepted that daily doses of 500 mg pyridoxine represent a potentially toxic dose for adults. The Food and Nutrition Board of the Institute of Medicine in USA set a tolerable upper intake level (UL) of 100 mg pyridoxine/day for adults. The UL calculated by the Scientific Committee on Food (SCF) of the European Commission, on the other hand, has been based on the lowest average dose producing side effects in premenstrual women. Including uncertainty and safety factors this UL was calculated to 7–15 mg pyridoxine/day for children and adolescents and 25 mg/day for adults [2,4].

## Diagnostic Principles

Because the intoxication symptoms resemble those detected in $B_6$, deficiency patients should be carefully examined in terms of dietary habits and checked for excessive self-medication. An obvious vitamin $B_6$ intoxication is verified by detection of unusual high plasma PLP levels above 86 nmoles/l and urinary 4-PA excretion above 680 nmoles/nmol creatinine [4].

## Therapeutic Principles

After deprivation of the medication with pyridoxine megadoses the neurological damages were recovered in all cases described so far.

# Pyridoxine Responsive Diseases

Roland Bitsch
Institute of Nutrition, Friedrich-Schiller-University Jena, Jena, Germany

## Synonyms

Vitamin $B_6$-inherited diseases; Homocystinuria; Oxalosis; B6-inherited diseases

## Definition and Characteristics

Due to the involvement of this vitamin within the amino acid metabolism, inherited errors responsive to pyridoxine refer first to enzymes in these pathways. In most cases, a binding weakness between the apoenzyme and the vitamin active coenzyme PLP is a decisive factor that can be overcome by saturation with the coenzyme, increasing the biological half-life and, thus, the overall enzyme activity at the new equilibrium.

Inborn errors affecting $B_6$ metabolism refer to:

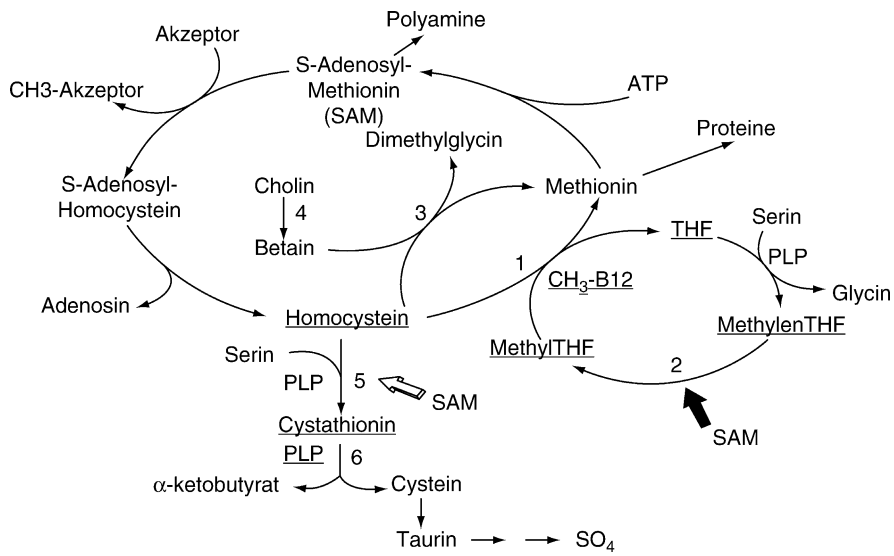
- *Homocystinuria,* an autosomal recessive deficiency of cystathionine-β-synthase in the homocysteine pathway (see Fig. 1).
- *Primary oxalosis, type I,* an autosomal recessive defect of the preferably in the liver expressed peroxisomal alanine-glyoxylate-aminotransferase, leading to hyperoxaluric urolithiasis and nephrocalcinosis (Fig. 2).

## Prevalence

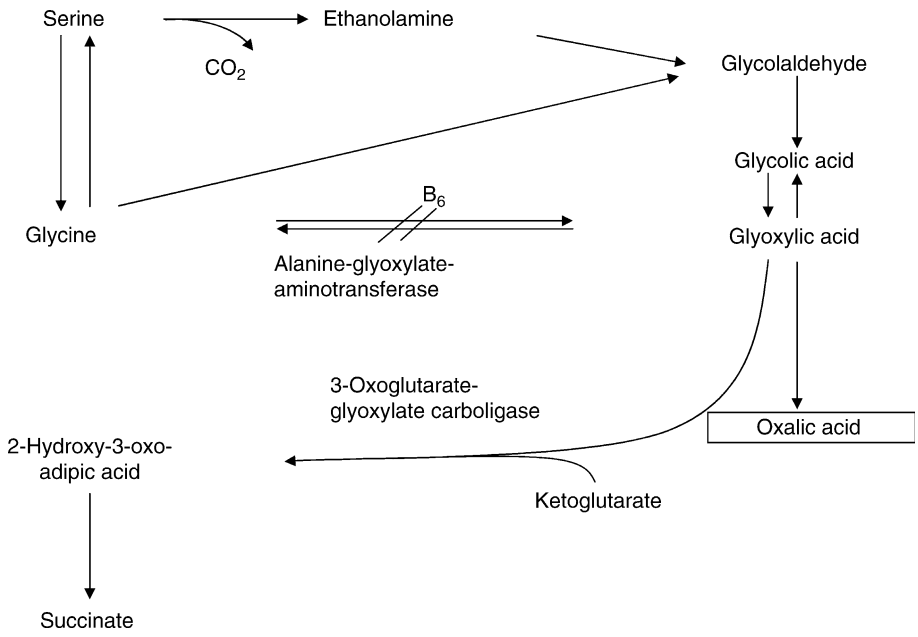
The incidence of homocystinuria is not accurately estimated, figures vary from 1/40,000 to 1/220,000 in the whole population. It is the most common form of homocystinuria due to a deficiency of cystathionine-β-synthase (CBS, EC 4.2.1.22). A higher frequency is reported for persons of Irish origin [1,2]. The primary oxalosis, type I, is a very rare hereditary disease. Exact data of the prevalence are not given but fall far below the homocystinuria prevalence. It is estimated that up to 3% of all children with nephropathias suffer from primary oxalosis [3,4].

## Genes

Mutations of the cystathionine-β-synthase (CBS) gene. There are more than 60 known mutations of this gene. The frequent mutation 1278 T representing 13% of all cases is vitamin $B_6$ responsive [1]. Hyperoxaluria, type I, is due to mutation of the AGXT gene, leading to deficient hepatic alanine-glyoxylate aminotransferase



**Pyridoxine Responsive Diseases. Figure 1** Homocysteine metabolism (according to [5]).



**Pyridoxine Responsive Diseases. Figure 2** Primary oxalosis (according to [4]; modify.)

activity. The gene has been located on chromosome 2 in the q 36–37 region. Three polymorphisms were identified that are preferentially associated [3].

## Molecular and Systemic Pathophysiology

Homocystinuria is the second frequent inborn error of metabolism after the phenylketonuria. CBS catalyzes the condensation of S-adenosyl-homocysteine with serine to cystathionine, thus lowering the homocysteine blood level (Fig. 1). It is assumed that S-adenosyl-methionine (SAM) exerts a modulating effect by activation of the CBS and allosteric inhibition of methylene-THF-reductase (MTHF-reductase). In folate and vitamin $B_{12}$ deficiency, SAM is depleted, the cystathionine synthesis is correspondingly inhibited, and homocysteine increases. In marginal $B_6$ deficiency, the SAM level is still not affected; only in clinical deficiency homocysteine increases.

If not treated in early childhood, skeletal changes, dislocated lenses, intravascular thromboses, osteoporosis, malar flushing, and, in some patients, mental retardation will occur [1,2].

The hereditary defect of the PLP-dependent alanine-glyoxylate-aminotransferase (AGT, EC 2.6.1.44) blocks the main metabolic pathway for glyoxylic acid, the rechange to glycine by transfer of an amino group. Only the condensation with oxoglutarate to 2-hydroxy-3-oxoadipic acid and the (non enzymatic) oxidation to oxalic acid are remaining as alternative pathways. The enhanced pool of glyoxylate is an immediate oxalate precursor and the irreversible oxidation of glyoxylic acid will consequently be intensified as an alternative pathway under these circumstances. Glycolic acid, glyoxylic acid, and oxalic acid accumulate. Marked overproduction of oxalate by hepatic cells results in the hyperoxaluria. Primary hyperoxaluric urolithiasis and nephrocalcinosis usually follow a very aggressive course leading to death from renal failure in the second, or early part of the third decade. The precursor glyoxylic acid can be diminished by inducing the biosynthesis of the apoenzyme of the AGT with therapeutical pyridoxine doses. There are, however, pyridoxine-sensitive and pyridoxine-resistant variants on the basis of genetic heterogeneity with respect to the mutation of the gene directing the synthesis of this enzyme whereby either the affinity of the binding site for the cofactor is affected to different degrees or the region of the molecule containing the cofactor binding site is deleted [3,4].

## Diagnostic Principles

In case of homocystinuria, in plasma and urinary excretion an abnormal accumulation of homocysteine, homocystine, the mixed disulfide homocysteine-cysteine, and methionine (only in plasma) is detected. This is particularly striking after administering an oral test dose of 3 g methionine (methionine load test). The selective nitroprussid screening test for sulfur amino acids in urine is positive. The CBS activity in skin fibroblasts or lymphocytes is decreased.

Definitive diagnosis of primary oxalosis, type I, is confirmed by liver biopsy with measurement of enzyme activity. Enhanced urinary excretion of oxalic acid and glycolic acid (above 0.45 mmol per day) as well as enhanced blood levels of oxalic acid (normal plasma values = 1–3 μmoles/l) can be detected, resulting in the development of nephrocalcinosis in juveniles already and deposition of oxalates in various tissues, as e.g., heart, spleen, and bone marrow. The growth and development of infants is restricted [3].

### Therapeutic Principles

Daily doses of 250–750 mg pyridoxine hydrochloride are needed to restore the amino acid blood levels in case of homocystinuria. If no response occurs, a methionine-restricted diet supplemented with cysteine is required because cysteine becomes an essential amino acid in homocystinuria [1,2].

Doses from 10 mg up to more than 400 mg per day can lower the hyperoxaluria and inhibit the formation of oxalate stones. Administration of 300 mg pyridoxine daily normalized within 12 months the oxalate levels as well as growth and weight development in a 3-month-old boy. Additionally, enhanced water and fluid intake is recommended. Pharmacological pyridoxine doses up to 1,000 mg per day are recommended for patients who are only partially responsive to the vitamin therapy [3,4].

### Synonyms

PC deficiency

### Definition and Characteristics

Despite its wide spectrum and heterogeneous clinical presentation, pyruvate carboxylase (PC) deficiency (OMIM 266150) has been classified into three clinical–biological phenotypes:

1. Type A [1] was primarily reported in North America and characterized by infantile onset, severe psychomotor retardation, seizures, pyramidal signs, hepatomegaly, renal dysfunction, and periventricular cysts. Mild to moderate lactic acidemia is almost constant.

The outcome is poor with a high mortality in the first years of life.

2. Type B [2] has been found mainly in Europe and particularly in France. Severe neonatal lactic acidosis, high lactate to pyruvate ratio, decreased 3-hydroxybutyrate to acetoacetate ratio, hyperammonemia, hypoglycemia, hypercitrullinemia, low plasma glutamine, and liver failure are the main biochemical features. These children manifest a very severe neurological dysfunction characterized by deep trunkal hypotonia, initially preserved level of consciousness but rapid deterioration including rigidity, hypokinesia, abnormal ocular movements, tremor, and seizures [3].Cystic periventricular leukomalacia is often associated. Very few infants survive past 3 months of age.
3. Type C refers to a benign phenotype consisting in recurrent hyperlactacidemia and surviving into childhood with mild or no neurological signs, although subcortical leukodystrophy has been described.

## Prevalence

PC deficiency is a very rare autosomal recessive inherited disorder. Its prevalence has not been determined.

## Genes

The PC gene contains 19 exons spanning approximately 16 kb of genomic DNA [1]. The map locus is 11q13.4-q13.5.

Type A is caused by a missense mutation; a homozygous 1828G-A transition resulting in an ala610-to-thr(A610T) substitution [1], a point 2229G-T transversion resulting in a met743-to-ile(M7431) substitution in the carboxylation domain of the enzyme, a homozygous 434T-C transition resulting in a val145-to-ala (V145-A) substitution, or a homozygous 1351C-T transition mutation resulting in an arg451-to-cys (R451C) substitution.

In type B, a compound heterozygosity for two mutations, namely a TAGG deletion at the exon 15/intron 15 splice site and a dinucleotide deletion in exon 16 (2491–2492delGT), has been identified.

## Molecular and Systemic Pathophysiology

PC is a mitochondrial nuclear-encoded biotin-containing enzyme. It catalyzes the first step of gluconeogenesis by converting pyruvate + $CO_2$ into oxaloacetate. The enzyme is almost totally dependent on the presence of acetyl-CoA and is activated when fatty acids are mobilized and acetyl-CoA is generated. It is an essential component of the Kreb's cycle, and provides the necessary substrate to different metabolic pathways: lipogenesis, gluconeogenesis, glycerogenesis, and formation of certain nonessential amino acids.

In the brain, PC plays an important anaplerotic role by replenishing the tricarboxylic acid cycle with four carbon metabolites, on the other hand, PC is an astrocyte-specific enzyme and supplies glutamine to neurons for neurotransmitter synthesis and is a key factor for myelinosynthesis by providing citrate that is necessary for lipidogenesis.

The explanation of the biochemical features found in PC deficiency (Fig. 1) lies in the particular situation that pyruvate reach the liver.

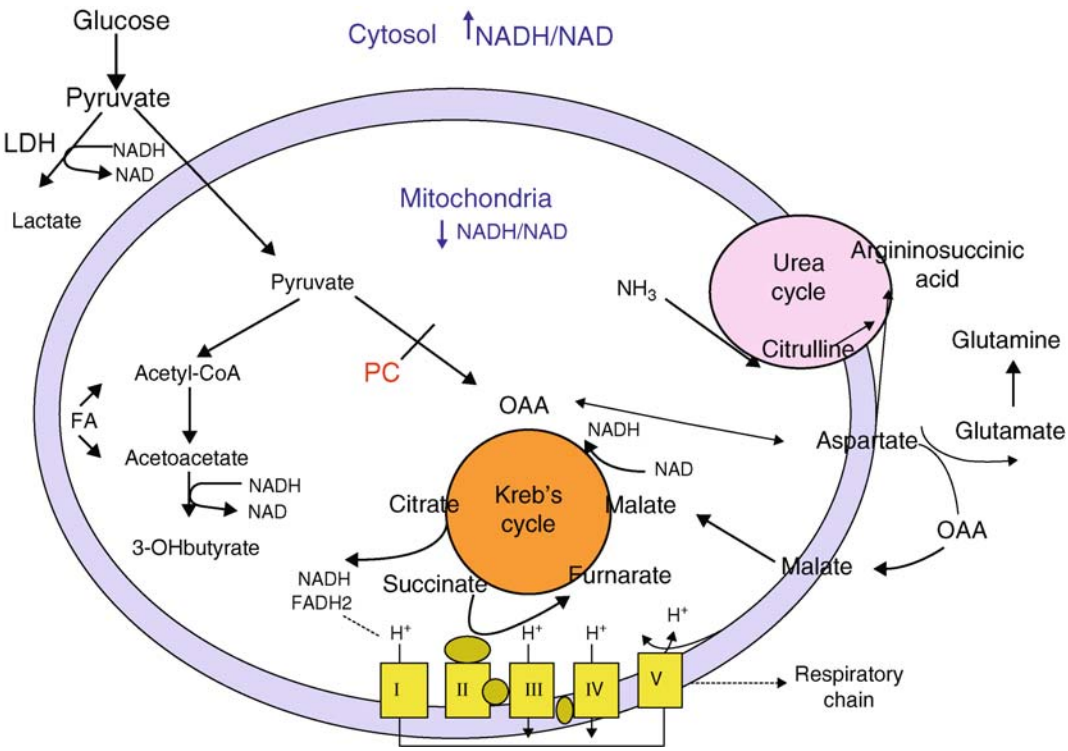
In the fasting state, pyruvate is ready to be transformed into glucose, however, due to the low PC activity there is on one hand a lack of oxaloacetate and on the other an excessive oxidation through pyruvate dehydrogenase in a moment where fatty acids are being oxidized. The high amounts of hepatic acetyl-CoA induce ketone body synthesis not only in the fasting state but also paradoxically at the fed state as well. Furthermore, in the case of type B, as oxaloacetate is the provider of four carbon replenishment for the Kreb's cycle, gluconeogenesis, and for provision of aspartate in the urea cycle, these abnormalities may explain hypoglycemia, hyperlactatemia, citrullinemia, and hyperammonemia. In type A and B activity is low in all tissues. Moreover, in type B PC activity is almost undetectable and explains its more severe phenotype. The type C, known as the benign phenotype with only recurrent episodes of hyperlactacidemia, seems to be due to the presence of two different transcripts that encode PC. These two transcripts differ in the first two exons. A mutation in the first two exons of the liver form would leave the brain form being expressed normally in contrast to a liver deficiency [4].

## Diagnostic Principles

Biochemical tests show metabolic acidosis, hypoglycemia, elevated lactate, pyruvate, and alanine. In type B lysine, proline, citrulline, and ammonia are frequently elevated and glutamine is low. The diagnosis is confirmed by measurement of the enzyme activity in fibroblasts. It can be also determined in the liver but it is not expressed in muscle. Prenatal diagnosis has been performed by measuring PC activity of amniotic fluid cells.

## Therapeutic Principles

Anaplerotic therapy, which is based on the concept that the energy defect might be improved by providing alternative substrate for the Kreb's cycle, has been used with relative success [5]. In this patient presenting a severe type B phenotype, an enteral formula containing 4 g of triheptanoin/kg weight (35% of total caloric intake) had an immediate effect within 24 h. Lactate, lactate/pyruvate ratio, ammonia, and citrulline decreased rapidly, glutamine increased progressively, and clinical



**Pyruvate Carboxylase Deficiency. Figure 1** PC deficiency leads to low oxaloacetate (OAA) production. OAA is related to urea cycle through the conversion to aspartate. The deficit of OAA limits aspartate required for the conversion of citrulline to arginosuccinate. This urea cycle dysfunction causes mild to moderate hyperammonemia. On the other hand, redox states in both the cytosol and the mitochondria are altered. In the cytosol, the high NADH/NAD ratio allows shifting pyruvate to lactate. By contrast in the mitochondrion, there is a low NADH synthesis because of the decreased of OAA, which is directly related to low energy production due to lack of substrate for the Kreb's cycle. The low NADH concentration will also impair the respiratory chain function. Furthermore, the low NADH/NAD ratio permits acetoacetate to accumulate rather than being converted to 3-hydroxybutyrate. LDH, lactate dehydrogenase; FA, fatty acids; NAD, nicotinamide adenine dinucleotide; ATP, adenosine triphosphate; ADP, adenosine diphosphate.

improvement without signs of neurodegeneration over time was observed. Orthotopic liver transplantation has been reported to reverse ketoacidosis and renal dysfunction and to ameliorate the lactic acidosis; however, low CSF glutamine did not improve.

## Rasmussen Encephalitis

Christian G. Bien, Christian E. Elger
Department of Epileptology, University of Bonn, Bonn, Germany

### Synonyms

Rasmussen syndrome; Chronic encephalitis and epilepsy

### Definition and Characteristics

Rasmussen encephalitis (RE) is a severe immune-mediated brain disorder leading to unilateral hemispheric atrophy, associated progressive neurological dysfunction and – usually – intractable seizures. It mainly affects children with a peak of incidence at the age of six to seven years. However, adolescent and adult cases have been reported and probably account for about 10% of all cases [1].

### Prevalence

RE is a rare disease. Large epilepsy centers diagnose approximately two new cases per year.

### Genes

RE is at present envisaged as a sporadic disease. There is no evidence for a distinct genetic component.

### Molecular and Systemic Pathophysiology

RE is an example of a disorder in which a humoral autoimmune genesis was proposed before the pathogenesis was linked to T cells. The hypothesis of antibody (ab) mediated autoimmunity evolved from a serendipitous observation. Four rabbits were immunized to raise abs against subunit 3 of the ionotropic glutamate receptor (GluR3). Subsequently, two of them developed seizures. Histopathological studies of their brains showed bilateral cerebral inflammatory changes, which were interpreted as mimicking those in RE. Later on, three out of four RE patients but none of 21 controls were found to harbor those serum GluR3 abs. One out of the GluR3 ab positive patients was treated by plasma exchange and showed a transient improvement. Recent studies of larger RE and control groups, however, did not find a difference between the number of GluR3 $ab^+$ patients in RE and non-inflammatory epilepsy groups [2].

Today, RE is seen as a disease mediated by cytotoxic T cells. The most relevant data regarding T cell pathology in RE have been obtained by studies on brain specimens from patients that had been collected during epilepsy surgical procedures or diagnostic open brain biopsies. Such studies have shown that T lymphocytes are the main components of the cellular infiltrates in RE brains. Granzyme B (GrB) mediated cytotoxic T lymphocytes attack neurons immunologically. $CD3^+$ $CD8^+$ T cells

containing GrB granules are attached to neurons and astrocytes expressing major histocompatibility complex class I Astrocytes and neurons die by apoptosis [3,4]. PCR assessment of T cell receptor Vβ gene transcripts suggested a local lymphocytic immune process in RE, including restricted T cell populations that have probably expanded from a few precursor T cells responding to discrete antigenic epitopes [5]. It is, however, still unknown which antigen is or which antigens are the target(s) of the immunological attack. The answer to this question will probably also help to unravel the cause of the enigmatic unilaterality of RE.

## Diagnostic Principles

Recently, formal diagnostic criteria have been published [1]. They rely on the unilaterality and the progressive character of the disorder. In early stages of the disorder (prior to the functional and structural decline) or in rare cases with atypical presentation, open brain biopsy is recommended to permit rapid diagnostic clarification in order to be able to start immunotherapy as soon as possible.

## Therapeutic Principles

Apart from anticonvulsive treatment, patients are treated with immunosuppressive or immunomodulating agents. No prospectively generated evidence is available to recommend a particular regimen. Retrospective case reports and small case series suggest the efficacy of corticosteroids, i.v. immunoglobulins and plasmapheresis/immunoadsorption for seizure reduction and prevention of functional loss and of tacrolimus for tissue and function loss. Hemispherectomy, a surgical procedure performed for seizure relief, is indicated (and highly effective) if a patient suffers from intractable seizures and is at no risk of relevant deterioration of neurological functions from this procedure. This type of surgery is therefore usually reserved for advanced cases with residual severe neurological dysfunction brought about by the disease course [1].

## Recessive Robinow Syndrome

Ali R. Afzal
Department of Cardiological Sciences, St. George's Hospital Medical School, London, UK

### Synonyms

Fetal face syndrome; Costovertebral segmentation defect with mesomelia; Covesdem syndrome

### Definition and Characteristics

The autosomal recessive form of Robinow syndrome is a severe skeletal dysplasia with short stature, mesomelic limb shortening, segmental defects of the spine, rib fusion, brachydactyly (shortening of the digits), congenital heart disease, genital hypoplasia, and dysmorphic facial features with gum hypertrophy.

### Prevalence

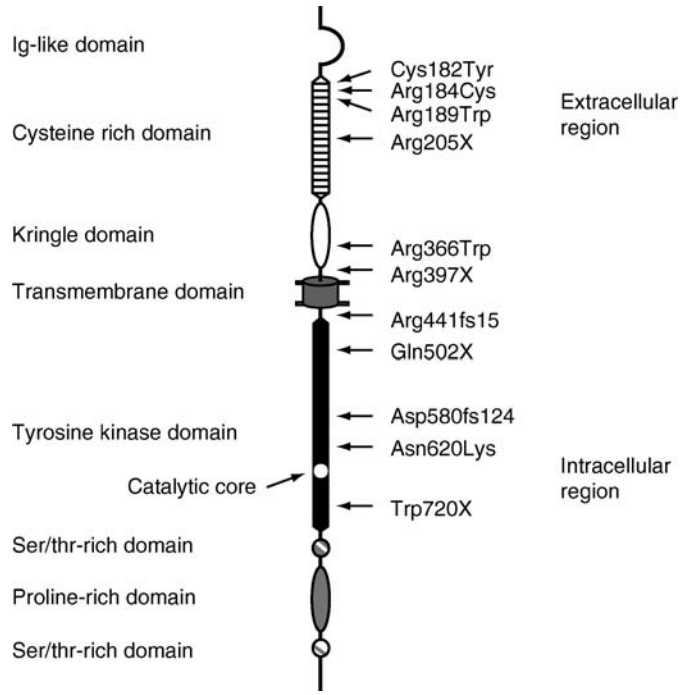
Recessive Robinow syndrome is very rare. It occurs more frequently in populations with consanguineous marriages such as Middle East, Pakistan, and Turkey.

### Genes

Recessive Robinow syndrome is caused by homozygous mutations in ROR2 coding for a receptor tyrosine kinase, localized on chromosome 9q22. The disease is allelic to Brachydactyly B1 (see ►Brachydactyly Type B). The gene responsible for the dominant form of the disease is unknown.

### Molecular and Systemic Pathophysiology

ROR2 contains nine exons and encodes a 4092-bp transcript. The ROR2 gene codes for a cell surface orphan receptor tyrosine kinase, which consists of 943 amino acids and binds to an as yet unidentified ligand. It contains distinct extracellular and intracellular motifs and one transmembrane domain. The extracellular domain(s) interact with either soluble ligands or cell membrane proteins, i.e., other receptors. The intracellular portion contains the catalytic kinase domain that directly interacts with intracellular components of the relevant signaling pathways (see also Brachydactyly type B). Recessive Robinow syndrome is caused by different homozygous missense and truncating mutations. The described sites of mutations in recessive Robinow syndrome are shown in Fig. 1. It is notable that mutations causing RRS are located in different domains throughout the ROR2 gene, yet the resulting phenotype is rather consistent, suggesting that these mutations (nonsense, frameshift, and missense) have similar consequences for protein function, i.e., cause loss of function of the protein. Some clustering of missense mutations occurred in the cysteine-rich domain, pointing to structurally/functionally important residues of this domain in the ROR2 protein. The ROR2 signaling cascade plays an important role in the control of most basic cellular processes including proliferation, differentiation, and precise migration of specially chondrocytes among the other tissues. This results in normal formation and ossification of all bones that undergo endochondral ossification, i.e., limbs, fingers and toes, ribs, and vertebrae. ROR2 is also expressed in the developing face, i.e., the frontonasal process. These involvements explain the skeletal and facial anomalies observed in



**Recessive Robinow Syndrome. Figure 1** Shows location of mutations (see arrows) in autosomal recessive Robinow syndrome. fs, frameshift mutation; X, stop mutation.

recessive Robinow syndrome. For mode of activation and function of ROR2 (see ►Brachdactyly type B).

## Diagnostic Principles

The autosomal recessive form is more severe than the dominant form, with more pronounced skeletal anomalies such as greatly reduced stature, markedly shortened limbs, segmental defects of the vertebrae, and rib fusion.

## Therapeutic Principles

Penile size improvement could be achieved using prolonged HCG stimulation. Surgery may be needed to resolve some of the cardiac and skeletal complications.

# Recurrent Aphthous Ulcers

Sirajedin Natah[1], Ritva Häyrinen-Immonen[2], Yrjö Konttinen[3]
[1]Gastrointestinal Research Group, Department of Physiology & Biophysics, University of Calgary, Calgary, AB, Canada
[2]Vantaa Dental Clinic, Helsinki, Finland
[3]Department of Medicine, Biomedicum, University of Helsinki, Helsinki, Finland

## Synonyms

RAU

## Definition and Characteristics

Recurrent aphthous ulceration (RAU) is an inflammatory condition of unknown etiology characterized by painful recurrent, single or multiple ulcerations of the oral mucosa. The condition is classified as minor, major, and herpetiform on the basis of ulcer size and number. The minor form of RAU is the most common and is characterized by shallow round or oval lesions that are less than 10 mm in diameter and surrounded by an erythematous halo [1]. Minor RAU heals within 10–14 days without scarring whereas the major RAU may persist up to 6 weeks and often heal with scarring.

### Prevalence

They occur in men and women of all ages, races and geographic regions. It is estimated that at least one in five individuals has at least once been afflicted with aphthous ulcers. The peak age at onset is the second decade, and a high prevalence and severity of disease has been found in students of high socio-economic background.

### Molecular and Systemic Pathophysiology

Pathogenesis is likely to be multifactorial, with potential predisposing factors including altered immunoregulatory balance, infection with bacteria or viruses such as herpes viruses, hematological deficiencies in iron, folate, zinc or vitamin B, and food hypersensitivity and allergies. Local trauma, stress, drugs and hormonal changes may also play a precipitating role in the development of RAU. Interestingly, smoking appears to reduce the likelihood of RAU, with the condition sometimes occurring or recurring in patients who have ceased smoking. Several systemic diseases such as Behçet's disease, Reiter's syndrome, celiac disease, Crohn's disease, ulcerative colitis, HIV infection, Magic syndrome, Sweet syndrome, periodic fever, aphthosis, pharyngitis, adenitis (PFAPA) syndrome, cyclic neutropenia, and immunoglobulin A (IgA) deficiency can be associated with an increase in the prevalence or severity of RAU. Gamma-delta T cells are increased in density in the epithelium lateral to the ulcer, whereas neutrophils were found to have marked concentration at the ulcer area in the ulcerative phase of the lesion. Some cross-reactivity between the microbial 65-kDa heat shock protein (Hsp) and the 60-kDa human mitochondrial Hsp has been demonstrated. Thus, RAU may be a T-cell-mediated response to antigens of streptococcus oralis that cross-react with the mitochondrial Hsp and induce oral mucosal damage [2]. However, the exact mechanism of epithelial cells destruction and ulceration is still not known and remains to be identified.

### Diagnostic Principles

Due to the absence of a definitive etiology or diagnostic test for RAU, the identification of RAU in clinical practice usually relies on the combinations of history, clinical features and histopathology.

### Therapeutic Principles

Lesions of RAU can be extremely painful and lead to difficulty in speaking or eating. Since the exact nature of RAU remains unclear, no curative therapy is available at the present time. The first step towards management of RAU is to detect and treat any modifiable predisposing factor or underlying systemic disease. In general, topical therapies such as topical corticosteroids, antibacterial mouth rinses, and Amlexanox are commonly used to treat RAU. For the severe and constantly recurring ulcerations, systemic medications such as prednisone, azathioprine, thalidomide, colchicines, cyclosporine, pentoxyfylline, azelastine and dapsone have shown some effectiveness for the treatment of RAU.

### Synonyms

RE-MDD

## Definition and Characteristics

See [1]. Most studies indicate that the lifetime prevalence of MDD is between 5 and 10%, with women twice as likely to be affected as men. Suicide, a tragic consequence of MDD, has been reported to occur in 10–15% of patients who were previously hospitalized for depression, a rate of death that is orders of magnitude greater than that reported for the American population as a whole. In addition to suicide, an even greater absolute increase in age specific mortality from natural causes has been reported for individuals who suffer from MDD and for their family members. The significance of these public health problems has been highlighted by two recent reports from the U.S. Surgeon General. According to the World Health Organization, MDD is a leading source of disability worldwide.

## Genes

Evidence from family, segregation, twin and adoption studies supports a role for inherited factors in the development of MDD. About half of the risk of developing MDD arises from the contributions of genes. This is an average estimate that may vary from patient to patient, along with the specific risk alleles involved.

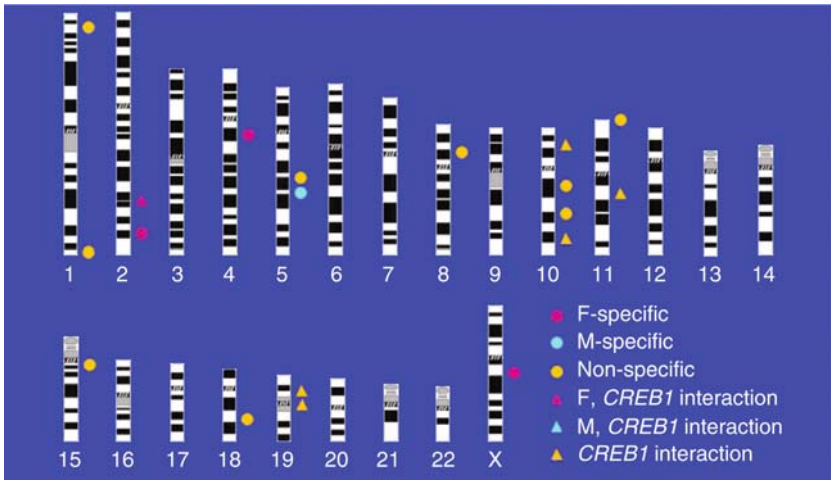
The first linkage scan of the entire human genome for genes that influence the development of MDD employed 81 extended families identified by individuals who suffered from recurrent, early onset (≤25 years) MDD [2, 3], a severe and strongly familial subtype [1]. These findings provided an initial glimpse of the genetic architecture of MDD, as shown in Fig. 1. Nineteen chromosomal regions contained linkage peaks that reached genome wide statistical significance (genome wide adjusted $p < 0.05$) and ten of these were "highly significant" (adjusted $p < 0.001$). The findings indicated that these loci:

- Frequently have sex specific effects, predominantly affecting the risk of depression in women
- Often work together to influence risk
- Typically affect the risk of a spectrum of depressive disorders as well as alcoholism and other addictions (pleiotropy)

This linkage analysis was extended by including the history of a suicide attempt as a covariate to identify chromosomal regions that harbor genes that influence the risk of this behavior in the context of mood disorders [4]. This approach identified six linkage peaks with maximum multipoint ΔLOD scores that reached genome wide adjusted levels of significance. These findings provided evidence for suicide risk loci that are independent of susceptibility loci for mood disorders and suggest that the capacity for suicide risk loci to affect the development of suicidal behavior depends on the psychiatric disorder or subtype with which they interact.

## Molecular and Systemic Pathophysiology

The results of a candidate gene analysis at these loci re-focused attention on cell signaling pathways, rather than particular neurotransmitters [3]. Since these signaling pathways are used by all cells, not just brain cells, the susceptibility genes for clinical depression may contribute directly to the development of systemic medical problems, not just mental disorders. That may be why nearly half the deceased members of the 81 families studied died before reaching 65, typically of "natural" causes [1].



**Recurrent, Early-Onset, Major Depressive Disorder. Figure 1** Chromosome locations of susceptibility loci for depressive disorders.

The highest maximum LOD score observed, 8.19, occurred for recurrent MDD at D2S2321 (205 cM), located 121 kb proximal to CREB1. This is the highest LOD score reported for a susceptibility region for any psychiatric disorder to date and CREB1 is an attractive candidate susceptibility gene. These results are supported by case control studies and the observation that five other risk loci for mood disorders revealed evidence of interaction with the CREB1-containing region in the genome-wide linkage scan [3].

Sequence variations in the CREB1 promoter and intron 8 have been detected that cosegregate with mood disorders or their absence, in women from these families, identifying CREB1 as a likely sex limited susceptibility gene for unipolar mood disorders [5]. The rare CREB1 promoter mutations associated with the development of mood disorders in these families produce functional alterations in promoter activity that are both brain cell specific and dependent on gonadal steroid hormones. As a result, alleles that predominantly affect the development of mood disorders in women may exert the greatest risk at times of large fluctuations in female gonadal hormones (menarche, menses, pregnancy/childbirth, menopause) and diminish after age 35–40, when sex hormone levels begin to fall.

These findings provide new insights into the clinical biology of mood disorders and related conditions. They also suggest new molecular targets for the development of medications to treat or prevent these disorders, as well as strategies for more optimally using drugs that are already available.

# Red Cell Pyruvate Kinase Deficiency

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

## Definition and Characteristics

Inherited (rarely acquired) deficiency of erythrocytic pyruvate kinase (PK), an enzyme involved in the metabolic pathway of red blood cell glycolysis, leading to clinical syndromes varying from life-threatening hemolytic anemia with kern-icterus in the new born to a compensated chronic hemolytic anemia [1].

## Prevalence

Rare, worldwide distribution, estimated prevalence for heterozygosity 1% in USA, 2.4% in Africa, and 3% in Japan [1].

## Genes

PK exists in several isoforms, produced by two genes. The L-gene, located on chromosome 1q21, encodes two isoforms; L-PK and R-PK, the former being red cell PK [1].

## Molecular and Systemic Pathophysiology

PK deficiency results in a decreased utilization of red cell glucose, leading to reduced ATP generation. Proximal of the enzymatic block in PK deficiency 2,3-diphosphoglycerate (2,3-DPG) is generated and is increased in red cells of PK-deficient individuals. The mechanism leading to hemolytic anemia is not elucidated. Clinically affected individuals are either homozygous for a specific PK mutation or doubly heterozygous for distinct mutations. Heterozygotes are not affected but do have decreased PK activity. Due to chronic hemolytic anemia, patients can be characterized by increased incidence of bilirubin gallstones, hepatosplenomegaly, secondary iron overload, skin ulcers, and folate deficiency. Acquired PK deficiency can occur for example due to bone marrow damage after chemotherapy. Other

enzymatic defects of glycolytic enzymes, as well as abnormalities of purine and pyrimidine metabolism, also leading to hemolytic syndromes have been reviewed [1,2].

### Diagnostic Principles

Suspect in individuals in whom more common causes of hemolytic anemia are ruled out. Demonstration of high 2,3-DPG levels suggests the diagnosis, screening assays to detect reduced enzyme activity, is available but is not sensitive as red blood cells with lowest PK activity are mostly removed by the spleen. Specialized laboratories can detect mutations at the DNA level [1].

### Therapeutic Principles

Largely supportive (blood transfusions, folic acid supplementation), with splenectomy performed in severely transfusion-dependent patients in order to reduce the frequency of transfusions, even though the hemolytic process is not halted. Importantly, the degree of anemia should not be used as the sole indicator for transfusion or splenectomy, because the increased red blood cell 2,3-DPG levels result in a rightward shift of the oxygen dissociation curve. Hence, even in patients with low hemoglobin levels, oxygen is more readily available and anemia better tolerated than would be expected [1]. Bone marrow transplantation has been performed [3].

## Red Wolf

►Lupus Erythematosus

## Refeeding Hypophosphatemia

►Refeeding Syndrome

## Refeeding Syndrome

Mark A. Marinella
Department of Internal Medicine, Wright State University School of Medicine, Dayton, OH, USA

### Synonyms

Refeeding hypophosphatemia; RFS

### Definition and Characteristics

Refeeding syndrome (RFS) is a common, yet underappreciated, complication occurring in hospitalized patients and is characterized by hypophosphatemia often in conjunction with hypokalemia, hypomagnesemia, hyperglycemia, and fluid retention [1]. RFS typically affects malnourished patients upon administration of a carbohydrate load such as glucose-containing fluid, enteral feeding, or total parenteral nutrition (TPN) [1,2]. In the subnourished state, body stores of phosphorus are depleted and administration of glucose results in the increased formation of high-energy phosphate bonds and insulin-mediated transcellular shift of phosphorus, leading to severe hypophosphatemia. Hypokalemia and hypomagnesemia are common. Depletion of serum phosphorus leads to diminished production of adenosine triphosphate (ATP), creatine phosphokinase (CPK), and 2,3-diphosphoglycerate (2,3-DPG), which results in protean cellular and organ dysfunction [1].

Risk factors for RFS include poor oral intake, vomiting, diarrhea, nasogastric suction, anorexia nervosa, surgery, old age, uncontrolled diabetes, and chemotherapy [2]. RFS typically occurs within 2–4 days of refeeding. Dangerous manifestations of RFS include sudden cardiac death or heart failure from hypophosphatemia-induced cardiac dysfunction. Severe hypophosphatemia leads to diminished cardiomyocyte ATP stores resulting in systolic dysfunction and cardiac failure. Fatal cardiac arrhythmias may result not only from hypophosphatemia, but also from hypokalemia and hypomagnesemia [1–3]. Hypophosphatemia impairs oxygen delivery due to decreased levels of 2,3-DPG causing a leftward shift of the hemoglobin oxygen dissociation curve. Hypophosphatemia may also cause hemolytic anemia, impaired neutrophil chemotaxis, thrombocytopenia, rhabdomyolysis, and respiratory muscle weakness [1,3]. Other characteristics of RFS include delirium, parasthesias, seizures, and tetany. Another potential complication is Wernicke's encephalopathy, a syndrome characterized by ophthalmoplegia, ataxia, and delirium, resulting from acute thiamine depletion during carbohydrate administration [3]. Table 1 displays risk factors for and complications of RFS.

**Refeeding Syndrome. Table 1** Risk factors for and complications of refeeding syndrome

| Risk factors | Complications |
|---|---|
| Poor oral intake/starvation | Ventricular arrhythmias/sudden death |
| Vomiting/diarrhea | Heart failure |
| Alcoholism | Infection/sepsis |
| Anorexia nervosa | Shock/hypotension |
| Surgery | Hemolysis |
| Old age | Thrombocytopenia |
| Diabetes mellitus | Respiratory failure |
| Nasogastric suction | Rhabdomyolysis/myopathy |
| Malignant disease/ chemotherapy | Delirium |
| Tube feeding/TPN | Seizures |

## Prevalence

The exact prevalence is unclear, but a busy clinician will encounter RFS quite frequently if one monitors electrolytes in at-risk patients.

## Molecular and Systemic Pathophysiology

Phosphorus in the form of phosphate ($PO_4^{2-}$) is the most abundant intracellular anion and participates in numerous cellular activities. Serum levels of phosphorus are influenced by transcellular shift and loss in body fluids [1,2]. Acute transcellular shift results from alkalosis, hyperglycemia, and hyperinsulinemia due to carbohydrate/glucose administration. Phosphate acts as an intracellular buffer and buffers hydrogen ions excreted in the urine. Also, phosphorus is a vital component of various cellular phospholipids, nucleoproteins, and nucleic acids, as well as enzymatic systems such as ATP, 2,3-DPG, and CPK [3,4]. Hypophosphatemia in RFS ensues not only from depleted stores but also increased catabolic demand resulting in increased glucose-6-phosphate utilization as well as increased production of ATP, CPK, 2,3-DPG and other phosphate-containing proteins and enzymes [1,2].

Dietary phosphorus is absorbed in the jejunum by passive transport, filtered at the glomerulus, and reclaimed by the convoluted tubules. The proximal convoluted tubule is the primary site of phosphate regulation via the apical membrane $Na/PO_4$ cotransporter (NaPi-2) which is under the influence of parathyroid hormone [4]. Serum phosphorus is also influenced by serum calcium and creatinine clearance.

Increased cellular demands for water, potassium, and magnesium accompany RFS and contribute to cell and organ malfunction. Increased cellular demand for oxidative phosphorylation reactions can lead to sudden depletion of thiamine and Wernicke's encephalopathy.

## Diagnostic Principles

The key diagnostic principle of RFS is anticipating the electrolyte derangements in at-risk patients. Any subnourished or acutely ill patient should be considered vulnerable and daily monitoring of phosphorus, potassium, magnesium, and glucose should be undertaken. In addition, clinical findings as fluid retention, muscle weakness, respiratory distress, and neurologic changes should be monitored. Most importantly, one should consider cardiac rhythm monitoring or electrocardiography to assess for electrolyte-induced QT-interval prolongation that can result in ventricular arrhythmias and sudden death [1–3].

## Therapeutic Principles

Phosphorus replacement with either potassium or sodium phosphate is vital with severe hypophosphatemia (serum level <1.5 mg/dl). If hypokalemia is present, intravenous potassium phosphate can be given at a dosage of 0.08 mmol/kg over several hours [5]. With modest hypophosphatemia, oral phosphate salts are appropriate [1,5]. Overzealous administration of phosphate salt can lead to hypocalcemia and tetany; as such, it is vital to monitor electrolytes. Hypomagnesemia can be treated with intravenous magnesium sulfate or oral magnesium oxide. Thiamine administration is vital during the first few days of nutritional repletion. If tube feedings or TPN are administered, the rate should be slowly increased over 2–4 days to minimize the risk of profound electrolyte depletion.

# Refsum Disease

Alfried Kohlschütter
Department of Pediatrics, University Medical Center, Hamburg, Germany

## Synonyms

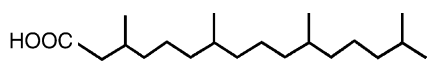
Heredopathia atactica polyneuritiformis; Phytanic acid oxidase deficiency

## Definition and Characteristics

Refsum disease (MIM 266500) is a slowly progressive neurodegenerative disease characterized by retinopathy, cerebellar ataxia, and peripheral neuropathy. Sensorineural hearing loss, anosmia, ichthyosis, skeletal malformations, and cardiac abnormalities are inconstant features. Cerebrospinal fluid protein levels are elevated. Symptoms are related to the accumulation of the toxic substance, phytanic acid (Fig. 1), which is taken up from food and cannot be metabolized properly due to a genetic enzymatic deficiency.

## Prevalence

1 case per 1,000,000. The genetic transmission is autosomal recessive.



3, 7, 1, 15-Tetramethylhexadecanoic acid

**Refsum Disease. Figure 1** Chemical structure of phytanic acid, a natural branched-chain fatty acid.

## Genes

Refsum disease is genetically heterogeneous; mutations in two genes, PHYH (also named PAHX, localized in 10pter-p11.2, with many different mutations identified) and PEX7 (localized in 6q22-24), have been shown to cause Refsum disease [1].

## Molecular and Systemic Pathophysiology

The PHYH (or PAXH) gene encodes the peroxisomal enzyme phytanoyl-CoA hydroxylase, which alpha-oxidises phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) and allows the first step of its degradation. The PEX7 gene codes for the peroxine 7 receptor, which allows the import of phytanic acid in peroxisomes. The consequence of both genetic defects is the accumulation of phytanic acid, the toxicity of which seems partly a direct one through damaging mitochondrial membranes, partly it is related to its regulatory effects on specific nuclear receptors. Phytanic acid can activate the nuclear retinoid-X receptor, which is involved in a variety of cellular processes, including regulation of fatty acid metabolism. Phytanic acid is also a ligand for peroxisome proliferator-activated receptor (PPAR) alpha. Both receptors are involved in the regulation of genes encoding for proteins that function in lipid and glucose metabolism. The very high levels of phytanic acid found in Refsum disease patients perturb normal cellular lipid homeostasis significantly through this mechanism [2].

## Diagnostic Principles

The diagnosis of Refsum disease is established by the demonstration of an isolated phytanic acid accumulation in plasma together with studies in cultured skin fibroblasts to establish defective alpha-oxidation of phytanic acid and deficient phytanoyl-CoA hydroxylase activity [3].

## Therapeutic Principles

As phytanic acid comes exclusively from food (green vegetables, herbivore animals, fish), a strict diet can effectively lower the plasma phytanic acid levels, prevent progression and lead to partial regress of symptoms. Life-threatening toxic conditions can occur in a state of exaggerated catabolism (e.g. slimming cures). In such situations lipid apheresis using various methods is helpful [3,4].

## Reifenstein Syndrome

Tam Nguyen
University of Duesseldorf, Duesseldorf, Germany

### Synonyms

Incomplete/partial androgen insensitivity syndrome; Type I familial incomplete male pseudohermaphroditism; Incomplete testicular feminization; Gilbert-Dreyfus syndrome; Lubs syndrome; Rosewater syndrome

### Definition and Characteristics

Reifenstein syndrome is a term comprising a heterogeneous group of androgen deficiency syndromes due to X-linked recessive androgen receptor defect in 46, XY men with normal androgen secretion. Females are clinically not affected.

### Prevalence

Exact frequency is not known, but is estimated to be as common as complete testicular feminization.

### Genes

Androgen receptor gene (Xq11-12).

### Molecular and Systemic Pathophysiology

Androgens play a crucial role in various stages of male development (masculinization and virilization). The binding of androgens to the androgen receptor in the nucleus of their target cells results in promotor binding of the hormone–receptor complex and hence regulation of gene transcription of androgen–regulated genes. In Reifenstein syndrome different point mutations of the androgen receptor gene lead to various amino-acid exchanges in the androgen- or DNA-binding domain of the receptor; thus androgen or DNA binding is lowered and transcriptional stimulation is decreased. In opposition to testicular feminization, Reifenstein syndrome is characterized by only a partial receptor defect.

In mild cases of androgen resistance, infertility may be the only symptom. In more severe cases, the external genitalia of affected individuals vary from microphallus to pseudovagina. The internal genital tract is characterized by a lack of Muellerian duct derivates and hypoplastic Wolffian duct derivates. The testes have reduced number of germ cells with azoospermia. At puberty, affected individuals usually develop gynecomastia. Body hair and beard are decreased, axillary and pubic hairs are normal.

### Diagnostic Principles

Plasma testosterone and luteinizing hormone at or above the upper limit of the normal male range; deficient androgen-binding capacity in cultured genital skin fibroblasts; family history; identification of the androgen receptor gene mutation.

### Therapeutic Principles

Causal treatment is not possible. The patient may wish measures of sex reassignment.

# Rejection, Acute

Anushree C. Shirali[1], Daniel R. Goldstein[2]
[1]Department of Internal Medicine, Section of Nephrology, Yale University School of Medicine, New Haven, CT, USA
[2]Department of Internal Medicine, Section of Cardiovascular Medicine, Yale University School of Medicine, New Haven, CT, USA

## Synonyms

Organ/allograft rejection

## Definition and Characteristics

Acute rejection is an inflammatory response reaction by the immune system in response to an implanted solid organ transplant (known as an allograft). The allograft is recognized as foreign and activates the host innate and adaptive immune systems. The $CD4^+$ T lymphocyte is a key mediator of acute rejection and orchestrates the generation of effector $CD8^+$ T cells and B cells. These effector cells induce injury to the transplanted organ via various methods, including direct cytotoxicity and antibody mediated mechanisms. Thus, both cellular and humoral mediated injury can result and coexist in acute rejection. The cumulative effect is allograft dysfunction, loss or decreased long-term survival.

## Prevalence

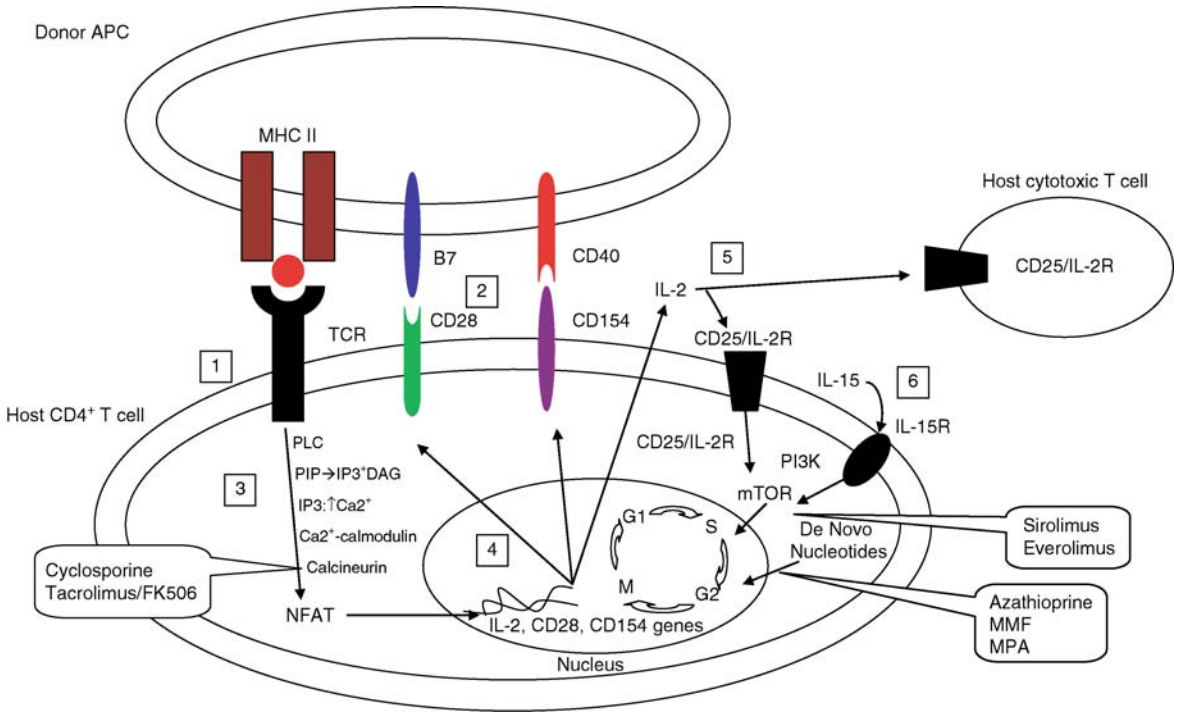
Acute rejection rates vary according to the transplanted organ (e.g., lung: most immunogenic, liver: least immunogenic) as well as donor and recipient factors. The advent of cyclosporine in the 1980s was a major advance, which in conjunction with other immunosuppressive protocols has improved 1-year graft survival up to 90% at major transplant centers Although, survival rates for long transplantation is 70% at 1 year. Nonetheless, acute rejection remains a common cause of allograft dysfunction, especially in the early post transplant period. Certain groups face higher immunologic risk for acute rejection, including younger patients, African Americans, and highly sensitized recipients (e.g., multiparous patients).

## Genes

Acute rejection results from an antigenic barrier between host and recipient. In humans, the principal antigens that mediate graft rejection are peptide products of a cluster of genes located on chromosome 6, called the major histocompatibility complex (MHC) or human leukocyte antigen (HLA) system. HLA genes encode two distinct classes of cell surface molecules. HLA Class I molecules are expressed on nearly all nucleated cells, while class II expression is restricted to B lymphocytes, monocytes, and activated T lymphocytes. There are three different class I (HLA-A, -B, -C) and class II (HLA-DQ, -DR, -DP) loci, but the entire MHC is inherited in Mendelian fashion as a haplotype from each parent. The HLA system is highly polymorphic at each locus and thus, mismatches between host and donor MHC during transplantation particularly at the HLA-A, HLA-B, and HLA-DR loci, result in rejection. Indeed, minor mismatched transplants undergoes acute graft rejection. HLA matched grafts can still be rejected due to differences in so-called minor-antigens [1].

## Molecular and Systemic Pathophysiology

As shown in Fig. 1, host $CD4^+$ T cell activation and proliferation in response to a foreign antigen is a principal feature of acute rejection. $CD4^+$ T cell receptors (TCR) recognize and bind foreign MHC on donor antigen presenting cells (direct pathway) or foreign peptides derived from donor MHC introduced by host antigen presenting cells (APCs) in the context of self MHC (indirect pathway). The direct pathway creates a particularly vigorous T cell response that can induce acute rejection. With TCR engagement, the $CD4^+$ T cell initiates a series of signal transduction pathways (including calcium-calcineurin, NFκ-B, and MAP kinase) that results in production and secretion of interleukin-2 (IL-2). IL-2 is a potent cytokine that induces autocrine effects of T cell proliferation and clonal expansion as well as exocrine effects such as production of various proinflammatory cytokines. After TCR signaling, a second signal is necessary for continued activation and expansion of the $CD4^+$ T cell. The costimulation is provided by the binding of accessory ligands on the APC to receptor sites on the $CD4^+$ T cell. Examples of these interactions include B71/2-CD28 and CD40-CD154. In the absence of



**Rejection, Acute. Figure 1** Host $CD4^+$ T cell activation is central to acute rejection and consists of the following steps: 1. Recognition of a foreign MHC on donor APC causes engagement and activation of the host $CD4^+$ T cell. 2. Costimulation by ligand pairs on donor APC and host $CD4^+$ T cell maintains activation. 3. Engagement of host $CD4^+$ TCR begins a signal transduction cascade involving the PLC-Calmodulin-Calcineurin pathway. The final step involves activation of the transcription factor NFAT. 4. Translocation of NFAT into the nucleus results in upregulated transcription of genes involved in the alloreactive immune response, including the cytokine IL-2. 5. IL-2 has paracrine effects such as activating cytotoxic T cells, as well as autocrine effects of stimulating host $CD4^+$ T cell division. 6. Host $CD4^+$ T cell division is stimulated by IL-2, with added stimulation by IL-15, which is secreted by many cell types including innate immune cells such as natural killer cells. Cell division is stimulated through the phosphatidyl-inositol-3-kinase (PI3K) pathway and the mTOR kinase, which has potent downstream effects on cell growth and division. Immunosuppressive drugs target various aspects of this process; some of their sites of action are noted above and detailed in Table 1. *Abbreviations:* APC-antigen presenting cell; TCR-T cell receptor; PLC-phospholipase C; NFAT-nuclear factor of activated T cells; PI3K- phophatidyl-inositol-3-kinase; mTOR-mammalian target of Rapamycin; MMF-mycophenolate mofetil; MPA-mycophenolic acid [2].

costimulation, the T cell becomes anergic. Indeed, the use of carimoletory wockado intreclinic is being evaluated. In contrast, activated $CD4^+$ T cells maintained by costimulation subsequently interact with and activate other cells of the immune system, either by direct cell–cell contact or via cytokine secretion. $CD4^+$ T cells can act on B cells to produce alloantibody production and complement mediated injury. Cytotoxic $CD8^+$ T cells can be similarly stimulated to produce allograft injury via soluble cytolytic factors or contact induced apoptosis. Emerging evidence indicates that the innate immune system also may play a role in acute allograft rejection. For example, the cellular elements of this system, monocytes and macrophages can be recruited to an allograft and produce delayed type hypersensitivity responses. Both clinical and experimental studies have provided evidence that receptors of the innate system, Toll-like receptors, may play an important part in the inflammatory response to transplantation.

## Diagnostic Principles

Biopsy of the affected organ is the diagnostic gold standard. Pathologic grading schemes such as the Banff criteria for renal allografts and the ISHLT grading system for cardiac transplants allow clinicians to judge the severity of allograft rejection. Cellular rejection is characterized by an interstitial and perivascular predominately lymphocytic infiltrate. Capillary endothelial swelling, fibrin thrombi, fibrinoid necrosis, and interstitial hemorrhage characterize acute humoral rejection, with complement (C4D) deposition within transplant capillaries representing a hallmark feature. Clinical diagnosis varies according to organ type, and not all transplant patients may be symptomatic. Laboratory

**Rejection, Acute. Table 1** Common pharmacological approaches employed in clinical practice for the prevention and treatment of acute rejection. Maintenance and induction immunosuppressive regimens are geared towards preventing acute rejection. Treatment generally involves use of corticosteriods and depending on histological severity of rejection, use of depleting polyclonal or monoclonal antibodies. *Abbreviations:* NFAT-nuclear factor of activated T cells, IMDPH-inosine monophosphate dehydrogenase, FKBP- FK-506 binding protein, mTORmammalian target of rapamycin kinase [3]

| Name of drug | Class of drug | Mechanism of action | Notes/side effects |
|---|---|---|---|
| *Maintenance immunosuppressants* | | | |
| Cyclosporine | Calcineurin inhibitor | Binds cyclophilin to form a complex which binds to calcineurin and inhibits its downstream phosphorylation of NFAT | Acute renal dysfunction via vasoconstriction. Increases TGF-β, causing chronic renal fibrosis |
| FK-506 (Tacrolimus) | Calcineurin inhibitor | Complexes to a cyclasmic binding protein (FKBP) to attach and inhibit calcineurin | As above. As with cyclosporine, implicated in post transplantation diabetes mellitus |
| Azathioprine | Anti-metabolite | Releases 6-mercapcurine and incorporates into cellular DNA, inhibiting purine synthesis and gene replication | Potent myelosuppression may cause lymphopenia |
| Mycophenolate Mofetil Mycophenolic Acid | Anti-metabolite | Inhibits IMDPH, an enzyme important in de novo purine synthesis | Preferred over azathioprine. Side effects include diarrhea, lymphopenia |
| Sirolimus, Everolimus | TOR inhibitor | Complexes to FKBP, binding and inhibiting mTOR kinase activation of the cell cycle | May impair wound healing. Potential anti-tumor activity |
| Corticosteroids | Glucocorticoids | Thought to inhibit multiple pathways of T cell activation as well as inflammatory cytokine production | Extensive adverse effect profile including glucose intolerance, osteoporosis, etc. |
| *Induction immunosuppressants* | | | |
| Horse antithymocyte globulin (Atgam), Rabbit antithymocyte globulin (Thymoglobulin) | Polyclonal antibodies | Binds to multiple T cell activation markers (CD3, CD45, etc.), causing inhibition of T cell activity and depletion of T cells | Higher risk of infections, especially opportunistic infections (e.g., CMV). Rare but potent induction of serum sickness. Repeated use increases risk of malignancy |
| Muromonab (anti-CD3), Alemtuzumab (anti-CD52), Rituximab (anti-CD20) | Monoclonal antibodies, depleting | Binds to specific T cell (CD3, CD52) and/or B cell activation markers (CD20, CD52), resulting in complement mediated lysis and cell death | May result in hypersensitivity symptoms (e.g. pulmonary edema with anti-CD3) and cytokine release syndrome |
| Basiliximab, Dacluzimab (anti-IL-2) | Monoclonal antibodies, nondepleting | Blocks IL-2 receptor on the activated T cell, inhibiting further activation of T cells | Generally well tolerated. As only activated T cells are targeted, does not cause generalized T cell lymphopenia |

markers of organ function (e.g. liver profile, serum creatinine) provide an adjunct to diagnosis, though these tests may lag behind histological evidence of rejection.

## Therapeutic Principles

Maintenance immunosuppressive medications prevent acute rejection. These encompass corticosteroids, calcineurin inhibitors (cyclosporine), mTOR inhibitors (rapamycin), and anti-proliferative medications (mycophenolate mofetil). Treatment of acute cellular rejection episodes includes use of corticosteroids and if histological severity dictates, polyclonal or monoclonal anti-T cell antibodies. The specific drugs and their mechanisms are detailed in Table 1 [3].

# Rejection, Chronic

Millie Samaniego[1], Bruce Kaplan[2]
[1]University of Wisconsin School of Medicine and Public Health, Madison, WI, USA
[2]University of Illinois at Chicago Transplant Center, Chicago, IL, USA

## Synonyms

Chronic alloimmune injury; Interstitial fibrosis/tubular atrophy; Chronic active antibody-mediated rejection

## Definition and Characteristics

Chronic active alloimmune injury (CAI) of the transplant can be caused by both T-cell and antibody (Ab)-dependent mechanisms.

In kidney transplants (KTx), CAI is a chronic inflammatory process associated primarily with a T-cell infiltrate that affects the tubules and interstitium, resulting in the obliteration and narrowing of endothelial and epithelial structures (i.e., tubular atrophy), and replacement of the organ parenchyma by interstitial fibrosis. Other inflammatory cells including macrophages/monocytes, B-cells, NK cells and plasma cells can also be present and might contribute to alloimmune injury. Glomerular changes can also occur in the form of transplant glomerulopathy (TG) a lesion defined by the double contouring of the glomerular basement membrane [1]. TG is thought to be closely related to Ab-mediated injury.

Chronic active Ab-mediated rejection (CAMR) is diagnosed by a triad of morphological features – TG, peritubular capillary basement membrane multilayering (PTCBMML), and/or fibrous intimal thickening in arteries without duplication of the internal elastica [1]; diffuse C4d deposition in PTC as marker of Ab-injury of the graft [2], and donor specific Ab in recipient's sera [1,2].

## Prevalence

A history of clinical or sub-clinical biopsy-proven acute rejection (BPAR) is the most important immunological predictor of CAI [3]. The prevalence of immunological CAI has been reported in two prospective studies based on protocol biopsies. Nankivell et al. [3] showed that by 1-year post-transplantation, moderate CAI was present in 25.6% of biopsies with any type of subclinical rejection compared to 7.5% of biopsies without such evidence. In this study, a previous episode of subclinical rejection was a positive predictor of CAI at 1-year post-transplantation, suggesting that alloimmune injury was an important contributor. The best-controlled demonstration of the prevalence of CAI at 2-year post-transplantation showed that 77.4% of biopsies from patients with early BPAR had CAI compared to 60.4% in patients without it. It is estimated that CAMR can occur in anywhere from 3 to 12% of patients.

## Genes

Despite its promise, gene microarrays have not yet been used extensively to study CAI after transplantation. Sarwal et al. [4] studied the molecular heterogeneity of KTx biopsies performed for acute dysfunction. Based on hierarchical clustering, these authors were able to identify three distinct gene profile patterns. In patients with CAI (i.e., chronic and acute rejection), the most striking feature was the expression of genes involved in cellular proliferation and cycling suggesting ongoing tissue repair (e.g., Cyclin B1, Cyclin A2, Cell division cycle 20 and 27, and CC chemokine (CK) receptor 5). In this study, biopsies with B-cell gene transcripts were associated with a worse outcome, supporting the hypothesis that Ab-mediated events have an adverse impact on long term transplant function.

In a subsequent study, Scherer et al. [5] studied the gene expression profiles of protocol KTx biopsies obtained in 17 Pts. Patients who developed CAI at 12 months after transplantation displayed upregulation of ten genes by oligonucleotide microarrays in spite a normal histology at 6 months. Some of the upregulated genes included APRIL, an important survival factor for B-cells that can also lead to B-cell activation and CD40L-independent antibody isotype-switch, genes involved in vascular remodeling and smooth muscle cell proliferation (HOXB7), and genes involved in tissue repair such as cytokeratin.

In a recent study, Cheng et al. studied the gene profile of TG using KTx protocol biopsies. Compared to biopsies of patients with normal KTx histology and native kidney biopsy controls, TG showed upregulation of CK and CK receptors, and complement (C) system transcripts ($P < 0.01$). In biopsies with T-cell and macrophage glomerulitis, CD3, CD4, CD154, CD80 and CD86 transcripts were present at high levels. Of note, B-cell transcripts were not different in TG biopsies than in KTx biopsies with normal histology.

Notwithstanding the polymorphic nature of the chronic rejection response, the association of specific gene polymorphisms with transplant outcomes has yielded some associations. However, validation and reproducibility of gene polymorphisms has been elusive.

## Molecular and Systemic Pathophysiology

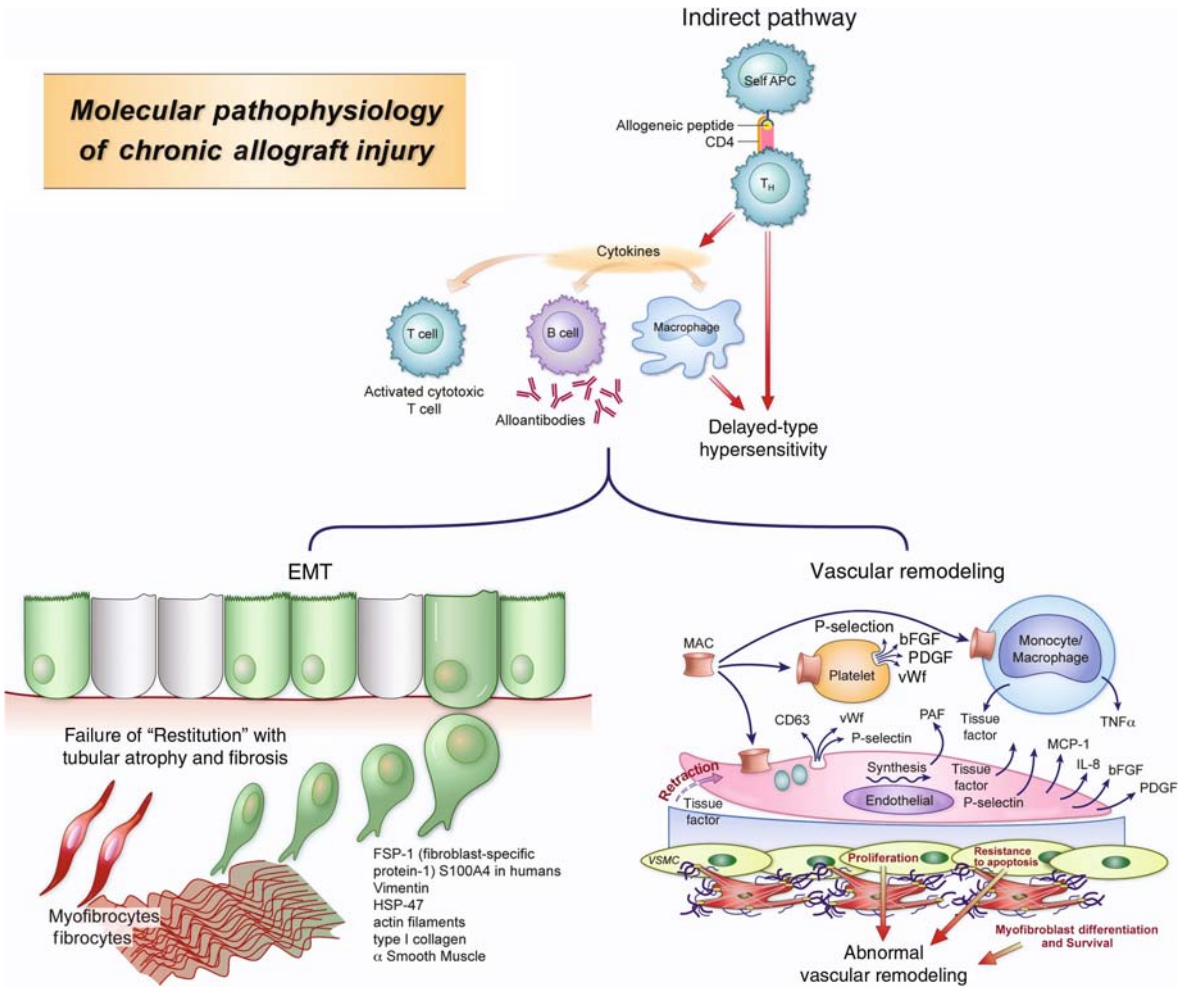
The indirect pathway of antigen presentation and allorecognition – in which catabolized donor MHC peptides are presented by self-MHC on recipient antigen presenting cells to recipient $CD4^+$ helper T-cells ($CD4^+$) – is considered to have the dominant role in immune CAI. Activated $CD4^+$ cells produce cytokines that activate and induce the clonal expansion of $CD8^+$ cytotoxic T-cells (i.e., IL-2, IFN-γ), proliferation, activation and differentiation of B-cells into 46-producing cells or B-memory cells (i.e., IL-2, IL-4, IL-10), and activation of the macrophage lineage (i.e., lymphotoxin and IFN-γ). Activation of these effectors results in alloimmune CAI via cell-mediated cytotoxicity, 46-mediated injury and delayed type hypersensitivity.

In CAMR, the target of injury is the endothelial cell of the graft microvasculature. The mechanisms of injury involve both complement dependent and independent pathways that result in smoldering endothelial cell activation and damage, production of reactive oxygen species, and pro-fibrotic cytokines and growth factors such as bFGF, PDGF and thrombospondin-1 – a known activator of latent TGF-β-1.

Repetitive alloimmune injury (Fig. 1) elicits local inflammation and initiates a vicious cycle of injury and repair. In this process, cytokines drive the normal repair of injured epithelium by local fibroblasts (mesenchymal-epithelial transition – MET) into an aggressive process of proliferation, excessive secretion of collagens and extracellular matrix, destruction of the normal interstitial architecture and disabling of the epithelium (i.e., epithelial-mesenchymal transition – EMT). This process culminates in the development of interstitial fibrosis and tubular atrophy.

## Therapeutic Principles

The treatment of CAI is not well defined. Immunosuppressive interventions used for the minimization of non-alloimmune injury of the allograft are unlikely to be of



**Rejection, Chronic. Figure 1** Molecular pathophysiology of chronic allograft injury.

benefit. The suppression of both T- and B-cell memory responses, necessary to prevent CAI, requires immunosuppression with calcineurin inhibitors thereby making its elimination unwise; whereas the proteinuria associated with TG makes the use of m-TOR inhibitors impractical in spite the beneficial effects of these agents on fibroblast proliferation.

In the treatment of CAMR, the use of tacrolimus (TAC) and mycophenolate mofetil (MMF) rescue therapy has been a preferred intervention based on the potential beneficial effect of MMF on chronic rejection, and the perceived effect of TAC and MMF on B-cell function. However this protocol has not been consistently effective.

In addition to immuno-suppressants, other agents used for the prevention/treatment of chronic Ag-independent injury of the graft such as ACE-inhibitors and ARBs can ameliorate the fibrosis of CAI. In the future, regulation of EMT using inhibitors of PDGF and its receptor (i.e., aptamers and Glivec®) or agonists of bone morphogenic protein-7 may be of help in the containment of interstitial fibrosis/tubular atrophy.

# Relapsing Polychondritis

Ann-Sofie Hansson
Department of Clinical Immunology, Sahlgrenska University Hospital, Gothenburg, Sweden

## Synonyms

Polychondropathia; Diffuse perichondritis

## Definition and Characteristics

Autoimmune disorder characterized by an erosive inflammation in extra-articular cartilage, such as, the external ear, the nose, and the trachea.

## Prevalence

Relapsing polychondritis is a rare disease and few epidemiological data are published. An estimation of an annual incidence in the state of New York was 3.5 cases in 1 million inhabitants.

## Genes

A correlation between relapsing polychondritis and the major histocompatibility complex II (MHC II) molecule has been reported. HLA-DR4 was found with a significantly higher frequency (50–60%) in polychondritis patients than in healthy controls (25%) but no correlation to any subtype was observed.

## Molecular and Systemic Pathophysiology

The pathogenic mechanisms in relapsing polychondritis are poorly known, but in the clinics the disease is regarded as a complex autoimmune disorder in which the cartilage is attacked by an erosive inflammation involving the humoral as well as the cellular immune response.

Several cartilage-specific antibodies are detected in sera from patients with relapsing polychondritis, and antibody responses to the collagens are commonly found. The level of antibodies to collagen type II (CII) correlates with disease severity, and the levels are especially high in the early and acute phases of the disease [1]. Collagen type IX and type XI are also targets for an antibody production in these patients. Immunization of rodents with CII induces arthritis and chondritis of the external ear, signs that mimic the symptoms seen in patients with relapsing polychondritis, which support the pathogenic role of the collagens [2]. Antibodies to non-collagenous cartilage proteins, such as matrilin-1 (previously known as cartilage matrix protein, CMP) and cartilage oligomeric matrix protein (COMP), are also detected in sera from polychondritis patients. The severity of respiratory symptoms has been shown to correlate with the concentrations of antibodies to matrilin-1, a finding that is further supported by the fact that immunization of rats and mice with matrilin-1 induces respiratory distress in several strains [3]. Depositions of complement factor 3 and/or immunoglobulins in affected auricular cartilage and in the renal mesangium indicate a role for immune complexes. There are few publications on the role of the cellular immune response in relapsing polychondritis but CD4+ T cells have been detected in infiltrates of affected tracheal cartilage and

were reported in separate reports of two patients with severe tracheomalacia, T cell responses to collagen type IX and type XI, and to matrilin-1.

### Diagnostic Principles

Diagnosis is based on three out of the following six McAdam criteria including a histological confirmation: bilateral auricular chondritis, non-erosive seronegative inflammatory polyarthritis, nasal chondritis, ocular inflammation, respiratory tract chondritis, and audiovestibular damage [4]. Alternative criteria for diagnosis have been suggested using two or more of the McAdam signs (mentioned above) together with therapeutic effects of dapsone and/or positive histology. In approximately 20% of the patients the kidneys are affected by inflammation and 30% of the patients have a concurrent autoimmune disease, RA being the most common one.

### Therapeutic Principles

*Pharmacological therapy*: NSAID, dapsone, colchicines, systemic corticosteroids, methotrexate, azathioprine, and cyclophosphamide.

*Other treatments*: Due to severe respiratory symptoms, intensive care and tracheotomy is occasionally required.

►Polychondritis, Atrophic

### Synonyms

Renal artery stenosis; RAS; Renovascular disease; Renal artery obstruction; Renovascular hypertension; Ischemic nephropathy

### Definition and Characteristics

RAS is a narrowing of one or both renal arteries or their major branches. RAS becomes clinically significant, resulting in renovascular hypertension and ischemic nephropathy, when it causes a roughly 40% decrease in renal perfusion pressure. This generally occurs when the lesion involves at least 75% of the luminal diameter. The two most common forms of RAS are atherosclerostic RAS (ARAS), which causes approximately 90% of RAS, and fibromuscular dysplasia (FMD), which accounts for <10% RAS. ARAS typically involves the proximal renal artery, FMD the middle and distal segments. ARAS is more likely to produce renal dysfunction and in general is more progressive and less amenable to cure than FMD.

### Prevalence

Up to 55% of individuals aged 35–64 years old in industrialized countries have hypertension; 1–2% of these cases are caused by RAS. RAS may at least

contribute to the renal failure of 15–27% of patients starting hemodialysis. 6.8% of the elderly population may have RAS, while significant RAS (presumably predominantly ARAS) has been demonstrated in 6.3–19.2% of patients undergoing cardiac catheterizations [1]. The prevalence of ARAS rises as people age, particularly if they have coronary artery disease, peripheral vascular disease, aortoiliac occlusive disease or cerebrovascular disease. FMD is rare, classically seen predominately in women aged 15–50, but may be more common in the elderly with RAS than previously realized.

## Genes

There is no clearly defined genetic link to ARAS, though one report suggests that angiotensin 1 converting enzyme D allele may be associated with an increased incidence of atherosclerotic vascular disease, including ARAS [2]. There may be a familial predisposition to multifocal FMD, but no genes have been convincingly linked to the disorder.

## Molecular and Systemic Pathophysiology

The severity of hypertension and renal damage is not directly correlated with the degree of proximal renal artery obstruction. Initially, decreased flow or pressure stimulates renin release, possibly mediated by cyclooxygenase-2 production of prostacyclin, generating higher angiotensin II (Ang II). Peripheral Ang II receptor stimulation leads to vasoconstriction and thus a rise in blood pressure. Ang II also stimulates NADPH oxidase, the major reactive oxygen species (ROS) producing enzyme, and vasoconstrictor prostaglandins. In humans and in the experimental two-kidney one clip (2K1C) model, the most widely used animal model for unilateral RAS, plasma renin activity may fall to near normal levels after prolonged obstruction. Continued hypertension may be due to local renin angiotensin aldosterone system activation, an enhanced slow pressor response to Ang II, fluid retention and enhanced oxidative stress which in turn causes vascular remodeling and endothelial dysfunction [3]. The often-correctable hypertension of FMD is more consistently renin-dependent than that due to ARAS.

ARAS is more likely than FMD to result in kidney failure. Multiple layers of microvascular injury may, over time, produce renal damage. Atheroemboli may be evident on biopsy, and on a more molecular level decreased nitric oxide or nitric oxide activity as well as increased renin and Ang II cause local ischemia, tubular injury and interstitial fibrosis. Elevated oxidative stress, seen in both the obstructed and contralateral kidney, may also contribute to tubular injury and the development of fibrosis [4]. In both human and animal models the contralateral kidney often demonstrates impaired function and is particularly dependent on vasodilatory prostaglandins and nitric oxide.

## Diagnostic Principles

Suspect RAS in hypertensive patients with new onset hypertension, negative family history of hypertension, "flash" pulmonary edema, renal failure with any antihypertensive agent but particularly angiotensin-converting enzyme (ACE) inhibitors or Ang II receptor blockers (ARBs), or an abdominal bruit (both systolic and diastolic). Angiography is the gold standard for diagnosis, but is potentially nephrotoxic. Other imaging modalities include Doppler ultrasonography, magnetic resonance angiography and captopril renography. Intravascular ultrasound may be particularly sensitive for FMD [5].

## Therapeutic Principles

Blood pressure in both ARAS and FMD is often controlled with ACE inhibitors or ARBs. In difficult to control hypertension, percutaneous renal artery angioplasty (PTRA) may be considered. PTRA, which has essentially replaced surgical revascularization, is more likely to lead to a cure of hypertension in FMD than in ARAS. Intervention may also be considered for patients with episodes of flash pulmonary edema or progressive renal failure. PTRA is more successful in salvaging renal function if the kidneys are at least 8 cm in size and if the serum creatinine is less than 4 mg/dl.

## Synonyms

Kidney cancer

## Definition and Characteristics

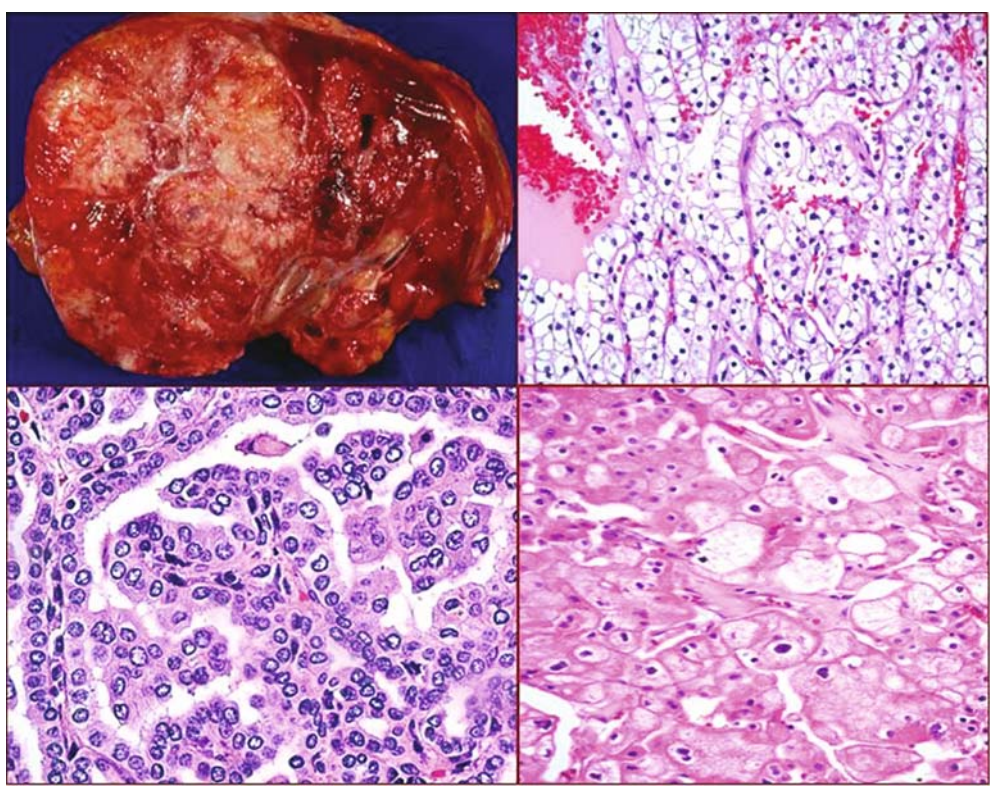
RCC is a heterogeneous disease comprising several histological subtypes having varied clinical outcomes. Clear cell carcinoma is the most common subtype.

## Prevalence

There are about 36,000 new cases and 12,000 deaths a year in the USA. There exists a 1.6:1.0 male predominance, with the peak incidence in the sixth and seventh decades. A 2% increase in incidence is noted annually. Twenty-five percent of the patients present with either locally advanced or metastatic disease.

## Molecular and Systemic Pathophysiology

A small percentage (<3%) of RCC cases are hereditary, associated with germline mutations of cancer-related genes such as von-Hippel Lindau (VHL), MET, fumarate hydratase (FH), and Birt-Hogg-Dubé (BHD) [1]. A few reported RCC families are associated with a constitutional chromosome 3 translocation. The vast majority of RCCs are sporadic and are subdivided based on their histology: clear cell (75%), papillary (12%), chromophobe (4%), collecting duct, and unclassified (a subgroup of tumors not fitting the diagnosis of the other subtypes). Most of these subtypes are characterized by distinct chromosomal and genetic alterations. For example, the clear cell type is characterized by frequent loss of chromosome 3 and somatic VHL mutations, as well as papillary RCC chromosomal gain of 7, 16, and 17. Gene expression profiling has supported and



**Renal Cell Carcinoma. Figure 1** Macroscopic view of RCC (*top left*) and different histological subtypes of RCC: clear cell (*top right*), papillary (*bottom left*) and chromophobe (*bottom right*).

expanded this molecular subclassification by further delineating good and poor outcomes of these tumors based on their molecular signatures [2]. RCCs are thought to arise from renal tubular epithelial cells, and to date several risk factors have been established, including smoking, hypertension, obesity, and specific industrial chemicals.

## Diagnostic Principles

Hematuria, flank pain, and an abdominal mass are the elements of classic presentation [3]. However, the more common presentations today include incidental finding on a radiological examination as well as the nonspecific symptoms of weight loss, anemia, fatigue, and pain. Radiological investigation (e.g., ultrasound, CT, and MRI) is the most common means for detecting RCC. Biopsy is not routinely performed, and diagnosis is confirmed on histology. Family history may reveal a genetic origin, and detection of germline mutations confirms the diagnosis of rare hereditary cases.

## Therapeutic Principles

Surgery remains the mainstay of therapy. Nephrectomy is performed in the patients with primary RCC, as well as for the patients receiving systemic treatment for metastatic disease [3]. A solitary metastatic lesion can be surgically excised. Immunotherapy – especially interleukin-2 and interferon-alpha – is recommended for the patients with metastatic RCC. Allogeneic stem-cell transplantation has been used with some success in refractory cases. Conventional radiotherapy is indicated in certain RCC metastatic cases for symptom relief. Stereotactic radiosurgery delivering conformal, high-dose, focused radiation has been used effectively for controlling metastatic lesions both in the brain and in extracranial sites. Novel anti-angiogenic agents such as bevacizumab, sorafenib and sunitinib are particularly promising as the mainstay of therapy. Very recently, the FDA approved sorafenib, sunitinib, and temsirolimus for treatment of advanced RCC.

# Renal Failure, Chronic

Sudha K. Iyengar[1], Barry I. Freedman[2]
[1]Epidemiology and Biostatistics, Ophthalmology and Genetics, Case Western Reserve University, Cleveland, OH, USA
[2]Internal Medicine, Section on Nephrology, Wake Forest University School of Medicine, Winston-Salem, NC, USA

## Synonyms

Chronic kidney disease; CKD; End-stage renal disease; ESRD; Uremia; CRF

## Definition and Characteristics

Two human kidneys contain approximately two million nephron units, each consisting of a single glomerular capillary tuft. These relatively porous capillaries continually filter the blood and produce more than 1501 of ultrafiltrate each day. In health, the remaining nephron segments reabsorb the vast majority of filtered water and electrolytes, maintain acid-base balance, and produce or activate hormones necessary for bone health (1,25 di-hydroxy vitamin D) and preservation of red cell mass (erythropoietin).

The early stages of CKD are often clinically silent, as non-specific symptoms such as fatigue and peripheral edema often do not develop until less than 25% of renal function remains. An abnormal urinalysis (proteinuria, hematuria and/or leukocyturia), elevated blood urea nitrogen (BUN) and serum creatinine concentrations, metabolic acidosis and electrolyte disorders typically lead to the detection of CKD prior to clinical symptomatology. Excessive urinary albumin excretion and reduced glomerular filtration rates (GFR), both typically seen in CKD, are potent and independent risk factors for systemic atherosclerosis. In fact, the majority of individuals with CKD will succumb to complications of cardiovascular disease (CVD) before the initiation of renal replacement therapy. Anemia and renal osteodystrophy typically develop when less than 50% of renal function remains.

Common causes of the initiation and progression of CKD include systemic diseases involving the renal microcirculation (diabetes mellitus, hypertension, and systemic lupus erythematosus [SLE]). Systemic and renal-limited syndromes affecting the glomerular capillaries (chronic glomerulonephritis), renal interstitium (tubulo-interstitial nephritis), Mendelian disorders (autosomal dominant polycystic kidney disease [ADPKD]), congenital and developmental anomalies, and toxin exposures also can cause CKD. Type 2 diabetes mellitus

is now the commonest cause of CKD in the developed world. Marked familial aggregation of diabetic nephropathy is widely observed. Familial clustering of CKD has also been widely reported in hypertensive, autoimmune and infectious diseases (Human Immunodeficiency Virus [HIV]-associated nephropathy). Familial aggregation in common, complex forms of CKD, independent from systemic blood pressure and glycemic control, suggest that inherited factors contribute to the pathogenesis of CKD.

## Prevalence

Variable, based upon ethnicity, geography and etiology. Among adult Americans, an estimated 19.2 million (m) have CKD of various stage (5.9 m albuminuria with normal GFR; 5.3 m albuminuria with GFR 60–89 ml/min; 7.6 m with GFR 30–59 ml/min; 0.4 m with GFR 15–29 ml/min; and 0.3 m with ESRD) [1]. The prevalence of ESRD in the U.S. and Japan (together accounting for 42% of the world population with treated ESRD) ranged from 1,090 (U.S.) to 1,940 (Japan) patients per million (ppm) in 2004 [2]. Among Americans with ESRD, the adjusted incidence rate was 339 ppm in 2004. Relative to whites (263 ppm), a 3.7-fold excess incidence rate was observed in blacks (968 ppm) and a twofold excess rate in American Indians [3].

## Genes

*Atypical Hemolytic Uremic Syndrome*: Deletions in complement factor H (CFH) on 1q32, complement factor I (CFI) on 4q25 and membrane cofactor protein (MCP) on 1q32, additional involvement of the complement activation gene cluster on 1q32. The vast majority of aHUS associated CFH mutations are present in the heterozygous form and include missense mutations, nonsense mutations and deletion, insertion or duplication of one or more nucleotides. The proportion of missense accounting for about 71% of all CFH-associated aHUS is large. Small deletions, insertions or duplications and nonsense mutations constitute about 17% and 10%, respectively. About half of the CFH mutations found in aHUS (48%) are clustered in the C terminus region that codes for short complement repeats (SCRs) 19 and 20, a region that interacts with C3b.

*Autosomal Dominant Polycystic Kidney Disease (ADPKD)*: Nonsense mutations, deletions, frameshifts, missense mutations, aberrant splicing, transitions and larger-scale rearrangements of polycystin 1 (PKD1) on 16p13.3-p13.2, and nonsense mutations, frameshifts, splicing variants, missense mutations, and deletions in polycystin 2 (PKD2) on 4q21-q23.

*Autosomal Recessive Polycystic Kidney Disease (ARPKD)*: Truncating, missense mutations in the fibrocystin gene on 6p21.1-p12.

*Hereditary Nephrotic Syndrome*: Deletions; insertions; nonsense, missense, and splicing mutations in nephrin (NPHS1) on 19q13.1 and podocin (NPHS2) on 1q35-q31.

*Focal Segmental Glomerulosclerosis (FSGS)*: Missense mutations in alpha actinin 4 (ACTN4) on 19q13 (FSGS1), transient receptor potential cation channel 6 (TRPC6) on 11q21–q22 (FSGS2), and nonsense, splicing mutations in CD2 associated protein CD2AP on 6p12.3.

*IgA Nephropathy (IgAN)*: Primary genetic cause of IgAN is unknown.

*Membranoproliferative Glomerulonephritis (MPGN)*: Homozygous nonsense mutations in complement factor H (CFH) deficiency on 1q32. See aHUS.

*Systemic Lupus Erythrematosus Nephritis (SLEN)*: Copy number variants in activatory Fc receptor for IgG, FcGR3 (also known as FcγRIII) on 1q23.

*Other Diseases:* A variety of other diseases whose etiology is unknown and multifactorial, such as diabetic nephropathy and hypertensive nephrosclerosis, are also classified under this category. They form the bulk of the disease burden for CKD. While newer studies have suggested specific genetic loci, confirmation studies need to establish definitive connections between these loci and renal failure. We have not attempted to review this extensive literature because of lack of confirmatory studies that have a firm molecular basis.

## Molecular and Systemic Pathophysiology

The kidney is a vascular organ with a specialized capillary bed, the glomerulus, which filters plasma to generate excreted urine containing unwanted substances. The glomerulus is composed of the capillary "fenestrated" endothelial cells, the glomerular basement membrane (GBM), glomerular epithelial cells (podocytes) and mesangial cells. The filtration takes place through three layers of glomeruli, i.e. endothelial cells, GBM and podocytes. Mesangial cells participate only indirectly in filtration. The GBM is composed predominately of type IV collagen, which acts as a structural framework for the GBM and size-filters plasma proteins of larger than 150 kDa. In addition, the GBM also contains a small amount of type V collagen, laminin, and proteoglycans (mostly heparan sulfate). Like most basement membranes, which are thin sheet-like structures, the GBM functions to provide support to the surrounding cells. The cellular structure of glomeruli and other parts of the kidney are protected by membrane bound complement regulators, whereas the GBM lacks these regulators. Heparan sulfate, located on the GBM, acquires plasma CFH to provide complement regulation on the GBM, thereby protecting the glomeruli.

The podocytes are specialized epithelial cells that attach to the outer surface of the GBM and face the urinary space in the Bowman's capsule. The podocytes

foot processes interdigitate to form a network at the base of their attachment to the GBM. The network is bridged by cell-cell junctions called the slit diaphragm, with a 40 nm slit in between processes that enables filtration of albumin sized molecules, but retention of other metabolites. Many forms of renal failure result in the erosion of the slit diaphragm, widening the space between podocytes, such that bigger molecules have passage. This results in loss of the permselectivity and excretion of larger protein particles into the urine, eventually progressing from (micro) albuminuria to proteinuria.

*Atypical Hemolytic Uremic Syndrome (aHUS)*: Hemolytic Uremic Syndrome (HUS) is a rare disease characterized by damage to endothelial cells, erythrocytes and the glomeruli in the kidney. Approximately 90% of "typical" cases are due to Shiga toxin-producing E. coli (e.g. O157:H7) but 10% are atypical and can be attributed predominantly to genetic causes. aHUS can occur in either a sporadic or a familial form; the latter is rare and accounts for less than 3% of HUS. Cases with both autosomal recessive as well as autosomal dominant patterns of inheritance have been reported. Onset of autosomal recessive disease is usually early in childhood and recurrence is very frequent. The prognosis of this form is very poor, with a mortality rate of 60–70%. The autosomal dominant form can manifest both in childhood and in adults. It is often triggered by precipitating events such as infection, pregnancy, etc. Several studies report incomplete penetrance of about 50%, with most individuals presenting with disease before age 30. This suggests the involvement of additional genetic and/or environmental factors in the expression of the disease.

aHUS is a disease of complement dysregulation. The complement system, a critical component of innate immunity provides the first line of defense against infectious agents. In addition to mutations in CFH, mutations in two other genes, complement regulator membrane cofactor protein (MCP) and regulatory serine protease Factor I (FI) gene, have also been implicated in aHUS. A total of 69 different mutations are associated with aHUS and are cataloged in a comprehensive web-based database (www.FH-HUS.org).

On a functional basis CFH mutations that cause aHUS are classified into two types by analogy with coagulation protein defects: Type I and Type II. Of all the CFH mutations associated with aHUS, about 38% of the mutations are of type II, and 23% are type I mutations. The remaining mutations either do not have sufficient data or the FH levels were in the normal range and hence the mutant protein could not be identified in patients' plasma (www.FH-HUS.org). Type I mutations result in reduced plasma CFH levels, indicating a secretary defect or rapid degradation of protein. Type I mutations either affect the framework residues, such as the central conserved Cys residues, or non-framework residues [4]. The protein coded by these mutant CFH genes is expressed intracellularly and is retained in the cytoplasm. Type II mutations occur with normal level of functionally defective plasma CFH. Approximately 81% of type II mutations are missense, with a mutation hotspot in short complement repeats (SCRs) 19 and 20 with 76% of mutations located in this region. These mutations are associated with impaired binding to anionic molecules including those on endothelial cells. Both type I and type II mutations results in prolonged half-life of the C3 convertase, thereby enhancing complement activation.

*Autosomal Dominant PKD (ADPKD)*: Polycystic kidney disease is a very common monogenic nephropathy with varying prevalence in inter-continental populations (prevalence >1 in 1,000) resulting from bilateral, age related, multiple fluid-filled renal cyst development that leads to enlarged kidneys and renal failure. The cysts may get infected or bleed leading to additional complications. Concomitant hepatic, pancreatic, and cardiovascular complications may also occur. Cysts in other organ systems have also been reported, though not as frequently. Non-invasive techniques, such as ultrasound, are frequently used to diagnose PKD, but occasionally it may be necessary to use computed tomography (CT) scans or Magnetic Resonance Imaging (MRI) for more difficult to detect cases. A higher than usual mortality rate is associated with PKD, predominantly due to cardiac abnormalities and sepsis.

ADPKD is the more common form of PKD and is the outcome of mutations in two genes, Polycystin 1 on 16p13.3 (PKD1) and Polycystin 2 on 4q21-q23 (PKD2). Mutations in PKD1 cause 85% of ADPKD. The other 15% is attributed to mutations in PKD2, although there is a third, unknown, rare, PKD3 locus. PKD1 has 46 exons, a transcript size of 14 kb and 52 kb of genomic sequence. PKD2 occupies more genomic space at 68 kb, with 15 exons and a smaller transcript size of 5 kb. PKD1 resides in the proximity of six other pseudogenes with ~95% homology to PKD1, and very similar transcripts. Mutation detection is difficult because only 3.5 kb of PKD1 is unique. There is considerable variance in the age-at-onset of PKD within and between families. PKD1 mutations lead to more severe phenotypes, at earlier ages, although the type (nonsense, missense, etc) and location of the mutation matters in the ultimate development of disease. Loss of heterozygosity studies in cysts, studies of germline and somatic mutations, and gene targeting in animal models has led to the hypothesis of a "two-hit" disease model, similar to the development of cancer. Unfortunately, prediction of disease severity and outcome from the type of mutation has not been feasible, as the genotype-phenotype relationship is complicated by effects of unidentified modifier genes and environmental determinants. Cyst formation is initiated by genetic predisposition, but the expansion phase is controlled by many factors.

Polycsytin 1 and 2 proteins are expressed ubiquitously but in the kidney are located in the primary cilium of the renal epithelium. Polycystin 1 is a 4302 amino acid protein, with 11 transmembrane domains, a short cytoplasmic C-terminus and a large extracellular domain. It has a primary role in vascular smooth muscle cells. Polycystin 2, a 968 amino acid protein, is a member of the transient receptor potential (TRP) superfamily of $Ca^{2+}$ permeable ion channels. Polycystin 1 and 2 interact at the molecular level via their C-termini and form a complex that co-localizes to the primary cilium of the renal epithelium. They function to sense flow stress, a mechanotransduction response, initiating a cascade of intracellular $Ca^{2+}$ signals. Other moieties that participate in this cellular response are fibrocystin (see ARPKD) and inversin (see nephronopthisis type 2). Together all the PKD genes comprise ciliopathies, a novel type of pathological mechanism for disease. Polycytin 1 has a role in the cell cycle in addition to its role in the cilium, thus mutations in this gene show a more severe outcome.

*Autosomal Recessive Polycystic Kidney Disease (ARPKD)*: ARPKD presents in infancy with a prevalence ranging from 1 in 6,000 to 1 in 40,000 newborns. Neonates with ARPKD have high mortality rates up to 30%, and of those who survive 50% develop ESRD. As described earlier mutations in a single gene, fibrocystin (PKHD1) on 6p21, cause ARPKD. PKHD1 (also known as fibrocystin/polyductin/tigmin (FPC)) has 86 exons, encodes a protein of 4074 amino acids for which the longest associated transcript length is 16,235 bp. FPC is a protein that is expressed in the primary cilium of kidney tubular cells in association with the basal body. PHKD1 has a role in cilium morphology, tubule morphogenesis and mitosis. Similar to PKD1 and PKD2, mutations in this gene result in the PKD ciliopathy, although no physical connections between PKD1, PKD2 and FPC are postulated. Their common link may be through a motor protein, kinesin-2 [5] with FPC also playing a role in sensing flow.

As many as 305 different mutants are listed in the ARPKD/PKHD1 database (http://www.humgen.rwth-aachen.de). Of these a greater proportion (60%) are missense mutations. Truncation, splicing (frameshift) and nonsense mutations are also observed. Homozygous truncation mutations lead to earlier neonatal deaths and patients with missense mutations show a survivor bias.

*Hereditary Nephrotic Syndrome*: A rare autosomal recessive disorder in other parts of the world, congenital nephrotic syndrome of the Finnish type (CNF) is more commonly seen in neonates in Finland, a population that derives from a limited number of founder individuals. It has a prevalence of 1 in 8,000–10,000 newborns in Finland. The disease is also common among Mennonites in Lancaster County, PA, which is also a founder population. CNF initiates in utero and presents with massive proteinuria, resulting in an increase in alpha-fetoprotein in the amniotic fluid. This increase is mirrored by a smaller rise in the maternal serum concentrations of the same, leads to an enlarged placenta, and increased fetal birth weight. The disease has a high mortality rate and survival is dependent on immediate nephrectomy and renal replacement therapy.

The steroid-resistant form of nephrotic syndrome (SRNS) is also autosomal recessive with onset between 3 and 5 years of age and quick progression to ESRD. The clinical spectrum of the disease is varied and individuals range from minimal change to focal segmental glomerulosclerosis (FSGS). Some adult sporadic patients with FSGS have also been observed. CNF and SRNS are sometimes called Mendelian forms of FSGS.

CNF results from mutations in a gene called nephrin (NPHS1) that was positionally cloned from chromosome 19. Nephrin is a 26 kb gene belonging to the Immunoglobulin (Ig) superfamily and is a critical component of the slit diaphragm. It is 1241 amino acids in length, with eight C2-like Ig modules, a single fibronectin type III module, an extracellular domain and a transmembrane region. Besides its critical structural role in the slit diaphragm, nephrin is a transmembrane adhesion molecule that is involved in podocyte cell-cell signaling because of its location in the lipids rafts of the slit diaphragm. CNF predominantly (95%) results from two key mutations – Fin major (deletion of nucleotides 121 and 122) and Fin minor (protein translation stops prematurely at amino acid 1109).

A molecule that interacts very closely with nephrin in the slit diaphragm called podocin (NPHS2) is responsible for SRNS. Podocin was mapped to 1q25-q31 and its association with SRNS was established through positional cloning. Podocin is a 383 residue protein expressed exclusively in podocytes. Being a member of the stomatin protein family, podocin inserts into membrane but loops back after forming a hairpin like structure such that its C- and N-termini are located in the cytosol. Unlike NPHS1, the spectrum of mutations associated with NPHS2 is far broader including premature terminations and missense mutations; many are non-synonymous amino acid changes that likely result in retention of the protein in the endoplasmic reticulum. Podocin is a key molecule in formation of lipid rafts and it recruits other moieties such as nephrin and CD2-associated protein to these rafts [6]. These rafts are an essential part of the signaling cascade of the slit diaphragm, and mutations in podocin lead to effacement of the slit diaphragm.

*Focal Segmental Glomerulosclerosis (FSGS)*: FSGS is a heterogenous idiopathic syndrome with a similar pattern of renal injury that results from both immunologic and non-immunologic causes, but whose pathophysiology

is mostly unknown. FSGS is a common cause of renal failure accounting for up to 20% of patients undergoing renal replacement therapy. There is racial/ethnic variation in FSGS with a higher prevalence in black patients. FSGS can either be primary or associated with a number of other diseases such as HIV, diabetes, hypertension etc.

Mutations in three different genes, alpha actinin 4 (ACTN4), transient receptor potential 6 (TRPC6) and CD2-associated protein (CD2AP) are associated with adult onset FSGS, but in general mutations in these genes are rare in the general population, although comprehensive screens of large numbers of patients have not been conducted. Alpha actinin 4 mutations are point mutations which display dominant inheritance patterns with slow progression to FSGS in adulthood and lack of penetrance. ACTN4 is a member of the spectrin family of proteins that cross-links actin filaments and is highly expressed in podocytes. FSGS-associated mutants crosslink actin more strongly in vitro than wild type protein, thus affecting the cytoskeleton of podocytes. Mutations in six families with TRPC6 have been identified. TRP channels are membrane-spanning proteins which are implicated in a number of cellular processes such as mechanosensation, ion homeostasis, cell growth and PLC-dependent calcium entry into cells. TRP channels are assembled in a multimeric form (often tetrameric) to transport ions across the membrane barrier. TRPC6 is the most $Ca^{2+}$ sensitive of the TRP channels, and mutations in this gene either affect the $Ca^{2+}$ influx into cells or alter the interaction of this gene with other podocyte proteins. CD2AP is an adapter protein that functions within podocytes in signaling, vesicular trafficking and as a linker between the actin cytoskeleton and other proteins. Very few mutations have been seen in the CD2AP protein in human populations, although knockout mouse models of disease develop FSGS. Mutations in CD2AP were identified as a rare cause of haploinsufficiency in HIV nephropathy patients (2 in 45) due to a exon 7 splice acceptor mutation or nephrotic syndrome in a single patient due to a homozygous stop at amino acid 612 [7]. In summary, mutations in a few cases of FSGS have been identified but the vast majority of patients remained uncharacterized for mutations. Variation in MYH9 has recently been associated with FSGS in African Americans, but no mutations have been discovered as yet.

*IgA Nephropathy (IgAN)*: IgA nephropathy as described in the name is characterized by mesangial deposits of immunoglobulin (Ig)A. IgAN is the most common form of primary glomerulonephritis but like FSGS IgA nephropathy is a complex multifactorial trait whose genetic basis remains unsolved [8]. The incomplete O-glycosylation in the IgA1 hinge has been suggested as the central mechanism in IgAN. The disease is heterogeneous, presents with other conditions, such as IgM nephropathy, Henoch-Schönlein purpura nephritis and FSGS, and often remains undetected because of the requirement for a biopsy. Approximately 15% of patients show familial aggregation but this also may be an underestimate because the disease presents intermittently and could easily be misdiagnosed or remain undiagnosed.

*Systemic Lupus Erythematosus Nephritis (SLEN)*: Lupus nephritis is a form of glomerulosclerosis that affects some individuals with systemic lupus erythematosus (SLE), an autoimmune disease characterized by autoantibodies to nuclear components. Both SLE and SLEN are recognized as being mediated by genes, even though the inheritance patterns are multifactorial and complex. Recently, reductions in the copy number of the activatory Fc receptor for IgG, FcGR3 (also known as FcγRIII) on 1q23 were associated with SLEN in human populations, although the initial observations were derived from animal models. Fc receptors are linkers in the immune pathway that connect humoral and cellular response and rats with lack of Fcgr3 have macrophage overactivity and are susceptible to develop glomerulosclerosis. Changes in copy number variant modulating expression has also been proposed for a variety of other autoimmune phenomena. It is currently unclear how much FcGR3 variation contributes to SLEN. Presumably because SLEN is multifactorial other loci will also contribute to disease etiology. These investigations are ongoing and will hopefully bear fruit.

## Diagnostic Principles

Major risk factors for the development of CKD include the presence of diabetes, hypertension and systemic diseases that can involve the kidneys (SLE, HIV infection). Additionally, African Americans, Hispanic Americans and American Indians are at higher risk than the Caucasian population. Individuals with close relatives having CKD or ESRD are at particularly high risk. These individuals require lifelong periodic screening for development of CKD.

The diagnosis of CKD requires performance of a thorough history and physical exam (including blood pressure), standard urinalysis, quantification of urinary microalbumin excretion (including in those without proteinuria on standard urinalysis), and measurement of serum electrolytes, BUN, creatinine and bicarbonate concentrations. It is necessary to apply an equation (Modification of Diet in Renal Disease, MDRD) in order to more accurately estimate renal function based upon age, gender and ethnicity (since muscle mass contributes to serum creatinine concentration and varies with age, gender and ethnicity).

In those with less than 50% remaining renal function, periodic measurement of phosphorus, calcium, parathyroid hormone, hemoglobin and iron stores are advised to detect and treat secondary hyperparathyroidism and renal disease-associated anemia.

## Therapeutic Principles

Recent research holds the promise for renal regeneration with the potential for improving kidney function. However, inadequately treated renal disease risk factors typically cause CKD to progress until an intercurrent CVD event or ESRD develops. Lowering systemic blood pressure and improving glycemic control delay the development and progression of diabetic nephropathy. Pharmacologic agents that lower blood pressure and reduce proteinuria (angiotensin converting enzyme inhibitors and angiotensin receptor blockers) are preferred agents in all forms of proteinuric CKD; many patients will require 3–5 classes of anti-hypertensive agents. Smoking accelerates progression of CKD to ESRD, hence smoking cessation is strongly recommended. Recent data on lipid lowering using statins suggest possible benefits in rate of decline of renal function in those with mild-moderate CKD, and possibly modest reductions in proteinuria. Importantly, agents that reduce albuminuria and improve blood pressure and glycemic control, smoking cessation and lipid lowering all lower the concomitant risk for CVD that is present in the high risk CKD population. Low protein diets may slow the progression of CKD, particularly in those with diabetic nephropathy. However this benefit must be tempered by difficulty complying with the diet and the concomitant risk of developing protein calorie malnutrition, itself a risk factor for mortality among dialysis patients.

Reducing dietary phosphorus ingestion and adding phosphate binders (non-aluminum, non-calcium containing binders may prove to be preferred), coupled with the judicious supplementation of vitamin D, vitamin D analogues and use of parathyroid calcium sensing receptor activators can prevent (and treat) secondary hyperparathyroidism. Recombinant human erythropoietin, and related compounds, reliably treats the anemia associated with CKD, minimizing the need for blood transfusions and susceptibility to sensitization.

In patients with ESRD and for those with symptomatic advanced CKD, various dialysis modalities clear renal toxins and excess solute (hemodialysis and peritoneal dialysis). Kidney transplantation offers survival benefits, improved quality of life and reduced costs; therefore kidney transplantation is the preferred modality among those who are healthy enough to be considered.

## Definition and Characteristics

Autosomal recessive renal uric acid transport defect associated with increased clearance of uric acid resulting

in low plasma uric acid concentrations (hypouricemia) and mild hyperuricosuria [1,2].

## Prevalence

The accurate worldwide frequency of hereditary renal hypouricemia is yet to be determined. The frequency in Japan has been estimated to be 0.12% [3].

## Genes

Hereditary renal hypouricemia is caused by mutational alterations in the gene SLC22A12, coding for the specific urate transporter URATE1 [4,5], which controls the uptake of filtered urate from the lumen into the proximal tubule cells (urate reabsorption) (Fig. 1). URAT1 is a urate-anion exchanger. The anions exchanged for urate uptake (such as lactate and nicotinate) enter the cells from the lumen presumably through the $Na^+$/anions cotransporter SLC5A8.

Urate secretion to the lumen is carried out by UAT, a urate transporter/channel that allows efflux of urate from the cells into the lumen and probably also to the peritubular space. Urate may also be secreted to the lumen through the ATP-driven human organic anion transporter MRP4. OAT1 and OAT3 are urate-organic anion exchangers (reviewed in [1]).

Mutational analyses in large populations established a correlation between the clinical and genetic features of hereditary renal hypouricemia patients and the significance of URAT1 in the regulation of serum urate level (reviewed in [1]).

Mutations in the SLC22A12 gene were detected in most affected patients studied. The SLC22A12 mutations found included missense, nonsense, deletion and splice-site mutations, scattered among almost all of the 10 exons of the SLC22A12 gene (reviewed in [1]).

## Molecular and Systemic Pathophysiology

Uric acid is the end product of purine metabolism in humans. It is formed in the liver during turnover of endogenous purines, principally from ATP breakdown or from exogenous purines in the diet degraded during absorption from the gut. Approximately one third of total uric acid produced is secreted into the gut and broken down by bacteria, the remaining two thirds being excreted via the kidneys.

Hereditary renal hypouricemia is a rare genetic disorder associated with a much higher renal clearance of uric acid than is seen in healthy age-matched controls.

Affected patients are usually asymptomatic. The hypouricemia as such has no known pathological consequences. However, uric acid is an antioxidant hypothesized to protect tissues against cancer and other injurious conditions. If uric acid has such a role, hereditary renal hypouricemia patients as well as other hypouricemic patients, renal as well as metabolic, may be predisposed to oxidative stress-induced diseases. Hereditary renal hypouricemia may be associated with uric acid or calcium urolithiasis and with idiopathic hypercalciuria [1,2]. In addition, hereditary renal hypouricemia has been recognized as a predisposition for exercise-induced acute renal failure. Although some patients affected with the latter complication require hemodialysis, the short-term prognosis of affected patients seems good. Most probably, the acute renal failure is caused by precipitation of uric acid, since acute uric acid nephropathy may occur in the presence of massive uricosuria.

## Diagnostic Principles

Persistent familial hypouricemia associated with an increased uric acid clearance, without evidence of a generalized disturbance of membrane transport (e.g. Fanconi or Hartnup syndromes) is characteristic of hereditary renal hypouricemia [1,2]. Other genetic metabolic causes of hypouricemia (e.g. xanthinuria or purine nucleoside phosphorylase deficiency) are not associated with an increased uric acid clearance and may thus be excluded. Acquired conditions should also be excluded [1,2]. Direct demonstration of mutations in the gene SLC22A12, coding for the defective URAT1 transporter, will confirm the diagnosis.

## Therapeutic Principles

Affected patients without associated clinical manifestations need no treatment. In cases where there is significant hyperuricosuria, urolithiasis may be prevented by either reducing uric acid formation (by reducing dietary purine intake or by allopurinol treatment) or by increasing uric acid solubility by ensuring a high fluid intake and by controlling urine pH [1,2]. To avoid occurrence of exercise-induced acute renal failure, patients should be advised to avoid strenuous physical activity and to ensure

adequate fluid intake at all times. These preventive measures are recommended despite the knowledge that the short-term prognosis of exercise-induced acute renal failure in this defect is generally good [1].

## Reperfusion of the Ischemic Myocardium

Naranjan S. Dhalla, Harjot K. Saini
St. Boniface General Hospital Research Centre, University of Manitoba, Winnipeg, MB, Canada

### Synonyms

Myocardial stunning

### Definition and Characteristics

Reduction of coronary blood flow is known to produce myocardial ischemia, which is associated with impaired heart function, changes in myocardial metabolism, depletion of high-energy phosphate stores and alterations in the cardiac ultrastructure. Although restoration of blood flow to the ischemic myocardium is essential for the improvement of cardiac function, reperfusion instituted beyond a certain period of ischemic insult by angioplasty, coronary-bypass or thrombolytic therapy has been invariably demonstrated to cause further depression in cardiac function commonly referred as myocardial stunning.

### Prevalence

Cardiac ischemia is the leading cause of death in Europe and North America. Reperfusion injury results from attempts to restore blood flow to the ischemic myocardium.

### Genes

A wide variety of genetic defects predispose to arteriosclerosis and thus cardiac ischemia.

### Molecular and Systemic Pathophysiology

This ischemia reperfusion (I/R)-induced myocardial injury has been associated with electrical abnormalities, imbalance of cationic homeostasis, release of massive amount of catecholamines, endothelial dysfunction, leakage of different intracellular enzymes, activation of various proteases and phospholipases, alterations

in signal transduction mechanisms, apoptosis and necrosis. In addition to causing marked abnormalities in cardiac metabolism, I/R injury has been shown to produce dramatic defects in subcellular organelles such as sarcolemma, sarcoplasmic reticulum, mitochondria, myofibrils and extracellular matrix; these changes are considered to explain the development of cardiac dysfunction under acute conditions. A wide variety of alterations in cardiac nucleus and gene expression for proteins in different subcellular organelles have also been reported to occur as a consequence of I/R injury and this is considered as to explain delayed recovery of heart function under chronic conditions (Fig. 1).

The I/R injury has also been reported to be associated with infiltration of leukocytes, altered expression of adhesion molecules, activation of platelets and degranulation of resident cardiac mast cells. Both intracellular $Ca^{2+}$-overload and oxidative stress have been proposed as the major mechanisms for causing the cellular injury due to I/R. The intracellular $Ca^{2+}$-overload is initiated by the accumulation of $H^{+}$ ions resulting in increased activity of the sarcolemmal $Na^{+}$-$Ca^{2+}$ exchanger, whereas the oxidative stress is produced by formation of different oxyradicals, alterations in redox potential, oxidation of catecholamines and production of various pro-inflammatory cytokines such as tumor necrosis factor-α and interleukin 1-β in the myocardium. The intracellular $Ca^{2+}$ overload has been shown to produce biochemical and molecular changes by activation of different phospholipases and proteases in addition to inducing alterations in gene expression (Fig. 2).

On the other hand, oxidative stress produces subcellular defects by modifying membrane lipids, protein sulfhydryl and amino groups as well as gene expression (Fig. 3). It has become evident that I/R injury is a complex problem and is one of the several factors which have been claimed to be intimately involved in the development of ischemic heart disease.

## Diagnostic Principles

Myocardial ischemia is apparent from clinical signs and symptoms, ECG and biochemical markers.

## Therapeutic Principles

Various agents such as $Ca^{2+}$-antagonists, β-adrenoceptor blockers, nitric oxide donors and antioxidants are used to treat the ischemic heart disease; however, these agents are effective partially. In view of the crucial role played by intracellular $Ca^{2+}$ overload and oxidative stress in inducing I/R injury, it is suggested that a combination therapy with agents which prevent the entry of $Ca^{2+}$ and attenuate the occurrence of oxidative stress in the myocardium could prove most beneficial in improving heart function during I/R.

## Synonyms

RTH

## Definition and Characteristics

Resistance to thyroid hormone (RTH) is a syndrome of reduced end-organ responsiveness to thyroid hormone (TH) [1–4].

It is characterized by elevated serum levels of free thyroxine ($T_4$), free triiodothyronine ($T_3$), and normal or slightly increased serum thyrotropin (TSH) concentration that responds to thyrotropin releasing hormone (TRH) in the absence of any illness, drugs, or defect in hormone transport or metabolism or any circulating antagonist in the plasma [1–3].

## Prevalence

RTH is encountered 1 in 50,000 live births with over 1,000 known cases [3] with equal frequency in both genders and appears to have wide geographic and ethnic distribution [1–4]. Familial occurrence has been documented in approximately 75% of cases [3,4].

## Genes

Mutations in the thyroid hormone receptor (TR) β gene are responsible for RTH and 122 different mutations, most of which are located in three clusters of the $T_3$ binding domain and the distal end of the hinge region of the TRβ, which have been identified as belonging to 300 families [3]. Inheritance is usually autosomal dominant but de novo cases are common. Recessive inheritance has only been reported in one family, and 44.4% of the de novo mutations occurred in mutagenic CpG dinucleotide hot spots [1–3].

## Molecular and Systemic Pathophysiology

The site of action for $T_3$, the biologically active form of the hormone, is in the cell nucleus. There, it interacts with TRs that are ligand-dependent nuclear transcription factors that regulate the rate of target gene transcription [1–3].

TRs belong to a superfamily of nuclear hormone receptor [1,4]. There are two TRs, alfa and beta, which are encoded by separate genes located on chromosomes 17 and 3, respectively. Alternate splicing generates three main receptor isoforms (TRβ1,TRβ2, and TRα1), which are widely expressed but have different tissue distributions. They have a common DNA binding domain (DBD) at their amino terminus, which interacts with specific DNA sequences, termed thyroid hormone response elements (TREs), usually located near the transcription start point of thyroid hormone-regulated genes. The TREs consist of half-sites with the consensus sequence AGGTCA. The TREs vary in number, spacing, and orientation and with regard to the ligand binding domain (LBD) that recognizes L-T3 [1,3]. $T_3$ binds at the LBD of the TR as dimer bound to specific DNA sequences. Dimers of unliganded (no $T_3$) TR bind to thyroid hormone response elements resulting in inhibition of expression of genes that are positively regulated by $T_3$ through association with co-repressor proteins. Binding of $T_3$ to the receptors results in release of the co-repressor protein, dissociation of the dimers, and formation of heterodimers of TR and retinoid X receptors that then bind coactivator proteins. These changes promote gene expression and increase the synthesis of specific proteins [1–4].

The mutant TRβ molecules have either a reduced affinity for $T_3$ or impaired interaction with one of the cofactors involved in the mediation of TH action [1–4].

## Diagnostic Principles

RTH is classified on clinical findings into generalized resistance to TH (GRTH), selective pituitary resistance to TH (PRTH), and isolated peripheral tissue resistance to TH (PTRTH) [1–4]. However, it is uncertain whether PRTH exists as a true TH resistance entity except in association with TSH-producing pituitary adenomas [3].

The most common clinical presentation in adult patients is a goiter or recurrence of a goiter following inappropriate treatment, mild to moderate growth

retardation, delayed bone maturation, and learning disabilities along with hyperactivity and tachycardia, compatible with thyrotoxicosis [1–4].

A standardized diagnostic protocol has been established to assess parameters of central and peripheral tissue effect of TH in the basal state and during the administration of three incremental doses of L-$T_3$. The three doses given in sequence each for 3 days are 50μ/day and two supraphysiologic doses of 100 and 200 μg/day [1–3].

Administration of TH ultimately suppresses TSH secretion [1–3]. Various responses of peripheral tissues to the administration of TH can be measured by basal metabolic and heart rates [1–3].

### Therapeutic Principles

There is no available treatment to fully correct the defect [1–4].

In most of the patients, the partial tissue resistance to TH can be adequately compensated for by the increased endogenous TH secretion. Such patients need not to be treated [1–4].

TH treatment is indicated to those who have received ablative therapy without knowledge of the diagnosis, limited thyroidal reserve, and concomitant presence of autoimmune thyroid disease [2].

If there is clinical hypothyroidism in patients in whom hormone resistance is at peripheral, tissue level can be treated by administration of supraphysiologic doses of TH [3].

It has been recently shown that treatment with supraphysiologic doses of $T_3$, given as a single dose every other day, is successful in reducing goiter size [5].

If the patients complain of symptoms of hypermetabolism, the choice of treatment is atenolol [2–4]. Antianxiety drugs can also alleviate symptoms of nervousness.

Dopaminergic drugs and somatostatin analogs can decrease the levels of thyroid hormone through suppression of TSH but they have low success rate in maintaining TSH suppression [2].

TRIAC (3,5,3′ triodothyroacetic acid) is a TH analogue that can be used to reduce the TSH and TH levels and alleviate some of the symptoms caused by the action of TH on peripheral tissues and reduce goiter size [1–4].

In the future, gene therapy with excision of the defective gene, in vitro fertilization (IVF), and implantation of selected oocytes that do not harbor abnormal alleles and development of specific TH agonists and antagonists that are TR isoform specific might be possible [4].

# Respiratory Syncytial Virus

Richard J. Sugrue
Division of Molecular and Cell Biology, School of Biological Sciences, Nanyang Technological University, Singapore, Singapore

## Synonyms

RSV; Human RSV; HRSV

## Definition and Characteristics

Although human respiratory syncytial virus (HRSV) was first reported in infants exhibiting respiratory distress in 1957 [1], it is now recognised as one of the most important causes of lower respiratory tract infection in young children. The virus is spread in respiratory droplets, and transmission can occur either directly during close contact between individuals, or by contact with contaminated surfaces. In temperate climates HRSV epidemics are seasonal, usually occurring from late autumn until early spring. In tropical climates HRSV infections occur through-out the year, but an increase in the HRSV infection rate is observed during the rainy seasons. Although the disease symptoms are usually relatively mild in healthy adults, severe complications, including bronchial pneumonia and respiratory failure, can occur in certain high-risk groups. These include neonates and premature babies, the elderly, and individuals with impaired immune and cardiac systems [2].

## Prevalence

Evidence suggests that by the age of 4, virtually all children have developed antibodies against HRSV, and that re-infection with HRSV occurs throughout adolescence and in later life.

## Genes

HRSV is grouped within the family paramyxoviridae, subfamily pneumovirinae, genus pneumovirus. The virus genome (vRNA) is a single-stranded non-segmented RNA molecule of negative polarity, which encodes for eleven virus proteins [3]. A leader (Le) region and trailer (Tr) region flank the vRNA at the 3′- and 5′ ends respectively, and transcription of the vRNA is initiated at the 3′ end. The vRNA contains ten individual genes (Fig. 1a), and each gene contains an open reading frame (ORF) that is flanked by a gene start (GS) and gene end (GE) sequence. With the exception of the M2 gene, which encodes the M2–1 and M2–2 proteins, each gene is transcribed and translated to give a single virus protein (Fig. 1b, c).

Most of the virus genes are arranged contiguously within the vRNA, and adjacent genes are separated by intergenic sequences. In the case of the M2 and L genes, the GE sequence for the M2 ORF is located after the GS of the L gene, thus creating an overlap between these genes. Transcription of an ORF is started at the GS sequence, and once the GE sequence is reached, the polyadenylated virus mRNA is released from the vRNA. The virus polymerase scans through the intergenic region until the GS sequence of the adjacent gene is reached and transcription of the ORF is reinitiated. The genes encoding the nonstructural proteins NS1 and NS2 are unique to members of the genus pneumovirus, while the M2 gene is found in other members of the subfamily pneumovirinae, which includes the genus metapneumovirus.

## Molecular and Systemic Pathophysiology

Several studies have shown that the expression of a number of specific proinflamatory cytokines, including interleukin 8 (IL8), MIP-1 and RANTES, are increased in humans infected with HRSV. Animal studies have demonstrated that HRSV infection leads to an enhanced chemokine expression in the lung, leading to lung eosinophilia. This has suggested that the induction of proinflamotory cytokines in the lower respiratory tract is a major factor in the appearance of severe manifestations of the disease in infected patients [4]. Data from several groups have suggested that the severity of HRSV infection may also be linked to co-infection with human metapneumovirus (HMPV). Although HMPV has been detected in patients with severe respiratory distress caused by HRSV, its role in HRSV pathogenesis has yet to be confirmed. There has been an increasing body of information that HRSV is able to counter the host's innate anti-virus immune response during infection by inhibiting interferon type 1 signaling, a process that involves the NS1 and NS2 proteins.

## Diagnostic Principles

The traditional and routine procedure for diagnosing potential HRSV infection involves virus antigen detection in nasopharyngeal aspirates using an immunofluorescence based assay. Alterative procedures include the detection of viral RNA in patients samples using the real time reverse transcriptase-polymerase chain reaction (RT PCR), and monitoring the appearance of HRSV antibodies in patients serum.

## Therapeutic Principles

There is currently no licensed vaccine to protect individuals from HRSV infection, although several vaccines generated by recombinant DNA technology are under development. The current preventative measures include good personal hygiene and passive immunization. Although the intravenous injection of human immune globulin with high titers of neutralizing

**Respiratory Syncytial Virus. Figure 1** HRSV genome structure and molecular architecture. (a) A schematic diagram showing the organisation of the virus genome. The gene order and location of the leader (Le) and trailer (Tr) sequences are indicated. (b) The virus genome gives rise to eleven virus proteins whose function and location are indicated. (c) A schematic diagram showing the molecular organisation of a mature HRSV particle.

HRSV antibody is an option (e.g. RespiGam®), the use of humanized neutralising HRSV monoclonal antibodies (e.g. Synagis®) remains the most effective method of protecting high-risk patients. However, the high cost of using Synagis has restricted its widespread use. Although ribavirin is licensed to treat infected individuals, results obtained during carefully controlled clinical studies have questioned its usefulness. In some cases a combination of ribavirin and immune globulin with high titers of neutralizing HRSV antibody has been effective in treating patients. It is worth noting that alternative antivirus strategies are currently in development, which includes the use of peptides and small molecules that inhibit virus entry, and the use of specific siRNA molecules that can prevent the expression of vital virus gene products.

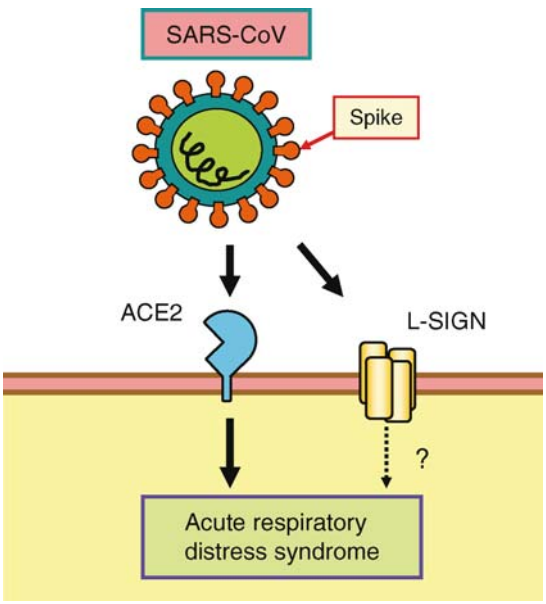
SARS

## Definition and Characteristics

The severe acute respiratory syndrome (SARS) is a newly emerged infectious disease, first recognized in November 2002 in Guangdong Province, China. It spread rapidly from China throughout the world during February to July 2003, with a mortality rate of 9.6% being listed in the WHO's April 21, 2004 concluding report [1]. SARS is a life-threatening and highly contagious respiratory illness with a high tendency to spread to household members and health care workers via close personal contact. Fever (over 38.0°C) occurs in nearly all patients, and often the symptom contains cough, dyspnea, or diarrhea. Symptoms usually appear 2–10 days following exposure, and in most cases, symptoms appear within 2–3 days. Approximately 16% of cases lead to acute respiratory distress syndrome (ARDS) and require mechanical ventilation with about 50% mortality. The causative organism was identified as a novel coronavirus, termed SARS coronavirus (SARS-CoV) [2]. SARS-CoV is thought to be introduced into humans from an animal reservoir by crossing the xenographic barrier, since SARS-CoV was isolated from civet cats in the local market in Guangdong, China (Fig. 1). The outbreak in early 2003 was controlled with public health measures that included use of broad case definition, hospitalization and isolation of suspected cases, quarantine and travel advisories. Although a limited number of cases of SARS have occurred after the outbreak in 2003, it is important to remember that exposure to two potential sources for infections – infected animals and laboratory-acquired infections – can lead to another outbreak of SARS.



**Respiratory Syndrome, Severe Acute.**
**Figure 1** SARS coronavirus (SARS-CoV) infects host human cells with the interaction of Spike with angiotensin converting enzyme 2 (ACE2), leading to acute respiratory distress syndrome. L-SIGN is also reported as a receptor.

## Prevalence

One major epidemic to date, between November 2002 and July 2003, with 8,098 known cases of the disease and 774 deaths. After the outbreak in 2003, 17 cases of SARS between September 2003 and May 2004. Four cases resulted from laboratory exposure, two of whom infected nine other cases and resulted in one death. The source of other four cases was uncertain but suspected to be nosocomial transmission.

## Genes

Angiotensin converting enzyme 2 (ACE2) is an essential receptor for SARS infection [3,4]. L-SIGN (CD209) is also reported as a SARS receptor despite yet to be defined further. Insertion/deletion polymorphism in the intron of ACE1 (ACE1, angiotensin converting enzyme 1), polymorphism in the exon 4 of CLECM (coding L-SIGN), and HLA-B*0703 and HLA-DRB1*0301 are suggested to be associated with the outcomes or mortality.

## Molecular and Systemic Pathophysiology

SARS is caused by infection of a novel SARS-CoV, which is phylogenetically categorized to group 2 coronoaviruses. Spread of the virus occurs via airborne droplets and close contact with patients. Coronaviruses are large, enveloped, spherical viruses about 100–120 nm in diameter, which contain single-stranded RNA with positive polarity. The severe symptoms and high mortality of SARS-CoV contrast to the mild common cold-like symptoms of previously known human coronaviruses, HCoV-229E and HCoV-OC43. SARS is largely a viral pneumonia and the lung pathology shows diffuse alveolar damage with multinucleate giant cells and a prominent increase of macrophages in the alveoli and lung interstitium. Both local viral replication and the immunologic consequences of the host response could lead to those damages. Indeed, the lack of β-interferon response as well as the enhanced expression of chemokines/inflammatory cytokines in SARS-CoV-infected cells has been reported [3,4].

## Diagnostic Principles

Initial symptoms are flu-like and may include the following: fever, myalgia, lethargy, gastrointestinal symptoms, cough, sore throat, and other nonspecific

symptoms. The only symptom that is common to all patients appears to be a fever above 38°C. Although a chest X-ray appearance of SARS is variable, showing increased opacity in both lungs is indicative of pneumonia in a patient with SARS.

SARS should be suspected in a patient who has any of the symptoms including a fever of 38°C (100.4°F) or more, either a history of contact (sexual or casual) with someone with a diagnosis of SARS within the last 10 days or travel to any of the regions with recent local transmission of SARS [1]. A probable case of SARS has the above findings plus positive chest X-ray findings of atypical pneumonia or respiratory distress syndrome [1]. The total number of white blood cells tends to be low. With the advent of diagnostic tests for the SARS-CoV, the WHO has added the category of "laboratory confirmed SARS" for patients who would otherwise fit the above "probable" category and who do not (yet) have the chest X-ray changes but do have positive laboratory diagnosis of SARS based on one of the approved tests (ELISA, immunofluorescence or PCR).

## Therapeutic Principles

Infection control is important. Suspected cases of SARS must be isolated, preferably in negative pressure rooms, with full barrier nursing precautions taken for any necessary contact with these patients.

Treatment is essentially symptomatic and supportive care. If patients show respiratory distress such as ARDS, intensive cares including mechanical ventilation and systemic management are required. There are no specific drugs for treatment available, while vaccines or neutralizing antibodies against SARS-CoV are currently under development. Antiviral drugs (ribavirin, lopinavir, and ritonavir), corticosteroids and type I interferon have been suggested to be effective in treating SARS patients, while a 2006 systematic review of all the studies done on the 2003 SARS epidemic found no conclusive evidence [5]. A few suggested that they caused harm. Nevertheless, treatment must be conducted case by case. For instance, critically ill SARS patients with progressive pulmonary infiltrates might be treated with pulse corticosteroids.

# Restless Legs Syndrome

Jan Kassubek, Alexander Unrath
Department of Neurology, University of Ulm, Ulm, Germany

## Synonyms

Ekbom syndrome; RLS

## Definition and Characteristics

The restless legs syndrome (RLS), first described as a disease entity in modern literature by Karl Axel Ekbom in 1945, is hard to categorize as a movement disorder or as a sleep/wake disorder since its key characteristic is an urge to move the legs, often accompanied by a wide range of sensory symptoms, which occurs during rest and thus results in nocturnal insomnia and chronic sleep deprivation. RLS encompasses both an idiopathic type with no apparent cause and a symptomatic syndrome often associated with iron deficiency, pregnancy or end-stage renal disease [1]. The clinical course is chronic and in general slowly progressive; the age of onset varies widely, from childhood (as an underestimated cause of sleep disorders) to >80 years of age. Idiopathic (primary) RLS is distinguished from symptomatic (secondary) RLS.

## Prevalence

Large epidemiological population-based studies showed that between 3 and 11% of the population in industrialized countries have cardinal symptoms [2], with a female preponderance. Among first-degree relatives of patients with RLS, the prevalence is 3–5 times greater than in persons without RLS.

## Genes

A high genetic locus heterogeneity and a complex inheritance is assumed. Three genomic regions in RLS susceptibility have been identified: one locus was mapped on 12q12-q21 (RLS-1, MIM102300), a further locus was mapped on 14q13-q21 (RLS-2, MIM608831) and a third locus on chromosome 9p (RLS-3), with recessive (RLS-1) and autosomal dominant (RLS-2, RLS-3) modes of inheritance.

## Molecular and Systemic Pathophysiology

The pathogenesis and pathoanatomy of RLS remains largely unknown to date. A dysfunction of distinct dopaminergic pathways in the central nervous system (e.g. of the mesocorticolimbic system) is assumed in the literature, indicated by the medication responses, for instance within the dopaminergic A11 cell group which

is located both in the spinal cord (axons) and in proximity to the hypothalamic circadian pacemaker. Other authors hypothesized that a defect in iron acquisition in neuromelanin cells is involved and showed that cells from RLS patients had a 40% decrease in ferritin heavy chain. The reasons for the observed increased frequency of RLS in association with specific central nervous system disorders such as spinocerebellar ataxia variants or multiple sclerosis remain speculative. A functional impairment of central somatosensory/motor processing was described in idiopathic RLS by neurophysiological and functional neuroimaging techniques. The role of the peripheral nervous system, if any, is uncertain.

## Diagnostic Principles

Clinical diagnostic criteria were defined by the International RLS Study Group [2], consisting of four essential criteria that must be all met for a positive diagnosis. The essential criteria are as follows:

1. An urge to move the legs, usually accompanied by uncomfortable or unpleasant sensations in the legs (sometimes the urge to move is present without the uncomfortable sensations and sometimes the arms or other body parts are also involved)
2. The urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity (lying, sitting)
3. The urge to move or unpleasant sensations are partially or totally relieved by movement (e.g. walking, stretching), at least as long as the activity continues
4. The urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night (this may not be noticeable in severe stages, but must have been previously present)

Additional supportive criteria exist, i.e. a positive response to dopaminergic treatment, periodic limb movements during wakefulness or sleep or a positive family history [2].

In the diagnostic work-up, common reasons for symptomatic RLS should be investigated, i.e. iron deficiency (low blood concentrations of ferritin), uremia or peripheral neuropathy (findings in the neurological examination or in nerve conduction studies). During pregnancy, women have an increased risk of experiencing RLS for the first time or, in pre-existing disease, a temporary worsening of symptoms; the causes of this association are unknown.

## Therapeutic Principles

The initiation of sleep hygiene measures is important. Dopaminergic agents are generally accepted as the first line of pharmacological treatment for RLS [1]. Levodopa (plus dopamine decarboxylase inhibitor) was shown to be effective in the treatment of RLS symptoms [3]; here, a combination of standard levodopa and slow-release levodopa was superior to standard levodopa alone. The non-ergot dopamine agonists pramipexole, ropinirole and rotigotine and the ergot-dopamine agonists bromocriptine, lisuride, pergolide and cabergoline have all been shown to be effective in double-blind studies [4, 5]. With mild or intermittent RLS, levodopa may be adequate, while with more severe disease or daytime symptoms, a dopamine agonist should be used [1]. A common problem during any dopaminergic treatment, especially with levodopa, is the development of "augmentation," which is defined as the shifting of symptoms to a period of time 2 h or earlier than was the typical period of daily onset of symptoms before pharmacological intervention [2] but is distinct from "rebound" in which RLS symptoms worsen in the early morning. Augmentation usually resolves with cessation of the medication and can be kept to a minimum by keeping the dose low [1]. As the second line of pharmacological treatment, opioids, anticonvulsants (e.g. gabapentin), clonidine and benzodiazepines (e.g. clonazepam) may be administered. No controlled studies on combination treatment are available yet. In symptomatic RLS, a causal treatment may be effective, e.g. supplement of iron.

# Restrictive Cardiomyopathy

Margaret R. Wallace[1], Daniel F. Pauly[2]
[1]Department of Molecular Genetics and Microbiology, University of Florida, Gainesville, FL, USA
[2]Department of Medicine, Division of Cardiovascular Medicine, University of Florida, Gainesville, FL, USA

## Synonyms

RCM

## Definition and Characteristics

Cardiomyopathies are broadly categorized as dilated, hypertrophic, and restrictive, with restrictive cardiomyopathy being the least common type [1]. RCM is characterized by cardiac remodeling that results in impaired diastolic filling of the ventricles. There is normal heart wall thickness in early stages (in contrast to hypertrophic cardiomyopathy) and normal systolic functions (in contrast to dilated cardiomyopathy).

## Prevalence

The prevalence is thought to be less than 20 per 100,000 [1].

## Genes

TNNI3: encodes cardiac troponin I, on chromosome 19p13.2
DES: encodes desmin, the intermediate filament, on chromosome 2q35
CRYAB: encodes alpha-beta crystalline, on chromosome 11q22MYOT encodes myotilin, a component of the Z-disk, on chromosome 5q31

## Molecular and Systemic Pathophysiology

The molecular pathogenesis of RCM is the least understood of the cardiomyopathies. Some inherited cardiomyopathies, including RCM, can also have abnormal desmin accumulation (desminopathy) [2].

## Diagnostic Principles

The major abnormality in RCM is in the late filling phase of the ventricle due to decreased myocardial compliance (myocardial stiffness) [3]. The impaired filling of the ventricles results in atrial dilatation and increased systemic and pulmonary venous pressure, leading to heart failure. Clinical features often include exertional dyspnea, orthopnea, hepatomegaly, peripheral edema/ascites, Kussmaul's sign, and abnormal atrial rhythms [3]. X-ray findings may show enlarged heart and pulmonary venous congestion. EKG findings include atrial enlargement and ST-T wave abnormalities. The echocardiogram findings usually include atrial dilatation, normal ventricular cavity size, normal ventricular wall thickness (or mild hypertrophy); Doppler findings include short mitral deceleration time, and pulmonary vein flow reversed, which occurs during systole and at the time of atrial contraction; cardiac catheterization findings include high ventricular pressure at onset of diastole with further rise during ventricular filling [3]. There is a prominent Y descent in early diastole followed by a rise during the rapid filling phase (producing square root or dip-and-plateau pattern); endomyocardial biopsy findings often show myofiber hypertrophy and mild-to-moderate interstitial fibrosis. Diagnosis is made based on the clinical constellation of these findings [3]. Underlying causes of RCM can include endomyocardial fibrosis, Loffler's endocarditis, hemochromatosis, glycogen storage disease, and amyloidosis, however in many patients RCM is primary. Primary RCM is typically sporadic, with no family history, and there are increasing reports of inherited cases with an autosomal dominant mode of transmission and onset in childhood or early adulthood [1,2]. Thus, sporadic cases may represent de novo mutations, and it is possible that most or all of primary RCM may have a genetic origin. Mutation analysis of TNNI3, DES, MYOT, and CRYAB genes may be useful in testing for genetic etiology, although almost certainly additional causative genes will be found in the future [1]. Some of the features of restrictive, dilated, and hypertrophic cardiomyopathy can overlap, and similarly, mutations in some genes can lead to more than one type of cardiomyopathy (even within the same family) [1]. Immunohistochemical staining of cardiac muscle (and sometimes skeletal, especially if skeletal myopathy is present) with desmin antibodies can aid in the diagnosis of desminopathy [2].

## Therapeutic Principles

Patients with restrictive cardiomyopathy usually progress to heart failure and have a poor prognosis without heart transplantation.

# Restrictive Lung Disease

Alfredo Chetta, Dario Olivieri
Department of Clinical Sciences, Respiratory Disease Section, University of Parma, Parma, Italy

## Synonyms

Diffuse parenchymal lung diseases; Idiopathic pulmonary fibrosis; Interstitial lung disease; Sarcoidosis; Kyphoscoliosis; Neuromuscular disorders; RLD

## Definition and Characteristics

Restrictive lung disease (RLD) comprises a heterogeneous group of chronic disorders characterized by a decrease in the ability to expand the lungs, as a consequence of either inflammation and/or scarring of the lung parenchyma (diffuse parenchymal disease) [1] or disease of the components of the respiratory pump, such as the pleura, chest wall, and neuromuscular apparatus (extraparenchymal disease) (Fig. 1). There is no unique molecular pathogenetic mechanism in RLD, given the heterogeneity of the disease. Furthermore, the molecular pathophysiology of the different diseases comprised in RLD is not yet well known. This chapter deals with RLD due to diffuse parenchymal diseases.

## Prevalence

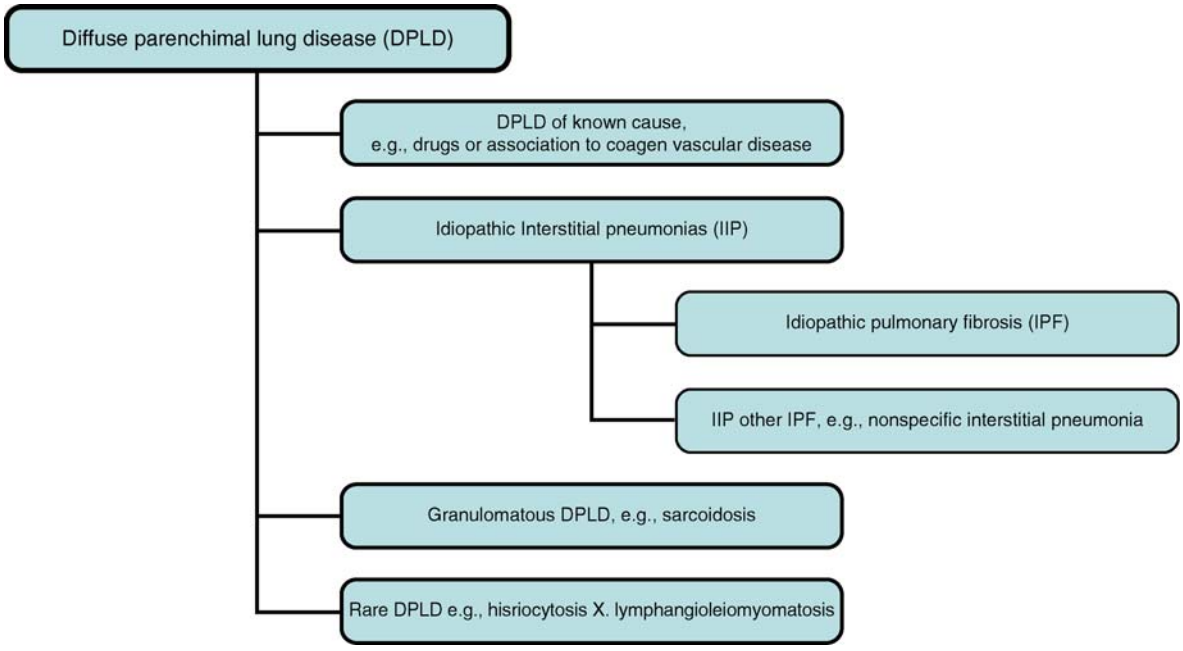
The prevalence of idiopathic pulmonary fibrosis (IPF) has been estimated to be around 3–8 cases per 100,000 people. The prevalence of sarcoidosis is 10–20 cases per 100,000 persons. Worldwide, sarcoidosis is slightly more common in women. The prevalence of sarcoidosis in the USA is estimated to be 10–17 times higher among African Americans compared with White Americans. Lymphangioleiomyomatosis and lung involvement in tuberous sclerosis occur exclusively in premenopausal women.

## Genes

Since a familial variant of IPF exists, a genetic predisposition has been suggested. Human leukocyte antigen (HLA) genes have been associated with sarcoidosis susceptibility. In hypersensitivity pneumonitis (HP), beryllium lung disease was found to be associated to HLA-DPB1 Glu-69, as well as farmer's lung and pigeon fancier's lung to HLA B8.

## Molecular and Systemic Pathophysiology

The role of inflammation in IPF is controversial and IPF is now considered to be an epithelial/fibroblastic disorder. In IPF, a complex network of cytokines (tumor necrosis factor (TNF)-α, transforming growth factor (TGF)-β), and chemokines (CCL17, CCL22, CCL2, and CCL3) favors the recruitment of fibroblasts, monocyte–macrophages, lymphocytes, immune deviation toward a helper T–cell type 2 cytokine profile, and fibroblast proliferation followed by production of extracellular matrix and neoangiogenesis. In the pathogenesis of sarcoidosis, interferon-γ, TNF-α, interleukin (IL)-12 and IL-18 play a critical role in driving the Th1 involvement in the granulomatosis process. An increased expression of endothelin-1, which is mediated by TNF-α, TGF-β, and IL-8, may occur in scleroderma, a collagen vascular disease involving the lung parenchyma. Endothelin-1, a vasoconstrictor and mitogenic peptide, may play a role in fibrosis and collagen production. In systemic lupus erythematosus, granular deposits of immunoglobulin G and complement C3 were found along the alveolar walls, the interstitium, and endothelial cells, supporting the view that alveolar damage is mediated by immune complex deposition. In



**Restrictive Lung Disease. Figure 1** Diagrammatic representation of diffuse parenchymal lung disease.

HP, after antigen challenge, alveolar macrophages are activated and an array of proinflammatory cytokines, such as TNF-α, IL-1, and IL-8 are produced. At the same time, regulatory cytokines, such as IL-10, are also secreted and may play a role in dampening the inflammatory responses.

Irrespective of the different molecular pathophysiologies, in diffuse parenchymal diseases, gas exchange is compromised at the alveolar–capillary interface, and arterial hypoxemia in these disorders is mainly caused by ventilation–perfusion mismatching.

### Diagnostic Principles

Patients with parenchymal diseases complain of progressive exertional dyspnea and dry cough. Velcro crackles are common in most patients with interstitial lung disorders. Reticular, nodular, or mixed patterns, such as alveolar filling (i.e., ground-glass appearance), and increased interstitial markings are common radiographic abnormalities. The finding of honeycombing correlates with advanced fibrosis and indicates a poor prognosis. High-resolution computed tomography of the chest allows earlier diagnosis of IPF and helps to narrow the differential diagnosis. Pulmonary function testing does not indicate a specific diagnosis. All disorders are associated with a restrictive ventilatory defect with preserved airflow. The diffusing capacity of the lung for carbon monoxide is reduced in all patients and may be abnormal even when the lung volumes are preserved. Arterial blood gas values at rest may reveal hypoxemia. Exercise-induced oxygen desaturation is a common finding. Sequential lung function tests are invaluable for monitoring the disease course and assessing the response to therapy [2]. Bronchoalveolar lavage may cast light on the cellular and molecular pathophysiology of the disease, but is rarely useful for the specific diagnosis. On the other hand, a lung biopsy can provide information that leads to a specific diagnosis, assesses for disease activity, and predicts the prognosis [3].

### Therapeutic Principles

Corticosteroids, immunosuppressive agents, and cytotoxic agents are the mainstay of therapy for many of the diffuse parenchymal lung diseases [3]. Interferon γ-1b is also prescribed in patients with IPF. Oxygen supply is an ancillary therapy, which alleviates exercise-induced hypoxemia and improves performance. Emerging strategies to treat IPF patients include agents that inhibit epithelial injury or enhance repair, anticytokines and agents that inhibit fibroblast proliferation or induce fibroblast apoptosis. Patients who do not respond to medical therapy and patients with severe functional impairment and a deteriorating course should be listed for lung transplantation.

►Usher Syndrome

## Retinitis Pigmentosa with Autosomal Inheritance

Klaus Ruether
Department of Ophtalmology CVK, Charité, Berlin, Germany

### Synonyms

Retinopathia pigmentosa; Rod-cone dystrophy; Rod-cone degeneration

### Definition and Characteristics

Retinitis pigmentosa (RP) is the name of a group of several inherited diseases leading to degeneration of rod and cone photoreceptors. The term “retinitis” is a kind of misnomer, as inflammation is not the primary pathophysiological event of this disorder. However, the denomination is propagated such broadly that the use of

"retinitis" is accepted worldwide. RP exists as non-syndromic diseases as well as a part of a systemic disease, the latter not being subject of this essay. Symptoms of the disease are night blindness beginning during childhood and a progressive loss of peripheral vision. This loss of visual field leads to tunnel vision and later, between the 1940s and 1960s, to a severe visual handicap up to blindness.

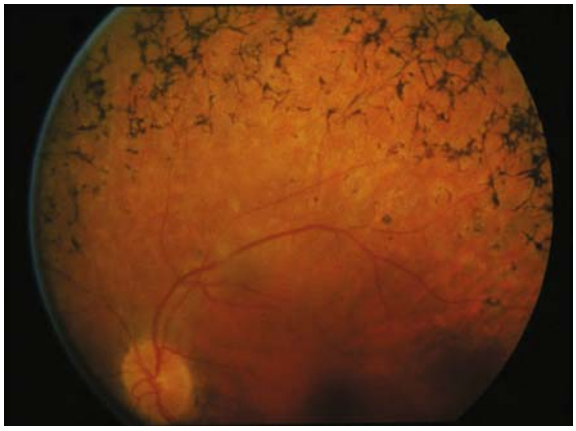
Morphologically, the disease is characterized by a bone-spicule-like pigmentation of the fundus (Fig. 1) sparing the macula at the beginning. Later on during life, the macula becomes also involved causing deterioration of visual acuity. Secondary changes of the fundus include optic atrophy, narrowing of retinal vessels, and opacities of the vitreous.

## Prevalence

1:4,000; in this number, the sex-linked disease is included that has a fraction of all RP cases of about 5–15%. The majority is autosomal recessive (including isolated cases, 50–60%) or autosomal dominant (30–40% of cases). RP is one of the leading causes for legal blindness in younger ages (20–60 years).

## Genes

For RP, the total number of identified autosomal genes and loci is 34. Out of those 27 genes have been identified (14 autosomal dominant, 13, autosomal recessive) (http://www.sph.uth.tmc.edu/Retnet/). RP is highly heterogenous and most of the genes are the cause of disease for only a very limited number of patients. One exception is rhodopsin, as mutations are cause of about 25% of autosomal dominant RP.



**Retinitis Pigmentosa with Autosomal Inheritance. Figure 1** Fundus photograph of a patient suffering from retinitis pigmentosa.

## Molecular and Systemic Pathophysiology

Due to the pronounced heterogeneity of the disease, there are a couple of different pathophysiological pathways in RP. Three important categories of proteins are important in which the absence or dysfunction leads to photoreceptor degeneration:

- Proteins of the visual transduction case including the visual cycle
- Proteins which are part of the cellular scaffold
- Proteins with general cellular functions

Errors in the visual transduction cascade are important reasons for retinal degeneration in RP. Although, the exact mechanisms are not known and it is conceivable that dys- or overfunction of this cascade may threaten photoreceptor survival. The best-known and frequent example is rhodopsin. It is also understandable that structural proteins as peripherin may have a deleterious effect on the cells if it is mutated. Many of the proteins with general cell functions are related to molecular transport in which defects may lead to deposits or loss of function. At the end of many if not all, pathophysiological processes related to RP the cell death is realized by apoptosis.

Typical RP begins with night vision problems due to a disease of the rod photoreceptor. However, the relevant problem for the patient is not the rod vision loss but the deterioration of cone vision. Therefore, one of the most important questions is how rod disease can lead to cone death. This is not completely understood but concepts like the rod-derived cone viability factor [1] are promising candidates last but not least for the development of therapeutic strategies.

## Diagnostic Principles

Diagnostic procedures for RP are well established. A carefully taken history often tells the kind of disease. The sequence night vision problems, such as visual field restriction, i.e., deterioration of visual acuity, represent the typical symptom cascade. Accordingly, examination of night vision (dark adaptometry), visual field (perimetry), and visual acuity are basic procedures. Pigment epithelium dystrophy and bone-spicule-like pigmentation of the fundus are often seen in RP patients but these features tend to be very variable and are sometimes not visible. Conversely, these signs are not specific and may represent a phenocopy of RP, e.g., in cases of postinflammatory retinopathies.

Due to this limitation, it is mandatory for each patient at least once in her/his life to undergo an electroretinographic examination (electroretinogram, ERG). Beside the establishment of the disease, it tells a lot about the specific kind of the disease and state of progression. Beside that, the multifocal ERG allows to determine the

central retinal function that is often preserved in RP and may serve as a valid objective parameter for progression.

There are some additional diagnostic techniques partly helping to find the diagnosis and others to deal with the complications. Optical coherence tomography (OCT) and fluoresceine angiography are valuable tools to find out about macular edema that may occur in the course of the disease. Recently, fundus autofluorescence has proved to be an important tool for early diagnosis and monitoring of progression.

There are some diagnostic tools outside ophthalmology, which are important. Very rarely, the determination of the phytanic acid level in the serum is mandatory to exclude Refsum's disease. This disorder is characterized by other neurological symptoms that, however, may be very subtle. Finally, molecular genetic tools gain increasing impact for the diagnosis, as more and more genes are known and the methods are getting easier and cheaper.

## Therapeutic Principles

Basically, there is no proven therapy for autosomal Retinitis pigmentosa. The first important task of a clinician establishing the diagnosis of RP is to rule out the presence of one of the very rare treatable forms of retinal degeneration, in particular, Refsums's disease (retinitis pigmentosa plus anosmia, deafness, polyneuropathy, dry skin, and cardiac conduction deficits), which can be treated by a phytanic acid restricted diet. The other treatable entity affecting adults is gyrate atrophy that can be recognized by the characteristic garland shaped zones of degeneration. For RP itself, there has been one therapy study implicating that the daily intake of 15,000 I.E. of vitamin A may be beneficial in terms of slowing down the progression of retinal function deterioration [2]. However, this study has been discussed controversially since its publication. Therefore, probably only a minority of patients has been treated this way. Since it has been observed that vitamin A may be harmful in ABCA4 knockout mice one should, be reluctant in advising the patient to take vitamin A unless the specific mutation is known. There is growing evidence that vitamin A is only beneficial in a subset of patients and genotyping has to be established.

There are many not proven interventions, offered to RP patients, called therapies. Some of the most prevalent are drugs affecting hemorheology, vitamins of different kinds, and acupuncture. The main problem of not evidence-based approaches is the risk that these interventions if effective at all may be beneficial but can also be harmful.

Due to the rapidly growing knowledge about the genetic and molecular basis of retinitis pigmentosa and allied diseases, the probability that therapeutic options will be available in the next 10–20 years has grown. In one of the early-onset forms of RP, the RPE65-related Lebers Amaurosis, gene therapy has been successful in a dog model and the application in humans is in preparation. In addition, this kind of therapy has been promising in several mouse models of other genetic defects. However, the potential risks are numerous and a careful planning is indispensable.

Other approaches are growth factors that have been shown to be beneficial in a number of mouse models [3]. Currently, there is a phase II/III trial in the US where the implantation a CNTF-releasing device into the vitreous is investigated (www. ClinicalTrials.gov). Although, there are also relevant theoretical risks as neovascularization or tumor growth, this approach appears to be feasible in the near future. One obvious advantage of is that it is not restricted to a certain gene defect.

There are numerous other approaches such as transplantation of retinal tissue, stem or precursor cells, docosahexaenoic acid, and antiapoptotic drugs, but none of them has shown to be beneficial in higher animal models or in humans. The development of artificial vision (retinal chip) has delivered promising results, but probably will only be useful for end-stage diseases.

# Retinitis Pigmentosa, X-chromosomal

Wolfgang Berger
Division of Medical Molecular Genetics and Gene Diagnostics, Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland

## Synonyms

RP2; RP3

## Definition and Characteristics

Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous group of retinal degenerations involving primarily the rod photoreceptor system. During disease progression, cones are also affected. RP is characterized by the premature death of photoreceptor cells, beginning in the periphery of the human retina. This leads to a progressive constriction of the visual field, to tunnel vision, and possibly complete blindness. There are sporadic and familial forms. The mode of inheritance is autosomal dominant (30–40%) or recessive (50–60%), or X-linked recessive (5–15%). More than 40 autosomal genes were associated with RP and the clinical variability or expressivity of a mutation even within families is very remarkable. The X-linked forms are more severe in terms of onset and progression. Most autosomal RPs have an age of onset in the third or fourth decade of life while the X-linked forms can start as early as in the first or second decade. Frequently, night blindness (insensitivity to dim light conditions) is one of the first symptoms of RP. According to the X-chromosomal mode of inheritance, the recurrence risk for male offspring of a female mutation carrier is 50% and half of their daughters are mutation carriers. There is no male to male transmission of the mutations.

## Prevalence

The prevalence of RP may vary in different populations (average: 30–40/100,000).

## Genes

The genes that carry mutations in patients with X-chromosomal RP were designated RP2 and RPGR (Retinitis pigmentosa GTPase regulator) and are located in Xp11.3 and Xp11.4, respectively. Both genes were identified by positional cloning approaches [1–3].

RPGR and RP2 are the major X-chromosomal genes and are mutated in 60–80 and 10–20% of all X-linked cases, respectively. Additional loci on the human X chromosome have been identified by genetic linkage studies but the underlying mutations are still unknown. Likely, these genes only account for a minority of X-linked RP cases. The functions of RP2 and RPGR are not yet understood in detail. The RPGR gene consists of at least 21 exons and shows an exceptional high degree of tissue-specific alternative splicing. One of the exons, designated ORF15, represents a mutation hotspot [4]. Sequence alterations in this exon may account for as much as 50–60% of all X-linked RP cases. The RP2 gene consists of five exons and codes for a predicted polypeptide of 350 amino acid residues. This protein contains a domain with homology to cofactor c, a protein involved in the ultimate step of beta-tubulin folding. Most of the mutations in RP2 lead to a premature stop of translation.

## Molecular and Systemic Pathophysiology

Important diagnostic measures include electroretinography, dark adaptometry, Goldmann perimetry (visual field testing), and fundus photography. Upon ERG, a reduced response of the rod photoreceptors can be observed. The visual field becomes more and more constricted during disease progression and fundi of RP patients contain attenuated blood vessels and characteristic pigment changes in the retinal periphery.

The RPGR protein has been localized to the connecting cilium of photoreceptor cells and might be involved in protein transport between the inner and outer segments of photoreceptor cells. It interacts with another protein located in the connecting cilium (RPGRIP1, RPGR interacting protein 1), which is mutated in patients with a more severe form of retinal degeneration called Leber congenital amaurosis (LCA). The designation RPGR refers to homology of the N terminus of the predicted protein to RCC1 (regulator of chromatin condensation 1), which is thought to be a guanine nucleotide exchange factor of the Ras-like GTPase Ran. It has not been proven so far that RPGR indeed regulates GTPase activity. Few patients with RPGR mutations show a ciliary dyskinesia phenotype or more complex disease symptoms including hearing loss, sinusitis, and chronic recurrent infections of the respiratory system. In general, female carriers are asymptomatic but a few exceptions exist that might be due to nonrandom X chromosome inactivation or dominant mutations. Indeed, some families with a dominant mode of inheritance of RPGR mutations have been described.

The RP2 gene product has been localized to the intracellular surface of the plasma membrane. It translocates into the nucleus upon DNA damage and exhibits exonuclease activity [5].

## Diagnostic Principles

The clinical diagnosis is based on electroretinography, visual field testing, and funduscopy. There are no clinical criteria for discrimination between X-chromosomal and autosomal forms of RP. Based on the family history and pedigree, X-linked inheritance can be diagnosed in families where only males are affected and no male to male transmission occurs. This is difficult, however, in small nuclear families with only one or two affected males. Molecular genetic testing is performed by sequencing of patients' DNA or other methods for mutation screening (e.g., microarrays). Molecular confirmation is needed for reliable genetic counseling of affected individuals and their families including the calculation of the recurrence risk.

## Therapeutic Principles

Currently, there is no cure for any form of the premature death of photoreceptor cells due to RP. It has been

shown in model systems that growth factors and neuroprotective factors can significantly slow down the degenerative processes and preserve vision. These observations may lead to therapeutic interventions in the future. In addition, gene therapy might be an alternative to treat X-chromosomal recessive forms of RP.

# Retinoblastoma

Dietmar Lohmann
Department of Human Genetics, University Duisburg-Essen, Essen, Germany

## Synonyms

Glioma retinae

## Definition and Characteristics

Retinoblastoma (Rb) is a cancer of the eye that originates from the developing retina. It is usually diagnosed in children under age of 5 years. A white pupillary reflex (leukocoria) or strabismus is the most common presenting signs. Rb can affect one eye (unilateral Rb, 60% of patients) or both eyes (bilateral Rb, 40%). Children with bilateral Rb often have multiple tumor foci. About 10–15% of patients have a positive family history (familial Rb). In some families, a parent or other close relative only has retinal scars or quiescent tumors (retinomas). More than 95% of patients with unilateral Rb and about 75% of patients with bilateral Rb have no family history of Rb (sporadic Rb). Patients with bilateral Rb have an increased risk to develop neoplasms outside of the eye (second tumors), including sarcoma and malignant melanoma. Second tumors are more frequent in patients treated by external beam radiation.

## Prevalence

1:15,000 to 1:20,000.

## Genes

RB1.

*Structure of the RB1 Gene*: The RB1 gene contains 27 exons in 180 kb on chromosome band 13q14. The 4.7 kb mRNA contains a single 2.7 kb open reading frame. It codes for a 928 amino acids nuclear protein that, dependent on the state of phosphorylation, enables the cell to pass to the S phase of the cell cycle. Several other functions have been documented.

*Spectrum of RB1 Gene Mutations*:

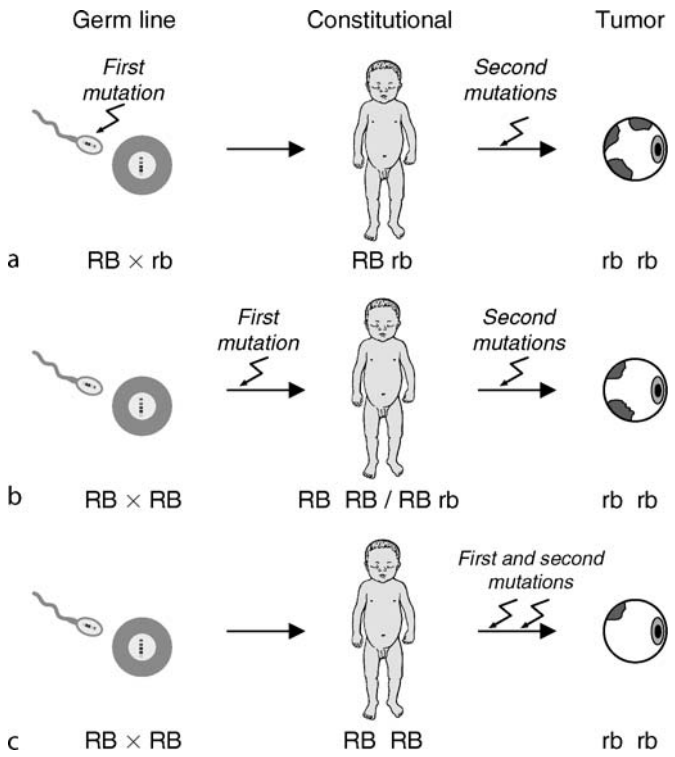
- Large rearrangements: large deletions or duplications of parts of the RB1 are detected in about 20 and 5% of patients with bilateral/familial and unilateral Rb, respectively.
- Point mutations: most patients with bilateral/familial Rb are heterozygous for single base substitutions or small length mutations. Although the spectrum of point mutations is heterogeneous, most result in premature termination codons.
- In 70% of tumors, somatic inactivation of one of the RB1 alleles is accompanied by loss of heterozygosity (LOH) at loci in chromosome 13q14.
- Somatic hypermethylation of the CpG-rich island at the 5′-end of the RB1 gene is detected in about 10% of Rbs and causes gene silencing.

## Molecular and Systemic Pathophysiology

Rb is caused by two mutations.

Development of Rb depends on mutations of both RB1 alleles (Fig. 1). The timing of the first mutation determines the genetic form of retinoblastoma:

1. Familial Rb: the first RB1 gene mutation has occurred in an ancestor and is transmitted via the germline. Family members who have inherited the mutant allele are heterozygous. Inactivation of the other, normal allele occurs in somatic cells (Fig. 1a).



**Retinoblastoma. Figure 1** Hereditary and non-hereditary retinoblastoma are distinct by the timing of the first mutation.

2. Most patients with sporadic bilateral Rb: the first mutation has occurred de novo in the germline of one of the parents (Fig. 1a).
3. Some patients with sporadic bilateral or sporadic unilateral Rb: the first mutation has occurred de novo during embryonal development of the patient. Rb development is initiated if a second mutation inactivates the normal allele in a cell that is part of the mutant sector (Fig. 1b).
4. Most patients with sporadic unilateral Rb: both mutations occur in somatic cells (Fig. 1c).

*Inheritance and Genotype-Phenotype Associations*: Patients heterozygous for a mutation (Fig. 1a) have hereditary predisposition to Rb. Carriers of premature termination mutations almost invariably develop bilateral Rb and families with mutations of this kind show autosomal dominant inheritance with complete penetrance. Missense changes, promoter mutations, and in-frame deletions are rare and usually are associated with incomplete penetrance and milder expression (unilateral Rb). Patients with mosaicism (see Fig. 1b) usually show milder phenotypic expression and can transmit predisposition to Rb only if germline cells are among the descendants of the first cell with the mutation. Most patients with sporadic unilateral Rb have no mutant RB1 alleles in their germline (see Fig. 1c).

**Retinoblastoma. Table 1**

| Clinical presentation | Risk to siblings | Risk to offspring |
|---|---|---|
| Sporadic unilateral Rb | ≤1% | 2–6% |
| Sporadic bilateral Rb | ≤2% | Close to 50% |
| Familial Rb | | |
| - Complete penetrance | Close to 50% | 50% |
| - Incomplete penetrance | <40% | <40% |

**Retinoblastoma. Table 2**

| Clinical presentation | Genetic analyses |
|---|---|
| Sporadic unilateral Rb | Mutation identification in DNA from tumor; two mutations have to be identified |
| Sporadic bilateral Rb | Identification of the predisposing mutation in DNA from peripheral blood or from tumor; because of mutational mosaicism in some patients, analysis of tumor DNA is preferred |
| Familial Rb | Mutation identification in DNA from peripheral blood of patients that have inherited a mutant allele |

### Diagnostic Principles

Diagnosis of Rb is established by examination of the fundus of the eye using indirect ophthalmoscopy. Histopathologic analysis can confirm diagnosis of Rb but is possible only after the eye is removed (enucleation).

Relatives of all patients with RB are at an increased risk to carry a predisposing RB1 gene mutation and, consequently, tumor development (Table 1).

In most cases, accurate risk prediction in relatives depends on identification of the mutation that caused Rb in the index patient (Table 2).

### Therapeutic Principles

Treatment of patients with Rb depends on tumor stage, the number of tumor foci in the eye, presence of vitreous seeding, and the age of the child. Treatment options include enucleation, external beam radiation, cryotherapy, photocoagulation, brachytherapy with episcleral plaques, and chemotherapy combined with local therapy. Prognosis is excellent if the tumor has not invaded extraocular tissues. Metastasizing Rb often has a fatal outcome.

## Retinopathia Pigmentosa

►Retinitis Pigmentosa with Autosomal Inheritance

## Retinopathy, Diabetic

Gabriele E. Lang
University Eye Hospital Ulm, Ulm, Germany

### Synonyms

Diabetic retinal microangiopathy; Diabetic macular edema; Proliferative diabetic retinopathy

### Definition and Characteristics

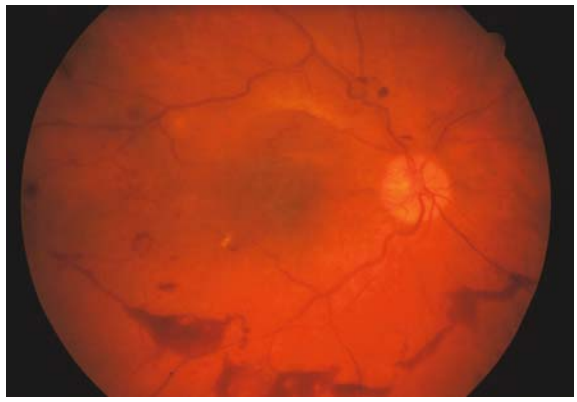
Diabetic retinopathy (DR) is characterized by vascular changes of the retina [1]. The classification is based on intra- and preretinal microvascular changes. It is divided into nonproliferative and proliferative DR (Fig. 1).

In nonproliferative DR, vascular changes are limited to the retina. The nonproliferative DR can progress to proliferative DR characterized by preretinal new vessel formation. The first morphological changes are microaneurysms. Further findings are hemorrhages, macular edema, deposits of hard exudates, cotton wool spots, venous beading, and intraretinal microvascular anomalies. In the later stages, preretinal neovascularization develops on the disc or elsewhere. Vision loss occurs with either center involving macular edema or vitreous hemorrhage.

### Prevalence

Diagnosed diabetes mellitus is most prevalent in the middle-aged and elderly population [1]. About 90% of the patients have type 2 diabetes. Duration of diabetes and severity of hyperglycemia are the major risk factors for DR. The prevalence of any DR is about 98% after 20 years and about 50% for proliferative DR after 15 years of type 1 diabetes mellitus; 50–80% of type 2 diabetic patients have DR after 20 years, and 10–30% have proliferative DR. A clinically significant diabetic macular edema is found in 15% of type 1 and 25% of type 2 diabetic patients after 15 years. Additional independent risk factors are arterial hypertension and hyperlipoproteinemia. Good glycemic control (HbA1c < 7%), good blood pressure control (≤135/85 mm Hg), and treatment of dyslipidemia are therefore mandatory.

Only 35–50% of patients with diabetes mellitus receive regular eye examinations, which are important for timely diagnosis and proper treatment. Better patient education and screening programs are needed to reduce the risk of blindness from DR.



**Retinopathy, Diabetic. Figure 1** Proliferative diabetic retinopathy with preretinal hemorrhage (*arrows*).

## Genes

An association was found between proliferative DR and the presence of HLA-DR phenotypes 4/0, 3/0, and X/X. There seems to be a mutation in the aldose reductase gene with increases susceptibility of DR in type 2 diabetics. An association of TGF-beta T869C gene polymorphism seems to be associated with an increased risk of DR. A genome-wide linkage analysis found evidence of linkage on chromosomes 1p, 3, and 12. VEGF gene polymorphism is an independent risk factor for DR in type 2 diabetes.

## Molecular and Systemic Pathophysiology

Molecular mechanisms and pathophysiology are complex [2]. Hyperglycemia leads to the development of advanced glycation endproducts, activation of the polyol pathway, and changes in the signal transduction. Results are hyperviscosity, prothrombotic and proinflammatory milieu, and oxidative stress. Histological loss of pericytes and endothelial cells, capillary closure, and preretinal neovascularization are found. Several growth factors are involved, the most important being vascular endothelial growth factor and insulin-like growth factor 1.

## Diagnostic Principles

Diabetic retinopathy can be detected with dilated pupil by ophthalmoscopy and stereoscopic biomicroscopy with the slit lamp [1].

Fundus photography helps to detect early stages of DR and neovascularization. For screening purposes nonmydriatic cameras are available.

Fluorescein angiography provides information about retinal perfusion, breakdown of the blood–retinal barrier, and neovascularization. It is helpful to detect macular edema, ischemic maculopathy, and proliferative DR.

The diagnosis and management of diabetic retinopathy is improved by imaging of ocular tissues by optical coherence tomography (OCT). It produces reliable, reproducible, and objective retinal images especially in diabetic macular edema, epiretinal membranes, and vitreoretinal traction. With the OCT, structural changes and quantitative assessment of macular edema are feasible as determined with retinal thickness and volume. OCT is based on the analysis of the reflections of low coherence radiation from tissue. Increased foveal thickness of ≥300 μm (normal 150 ± 20 μm) seems to correlate with significant visual loss due to diabetic macular edema.

## Therapeutic Principles

Tight glycemic and blood pressure control significantly reduces the incidence and progression of DR, but is difficult to achieve in clinical practice.

The gold standard is laser treatment of focal and diffuse diabetic macular edema and proliferative DR. The 5-year risk of blindness is reduced by 90% in proliferative diabetic retinopathy, and the risk of moderate visual loss from macular edema is reduced by 50–70%. In proliferative DR, panretinal laser treatment is done in about four laser sessions [1,3]. In macular edema, a focal laser treatment is performed in circumscribed edema with leaking microaneurysms. In diffuse macular edema, a grid laser treatment is applied to the whole macular area.

Early vitrectomy improves visual recovery in patients with proliferative DR and severe vitreous hemorrhage [4,5].

Off-label intravitreal injections of VEGF inhibitors or triamcinolone might be considered in special cases as an add-on treatment or where gold standard treatment has failed. Pharmacological interventions are still under investigation and there is no sufficient evidence at present for the efficacy. Therefore it cannot be currently recommended as routine use in DR.

Gene therapy is challenging because multiple genes are involved and of the difficulty to deliver vectors. Approaches include nanoparticles, loposomes, and iontophoresis. Helper-dependent adenovirus for the gene therapy shows stable gene transfer, regulated gene expression, and therapeutic efficacy in preclinical studies.

# Retractile Mesenteritis

►Mesenteric Lipodystrophy

# Retroperitoneal Xanthogranuloma

►Mesenteric Lipodystrophy

# Rett Syndrome

Peter Huppke
Department of Pediatric Neurology, Georg August University, Goettingen, Germany

## Definition and Characteristics

X-chromosomal disorder leading to mental retardation, loss of purposeful hand use in females and epilepsy.

*Clinical Features*: Rett syndrome (RTT[MIM 312750]) was first described in 1966 by Andreas Rett; however, international recognition was not until 1983 when Hagberg et al. described 35 patients [1,2]. The neurodevelopmental disorder is characterized by severe mental retardation, stereotypic hand movements, deceleration of head growth, and epilepsy. An initial period of normal or almost normal development that lasts 8–18 months is followed by a phase of stagnation and then motor and mental regression notably affecting hand function and speech. After this phase of rapid regression, the condition stabilizes and during the following years and decades, a very slow decline in motor abilities might be noted while the mental status remains stable. The spectrum of clinical phenotypes is extremely wide. Some girls never learn to sit, walk, and communicate while others only have a mild motor and mental handicap [3]. Very few males with Rett syndrome have been described. The clinical phenotype in boys varies from a severe encephalopathy that leads to death in the first year of life to unspecific mental retardation.

## Prevalence

Rett syndrome occurs almost exclusively in females with an estimated prevalence of 1 in 15,000 births.

## Genes

MECP2-gene coding for the methyl-CpG-binding protein 2 (MeCP2), localized on Xq28.

In 1999, the first mutations in the MECP2 gene causing Rett syndrome were reported [4]. Since then more than 200 different mutations have been described and can now be detected in more than 80% of girls suspected of Rett syndrome. In another 10–15% of patients, large deletions affecting the MECP2 gene can be found. Missense mutations cause a milder phenotype than nonsense mutations. In some cases, the phenotype can be very mild due to skewed X inactivation.

## Molecular and Systemic Pathophysiology

The MECP2 gene codes for the MeCP2, which is involved in the transcriptional control of genes. It binds to methylated CpGs in promoter regions and interacts with several different proteins that either enhance or reduce the expression of genes. Different mouse models of Rett syndrome are available that displays some of the features of human disorder.

**Rett Syndrome. Table 1** Necessary and supportive criteria for Rett syndrome according to [5]

| Necessary criteria |
|---|
| • Apparently normal prenatal and perinatal history |
| • Psychomotor development largely normal through the first 6 months or may be delayed from birth |
| • Normal head circumference at birth |
| • Postnatal deceleration of head growth in the majority |
| • Loss of achieved purposeful hand skill between ages 1½–2½ years |
| • Stereotypic hand movements such as hand wringing/squeezing, clapping/tapping, mouthing, and washing/rubbing automatisms |
| • Emerging social withdrawal, communication dysfunction, loss of learned words, and cognitive impairment |
| • Impaired (dyspraxic) or failing locomotion |
| **Supportive criteria** |
| • Awake disturbances of breathing (hyperventilation, breath-holding, forced expulsion of air or saliva, air swallowing) |
| • Bruxism |
| • Impaired sleep pattern from early infancy |
| • Abnormal muscle tone successively associated with muscle wasting and dystonia |
| • Peripheral vasomotor disturbances |
| • Scoliosis/kyphosis progressing through childhood |
| • Growth retardation |
| • Hypotrophic small and cold feet; small, thin hands |

## Diagnostic Principles

The clinical diagnosis is based on the clinical diagnostic criteria that were revised recently [5]. The diagnosis is confirmed by mutation and deletion analysis of the MECP2 gene.

## Therapeutic Principles

An effective therapy is currently not available; treatment is restricted to appropriate management of intervening problems such as control of seizures.

# Reye Syndrome

Johannes Häberle[1], Jean-Marc Nuoffer[2]
[1]Department of Pediatrics, University Hospital of Muenster, Muenster, Germany
[2]Institute of Clinical Chemistry, Inselspital, University Hospital and University of Bern, Bern, Switzerland

## Synonyms

Reye's syndrome

## Definition and Characteristics

Reye syndrome (RS) is a severe pediatric disorder characterized by an acute noninflammatory encephalopathy and fatty degeneration of the liver but it is not a clinical entity [1,2]. RS was first described in 1963 by Reye and colleagues. The illness is typically biphasic, with an apparent near-recovery from a viral type prodromal illness followed after a few days by persistent or recurrent vomiting, personality changes such as irritability, disorientation or confusion, delirium, convulsions, and loss of consciousness. The condition is associated with viral infections (varicella, influenza), with the exposure to toxins and drugs such as aspirin during a viral illness [3,4], and most importantly with underlying inherited metabolic disorders [5].

## Prevalence

Peak ages are between 5 and 14 years. The syndrome is rare in early infancy and adulthood. On the basis of the CDC (Center for Disease Control and Prevention), data from the USA, regional viral epidemics led to an incidence as high as 6 cases per 100,000 children younger than 18 years. According to data from France before the warnings of the use of aspirin but after extensive exclusion of an underlying metabolic disorder, the incidence of RS was 0.79/1,000,000 in children <15 years [1]. Potentially, as a result of both the decreased use of aspirin in pediatric viral illnesses [2] and the increased awareness of underlying metabolic disorders [5], the syndrome became rare.

## Molecular and Systemic Pathophysiology

The full pathogenesis is unknown but involves a generalized loss of mitochondrial function, which results in disturbances in fatty acid β-oxidation and urea cycle. More than 90% of patients had at least one viral episode (especially influenza B and A, varicella) during 3 weeks preceding the onset of RS (CDC surveillance from 1980 to 1997; [2]). Many of the affected children have been exposed to mitochondrial toxins, often salicylates (detectable in blood of >80% of patients during the CDC surveillance) but also insecticides, herbicides, aflatoxins, and others have an underlying inherited metabolic disorder. Histological studies show cytoplasmatic microvesicular fatty vacuolization in liver and other organs. In addition, mitochondria are reduced in number and show a pleomorphic and swollen appearance. However, these changes are not specific. As a result of the mitochondrial dysfunction, hyperammonemia occurs leading to astrocyte swelling, cerebral edema, and increased intracranial pressure.

## Diagnostic Principles

The diagnosis of RS should be suspected when confronted with an acute noninflammatory encephalopathy and hepatopathy in a child. There is, however, no specific test for RS, so the diagnosis must be one of exclusion and a thorough metabolic work-up should be

performed in any patient if possible in the acute phase of the disease:

- Free fatty acids (serum or plasma), ketone bodies (plasma)
- Organic acid profile (native spot urine) by GC–MS
- Orotic acid (native spot urine) by HPLC
- Reducing substances (urine) with Clinitest
- Amino acids (plasma and urine) by HPLC or cation exchange chromatography
- Carnitine, free and total (serum) by Tandem mass spectrometry
- Acylcarnitine esters (serum or on a Guthrie card) by Tandem mass spectrometry

Eventually specific loading tests or enzymatic studies may be necessary for further investigation of a suspected metabolic disorder.

The CDC proposed the following diagnostic criteria with all of them required:

- Acute, noninflammatory encephalopathy documented clinically by (i) an alteration in consciousness and (ii) a record of the cerebrospinal fluid containing $\leq 8$ leukocytes/mm$^3$ or a histologic specimen demonstrating cerebral edema without perivascular or meningeal inflammation associated with (i) a microvesicular fatty metamorphosis of the liver on histology or (ii) a greater than equal to threefold increase in the levels of the serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), or serum ammonia.

## Therapeutic Principles

Although there is no specific treatment available, early initiation of a closely monitored symptomatic therapy is vital to ensure full recovery without neurological sequelae. Correction of hypoglycemia and metabolic acidosis should be ensured as well as maintenance of the vital parameters. Special attention should be paid for the prevention of increased intracranial pressure, which is the major cause of morbidity and mortality (e.g., by avoidance of fluid overload, by elevation of the head). Medical treatment of hyperammonemia might be tried by using sodium phenylbutyrate or sodium benzoate but both drugs require acetyl-CoA for their action that might be lacking in the patients liver. High levels of ammonia, therefore, require extracorporeal detoxification, best by hemodialysis.

The prognosis largely depends on the severity and duration of the neurological phase of RS. With early recognition and prompt initiation of therapy, complete recovery is reported for between 62% [2] and 77% [1] of the patients. Surviving patients often have neurological impairment, particularly, as a result of profound and longstanding hyperammonemia. Death is usually the result of the increased intracranial pressure but can also be caused by myocardial dysfunction and multiple organ failure.

## Synonyms

ARF

## Definition and Characteristics

Acute rheumatic fever (ARF) is an immune mediated multi-system inflammatory disease that follows infection by streptococcus pyogenes. It occurs predominantly in children aged 5–15 years. ARF is an acute febrile illness, characterized by inflammation of several tissues, which gives rise to one or more of the following manifestations, carditis (mainly valvulitis), arthritis, chorea, erythema marginatum and subcutaneous nodules. Whilst damage to the joints, brain, skin and subcutaneous tissues is self-limited and benign, damage to cardiac valvular tissue may become chronic and lead to rheumatic heart disease.

## Prevalence

The incidence of ARF decreased dramatically in industrialized nations in the twentieth century to rates of less than 1 per 100,000 in children aged 5–14 years, although outbreaks of ARF in the United States have been described over the past 20 years. ARF is a disease of poverty and therefore the major burden of disease lies in developing countries and in economically disadvantaged indigenous populations in industrialized countries [1]. The incidence of ARF in school aged - children in these populations ranges between 30 and 250 per 100,000. The difference in epidemiology between industrialized and developing countries is almost certainly due to environmental factors such as poor living conditions, overcrowding and access to health care.

## Genes

Between 3 and 6% of any given population appears to have the potential to develop ARF following infection by s. pyogenes. Family studies have indicated that this susceptibility has a genetic basis. However, a specific gene that plays a clear role in the pathogenesis of ARF has not been identified. Investigation into human leukocyte antigens has suggested associations with various Class II alleles, but these associations are inconsistent across different populations. The most consistent marker of susceptibility appears to be the B-cell non-HLA antigen D8/17. Studies in families suggest that this marker is possibly inherited in an autosomal recessive fashion.

## Molecular and Systemic Pathophysiology

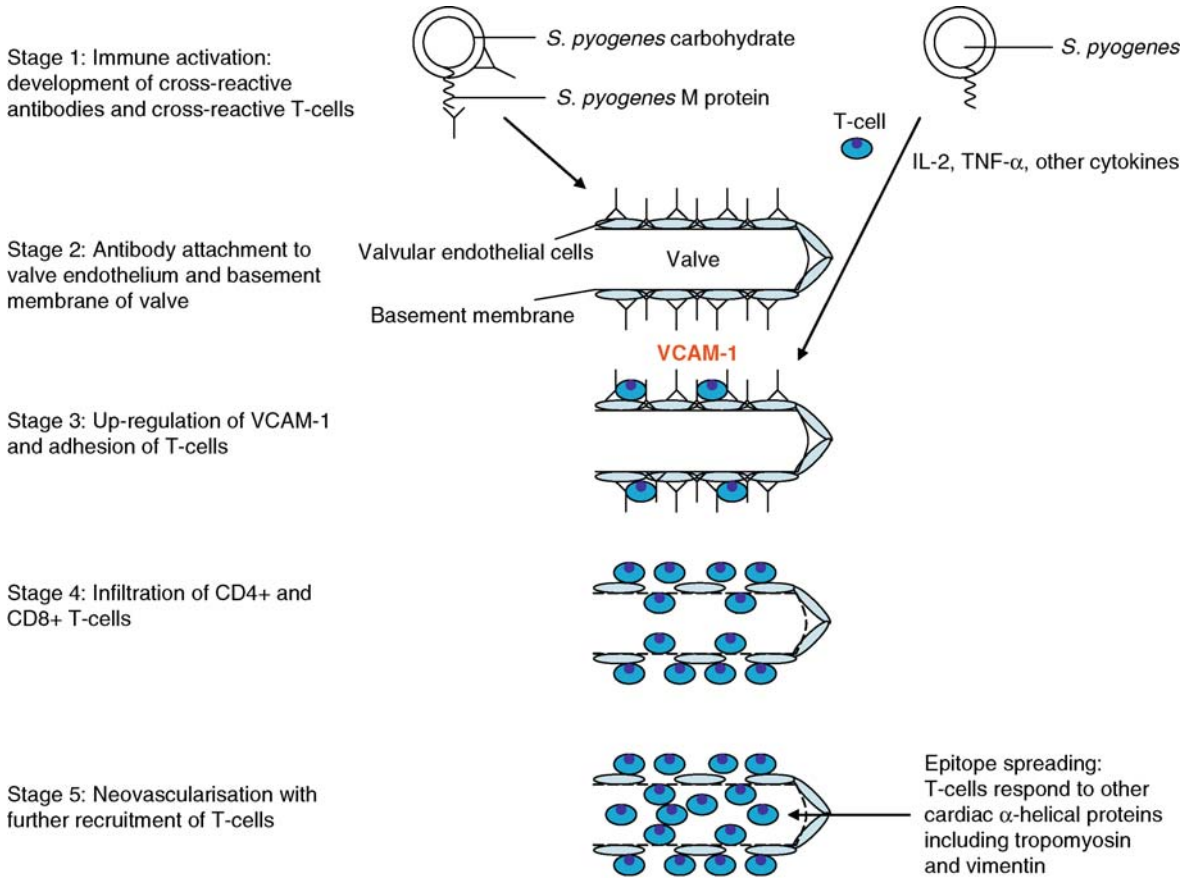
Although it is clear that ARF is an autoimmune disease, the exact pathological mechanism has not been elucidated. It is believed that both cross-reactive antibodies and cross-reactive T-cells play a role in the disease. Molecular mimicry between s. pyogenes antigens and human host tissue is thought to be the basis of this cross-reactivity [2]. Putative cross-reactive epitopes on s. pyogenes are the M-protein and N-acetyl glucosamine, among others. The M-protein is located on the surface of the bacteria and is the major virulence factor of s. pyogenes. N-acetyl glucosamine is the immunodominant epitope of the group A streptococcal carbohydrate. Monoclonal antibodies against both of these antigens cross-react with cardiac myosin and other α-helical cardiac proteins such as laminin, tropomyosin, keratin and vimentin as well as proteins in other target organs involved in ARF. The α-helical coiled-coil structure of the M-protein is of particular interest as it has conformational homology with these human cardiac proteins. Epitope sharing with cardiac myosin and laminin has been mapped to amino acid sequences within the B- and C-repeat regions of the M-protein. Human T-cell clones from the peripheral blood of patients with ARF proliferate in response to the B-repeat region of the M-protein and to epitopes in the S2 and LMM regions of human cardiac myosin.

It has been proposed that the carditis of ARF is initiated by cross-reactive antibodies that recognize the valve endothelium and laminin (Fig. 1) [3].

It is also been proposed that T-cells cross-reactive with M-protein migrate from the periphery to the heart. Vascular cell adhesion molecule-1 (VCAM-1) is up-regulated at the valve and aids in recruitment and infiltration of these T-cells. The T-cells initiate a predominantly TH1 response with the release of γ-IFN. Inflammation leads to neovascularization, which allows further recruitment of T-cells. It is believed that epitope spreading may occur in the valve whereby T-cells respond against other cardiac proteins such as vimentin and tropomyosin, leading to granulomatous inflammation and the establishment of chronic rheumatic heart disease.

## Diagnostic Principles

Diagnosis of ARF is made on clinical grounds by use of the Jones criteria, which require the presence of certain clinical manifestations and evidence of recent infection with s. pyogenes to make the diagnosis [4]. Carditis, polyarthritis, chorea, erythema marginatum and subcutaneous nodules have been designated as major



**Rheumatic Fever, Acute. Figure 1** Diagrammatic representation of the immuno-pathogenesis of acute rheumatic fever at the level of cardiac valvular tissue.

manifestations, fever, monoarthritis or polyarthralgia, raised inflammatory markers and prolonged PR interval on electrocardiogram as minor manifestations. Recent scarlet fever, growth of or positive antigen test for s. pyogenes from a throat swab or positive serology for s. pyogenes are sought as evidence of preceding infection. A diagnosis of a first episode of ARF requires that two major or one major and two minor manifestations are present in addition to evidence of recent s. pyogenes infection. A World Health Organization expert group subsequently recommended that, in patients with pre-existing rheumatic heart disease, an ARF recurrence may be diagnosed in the presence of only two minor manifestations and evidence of recent s. pyogenes infection [4].

## Therapeutic Principles

The initial priority in management is to confirm the diagnosis of ARF and sometimes treatment may need to be delayed until a clear diagnosis can be made [5]. Non-steroidal anti-inflammatory drugs are very effective in reducing fever and the pain caused by arthritis. Milder cases of chorea can be managed without medication, but valproic acid or carbamazepine may be used in severe cases. Diuretics are important in the treatment of heart failure due to carditis. Corticosteroids may be used in the treatment of severe carditis, but there is no evidence they have an effect on long-term outcome. The only treatment that can reduce the likelihood or severity of subsequent rheumatic heart disease is long term and regular antibiotic secondary prophylaxis to prevent recurrences of ARF. All patients with a diagnosis of ARF should be started on 3- or 4-weekly injections of benzathine penicillin G. The duration of secondary prophylaxis depends upon the severity of the valvular involvement with very mild cases requiring at least 5 years of treatment and severe cases often requiring lifelong treatment.

# Rheumatoid Arthritis

Iain B. McInnes
Division of Immunology, Infection and Inflammation, Glasgow Biomedical Research Centre, University of Glasgow, Glasgow, UK

## Synonyms

None in common usage

## Definition and Characteristics

Symmetrical inflammatory arthropathy, incident across a broad age range (median onset sixth decade), characterized by articular pain, stiffness (especially in the morning), swelling and loss of function. Onset can be in any diarthrodial joint, but distribution typically includes metacarpal and proximal interphalangeal (IP) joints of hand, metatarsal and IP joints of the foot, knee, hip and shoulder joints, and axial skeleton, particularly cervical spine. Synovial inflammation is associated with progressive cartilage and bone erosion, consequent deformity and accelerated functional decline. Extra-articular clinical features include scleritis, uveitis, pulmonary nodule formation (rarely bronchiolitis), neuropathy, small vessel vasculitis, and extensor surface nodule formation. Accelerated atherogenesis and cardiac failure account for reduced life expectancy (3–15 years). Rapid functional impairment, socio-economic decline, reduced employment prospects and poor educational achievement are all associated with disease.

## Prevalence

Current estimates around 0.8–1% in Caucasian populations. Incidence reducing for reasons as yet unclear. Isolated communities with high prevalence identified in native North American populations.

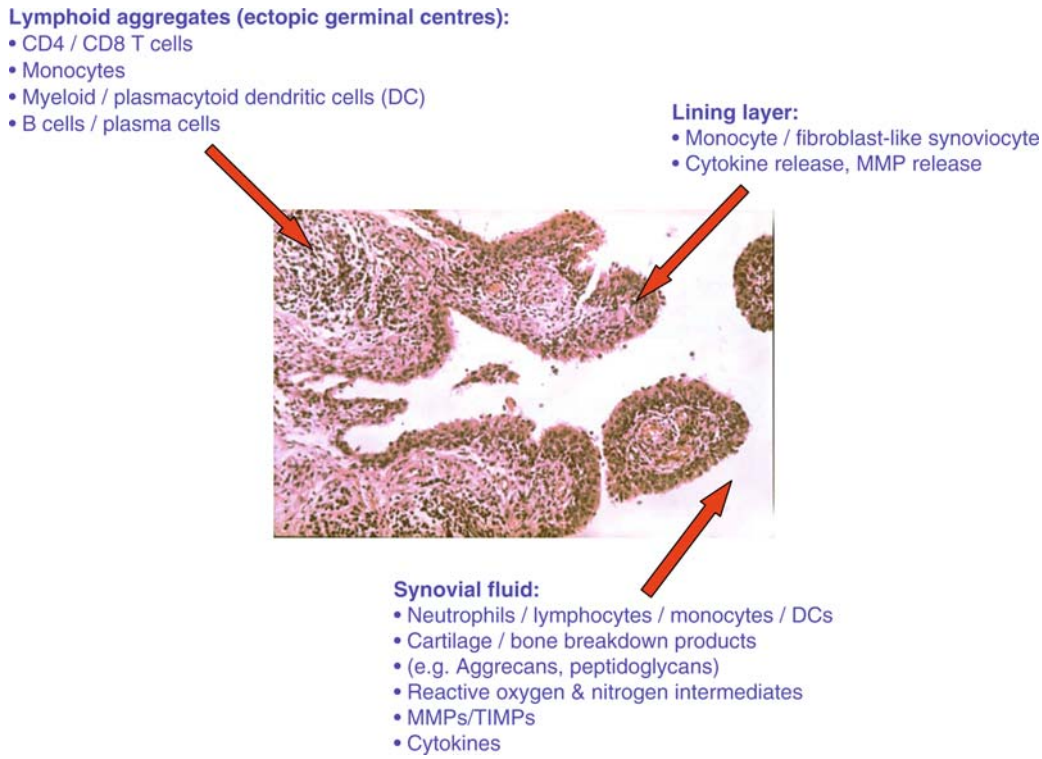
## Genes

A multigenic disorder: monozygotic twin concordance approximately 30%. Disease incidence and severity related to HLA DR1, DR4 – disease related MHC class II alleles exhibit common amino acid motif in peptide-binding groove (QKRAA) termed "shared epitope." Recent association and linkage studies implicate PTPN22 as second established genetic susceptibility locus for RA [1]. Numerous association studies implicate polymorphisms in immune related genes e.g. TNFα, IL-10 and complement products.

## Molecular and Systemic Pathophysiology

RA comprises a chronic inflammatory syndrome associated (perhaps causally) with autoimmunity (Fig. 1).

Inflammatory infiltration of the normally relatively acellular synovial membrane represents the pathognomonic lesion in RA and accounts for the cardinal clinical features [2]. The infiltrate exhibits characteristic microarchitecture comprising a 5–10 cell lining layer containing predominantly macrophages and fibroblast-like synoviocytes (FLS) retained via a cadherin-11 dependent pathway (but lacking a basement membrane), overlying a deeper interstitial area containing FLS, macrophages, T and occasional B lymphocytes, plasma cells, mast cells, myeloid and plasmacytoid dendritic cells. Lymphoid aggregates are detected in a majority of tissues and may resemble ectopic germinal centers (containing CXCL13, CCL21); these increase in frequency with disease duration and may be associated with poorer prognosis. Proliferative neovascularization and lymphangiogenesis subserve this organizing infiltrate. B cell maturation, somatic hypermutation and local plasma cell residency support characteristic autoantibody formation, including IgG and IgM rheumatoid factors (RF) and anti-cyclic citrinullated peptide (CCP) antibody. B cells also likely mediate local cytokine release and (auto?) antigen presentation. High concentrations of pro-inflammatory cytokines are detected in the synovial membrane and fluid including TNFα, IL-1β, IL-6, IL-12, IL-15, IL-18, IL-23 and IL-32, together with antagonistic activities including soluble TNF receptors (p55 and p75), IL-1Ra, and IL-10 [3]. Specific cytokine blockade, in synovial cultures, in relevant rodent arthritis models (particularly collagen-induced arthritis in DBA/1 mice) and in clinical trials, indicate that TNFα is pivotal in this dysequilibrium. Cartilage damage arises via at least two pathways: (i) FLS possess semi-autonomous characteristics including loss of anchorage independence, resistance to apoptosis (via SUMO and sentrin expression) and likely invade mineralized and non-mineralized cartilage at the "cartilage-pannus junction" in part through local synthesis of matrix metalloproteinases (particularly MMP1 and MMP3) to levels that exceed TIMP concentrations. (ii) Cytokine-mediated chondrocyte activation (e.g. via IL-1β, IL-17, TNFα) further reduces cartilage matrix component synthesis and



**Rheumatoid Arthritis. Figure 1** An H&E synovial biopsy lesion is shown with the key functional areas delineated. The major cellular or molecular components in each compartment are depicted in the boxes. MMP matrix metalloproteinase, TIMP tissue inhibitor of MMP.

repair. Bone destruction is attributed to synovial maturation and activation of osteoclasts under the local influence of RANKL, IL-1β and TNFα. This promotes typical subchondral bone erosion that further impairs cartilage integrity. Tissue damage in turn likely feeds back to amplify inflammatory pathways via ligation of several TLR moieties, particularly TLR2 and TLR4. A wide variety of signaling cascades have been detected in synovial membrane leukocyte and FLS subsets including MAPK, NF-κB, NFAT, JAK/STAT dependent pathways and inhibitor studies are underway targeting many of these pathways.

## Diagnostic Principles

Diagnosis is made upon fulfillment of 1987 American College of Rheumatology criteria [4]. Early disease may be difficult to distinguish from self-resolving, or from other persistent inflammatory arthropathies. Diagnosis relies on clinical assessment of symptoms and synovitis, together with characteristic radiographic appearances of peri-articular osteoporosis and erosion. Recent application of high-resolution ultrasound with laser doppler scanning and contrast enhanced magnetic resonance imaging have considerably improved the sensitivity for detection of synovitis and early bone/cartilage erosion. Various algorhythms employing these imaging modalities and autoantibody profile (particularly anti-CCP, RF) are under evaluation for improved sensitivity and specificity to define poor prognostic patients.

## Therapeutic Principles

Early aggressive intervention is now considered optimal to achieve rapid control of inflammatory disease and thereby minimize articular damage and accrual of comorbidity [5]. Such intervention comprises early use of disease modifying anti-rheumatic drugs (DMARDs) together with subsequent introduction of biologic agents. DMARD selection usually entails methotrexate, followed by addition of (combination therapeutics) or replacement with sulphasalazine, hydroxychloroquine and leflunomide, dependent upon efficacy and tolerance. Biologic agents that target TNFα are now indicated, dependent upon health economic culture, after methotrexate failure or intolerance. TNFα blocking agents include etanercept (TNF receptor p75:Ig Fc), infliximab (chimeric anti-TNF antibody) and adalimumab ("human" anti-TNF antibody). These agents act synergistically with methotrexate to achieve significant responses in approximately 70% of RA patients, both in reducing clinical disease activity and

in retarding radiographic erosion progression. Similarly, B cell depletion (anti-CD20; rituximab) suppresses clinical disease activity and erosion progression whereas administration of abatacept (CTLA-4:Ig) also suppresses disease activity. Future biologic interventions will likely target IL-6, IL-12/23 and IL-15. The optimal strategy of intervention is not yet clarified – step-up therapy based on initial monotherapy to which is added more aggressive agents upon failure to suppress disease activity appears similar to step down or parallel therapeutics in which combination agents are introduced at outset and adjusted per disease activity. Early introduction of TNF blocking biologic agents may confer greater magnitude and duration of response although larger robust studies are ongoing to confirm this possibility. Multidisciplinary teams provide ongoing access to physical and occupational therapies. Symptomatic treatments include non-steroidal anti-inflammatory drugs and COX2 selective agents, and a variety of analgesic agents. Low dose corticosteroid is advocated by some evidence to retard radiographic progression. Less commonly myocrisin, azathioprine and ciclosporin are employed in resistant disease. In end stage joint failure, recourse may be made to arthroplasty or to tendon repair as indicated.

# Rheumatoid Lung Disease

Javier Rangel-Moreno, Troy D. Randall
Trudeau Institute, Saranac Lake, NY, USA

## Synonyms

Interstitial lung disease

## Definition and Characteristics

Rheumatoid arthritis (RA) affects symmetrically both sides of the body – most often wrists and finger joints. Systemic manifestations of RA include cutaneous vasculitis, neuropathy, splenomegaly (Felty's syndrome), pericarditis and interstitial lung disease. Rheumatoid lung disease is characterized by pleural effusions, pulmonary fibrosis, lung nodules and pulmonary hypertension. Common symptoms associated with the disease include shortness of breath, cough, chest pain and fever. Similar to the inflamed joints of RA patients, the lungs of patients with rheumatoid lung disease develop organized inflammatory lesions termed inducible bronchus associated lymphoid tissue (iBALT) (Fig. 1). These areas appear to support local expansion and differentiation of autoreactive cells and exacerbate local pathology [1].

## Prevalence

The prevalence of RA is around 0.3–1.2% (0.92% of Americans). Women are 2–3 times more susceptible than men. The prevalence of rheumatoid lung disease in patients with RA depends on the method used for diagnosis: chest X rays (5%), high resolution CT scans (10–40%).

## Genes

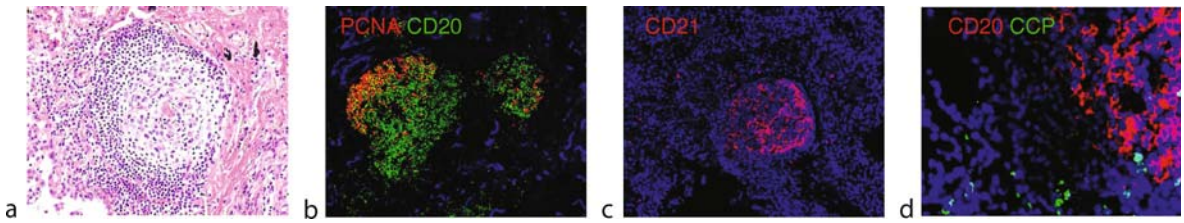
- Fc receptor-like 3 (FCRL3)
- Human leukocyte antigen DRB shared epitope (HLA-DRB SE) [2]
- Peptidyl arginine deiminase type 4 (PADI4) [2]
- Protein tyrosine phosphatase non-receptor type 22 (PTPN22) [2]
- Cytotoxic T lymphocyte antigen 4 (CTLA4)

## Molecular and Systemic Pathophysiolology

RA is a complex and poorly understood disease [3]. However, the characteristic presence of antibodies to citrullinated proteins (anti-CCP) suggests that there are pathogenic mechanisms unique to RA. Recent studies suggest a link between smoking, HLA-DRB SE, anti-CCP and RA [2]. Smoking has long been linked to RA and worsens articular disease as well as rheumatoid lung disease. Exposure to cigarette smoke leads to the activation of PADI enzymes that deiminate arginine to citrulline, producing autoantigens like citrullinated collagen and fibrinogen. Autoantigenic peptides containing citrulline residues are preferentially bound by HLA-DRB SE proteins and are presented to T cells, which interact with CCP-specific B cells found at sites containing autoantigen and produce inflammatory cytokines and autoantibodies, which accelerate disease. Bacterial or viral infections of the respiratory tract may also exacerbate pulmonary inflammation and rheumatoid lung disease.

## Diagnostic Principles

The diagnosis of RA was formerly based on detection of rheumatoid factor (RF). However, RF is also associated with other autoimmune diseases. The detection of anti-CCP is currently considered the most specific



**Rheumatoid Lung Disease. Figure 1** Histology of iBALT in patients with rheumatoid lung disease. (a) Sections of lung biopsies from patients with rheumatoid lung disease contain organized lymphoid areas, (b) B-cell follicles with germinal centers, (c) Follicular dendritic cells, and (d) anti-CCP producing plasma cells. Sections (b–d) are counterstained with DAPI (blue).

marker of RA [2,3]. The diagnosis of rheumatoid lung disease is based on evaluation of pulmonary function, radiology, serology and lung biopsy. High resolution CT scans are preferred to chest X-rays due to their sensitivity and specificity. Bronchoscopic, video-assisted, or open lung biopsy allows the histological characterization of pulmonary lesions, which can distinguish rheumatoid lung disease from other interstitial lung diseases [1].

## Therapeutic Principles

Fast-acting, first-line drugs for RA include aspirin and corticosteroids, which alleviate pain and reduce inflammation. Slow-acting, second line drugs termed disease modifying antirheumatic drugs (DMARDs), include gold, methotrexate and hydroxychloroquine (Plaquenil), which promote disease remission and prevent progressive joint destruction. In patients with less severe RA, pain relievers, anti-inflammatory drugs and physical rest are sufficient to improve quality of life. In patients with joint deformity, surgery is the only alternative for recovering articular function. A potential side effect of methotrexate is pulmonary toxicity, which can exacerbate rheumatoid lung disease.

Tumor necrosis factor (TNF) antagonists [4], including etanercept, infliximab and adalimumab are now used to treat RA – often in combination with methotrexate or other DMARDs. Prolonged use of these antagonists can lead to the production of anti-antagonist antibodies, which can be reduced using combination therapy with methotrexate. TNF antagonists also predispose patients to infection with particular pathogens, such as Staphylococcus aureus, atypical bacteria, fungi and Mycobacterium tuberculosis. Baseline tuberculin testing and chest radiographs are recommended prior to treatment.

Interleukin 1 (IL-1) antagonists (Anakinra), are also used to treat RA. The simultaneous administration of IL-1 antagonists with TNF antagonists is not recommended, due to increased rates of infection.

B cell depletion therapy using anti-CD20 (Rituximab) is also used to treat RA [5] – often in patients who failed to benefit from TNF antagonists. The advantage of B depletion therapy is that it may be able to reset the B cell repertoire and allow the regeneration of non-autoreactive B cells. Surprisingly, B cell depletion does not eliminate long-lived antibody-producing plasma cells and only reduces the production of some types of autoantibodies, suggesting that the lack of B cells is important for functions other than antibody production.

# Rheumatoid Spondylitis

►Ankylosing Spondylitis

# Rhinitis, Allergic

Werner J. Heppt, Annette Cryer
Department of Otorhinolaryngology, Klinikum Karlsruhe gGmbH, Karlsruhe, Germany

## Definition and Characteristics

Ig-E mediated inflammation of the nasal mucosa triggered by allergen exposure.

## Prevalence

9–24% of adults and up to 42% of children in the US [1,2]. It starts mostly in childhood (before age 20 in

80% of cases) leading to significant morbidity (local and general symptoms, impairment of social life and efficiency) for years and decades. Positive immediate hypersensitivity skin tests are significant risk factors for the development of new symptoms of seasonal allergic rhinitis. Other risk factors are the early introduction of foods or formula, heavy maternal smoking during the first year of life, exposure to indoor allergens (e.g. animals, dust mite), IgE-levels >100 IU/ml before age 6 and parental allergic disorders.

## Genes

Atopy is the transmitted disposition to develop allergies like rhinoconjunctivitis, asthma, urticaria, atopic dermatitis and food allergies. It has been linked to several chromosomes such as 5q, 11q [3], 13q14 and to polymorphisms in the IL-18 gene [4]. With two healthy parents the atopy risk for a child is 5–15%, with one atopic parent 20–40%, with an atopic sibling 25–35% and with two atopic parents even 60–80% [2].

## Molecular and Systemic Pathophysiology

In the phase of sensitization antigens are processed by antigen-presenting cells, which lead to a switch from the development of TH1-lymphocytes to TH2-lymphocytes. TH2-cells release mediators such as IL-4 and IL-13. These cytokines and other costimulatory signals such as CD40L cause the transcription of gene products by B-lymphocytes and IgE by plasma cells [2]. Gene induction is orchestrated by the coordinated action of the transcription factors STAT6, NF-kappaB, PU.1 and C/EBP [5].

The next allergen contact leads to an allergic response, which is divided in early reaction (<2 hours) and a late phase reaction (2–24 hours). In the early phase reaction histamine is degranulated from mast cells and basophiles after cross linking of IgE-molecules by antigens. It produces itching, sneezing, profuse watery secretion and nasal stuffiness. In addition, mast cells secrete proinflammatoric cytokines e.g. IL-1, IL-6 and TNF-α. The late phase reaction is ycharacterized by a chemotaxis (induced by IL-5 and other leucotriens) of mainly eosinophilic leukocytes, which secrete proinflammatory mediators such as major basic protein, eosinophilic cationic protein and others. These late phase mediators are thought to damage the epithelium and other cells, which promotes the tissue damage of chronic allergic reactions.

## Diagnostic Principles

Evaluation of patients history is essential to when, where, and under which conditions symptoms arise. Nasal endoscopy shows swelling of the mucosa and increased clear mucus and has to rule out other nasal and sinus diseases. Skin tests (prick, intracutaneous) and in vitro diagnosis (IgE-antibodies) demonstrate sensitization against specific allergens. Clinical relevance and sensitization in the key area may be proved by nasal and/or conjunctival challenge and by cytology of nasal mucosa.

## Therapeutic Principles

Allergen avoidance or reduction is the best therapy, as is successfully performed for house dust mite (encasing of the matress, pillows etc.). Nowadays specific immunotherapy (SIT) is recommended in the early course to reduce the allergic symptoms and to prevent further sensitizations as well as the development of asthma. This is true for most of the allergens like pollen and house dust mite. Sublingual SIT gains growing importance whereas subcutaneously administered SIT is well established. Drugs for symptomatic treatment in a stepwise manner are: topical chromones, antihistamines (topical and systemic), glucocorticosteroids (topical and systemic).

On condition of a hyperplastic nasal mucosa turbinoplasty procedures may help to treat nasal obstruction successfully.

## Synonyms

Chondrodysplasia punctata rhizomelic form; Chondrodystrophia calcificans punctata; RCDP type 1; RCDP

R

type 2 (DHAPAT deficiency); RCDP type 3 (ADHAPS deficiency)

## Definition and Characteristics

Autosomal recessive disorder of peroxisomal metabolism leading to skeletal abnormalities, congenital cataracts and severe psychomotor retardation.

## Prevalence

The incidence of rhizomelic chondrodysplasia punctata is estimated to be one in 100,000.

## Genes

PEX7; GNPAT; AGPS.

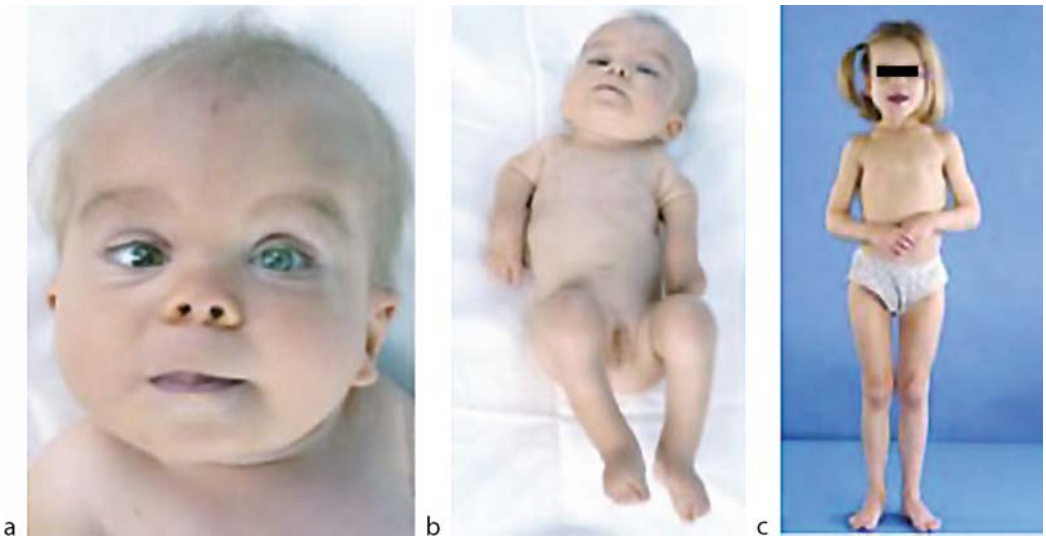
## Molecular and Systemic Pathophysiology

Rhizomelic chondrodysplasia punctata (RCDP) is a rare multisystem disorder of peroxisomal metabolism. Peroxisomes are ubiquitous cellular organelles involved in both catabolic and anabolic processes like β-oxidation of very long chain fatty acids (VLCFA), α-oxidation of phytanic acid and biosynthesis of plasmalogens. Their importance has been emphasized by the discovery of several peroxisomal disorders since the beginning of the 1980s. Peroxisomal disorders can be divided in those diseases that are caused by a single enzyme deficiency and those that affect peroxisomal biogenesis leading to multiple enzyme defects [1]. RCDP is genetically heterogeneous and can be caused by mutations in three different genes, namely PEX7, GNPAT, and AGPS. The three genetic subtypes of RCDP are clinically indistinguishable with stippled foci of calcification within the hyaline cartilage, coronal clefts of the vertebral bodies, symmetrical shortening of the proximal limbs (rhizomelia), dwarfism, joint contractures, congenital cataracts and severe psychomotor retardation (Fig. 1).

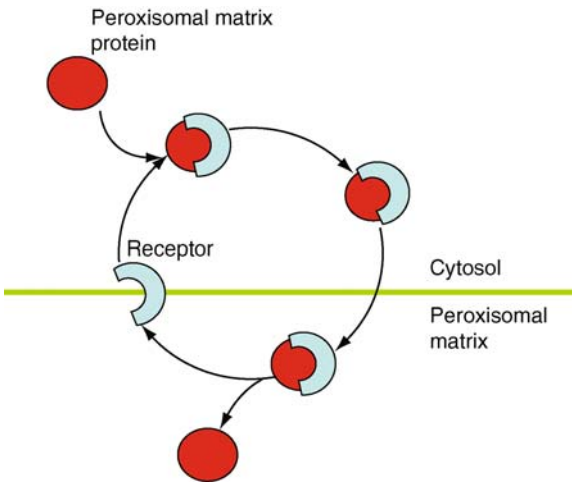
RCDP type 1 (OMIM 215100) is characterized by defects in multiple peroxisomal enzymes. This subtype is caused by mutations in the PEX7 gene encoding the cytosolic receptor that plays a crucial role in the accurate targeting of enzymes containing the peroxisomal targeting signal 2 (PTS2) towards peroxisomes. Three PTS2 containing enzymes are known: (i) alkyldihydroxyacetonephosphate synthase (ADHAPS), (ii) phytanoyl-CoA hydroxylase and (iii) peroxisomal thiolase (Fig. 2).

Therefore, as a result of PEX7 deficiency, phytanic acid, which is derived from dietary sources, accumulates in an age and diet dependent manner, and plasmalogens are deficient. The L292X mutation is found to be by far the most common mutation causing RCDP type 1, accounting for approximately 50% of all cases [2]. RCDP type 2 (OMIM 222765) and 3 (OMIM 600121) are single enzyme deficiencies caused by mutations in GNPAT and AGPS genes encoding the enzymes DHAPAT and ADHAPS, respectively. These enzymes catalyze the initial steps in plasmalogen biosynthesis [1] (Fig. 3).

Plasmalogens are a special subgroup of phospholipids containing a vinyl-ether bond at the sn-1 position of the glycerol backbone. Although in vitro studies indicate that they may play a role in protection against reactive oxygen species, in cellular signaling and in the storage of poly unsaturated fatty acids, their role in vivo still remains unclear, leaving the mechanisms behind



**Rhizomelic Chondrodysplasia Punctata. Figure 1** RCDP phenotypes. (a/b) Severe phenotype of RCDP type 1. One-year old boy with typical facial appearance, rhizomelia and contractures of various joints. (c) Mild phenotype of RCDP type 1. Five-year old girl with no obvious rhizomelia and with the ability to stand without support.



**Rhizomelic Chondrodysplasia Punctata.**
**Figure 2** Import machinery peroxisomes. Peroxisomal matrix proteins are translated on free polyribosomes and directed to the peroxisomes by cis-acting peroxisome targeting signals (PTSs). Most use a C-terminal ser-lys-leu (SKL), or variant thereof, termed PTS1. A few proteins, namely ADHAPS, phytanoyl-CoA hydroxylase and peroxisomal thiolase use the *N*-terminal signal, termed PTS2, with a consensus sequence of R/KLX(5)Q/HL. In RCDP type 1 the absent or defective PEX7 leads to the accumulation of PTS2 proteins in the cytosol where they are inactive.

the pathology of RCDP unsolved [3]. However, the severe abnormalities seen in patients that lack plasmalogens and the fact that RCDP patients with only a mild deficiency in plasmalogens have less severe skeletal and neurological symptoms, underline the significance of having plasmalogens as important constituents of cellular membranes [4].

## Diagnostic Principles

In case of clinical suspicion of RCDP (e.g. rhizomelia and calcific stippling of the epiphyses on X-ray in the neonatal period but also congenital cataract and psychomotor retardation in childhood) the diagnosis of RCDP can be established by finding decreased levels of plasmalogens in erythrocytes. Phytanic acid might be increased in RCDP type 1. For definite diagnosis patients require enzymatic studies in fibroblasts and mutation analysis of the genes involved in RCDP.

## Therapeutic Principles

No curative treatment is available for RCDP patients. However, in RCDP type 1 a phytanic acid restricted diet is suggested if this branched chain fatty acid is significantly elevated [5]. Supportive therapy, including physiotherapy, anti-epileptics and correction of visual impairment is highly recommended to improve quality of life.

# Rhythmical Chorea

►Tardive Dyskinesia

# Rickets, Autosomal Dominant Hypophosphatemic

Harriet S. Tenenhouse
Department of Human Genetics, Montreal Children's Hospital Research Institute, McGill University, Montreal, QC, Canada

## Synonyms

Vitamin D resistant rickets; ADHR

## Definition and Characteristics

Autosomal dominant hypophosphatemic rickets (ADHR) (OMIM 193100) is characterized by short stature, rickets and osteomalacia, dental abscesses, isolated renal phosphate wasting, hypophosphatemia and abnormal regulation of renal vitamin D metabolism [1]. While these features are similar to those in X-linked hypophosphatemia (XLH, OMIM 307800) [1], the clinical manifestations in ADHR are more variable, with incomplete penetrance and delayed onset of the disease manifestations. In some ADHR adults, bone pain, weakness and insufficiency fractures have been reported [1].

## Prevalence

ADHR is extremely rare and only four unrelated families with this disorder have been reported to date. Incomplete penetrance and variable age of onset may account for missed or incorrect diagnoses.

## Genes

Linkage analysis mapped the ADHR locus to human chromosome region 12p13 in a large ADHR kindred [1]. The gene was subsequently identified by positional cloning and encodes a secreted peptide designated FGF-23 that is related to the fibroblast growth factor family [2].

## Molecular and Systemic Pathophysiology

FGF-23 is a 251 amino acid peptide that is processed to amino (N)- and carboxy (C)-terminal peptide fragments at a pro-protein convertase (furin) consensus cleavage site, Arg-His-Thr-Arg [3]. Missense mutations in each of the two critical arg residues in the furin cleavage site (R176Q, R179W, and R179Q) were identified in four unrelated patients with ADHR [2]. Moreover, it was demonstrated that recombinant FGF-23 peptides harboring these missense mutations are not processed to their N- and C-terminal peptide products [4]. These data suggest that gain of function mutations in the FGF23 gene, leading to the accumulation of unprocessed FGF-23, are responsible for the clinical features in ADHR. Several lines of evidence support this hypothesis. FGF-23 is abundantly expressed in tumors from patients with Oncogenic Hypophosphatemic Osteomalacia (OHO, also known as Tumor Induced Osteomalacia) [3], an acquired disorder with phenotypic features of ADHR and XLH thought to arise by the secretion of a phosphaturic factor produced by the tumors [1]. The serum concentration of FGF-23 is markedly elevated in patients harboring these tumors as well as in patients with XLH [5]. Subcutaneous implantation of CHO cells, stably transfected with FGF23 cDNA, elicits renal Pi wasting, hypophosphatemia, dysregulated renal vitamin D metabolism and a mineralization defect in mice [3]. Thus, the renal and skeletal abnormalities that characterize ADHR, XLH and OHO may involve defects in a common metabolic pathway.

## Diagnostic Principles

ADHR patients exhibit hypophosphatemia and isolated renal phosphate wasting, which is evaluated by measuring TMP/GFR using the nomogram of Bijvoet and Walton [1]. Serum calcitriol is inappropriately normal for the degree of hypophosphatemia and serum PTH is in the normal range. Radiological features of rickets are present in some affected children. Skeletal abnormalities may be apparent in adults, depending on the severity of the disease. Confirmation of the diagnosis of ADHR is achieved by the presence of mutations in the FGF23 gene.

## Therapeutic Principles

Treatment of ADHR is similar to that of XLH and consists of oral phosphate supplements, in four divided doses, and calcitriol [1]. Careful monitoring is essential to achieve an appropriate balance between the administered phosphate and calcitriol. There are no data on the complications of treatment in ADHR. In XLH, this regimen can lead to the development of secondary hyperparathyroidism and nephrocalcinosis [1].

### Synonyms

RBBB

### Definition and Characteristics

Right bundle branch block (RBBB) is defined as a delay of the conduction system in the proximal right bundle branch. Depolarization of the free wall of the right ventricle is delayed secondary to the slow conduction between the bundle of His and the right bundle [1]. The septal depolarization is not affected since the impulse is primarily launched by the Purkinje fibers, which arises proximally from the left bundle before the separation into the two left fasciculi. As a result of this, the depolarization of the left ventricle takes place at the regular time and rate whereas the right ventricle depolarization is delayed [2]. On physical examination, patients may have a widely split second heart sound during expiration and this split is further increased during inspiration [1].

### Prevalence

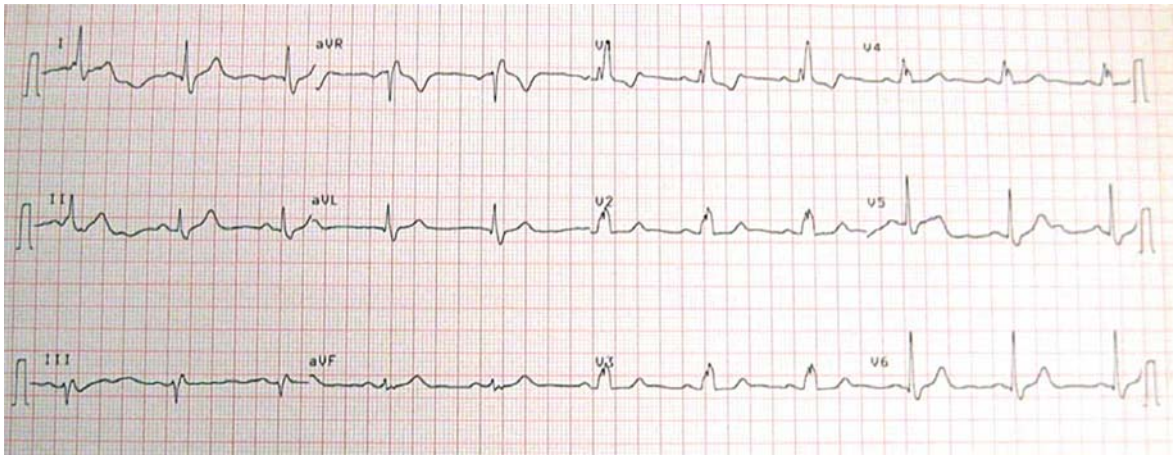
There has been a number of large epidemiological studies, which have played a major role in assessing the prevalence and prognosis of people with RBBB. Hansen reviewed 237, 000 ECGs at the United States School of Aerospace Medicine, and diagnosed 394 people (0.17%) with RBBB. In the 10 year follow-up, only two people developed a high-grade AV block [2]. However, in the Framingham study which followed 5,209 people with no cardiac disease for 18 years, 70 people (1.3%) developed RBBB; and most of them had hypertension and cardiomegaly. Hence, the prognosis of RBBB depends on the population that was studied. When the population is young and free of cardiac disease then the prognosis is excellent. On the other hand if the population is older and has a high incidence of cardiac risk factors, then there is a greater chance of developing high-degree heart block and sudden death [3].

### Genes

Hereditary RBBS is an autosomal dominant inherited disorder which may be due to a mutation of the gene SCN5A which has been mapped to chromosome 19 [4].

### Molecular and Systemic Pathophysiology

The right bundle branch (RBB) is a collection of Purkinje fibers, which arises from common bundle of His. It extends to the base of the anterior papillary muscle and bifurcates into anterior, posterior and lateral branches terminating in the free wall and lower septum of the right ventricle [1]. The blood supply to the RBB is variable and anastomoses are common. The blood supply to the septum is from the AV nodal artery and septal branches of the left anterior descending coronary artery. Ischemic heart disease and primary sclerodegenerative changes are the most common diseases associated with the development of RBBB. Other cardiac manifestations, which increase the risk of RBB, are hypertension, cardiac tumors, cardiomyopathies, myocarditis, and syphilitic, rheumatic and congenital heart disease [2]. In children, the key secondary cause of RBBB is intra-cardiac surgery for congenital abnormalities such as a VSD or a cardiac transplantation [3]. If the patient has premature atrial contractions or supraventricular tachycardia, intermittent RBBB may occur. This may be explained by a longer refractory period for the right bundle as compared to the left. RBBB is also associated with secundum atrial septal defect, Chagas' heart disease, perimyocarditis, blunt chest trauma and polymyositis. RBBB of acute onset is frequently related to pulmonary embolism or myocardial infarction [2].



**Right Bundle Branch Block. Figure 1** Classical RBBB with normal sinus rhythm.

### Diagnostic Principles

The diagnostic criteria of RBBB includes: (i) QRS interval ≥0.12 s, (ii) rSR' or M pattern of QRS complex in leads $V_{1–3}$ (iii), deep and slurred S waves in leads I, aVL and $V_{4–6}$, and (iv) secondary ST, and T wave changes in leads $V_{1–3}$ [2] (Fig. 1).

### Therapeutic Principles

There is no specific treatment for isolated RBBB. Since it is usually relatively benign, the only suggestive intervention is periodic follow-up and evaluation. In children, since RBBB may be linked to an underlying syndrome, a complete evaluation should be conducted to determine the cause of the RBBB [1]. In adults, yearly follow-up is standard [5]. The underlining cardiac risk factors should also be treated [3].

# Romano-Ward Syndrome

Joerg Zehelein[1,3], Markus Khalil[2], Michael Koenen[3]
[1]Department of Internal Medicine III, University Hospital Heidelberg, Heidelberg, Germany
[2]Department of Pediatric Cardiology, University Hospital of Heidelberg, Heidelberg, Germany
[3]MPI for Medical Research, Heidelberg, Germany

### Synonyms

RWS

### Definition and Characteristics

The Romano-Ward syndrome (RWS), an inherited arrhythmogenic heart disease, is the most frequent clinical variant of the long QT syndrome (LQTS). It is characterized by a prolonged QT interval on the surface ECG, syncopal attacks, and a high risk of sudden cardiac death due to ventricular tachyarrhythmias of the torsades de pointes type [1].

### Prevalence

The estimated prevalence is between 1:3,000 and 1:5,000 [2].

### Genes

Mutations associated with the RWS have been identified in six ion channel genes and two anchor protein gene (Table 1) and their hereditary transmission is in the majority of cases autosomal-dominant (>95%) [3].

In rare cases, however, RWS patients are carriers of multiple gene defects, including homozygosity for one mutation as well as compound heterozygosity for two or three mutations.

### Molecular and Systemic Pathophysiology

Sodium ($Na^+$) and potassium ($K^+$) currents have different effects on the duration of the cardiac action potential. A rapid inflow of $Na^+$ through $Na_v1.5$ channels induces cardiac depolarization, whereas $I_K$ currents (mainly $I_{Kr}$ and $I_{Ks}$) drive the repolarization of cardiomyocytes [1]. RWS mutations in ion channel genes compromise both, the expression, by introduction of premature stop codons or splice mutations, as well as the function of ion channel subunits, by deletion, insertion, or replacement of amino acids.

In consequence, the cardiac action potential is prolongated by enhancing the $I_{Na}$ current ("gain-of-function" mutations in LQT3 and 10) (Table 1) or alternatively by reducing the repolarizing $I_{Kr}/I_{Ks}$ currents ("loss-of-function" mutations in LQT1, 2, 5,

**Romano-Ward Syndrome. Table 1** Genes and proteins associated with the Romano-Ward syndrome

| Genotype | Locus | Gene | Protein | Function | Current | Mutation frequency |
|---|---|---|---|---|---|---|
| LQT1 | 11p15.5 | KCNQ1 | KvLQT1 | Ion channel α-subunit | $I_{Ks}$ | ~49% |
| LQT2 | 7q35-36 | KCNH2 | hERG | Ion channel α-subunit | $I_{Kr}$ | ~39% |
| LQT3 | 3p21-23 | SCN5A | $Na_v1.5$ | Ion channel α-subunit | $I_{Na}$ | ~10% |
| LQT4 | 4q25-27 | ANK2 | Ankyrin B | Anchoring protein | – | Unknown |
| LQT5 | 21q22.1-22.2 | KCNE1 | minK | Ion channel β-subunit | $I_{Ks}$ | ~1.7% |
| LQT6 | 21q22.1-22.2 | KCNE2 | MiRP1 | Ion channel β-subunit | $I_{Kr}$ | ~0.7% |
| LQT9 | 3p25 | CAV3 | Caveolin-3 | Anchoring protein | – | Unknown |
| LQT10 | 11q23.3 | SCN4B | $Na_{v\beta}4$ | Ion channel β-subunit | $I_{Na}$ | Unknown |

and 6) (Table 1). The impact of these changes are strongly dependent on the individual genotypes, but finally all patients develop a prolongation of the cardiac action potential diminishing the repolarizing capacity of cardiomyocytes with the consequence of an increasing vulnerability for triggering malignant ventricular arrhythmias. In vitro studies of mutated channels describe multiple mechanisms of functional failure. Mutated subunits may coassemble with wild-type subunits and reduce channel function in a dominant-negative manner. Other mutations produce defective subunits unable to interact with wild-type subunits leading to a reduction of currents by 50% (haploinsufficiency). A reduction of channel function may also be explained by mutant subunits that fail to reach the cell membrane due to impairment of protein trafficking [1,2,4].

Based on the ion channel expressing genes associated with LQT1-3,5,6 and 10 (Table 1), the RWS was initially considered as a "channelopathy." Recently, mutations in two nonchannel genes have been identified in RWS patients, encoding the structured proteins Ankyrin B and Caveolin-3 (Table 1). Ankyrin B and Caveolin-3 are intracellular proteins thought to be involved in ion channels anchoring to the cellular membrane [1,3].

## Diagnostic Principles

The RWS is diagnosed by analysis of the surface electrocardiogram (QT prolongation in the surface ECG), the family history (cases of unexpected sudden death), and the clinical presentation with syncope and fainting. The averaged age of the first onset of symptoms (syncope or sudden death) is 12 years, but cannot be predicted in an individual case. An earlier appearance of cardiac events is regularly associated with a more severe form of RWS. Screening of the RWS-associated genes identified the genetic changes in about 50–75% of clinically affected individuals. The RWS phenotype may be very heterogenous and can vary from complete asymptomatic individuals to severe symptomatic cases, even among patients carrying the same mutation. This feature reflects a variable penetrance of RWS mutations referring to the influence of modifying factors provided by the patients and depending on their environmental or genetic background [1,3].

The incidence of cardiac events in RWS patients is often triggered by physical or emotional stress, and demonstrates a gene-specific association in most cases. So, swimming and auditory stimuli are particularly frequent triggers in LQT1 and LQT2 patients, respectively [4,5]. Several clinical studies have shown that identification of the causative RWS gene can improve the individual risk stratification for the prognosis of concerned patients [3].

## Therapeutic Principles

A rapid increase in sympathetic activity is the trigger for most of the clinical events in RWS patients. Consequently, antiadrenergic therapy with beta-blockers is the cornerstone in the treatment of the RWS [3]. For patients definitely unresponsive to this approach, the application of an implantable cardioverter defibrillator (ICD) and/or – in rare cases – a left sided cardiac sympathetic denervation has been recommended. The response of RWS patients to beta-blocker therapy is clearly dependent on their genotype, and this peculiarity is reflected by the fact that the protection of recurrent clinical episodes of patients with beta blocker therapy was higher and the death rate was lower in LQT1 (81 and 4%, respectively) than in LQT2 (59 and 4%, respectively) and LQT3 (50 and 17%, respectively) [5]. The identification of molecular mechanisms that provoke RWS will lead to novel and genotype orientated pharmacological strategies. Preliminary clinical data show that "Gain-of-function" mutations in LQT3 can be antagonized by the $Na^+$ channel blocker mexiletine offering a new approach for a genotype-specific RWS therapy [3].

# Rosacea

Christos C. Zouboulis
Departments of Dermatology, Venereology, Allergology and Immunology, Dessau Medical Center, Dessau, Germany

## Synonyms

Acne rosacea

## Definition and Characteristics

Exclusively human chronic cutaneous disorder characterized by transient and later persistent erythema due to prominent vasodilatation accompanied by telangiectasia, interspersed by episodes of inflammation with evident swelling, papules, and pustules [1]. The disease affects classically the centrofacial region (particularly nose, forehead, cheeks, and chin). Keratoconjuctivitis sicca is present in 40% of the patients, and ocular involvement (blepharitis, conjuctivitis, iritis, iridocyclitis, keratitis) is common in rosacea (5–58%). Rhinophyma (diffuse connective tissue and sebaceous gland hyperplasia of the nose) and extrafacial rosacea (retroauricular region, neck, central chest, and/or back) can also be present. In contrast to acne, no comedones develop in rosacea. A provisional classification system defines four subtypes (erythematotelagiectatic, papulopustular, phymatous, and ocular rosacea) and one variant (granulomatous rocasea), whereas evolution from one subtype to another may or may not occur (Table 1) [2].

## Prevalence

It is a common skin disease with an estimated prevalence of 10%, typically appearing between the ages of 30 and 50 years [1]. It is mostly observed in patients with fair skin and similarly affects women and men, whereas the latter experience a more severe course. Facial edema, keratitis, and rhinophyma are bad prognostic signs. The incidence is higher in patients with gastrointestinal diseases, those working outdoors, and under changing weather conditions. Noxious stimuli such as sunlight, physical and mental stress, and ingestion of alcohol, coffee, tea, and spicy foods may lead to an increased vascular response and are accused to be aggravating factors.

## Genes

Rosacea is considered a clinical pattern evolving in a genetically susceptible individual in response to a host of exposures [3]. No gene associations have been reported yet.

## Molecular and Systemic Pathophysiology

The etiology and pathogenesis of rosacea remains unclear and there are no histologic or serologic markers. Vasoactive neuropeptides, such as vasoactive intestinal polypeptide, have been associated with the disorder [3]. Furthermore, substance P has been linked to the disease for its ability to stimulate fibroblast proliferation and influence local cytokine activity. Among other sites, substance P is stored in gastric mucosal enterochromaffine cells, and its release is related to feeding and may cause reduction of gastric acidity, whereas a role for gastric hypoacidity has been suggested in rosacea. Clogging of the acroinfundibulum with Demodex folliculorum, vitamin B deficiency, local infection, and infection with Helicobacter pylori have also been associated with rosacea.

**Rosacea. Table 1** Subtypes and variants of rosacea and their characteristics (from [2])

| Subtype | Characteristics |
|---|---|
| Erythematotelangiectatic | Flushing and persistent central facial erythema with or without telangiectasia |
| Papulopustular | Persistent central facial erythema with transient, central facial papules or pustules or both |
| Phymatous | Thickening skin, irregular surface nodularities and enlargement. May occur on the nose, chin, forehead, cheeks, or ears |
| Ocular | Foreign body sensation in the eye, burning or stinging, dryness, itching, ocular photosensitivity, blurred vision, telangiectasia of the sclera or other parts of the eye, or periorbital edema |
| **Variant** | **Characteristics** |
| Granulomatous | Noninflammatory; hard; brown, yellow, or red cutaneous papules; or nodules of uniform size |

### Diagnostic Principles

The diagnosis is made from the clinical appearance of the patient (see Table 1).

### Therapeutic Principles

Effective treatment of rosacea includes avoidance of triggers or exacerbating factors, such as alcohol abstinence and application of sunscreens, as first line treatment, in combination with long-term topical (metronidazole) or oral antibiotic therapy (tetracyclines), topical retinoid or oral isotretinoin therapy, topical permethrin, topical azelaic acid and surgery, whereas Laser treatment, dermabrasion, and diathermy are options for progressive telangiectasia and rhinophyma [4,5].

►Pityriasis Rosea

## Roseola Infantum

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Exanthem subitum; Sixth disease; Exanthem criticum

### Definition and Characteristics

Roseola infantum is characterized by high fever that lasts 3–4 days followed by the sudden appearance of rash at defervescence (hence the term "exanthem subitum" meaning "sudden rash") [1]. The fever has an abrupt onset and the temperature commonly is in the range of 39–40.5°C. Most children are otherwise well and appear to be happy, alert, and playful. However, some children may exhibit periods of restlessness and irritability during times of increased fever. With defervescence, the typical exanthem appears. Characteristically, the rash is rose pink in color, macular, measuring 2–3 mm in diameter (Fig. 1).

The eruption is first seen on the trunk. It then spreads to the neck and proximal extremities, and occasionally the face. Typically, the rash blanches on pressure and subsides in 2–4 days [1]. Pruritus and desquamation are characteristically absent. Suboccipital, postauricular and cervical lymphadenopathy, palpebral and periorbital edema (Berliner's sign), tympanic membrane injection, erythematous maculopapular spots on the soft palate and vulva (Nagayama's spots), and mild

**Roseola Infantum. Figure 1** A 10-month-old infant with roseola infantum. Note the rose-pink macules on the trunk.

erythema of the pharynx may be present [2]. Most children recover without sequelae. Febrile seizures occur in approximately 10–5% of cases. Rarely, meningitis, encephalopathy, thrombocytopenic purpura, hepatitis, and pneumonia may occur [2].

### Prevalence

Roseola infantum occurs most frequently between 6 months and 2 years of age. Presumably, maternal antibodies protect most infants from infection during the first few months of life [2]. By 12 and 18 months of age, ~65 and 95% of children, respectively, have become infected [2]. Roseola infantum is rare after 4 years of age. The sex ratio is equal.

### Molecular and Systemic Pathophysiology

HHV-6 is the major cause of roseola infantum, the other cause being HHV-7. Both are enveloped double-stranded DNA virus with an icosahedral capsid. They are members of the Roseolavirus genus of the β-herpesvirinae subfamily [3]. HHV-6 is separated into HHV-6A and HHV-6B variants based on their genome sequence, antigenicity and biological characteristics [3,4]. HHV-6B accounts for more than 95% of primary HHV-6 infection in children in the United States whereas HHV-6A is more common in African children [4]. These viruses are trophic for CD4 + T lymphocytes, in which they replicate and may disseminate widely. HHV-6 uses CD46 as a cellular receptor which is present on the surface of all nucleated cells, whereas HHV-7 uses the CD4 receptor [3,4]. HHV-6 utilizes a number of strategies to downgrade the host's immune system, including enhancement of natural killer T-cell activity, suppression of peripheral blood mononuclear cell proliferation, and induction of numerous cytokines such as interferon-α, interferon–γ, interleukin -1β and interleukin-15 [3,4]. HHV-7 also enhances interleukin-15 and natural killer activity [4]. Transmission of the infection most likely results from asymptomatic shedding of virus in the respiratory secretions of the care-givers or other close contacts. The incubation period of HHV-6 is 5–15 days while the incubation period of HHV-7 is not known [2]. HHV-7 infection tends to occur somewhat later in life than HHV-6 and may account for second or recurrent cases of roseola infantum [5]. Febrile seizure may be related to the fever per se or it may result from direct viral invasion of the central nervous system.

### Diagnostic Principles

The diagnosis is mainly clinical. The main differential diagnosis is drug allergy in a febrile child who is receiving antimicrobial therapy. With drug allergy, the rash usually lasts longer and pruritus and fever may accompany the rash. Laboratory testing is currently restricted to research laboratories.

### Therapeutic Principles

There is no specific treatment. An antipyretic may be used to reduce fever and discomfort.

## Rosewater Syndrome

►Reifenstein Syndrome

## Rotator Cuff Disease

►Rotator Cuff Tendinosis

## Rotator Cuff Tendinosis

Kevin Kaplan, Robert J. Meislin
NYU Hospital for Joint Diseases, New York, NY, USA

### Synonyms

Rotator cuff disease; Tendinitis

### Definition and Characteristics

Four muscles that all originate on the scapula and insert in a circumferential fashion around the humerus form the rotator cuff. These muscles assist in all directions of shoulder motion and aid in glenohumeral stability. The tendons pass freely though the supraspinatus outlet between the coracoacromial arch and the humeral head.

Tendinosis is defined as degeneration secondary to atrophy (aging, microtrauma, vascular compromise)

and is not inflammatory in nature, whereas tendonitis involves an inflammatory response to trauma. In cases of the rotator cuff, these processes manifest as pain involving overhead activity. Patients may not recall a specific traumatic event and typically report gradual increasing weakness. Other common symptoms include crepitus, clunking, catching and a loss of motion. However, these symptoms are not specific and can be found in numerous other pathological processes.

## Prevalence

The presence of rotator cuff disease varies significantly depending on the patient population being discussed with no current literature being able to identify an exact prevalence.

## Molecular and Systemic Pathophysiology

Rotator cuff disease usually results from a combination of extrinsic and intrinsic pathways.

Extrinsic:

- Coracoacromial Arch Anatomy
- Overuse
- Overload
- Impingement
- Instability

Intrinsic:

- Vascular
- Degenerative changes – aging/overuse

Extrinsic causes include the anatomy of the coracoacromial arch, overload of the tendon, overuse, impingement syndrome, and shoulder instability. Impingement is a narrowing of the space between the acromion and the greater tuberosity that causes continued trauma of the rotator cuff complex. The shape of the coracoacromial arch, including the morphology of the acromion, can also contribute to impingement. Neer [1] characterized three stages of rotator cuff disease occurring as a result of extrinsic impingement: stage I – inflammation and edema, stage II – fibrosis and tendonitis, and stage III – partial or complete rotator cuff tearing.

Shoulder instability can also lead to rotator cuff disease as demonstrated by Jobe [2]. Subtle subluxations cause abnormal muscle activity around the shoulder. As a result, the scapula becomes fixed in an attempt to enhance stability. The rotator cuff muscles have to compensate for the loss of scapulothoracic motion and thus begin to fatigue. As they fatigue, the muscles become less competent and eventually the humeral head can migrate superiorly and impinge on the coracoacormial arch.

Internal impingement occurs as a result of repetitive overhead activities. During shoulder abduction and external rotation the undersurface of the rotator cuff can become in contact with the superior labrum creating minor trauma with repetition. In addition, the superior labrum can become damaged which may lead to further instability contributing to strain on the rotator cuff.

Intrinsic causes of rotator cuff disease include alterations in vascularity and degenerative changes within the substance of the tendons. Codman and Akerson [3] characterized the critical zone as an area approximately one centimeter from the insertion point of the supraspinatus on the humerus where the vascularity is poor. This is the hypothesized area where tendon degeneration and tears originate most commonly. The combination of a susceptible area in addition to external stress predispose to rotator cuff disease.

## Diagnostic Principles

After a complete history, a comprehensive physical exam should be performed including inspection, palpation, range of motion, strength testing, and provocative testing. Rotator cuff disease may be characterized by pain on palpation at Codman's point, which is located just distal to the anterolateral border of the acromion on the humerus. A discrepancy in range of motion or a loss of motion in one plane may indicate muscular or capsular tightness, which, as discussed previously, could alter shoulder biomechanics causing a strain on the rotator cuff tendons. Testing of shoulder stability is also important, given that instability may result in altered biomechanics as well. Impingement tests include Neer's and Hawkins', which are both sensitive, but not specific [4].

Plain radiographs may reveal an abnormally shaped acromion and in cases of severe rotator cuff disease may demonstrate cystic changes in the greater tuberosity or osteophyte formation on the acromion. Ultrasonography is also a useful tool, but is mainly beneficial in diagnosing rotator cuff tears. However, magnetic resonance imaging (MRI) remains the gold standard for diagnosing this entity. Rotator cuff disease may not be as evident on imaging modalities and physicians may have to rely on clinical exam for diagnosis.

## Therapeutic Principles

As rotator cuff disease represents an overuse injury or degeneration in most cases, the first line of treatment should be a period of rest (1 week) in addition to a short-term regimen of anti-inflammatory medication. After the initial rest period, the patient should be given a rehabilitation program to treat the proposed cause of pathology. In cases of instability, rotator cuff strengthening should be instituted, while stretching is indicated in cases of capsular tightness with most cases resolving.

With recurrent episodes, a subacromial injection of corticosteroids may be considered, but should be done only after the aforementioned protocol fails. Continued trauma may lead to a partial-thickness tear, which should be evaluated again with an MRI and may necessitate more aggressive treatment.

# Rotavirus Gastroenteritis

Alexander K. C. Leung[1], H. Dele Davies[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Pediatrics and Human Development, Michigan State University, East Lansing, MI, USA

## Definition and Characteristics

Rotavirus produces sporadic episodes of diarrhea. The incubation period is usually 1–3 days, and the duration of illness is generally 5–7 days [1]. In general, children with rotavirus gastroenteritis present with fever and vomiting early in the illness. Low-grade fever is seen in approximately 30–50% of children. Vomiting is a prominent clinical feature and is included in the case definitions of rotavirus disease used in vaccine clinical trials. The diarrhea is often explosive; stools are usually watery and number up to 10–20/day. Stools do not usually contain blood, but mucus is found in approximately 20% of cases. Stools infected by rotavirus have a distinctive odor [1]. The severity of gastroenteritis decreases with subsequent infections [1].

*Virology*: Rotavirus is a double-stranded RNA virus of the Reoviridae family. The virus is nonenveloped, with a diameter of about 70 nm. It is named rotavirus because of its characteristic appearance on electron microscopy as a hubbed wheel with spokes (*rota*, "wheel" [Latin]). The viral capsid is icosahedral and consists of three concentric shells [2]. The outer capsid is composed of two structural proteins, VP4 and VP7; the inner capsid is composed of VP6; and the core is composed of VP1, VP2, and VP3 [2]. The core encloses and interacts with the viral genome, which consists of 11 segments of double-stranded RNA; these segments range in size from approximately 660–3,300 base pairs [2]. The genome segment contains one or, in the case of genome segment 11, two open reading frames. These RNA segments encode six structural proteins (VP1–VP4, VP6, VP7) and six nonstructural proteins (NSP1–NSP6). VP6 is the major group-specific antigen. Rotavirus can be classified into seven groups (A–G) on the basis of VP6 differences. Group A is the most common rotavirus causing human illness. Serotype specificity is determined by VP4 and VP7, according to their reactivity with neutralizing antibodies. The serotype defined by VP7 is referred to as a G serotype (because VP7 is a glycoprotein), whereas that defined by VP4 is referred to as a P serotype (because VP4 is a protease-sensitive protein).

## Prevalence

Rotavirus is ubiquitous; almost all children are infected with rotavirus by age 3. Rotavirus gastroenteritis is most common and severe in children 6–24 months of age [1].

## Molecular and Systemic Pathophysiology

Rotavirus preferentially infects enterocytes in the mature small intestine after the virus has been activated by cleavage of VP4 by trypsin-like proteases [2]. Infection is initiated in the proximal end of the intestine and spreads distally but is generally confined to the intestinal mucosa. Multiplication of rotavirus particles in mature enterocytes leads to destruction of these cells. Villous tips receive the most extensive damage, with sparing of the crypts. Viable crypt cells undergo rapid division; the net result of the loss of villous tips and the filling of crypts with rapidly multiplying cells is a marked decrease in the surface area of the gut lumen. Also, because villous cells are largely absorptive and crypt cells are secretory, villous cell dysfunction during infection leads to an imbalance between absorption and secretion, resulting in a net secretion. In addition, rotavirus infection increases the turnover of enterocytes; immature enterocytes are impaired in their absorptive capacity. The virus also can destroy disaccharidases in the small intestine. In addition, NSP4, a rotavirus enterotoxin, may cause release of calcium from the endoplasmic reticulum, with resultant increased secretion from the villous cells. Stimulation of the enteric nervous system by NSP4 and villous ischemia may be responsible for the diarrhea.

## Diagnostic Principles

Electron microscopy is the gold standard against which other methods are compared and the final arbiter for questionable specimens [3]. On the other hand, electron microscopy may not detect rotavirus particles per

milliliter of feces or disrupted viral particles. Electron microscopy is expensive, and examination of a large number of stool specimens by electron microscopy is time-consuming. Electron microscopy has been replaced by a variety of commercially available assays directed at detecting rotavirus antigen in stool. Enzyme-linked immunosorbent assays and latex agglutination assays for group A rotavirus antigen detection in stool are highly sensitive and specific and are the diagnostic methods of choice for routine clinical use.

### Therapeutic Principles

Rehydration and maintenance of proper fluid and electrolyte balance remains the mainstay of treatment. Currently, two vaccines are available for the prevention of rotavirus gastroenteritis and they are given by mouth. RotaTeq is a pentavalent (G1, G2, G3, G4, and P1) human-bovine reassortant vaccine whereas Rotarix is an attenuated monovalent vaccine (strain R1X4414) based on a human rotavirus isolate (strain 89–12). These vaccines have been proven to be safe and effective and intussusception does not seem to be a problem [4]. It is hoped that the use of these vaccines will reduce the global burden of rotavirus gastroenteritis [5].

## Rothmund-Thomson Syndrome

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Poikiloderma congenitale

### Definition and Characteristics

Rothmund-Thomson syndrome is an autosomal recessive genodermatosis characterized by poikiloderma, i.e. mottled hyper- and hypopigmentation with atrophy and telangiectases, most intense on light exposed skin but not necessarily confined to it [1]. Poikilodermatous skin changes are frequently accompanied by juvenile cataract, disturbances of hair growth, hypogonadism, saddle nose, congenital bone defects, and short stature. There is a high risk for osteosarcoma [2].

### Prevalence

Rothmund-Thomson syndrome is rare.

### Genes

At least some cases of Rothmund-Thomson syndrome are caused by mutations in the DNA helicase gene RECQL4 on chromosome 8q24.3 [3].

### Molecular and Systemic Pathophysiology

Although the biological functions of RecQ helicase family have not been clarified, these multiple helicases, as "guardian angels" of the genomes of higher eukaryotes, are suggested to be involved in maintaining the integrity of chromosomal DNA.

### Diagnostic Principles

Clinical features, distribution of lesions and age of onset point to the disease.

### Therapeutic Principles

Therapy is supportive.

### References

## Rotor Syndrome

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

### Synonyms

Familial nonhemolytic conjugated hyperbilirubinemia with normal liver histology

### Definition and Characteristics
Autosomal recessive disease with elevated conjugated and unconjugated bilirubin serum levels (50–100 μmol/l) without other liver function abnormalities. Normal liver histology. Total urinary coproporphyrin excretion is elevated.

### Prevalence
Extremely rare.

### Genes
Not identified.

### Molecular and Systemic Pathophysiology
Kinetic analysis of intravenous sulfobromophthalein disappearance curves has suggested that this disease is caused by defective storage and/or hepatic uptake of the dye and not by defective hepatic secretion [2,3]. Since serum bilirubin is partly conjugated, defective storage after conjugation, with reflux of the conjugate to the serum is the more likely mechanism [4]. The characteristic lysosomal pigment of ►Dubin-Johnson syndrome is missing in Rotor syndrome. Total urinary coproporphyrin excretion is elevated, with a relative increased proportion of coproporphyrin isomer I [3]. In Dubin-Johnson syndrome, total urinary coproporphyrin excretion is normal.

### Diagnostic Principles
Mildly elevated serum bilirubin that partly is of the conjugated type. The caveat here is that automated serum bilirubin tests have a poor performance in differentiating between conjugated and unconjugated bilirubin. High performance liquid chromatography analysis of serum biliribin is cumbersome but necessary to accurately differentiate the unconjugated and conjugated bilirubin species [5]. Liver enzymes and indicators of liver function in serum are normal. Abnormal 45 min retention after intravenous injection of sulfobromophthalein (34 ± 2% versus 4 ± 0.6% in controls [2]). Serum bile salt levels are normal. Urinary total coproporhyrin is elevated, 50–70% is coproporphyrin isomer I.

### Therapeutic Principles
None.

# Rubella Syndrome, Congenital

Alexander K. C. Leung[1], Reginald S. Sauve[1], William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Children's Clinic, Calgary, AB, Canada

## Definition and Characteristics

Congenital rubella syndrome is characterized by the classic triad of cataracts (Fig. 1), congenital heart disease, and sensorineural hearing loss [1].

**Rubella Syndrome, Congenital. Figure 1** This neonate had small eyes and bilateral cataracts as a result of congenital rubella syndrome.

The most common congenital heart defects are patent ductus arteriosus, pulmonary artery stenosis, and pulmonic valvular stenosis. During the neonatal period, congenital rubella can produce a myriad of transient clinical features and conditions, which include jaundice, anemia, hepatitis, hepatosplenomegaly, dermal erythropoiesis ("blueberry muffin" spots), thrombocytopenic purpura, generalized adenopathy, hypotonia, bulging anterior fontanelle with or without pleocytosis in the cerebrospinal fluid, corneal opacity, striated radiolucencies in the long bones ("celery stalk" lesions), interstitial pneumonia, myocarditis, myositis, nephritis, and meningoencephalitis [1]. The clinical features that might be present in the neonatal period and that might persist include cataracts, congenital heart disease, intrauterine growth retardation, microcephaly, microphthalmia, retinopathy ("salt and pepper retinitis"), and glaucoma. Clinical features that might present in later life include sensorineural hearing loss, mental retardation, progressive encephalopathy, psychomotor retardation, autism,

insulin-dependent diabetes mellitus, thyroid dysfunction, and immunologic defects [1].

## Prevalence

The probability of fetal infection is 80–90% if maternal infection occurs in the first 12 weeks of gestation but falls to 17% after 13 weeks of gestation [2]. The risk of congenital rubella is related to the prevalence of rubella. Approximately 2–24% of adults in North America are susceptible to rubella. In the United States there were 172, 353, and 267 confirmed cases of rubella in 1997, 1998, and 1999, respectively, which corresponds to fewer than 0.5 cases per 100,000. The World Health Organization estimates the annual worldwide incidence of rubella to be at least 100,000 cases [3].

## Molecular and Systemic Pathophysiology

Congenital rubella infection results from transplacental transmission of the virus during maternal viremia, which can begin 7 days before the onset of the rash [1]. After transplacental transmission, the virus spreads by a hematogenous route. Once the fetus is infected, the virus typically persists for the remainder of the gestation and also for several months postnatally. The virus has both a mitotic inhibitory action and a cytolytic action on fetal cells. Earlier infection produces more extensive damage. Congenital anomalies are rare when the exposure is after 20 weeks' gestation.

## Diagnostic Principles

Congenital rubella syndrome should be suspected in any infant born to a mother who either developed rubella or who was exposed to rubella at any time during pregnancy. Prenatal diagnosis of rubella in an amniotic fluid sample is possible by nested polymerase chain reaction [4]. The diagnosis can be confirmed by isolation of the virus from the nasopharynx or, less commonly, from the urine or cerebrospinal fluid. Serologic confirmation of the diagnosis is provided by demonstration of rubella-specific IgM either in the cord blood or in the blood of the infant at birth or shortly thereafter, or a stable or increasing serum concentration of rubella-specific IgG in the infant.

## Therapeutic Principles

Treatment is supportive. Infants with congenital rubella can transmit the disease as long as they shed the virus. Only those individuals with established immunity to rubella should care for an infant with congenital rubella. Long-term audiologic, neurodevelopmental, and ophthalmologic follow-up is indicated for early identification and management of these disorders [1]. Universal immunization is important to prevent congenital rubella. The current strategy is to immunize all children at 12–15 months of age with measles-mumps-rubella vaccine and to administer a second dose at 4–6 years. Those children who have not received the second dose at 4–6 years should receive the vaccine as soon as possible, but ideally no later than 11–12 years of age. Women should not be vaccinated during pregnancy and should avoid becoming pregnant for 3 months after vaccination. Determination of rubella immune status is widely required as a component of routine prenatal care.

# Rubinstein-Taybi Syndrome

Cristina Gervasini, Angela Bentivegna, Lidia Larizza
Division of Medical Genetics, San Paolo School of Medicine, University of Milan, Milan, Italy

## Synonyms

Broad thumbs and great toes; Characteristic facies, and mental retardation; Broad thumb-hallux syndrome; RSTS

## Definition and Characteristics

Rubinstein-Taybi syndrome (OMIM #180849)* is a rare congenital disorder characterized by postnatal growth retardation and psychomotor developmental delay, skeletal anomalies (broad and duplicated distal phalanges of thumbs and halluces are a landmark sign) and specific facial dysmorphisms. The latter include down-slanted palpebral fissures, broad nasal bridge, beaked nose and micrognathia [1]. In addition, patients with RSTS have an increased, although not well documented, risk of tumor formation.

## Prevalence

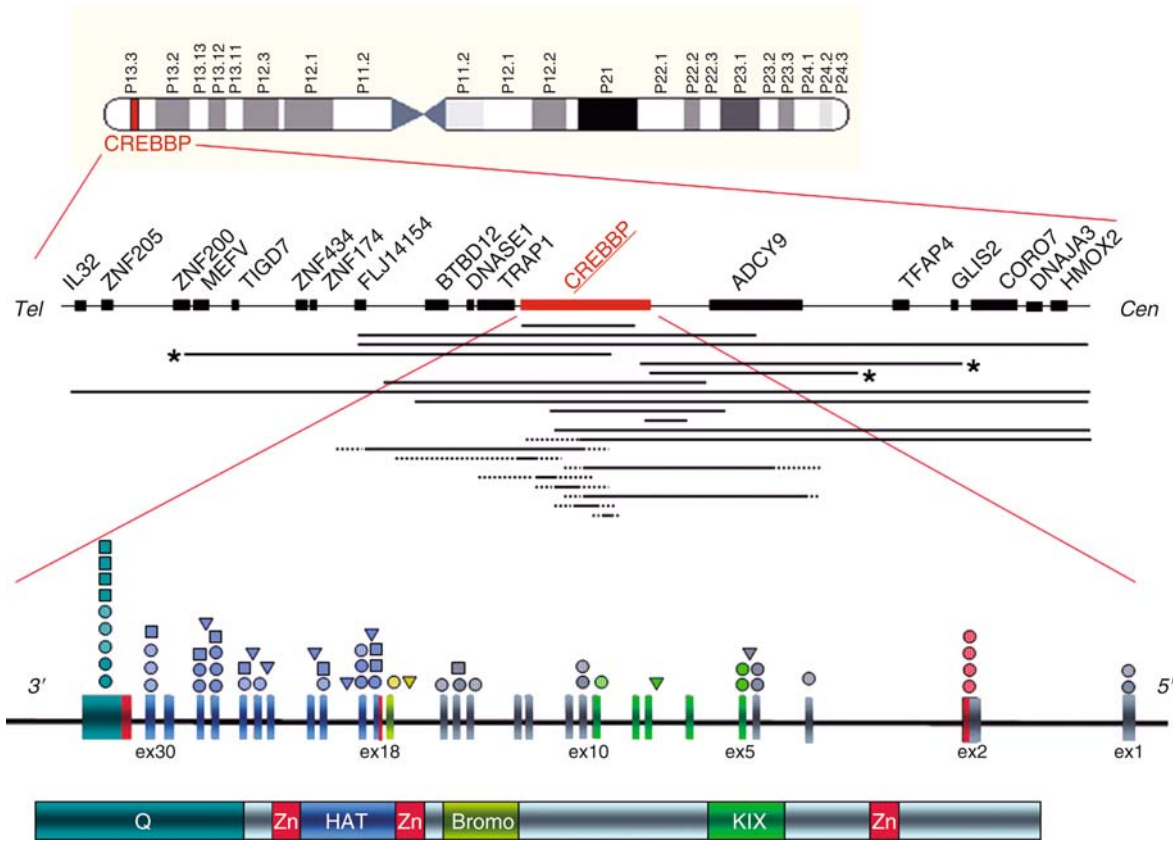
1:100,000–1:125,000.

*For Rubinstein-Taybi the symbol RSTS is recommended because the acronym RTS is used for Rothmund-Thomson syndrome and Rett syndrome, too

## Genes

Mutations in the gene encoding the cAMP Response Element-Binding Protein(CREB)-binding protein (CREBBP, also known as "CBP"), located on chromosome 16p13.3, were found to be responsible for causing the disorder [2]. The mutations identified in the patients range from differently sized microdeletions to point mutations (Fig. 1). A few translocations and inversions disrupting the gene have been reported too [3]. The deletions disrupt the gene removing it partially, entirely or extending to flanking regions. Studies on deletions breakpoints have shown that although no hot spot is identifiable, the CREBBP genomic region has an aspecific and generalized instability that accounts for its proneness to break. Interestingly, the breakpoints of deletions, inversions and translocations frequently cluster in a small interval comprised between CREBBP IVS1 and IVS2. This particularly unstable region is also affected by the breakpoints of translocations, interrupting CREBBP, which are specific of a subset of leukemia. The point mutations (frameshift, nonsense, splice-site and missense in decreasing order of prevalence) are spread in the entire length of the gene. It is to be noted that many mutations fall in the exons corresponding to the main histone acetyl transferase (HAT) protein domain.

RSTS is a genetic heterogeneous disorder as attested by the involvement of a second responsible gene [4]. The gene, EP300, located at 22q13.2, and its protein product, p300, share high sequence and functional homology with CREBBP. Moreover the two proteins have many common protein partners in their cellular functions. By extending to EP300 gene the mutation search on a consistent cohort of RSTS patients found



**Rubinstein-Taybi Syndrome. Figure 1** *Top*: Ideogram of chromosome 16 and chromosomal localization of the CREBBP gene. Middle: the genomic region including CREBBP (red) and flanking genes is zoomed. Deletions spanning CREBBP and adjacent sequences (accounting for about 10% of CREBBP mutations) are indicated by the black lines. Mosaic deletions (only three so far detected) are asterisked; dotted lines target low-resolution mapped breakpoints. Bottom: structure of CREBBP gene and protein. Different colours are used to link gene exons (pictured by rectangles) and corresponding protein domains. Reported point mutations are shown: filled circles (nonsense) and dotted circles (frameshift), squares (missense) and triangles (splicing). Most mutations cluster to exons corresponding to the HAT domain. Known domains from the carboxi-terminal are: Q = trait poly Glutaminic, Zn = zinc-finger, HAT = acetyl transferasic, Bromo = Bromodomain, KIX = CREB binding).

negative to CREBBP mutations, point mutations were detected at 3.3%: a percentage indicating the limited role of EP300 in RSTS.

## Molecular and Systemic Pathophysiology

Haploinsufficiency of CREBBP/EP300 is the probable cause of RSTS in humans, since no clear phenotypic differences are observed between patients carrying either microdeletions or truncating mutations [3]. CBP and the related p300 are transcriptional coactivators acting in different signal transduction pathways, thereby regulating the expression of many genes and playing an important role in the control of cell growth, cellular differentiation, and tumor suppression. They are able to stabilize the transcription complex by binding to several proteins simultaneously, functioning as a scaffold or physical bridge. CBP and p300 harbor histone acetyltransferase activity, a key transcription regulator, as hyperacetylation of *N*-terminal histone tails correlates with transcriptional activity. In addition, the two proteins can acetylate non-histone proteins including several sequence-specific transcription factors and the TFIIE and TFIIF basal transcription factors. Although CBP and p300 share the same functions, there are subtle but clear differences between them [4]. During embryogenesis, CBP and EP300 have similar, not fully overlapping expression patterns. In addition, experiments with the F9 teratocarcinoma cell line showed that retinoic acid signaling is p300-dependent and does not require CBP, whereas cAMP signaling depends on CBP and not p300. Recent work with transgenic mice pointed to the acetyl transferase function of p300 in myogenesis, while the acetyl transferase function of Cbp does not seem to be necessary to this process. The skeletal abnormalities found in heterozygous Cbp null mice are not shared by heterozygous Ep300 null mice. Conversely, there are not very striking phenotypic differences between patients with mutations in either the EP300 or the CBP gene [4]. Double-heterozygous mice null for the Cbp and Ep300 genes resemble the homozygous knockout mice for either gene, in that all three types of mice die in utero, a finding which led to the idea that the combined levels of CBP and p300 are critical during development [4]. However, it is unclear how a decrease in either protein leads to the specific features of RSTS. Perhaps the partial loss of p300 is compensated for by recruitment of CBP, and subsequent depletion of CBP then leads to RSTS. Alternatively, both proteins could be involved in a common function, and hence the total dosage would be required to prevent a syndrome like RSTS. If so, this common function has a relationship with their HAT activity because loss of the sole CBP HAT activity causes RSTS. Interestingly, there is a direct link between HAT activity and long-term memory. Heterozygous Cbp knockout mice have diminished mental capabilities which can be ameliorated by inhibiting histone deacetyltransferase. Transgenic mice with a dominant negative Cbp gene, in which only the HAT activity has been ablated, also show problems with long-term memory, which again can be reversed by a histone deacety lase inhibitor [5].

## Diagnostic Principles

The diagnosis is essentially clinical. The precise identification of the characteristic features is fundamental for a correct diagnosis. The major recognizable signs are the growth retardation, the beaked nose with low hanging septum, the broad thumbs and big toes and mental retardation. Additional investigations to check the duplication of the first rays of the hands and feet, the keloid's presence and dental anomalies can be useful for the diagnosis. Fluorescence in Situ Hybridization and molecular analysis can provide a diagnostic confirmation in detecting a microdeletion or a point mutation, but a negative result does not exclude the diagnosis since the mutation rate is far <100%.

Most important the genetic test should be provided in the context of the genetic counseling. Counseling provides informations to patient's families on both the syndrome and the care and follow-up of the RSTS child. Due to *de novo* occurrence of almost all mutations, yet unreported germ line mosaicism and the fact that very rarely RSTS patients have children, the probability of recurrence risk is negligible.

## Therapeutic Principles

The management strategies for RSTS patients are mainly symptomatic. A correct diagnosis is instrumental to anticipate and treat the medical problems. In the first months of life particular attention should be given to feeding problems, for possible heart defects and glaucoma. Weight gain and obesity may occur at the puberty. Orthopedic problems may be caused by joint hypermobility and lax ligaments. Sleep apnea, respiratory infections, frequent caries and keloid formation are currently noticed in RSTS patients. Specific attention to the first signs of tumor formation may assure adequate treatment and if optioned, an early intervention. A particular and continuous care is needed for the cognitive development and the possible behavioral problems in adult RSTS patients. Studies by using the above mentioned mice models suggest that some of the cognitive and functional deficits observed in mental impairment syndromes may not simply be due to defects originating during development but may result from the prolonged requirement throughout life for both the CREB co-activation and the histone acetylation function. The experiments in mice models with drugs replacing the CBP function or antagonizing the CBP counterparts are encouraging to search for a clinical treatment suitable to improve the neurological and psychiatric condition of RSTS patients.

## Definition and Characteristics

Clinically, the tumor usually presents as a large midline mass protruding between the coccyx and the anus, and is usually covered with normal intact skin (Fig. 1).

Rarely, the skin may be necrotic owing to a compromise in blood supply [1]. The anus is usually displaced anteriorly. Sacrococcygeal teratomas can be classified into four distinct anatomic types that differ in the degree of intrapelvic and extrapelvic extension: type I, predominantly external with minimal presacral extension; type II, external but with significant intrapelvic extension; type III, primarily pelvic and abdominal, but is apparent externally; and type IV, presacral with no external presentation [1]. Approximately 2–10% of sacrococcygeal teratomas are malignant before the affected infant is age 2 months, 50% are malignant by age 1 year, and almost 100% are malignant by age 5 years [2]. Malignant transformation is most likely to occur between age 4 months and 5 years. Malignant change is more frequent in males. A tumor with a large presacral component may cause gastrointestinal or urinary tract obstruction [1].

## Prevalence

Sacrococcygeal teratoma is the most common tumor in the neonatal period. The incidence is approximately 1 per 35,000–40,000 live births [3]. The female:male ratio is approximately 4:1 [1]. Most cases occur sporadically, although 14–50% of patients have a family history of twinning [1].

## Molecular and Systemic Pathophysiology

Teratomas are congenital tumors composed of tissues derived from the three primitive germinal layers: ectoderm, mesoderm, and endoderm [4]. Postsacral tumors are thought to arise from the pluripotent embryonic cells that occur in greatest concentration in Hensen's node of the primitive knot and presacral tumors from incomplete migration of germ cells from the yolk sac to the urogenital ridge [1]. The female gonads terminate their differentiation at 10 weeks in contrast to 7 weeks for the male testes [4]. Their totipotential cells, therefore, remain longer and are more prone to disturbances. This might account for the higher incidence of sacrococcygeal teratomas in females. Their midline distribution can be explained by the arrest or aberrant migration of the primordial germ cells [5]. Sacrococcygeal teratomas may be the result of twinning or abortive attempts at twinning, which might account for the higher incidence in monozygotic twins [1].

## Diagnostic Principles

The diagnosis is usually made during prenatal ultrasonography. Postnatally, the diagnosis is mainly clinical. A lateral radiograph of the abdomen may show anterior displacement of the rectum, sacral defects, and possible calcification within the tumor. Abdominal and pelvic ultrasonography, CT, and MRI help assess for any internal extension of the tumor, involvement of other organs, and the existence of metastatic lesions. MRI is particularly useful in the evaluation of spinal canal infiltration. A chest radiograph or CT is useful for revealing pulmonary metastasis. Serum $\alpha_1$-fetoprotein levels are elevated in 70% of children with malignant tumors, with normal levels in children with benign tumors [1]. Differential diagnosis includes meningocele, leiomyoma, lipoma, lymphangioma, hemangioma, dermoid cyst, neuroblastoma, chordoma, and tail-like remnant.

## Therapeutic Principles

If the tumor is greater than 5 cm on prenatal ultrasonography, Caesarean section is recommended to avoid dystocia and rupture of the tumor. Complete resection of the tumor and the coccyx is essential, for failure to remove the coccyx will result in local recurrence in 30% of cases [1]. If the tumor is not resectable, chemotherapy may shrink the tumor and

**Sacrococcygeal Teratoma. Figure 1** Infant with sacrococcygeal teratoma, presenting as a large mass in the sacrococcygeal area with anterior deviation of the anus.

render it resectable. Adjunct chemotherapy is also indicated for malignant tumors at stage II or greater and for the treatment of distant metastasis.

## Salmon Patches

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital
The University of Calgary, Calgary, AB, Canada

### Synonyms

Macular stain; Nevus simplex; Nevus flammeus neonatorum

### Definition and Characteristics

Salmon patches are the most common vascular lesions in infancy. The lesions are scarlet to pink, flat, can be totally blanched, and usually deepen in color with vigorous activity, crying, or changes in ambient temperature [1] (Fig. 1). In white infants, they are usually bright red or pink and are darker in Oriental or black infants [1]. The lesions are most commonly found on the nape, followed by the glabella, and eyelids [2]. Colloquially, the lesions on the forehead and eyelids are known as "angel's kisses" and the ones in the occipital area as "stork beak marks" or "stork bite marks." Other less common sites are the nasolabial folds, lips and sacral area [3]. Prominent lesions in the glabella are associated with Beckwith-Wiedemann syndrome, fetal alcohol syndrome, and Nova syndrome. Salmon patches are generally not associated with extracutaneous anomalies [3]. In spite of their midline location, most salmon patches, except those in the sacral area, are not associated with spinal dysraphism [3].

### Prevalence

In the Caucasian population, salmon patches are present in approximately 44% of all neonates [4]. They are less common in dark-skinned neonates [2]. Both sexes are equally affected [2]. The lesions tend to fade with time and they are rarely detected after the age of 6 years [4].

### Genes

There is no evidence of a Mendelian mode of inheritance.

### Molecular and Systemic Pathophysiology

Presumably, salmon patches are composed of ectatic dermal capillaries that represent the persistence of fetal circulating patterns in the skin [4].

**Salmon Patches. Figure 1** Typical salmon patches located on the occipital area.

## Diagnostic Principles

The diagnosis of salmon patches is clinical and no laboratory test is necessary. The condition should be differentiated from nevus flammeus (port-wine stain). Nevus flammeus is a capillary malformation characterized clinically by persistent macular erythema and pathologically by ectasia of the papillary and superficial reticular dermal capillaries, which are otherwise lined by normal–appearing flat endothelial cells. The capillaries become more ectatic with age and the color gradually deepens. The lesions of nevus flammeus are usually unilateral, segmental, and do not follow the lines of Blaschko. Nevus roseus is a lateralized telangiectatic birthmark characterized by a light-red or pale pink color, contrasting with the dark line of nevus flammeus [5]. The lesion tends to be arranged in a checkerboard pattern [5].

## Therapeutic Principles

Treatment consists of providing reassurance to the parents that the lesion will disappear or significantly regress with time [2]. Salmon patches on the eyelids and glabella usually disappear by 2–3 years of age [4]. Nuchal and sacral lesions tend to persist longer. Because of the possible association with occult spinal dysraphism, it is recommended routine ultrasound imaging of the lumbosacral spine be performed in neonates with salmon patches in the sacral area [3].

# Sandhoff's Disease

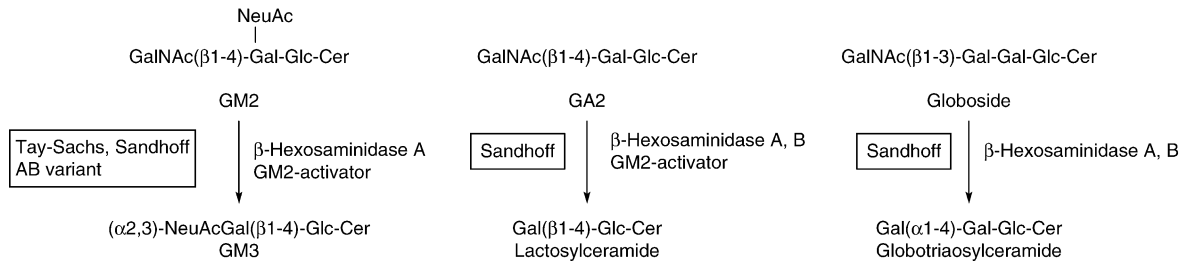
Thomas Kolter, Ute Schepers, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology and Lipid Biochemistry, Kekulé-Institute, University of Bonn, Bonn, Germany

## Synonyms

β-Hexosaminidase β-subunit deficiency; 0-Variant of the GM2-gangliosidoses

## Definition and Characteristics

Autosomal recessive defect in the β-subunit of the dimeric β-hexosaminidases A (αβ) and B (ββ) leads to accumulation of ganglioside GM2 in neuronal cells and of additional substances like globoside and oligosaccharides in other organs [1]. Together with ►Tay-Sachs disease and ►GM2-activator protein-deficiency, Sandhoff's disease belongs to the GM2-gangliosidoses [2].



**Sandhoff's Disease. Figure 1** Cells and Cellular Interactions: Neuropathology is generally similar to Tay-Sachs disease. In addition, occurrence of storage cells in systemic tissues that distinguishes the 0-variant from the B- and AB-variant.

### Prevalence

Heterozygote frequency is at 0.0036 in the general population. Increased frequency, e.g., in Northern Argentina, Saskatchewan, and Lebanon.

### Genes

HEXB, localized on chromosome 5q13. At least 26 mutations reported (Fig. 1).

### Molecular and Systemic Pathophysiology

The gross pathology is very similar in the variant forms of the GM2-gangliosidoses, except that visceral organ involvement is evident in 0-variant. Clinical phenotypes in the GM2-gangliosidoses vary from infantile-onset, rapidly progressive neurodegenerative disease that leads to death before age 4 years to later-onset forms, with more slowly progressive neurologic conditions and survival into childhood, adolescence, or with long-term survival. Clinical phenotypes of chronic forms are varying and include progressive dystonia, spinocerebellar degeneration, motor neuron disease, and psychosis [2].

### Diagnostic Principles

Enzyme assay in any tissue sample or body fluid, metabolic studies in cultured cells.

### Therapeutic Principles

Only supportive treatment is available to date. Clinical studies: stem cell transplants, substrate reduction therapy [3].

## SAP-B Deficiency

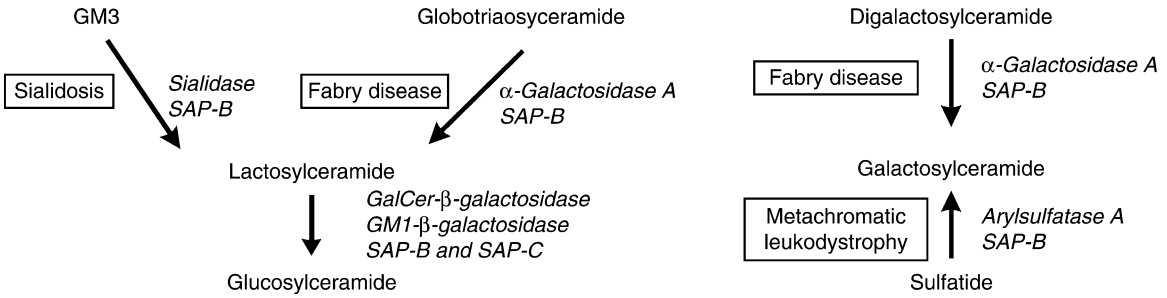
Ute Schepers, Thomas Kolter, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology & Lipid Biochemistry, Kekulé-Institute, University of Bonn, Bonn, Germany

### Synonyms

Sulfatide activator deficiency; SAP-1 deficiency

### Definition and Characteristics

Autosomal recessive defect in the sphingolipid activator protein B (SAP-B, saposin B). In addition to



**SAP-B Deficiency. Figure 1** Selected glycolipid substrates of SAP-B and diseases associated with its deficiency.

sulfatide, increased amounts of globotriaosylceramide and digalactosylceramide were excreted in the urine (Fig. 1).

## Prevalence

Only nine cases have been reported and no data of heterozygote frequency among general population are known.

## Genes

pSAP, localized on chromosome 10q22.1. Only seven mutations have been reported. Defects of SAP-B could be attributed to homoallelic point mutations, which destroyed the glycosylation site, substituted a cysteine residue, or generated a new splice site [1].

## Molecular and Systemic Pathophysiology

Clinical phenotypes vary from infantile onset, rapidly progressive MLD like disease (death before age 3 years) to later-onset forms like juvenile form (death before age 20 years) and adult form (death at age 22) [2].

In the infantile phenotype, signs included an ataxic gait, intellectual deterioration, muscle hypertonicity, a strongly reduced nerve-conduction velocity, metachromasia in peripheral nerves, high urinary sulfatide levels, dementia, and decerebration, and neuroimaged periventricular signs of demyelination, as in MLD. Clinical courses of the chronic forms vary. Psychotic histories can often be misleading and are followed by subtle signs of motor disability and vegetative (e.g., gall bladder) dysfunction, and late identification of leukodystrophy. Nerve-conduction velocity may remain almost unremarkable. The degree of demyelination is variable.

The clinical findings in SAP-B deficiency are similar to those in metachromatic leukodystrophy (MLD). Submucosal macrophages are filled with metachromatic material (ultrastructure of sulfatide storage), while neurons are crowded with non-metachromatic, but periodic acid-Schiff-positive material (ultrastructure of membranous bodies of the gangliosidosis type), and endothelial cells showed pleomorphic depositions.

## Diagnostic Principles

Analysis of the lipid pattern in urine sediment of patients may provide the first evidence for SAP-B deficiency. More confident results may be obtained by the determination of the SAP-B level in urine, fibroblast extracts, or tissue samples by ELISA. Since SAP-B is a non-enzymatic protein, the best diagnosis can be achieved by direct sequencing of pSAP cDNA.

## Therapeutic Principles

Only supportive treatment is available to date.

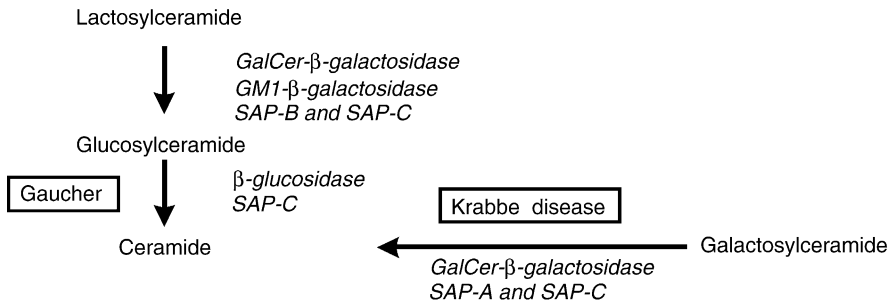
# SAP-C Deficiency

Ute Schepers, Thomas Kolter, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology & Lipid Biochemistry, Kekulé-Institute, University of Bonn, Bonn, Germany

## Synonyms

Glucosylceramidase activator deficiency; Gaucher activator deficiency; SAP-2 deficiency



**SAP-C Deficiency. Figure 1** Selected glycolipid substrates of SAP-C and diseases associated with its deficiency.

## Definition and Characteristics

Autosomal recessive defect in the sphingolipid activator protein C (SAP-C, saposin C). Accumulation of glucosylceramide especially occurs in spleen, liver, and brain (Fig. 1).

## Prevalence

Only a few cases have been reported and no data of heterozygote frequency among general population are known.

## Genes

pSAP, localized on chromosome 10q22.1. In three analyzed cases, SAP-C deficiency was attributed to point mutations. Further two missense mutations were identified [1].

## Molecular and Systemic Pathophysiology

SAP-C deficiency is a Gaucher-like disease with nearly normal β-glucosidase activity. Patients show hepatosplenomegaly by the age of 1 year. It is a juvenile visceromegalic and neuronopathic disease. Growth retardation, delayed skeletal maturation, hematologic signs of hypersplenism, Gaucher cells in the bone marrow, and increased serum acid phosphatase are early signs. After a dementing process, death usually occurs within the first three (mostly the second) decades of life.

The clinical findings in SAP-C deficiency are similar to those in Gaucher disease type 3. In vivo, SAP-C seems to be essential for the degradation of glucosylceramide. Its genetic defect causes accumulation of the lipid also in the brain. In liver and spleen, a large accumulation of glucosylceramide, but not of other lipids, is found, while the level of β-glucosidase is normal. Ultrastructurally, neuronal storage lysosomes reflected the cerebral lipid storing process. The membrane-bound inclusions contained lamellae stacked with parallel bilayers. Other inclusions have an electron-dense granular center and peripheral concentric or radial lamellae [2].

## Diagnostic Principles

The diagnosis may be verified by an immunochemical analysis of extracts of tissue samples or cultured skin fibroblasts from the patient or by molecular biology studies.

## Therapeutic Principles

Only supportive treatment is available to date.

## References

2. Beutler E, Grabowski G (2000) Gaucher disease. In: Scriver CR, Beaudet AL, Sly WS, Valle D (eds) The metabolic and molecular bases of inherited disease, Vol III, 8th edn, Chapter 146, McGraw Hill, New York, pp 3635–3669

# SAP-Precursor Deficiency

Ute Schepers, Thomas Kolter, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology & Lipid Biochemistry, Kekulé-Institute, University of Bonn, Bonn, Germany

## Synonyms

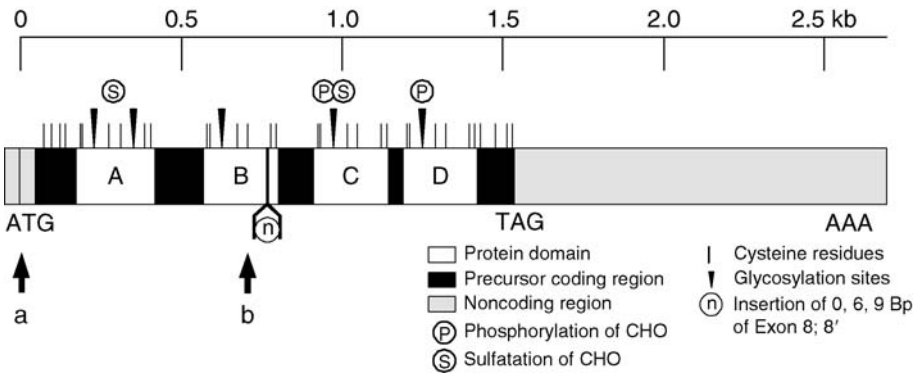
Sphingolipid activator protein deficiency; Prosaposin deficiency; Combined SAP deficiency

## Definition and Characteristics

Autosomal recessive defect in the sphingolipid activator protein precursor (SAP-precursor, prosaposin) protein leading to a total loss of all four known sphingolipid activator proteins or SAP-A, B, C, and D (saposins A-D) and an excessive storage of sphingolipids in several tissues (Fig. 1) [1,2,3].

## Prevalence

Only four cases have been reported and no data of heterozygote frequency among general population are known.



**SAP-Precursor Deficiency. Figure 1** Structure of the SAP-precursor cDNA. The four domains A-D encode for the mature proteins found in human tissues. Two mutations lead to a SAP-precursor deficiency: a, A1T (Met1Leu) a mutation of the translation start and b, a 1 bp deletion (c.803delG) within the SAP-B domain. This leads to a frameshift and premature stop.

## Genes

pSAP, localized on chromosome 10q22.1. Only two mutations have been reported that lead to this disease (Fig. 1) and one missense mutation.

## Molecular and Systemic Pathophysiology

The clinical findings are similar to those in Gaucher disease type 2. It is an infantile, acute neuronopathic, visceromegalic disease, with death occurring within the first 2 years of life. Massive hepatosplenomegaly and storage macrophages resembling Gaucher cells were observed in bone marrow. The neuropathology features neuronal storage and loss with a massive depopulation of cortical neurons and pronounced fibrillary astrocytosis. Paucity of myelin and stainable axons in the white matter go along with signs of active demyelination [2].

Enzyme studies with leukocytes showed a profound deficiency of β-galactosylceramidase activity as in Krabbe disease. The ultrastructure of liver, nerve, and skin biopsies confirm a lysosomal storage disease with abundant vesicular inclusions and additional membranous bodies in the liver sinusoidal cells [3].

## Diagnostic Principles

Immunochemical analysis of extracts of tissue samples or cultured skin fibroblasts from the patient or by molecular biology studies. Loading studies in cultured cells are recommended.

## Therapeutic Principles

Only supportive treatment is available to date.

# Sarcoid Myopathy

Bennett Myers[1], David N. Herrmann[2]
[1]Dent Neurological Institute, Orchard Park, NY, USA
[2]Departments of Neurology and Pathology, University of Rochester, Rochester, NY, USA

## Synonyms

Sarcoid myositis

## Definition and Characteristics

Sarcoidosis is a multisystem granulomatous disease of uncertain etiology that affects the lungs in 90% of patients, but can affect nearly any organ system, including muscle [1]. Asymptomatic involvement of muscle occurs frequently in sarcoidosis; however, in a small percentage of cases, weakness evolves. Symptomatic sarcoid myopathy has several forms, the most common of which is a slowly progressive, chronic myopathy, most often seen in post-menopausal women. It typically occurs late in the clinical course of sarcoidosis and is characterized by predominantly proximal weakness, atrophy and

fibrosis of proximal muscles and a normal creatine phosphokinase (CPK) level. A second presentation is that of a nodular myopathy, characterized by multiple enlarging, painful, palpable nodules caused by "infiltrative sarcoidosis." A rare form is an acute sarcoid myositis that can mimic dermatomyositis. Patients with this type have proximal weakness, fever and myalgias that evolve over less than three months. CPK levels may range from normal to >15,000 IU/L [1]. This form may be associated with an acute polyarthritis or erythema nodosum. Muscle contractures are rarely associated with sarcoid myopathy [1].

## Prevalence

The overall prevalence of sarcoidosis is 40 per 100,000, with the highest incidence in the USA (African Americans) and Sweden, but a low prevalence in the Far East [1]. Among all sarcoidosis patients, 50–80% will have granulomas on random muscle biopsy. However, only 1.4–2.3% of all sarcoid patients will have a symptomatic sarcoid myopathy.

## Genes

Sarcoidosis is associated with class I HLA-B8 and class II HLA-DR3 in Eastern Europeans and with HLA-Dw52 among Japanese [1]. Heterozygous mutations in the cystic fibrosis transmembrane regulator gene (CFTR) appear to predispose to sarcoidosis in some cases [2].

## Molecular and Systemic Pathophysiology

The etiology of sarcoidosis is uncertain, with evidence for both genetic and environmental factors. The increased prevalence of sarcoidosis in first-degree relatives of patients, as well as the association with certain HLA phenotypes in some countries, implies genetic predisposition. However, reports of spatial, seasonal and familial clusters of cases suggest a precipitating role for environmental factors or infectious antigens in a genetically susceptible host. There is as yet no convincing evidence linking any specific microorganism to sarcoidosis [1].

Pathological studies in sarcoid myopathy demonstrate noncaseating epithelioid granulomas identical to those seen in other organ systems. These are composed of infiltrating mononuclear cells (predominantly T lymphocytes and macrophages), as well as multinucleated giant cells. CD4+ T helper cells, including cells expressing the OX40 receptor, predominate and are found mostly at the center of granulomas, while CD8+ cells are at the periphery [3]. Aside from the granulomas, muscle biopsies often show endomysial chronic inflammation primarily composed of lymphocytes and plasma cells and/or foci of perivascular inflammation. Muscle fiber necrosis is not a prominent feature, except in severe cases of sarcoid myositis. Muscle fibrosis is seen in the chronic form of sarcoid myopathy [4]. The dysimmune response in sarcoidosis is of the Th1 type [5]. It appears to be triggered by the interaction of putative sarcoid antigens with specific T cell antigen receptors and HLA antigen presentation molecules. Activated T cells and macrophages predominantly release interferon-gamma, interleukin-2, TNF alpha and other Th1 cytokines (I L 12, IL 18), which further enhances the inflammatory response [5]. OX40+ cells have been suggested to promote clonal T-cell expansion in granulomas and modulate cytokine release. The causes of muscle fiber damage in sarcoidosis has been presumed to reflect an "innocent bystander effect" of the granulomas, mediated by mechanical compression and distortion of muscle fibers, however some data implicate infiltration of granulomatous inflammatory cells, with protease and possibly cytokine mediated muscle damage. This mechanism contrasts with typical polymyositis, where CD8+ T lymphocytes predominate and there is a primary immune attack on the muscle fibers, which show abnormal HLA 1 expression and lymphocytic invasion of non–necrotic fibers.

## Diagnostic Principles

Electromyography is valuable in demonstrating a "myopathic" process, with or without evidence of muscle fiber irritability. CPK elevation is a variable finding. In patients with known systemic sarcoidosis, the definitive diagnosis of sarcoid myopathy rests on the pathological finding of noncaseating granulomas in muscle, as concomitant corticosteroid use can also produce a proximal myopathy [1]. In patients without previously diagnosed sarcoidosis, other causes of granulomatous disease, including inflammatory bowel disease, tuberculosis, syphilis, fungal infections, vasculitides (Wegener's granulomatosis) and thymoma related paraneoplastic syndromes (e.g., granulomatous myositis, myasthenia gravis, myocarditis, thyroiditis overlap syndromes) must be considered. Other supportive features of sarcoidosis include a positive Kveim–Siltzbach reaction, an elevated serum angiotensin converting enzyme level, bilateral hilar lymphadenopathy, anemia, thrombocytopenia, leukopenia, hypergammaglobulemia, hypercalcemia, hypercalcuria, and the presence of anergy. Gallium-67 scans may be useful to identify areas of inflammation that may be biopsied to demonstrate the presence of systemic granulomas [1].

## Therapeutic Principles

Symptomatic sarcoid myopathy is treated with immunosuppression. Corticosteroids are first line therapy [1]. The

chronic form of sarcoid myopathy may be less responsive than the acute form, probably due to the presence of muscle fibrosis. Although improvement may not occur in the chronic form, the progression of weakness can usually be arrested. Cyclosporine, azathioprine, methotrexate, cyclophosphamide or chlorambucil have been used in steroid resistant cases or as steroid-sparing agents [1]. TNF alpha antagonists (e.g., infliximab) show promise in the management of neurosarcoidosis, however published data on use in sarcoid myopathy are lacking.

Vikram K. Mahajan[1], Nand Lal Sharma[1], Surender Kashyap[2]
[1]Department of Dermatology, Venereology & Leprosy, Indira Gandhi Medical College, Shimla, India
[2]Department of Pulmonary Medicine, Indira Gandhi Medical College, Shimla, India

### Synonyms

Pulmonary sarcoidosis; Mortimer's malady; Vanishing lung disease

### Definition and Characteristics

Sarcoidosis, a multisystem granulomatous disease, affects lungs in about 90% patients. Environmental exposures are believed to interact with genetic factors in determining its pattern, presentation, progression, and prognosis. However, attempts to elucidate its cause have been thwarted by lack of an animal model and failure to identify the antigen. The role of mycobacterium tuberculosis, atypical mycobacteria, borrelia burgdorferi, propionibacterium acne, viruses, and noninfectious environmental agents is yet to be authenticated. Formation of well-defined, compact, non-caseating, naked epitheloid cell granulomas with Langhans or foreign body type of giant cells in affected tissues is its hallmark feature. Fibrinoid necrosis may occur in large granulomas, and asteroid, Schaumann's, or Hamasaki-Wesenberg inclusion bodies are not specific for sarcoidosis. The common symptoms are dyspnea, wheezing, cough, and chest pain. General malaise, lethargy, and weight loss are not unusual. Bilateral hilar (occasionally unilateral) or mediastinal lymphadenopathy and parenchymal involvement occur more often. Pleural effusion, pleural thickening, pneumothorax, and cavitation are less common and hemoptysis is rare. The disease is chronic or progressive in 10–30%, while 10–20% patients develop severe respiratory disability or irreversible lung changes as end-stage lung fibrosis ensues [1].

### Prevalence

Sarcoidosis is worldwide, affects individuals aged 20–40 years, and women have it twice as often as men. It is severe, chronic, disabling, and eight times more prevalent in African Americans than whites. Its prevalence is high in Scandinavian countries, England, Ireland, North America, and Japan; it is less frequent in Central and South America, mainland China, and Africa. The reported prevalence in USA is 40 cases/100,000 populations and estimated cumulative lifetime risk for sarcoidosis is 0.85% for whites and 2.4% for blacks [1].

### Genes

Familial sarcoidosis without any consistent mode of inheritance is well recognized. The following HLA types appear to influence the pattern of the disease rather than determine its occurrence [2]:

- HLA-B8/DR3 gene – inherited as a sarcoid risk haplotype in patients with acute sarcoidosis.
- HLA-DRB1 gene – associated with sarcoidosis susceptibility and prognosis.
- HLA-DQB1*0201 gene – associated with resolved disease, decreased risk, and lack of progression.
- HLA-DQB1*0602 gene – associated with persistent disease.

Additionally, BTNL2 gene (class II MHC region of chromosome 6p) is suggested to impart susceptibility for developing sarcoidosis in individuals of African American and German origins [3]. Reports speculating non-HLA genes (Table 1) to influence susceptibility or severity need confirmation.

## Molecular and Systemic Pathophysiology

Table 1 lists immunologic abnormalities observed in sarcoidosis patients. Briefly, sarcoidosis granulomas form in the lungs apparently due to exaggerated immune reaction to some inhaled antigen of low solubility/degradability.

Macrophages bearing MHC-II molecule present these unknown antigens to Th1-type T-cells leading to their proliferation and activation. These activated T-cells release various cytokines including interleukin (IL)-2, TNF-α, monocyte chemotactic factors, macrophage migration inhibition factor, and leukocyte inhibitory factor. IL-2 activates and expands clones of T-lymphocytes leading to alveolitis. The monocyte chemotactic factor attracts blood monocytes into the lungs while other mediators such as macrophage migration inhibitory factor influence these trapped monocytes to transform into epitheloid cells and modulate granuloma formation. The granuloma formation and associated helper (CD4+) T-lymphocyte alveolitis cause tremendous alveolar injury. This stage is also marked by peripheral CD4+ T-cell lymphopenia and depressed cutaneous delayed hypersensitivity reactions. The interferon-γ produced by Th1 lymphocytes increases platelet-derived growth factor-β from macrophages, which stimulates fibroblasts, the main effector cells for fibrosis. Transforming growth factor-β and matrix proteins (laminin, fibronectin, collagen peptides,

elastin-derived peptides) are other fibroblast chemoattractants but the mechanism for their increased production remains unelucidated.

### Diagnostic Principles

The diagnostic work-up [4,5] includes confirmation by histopathology, assessment for progression, extent and severity of organ involvement, and likelihood of therapeutic outcome. Although the need of biopsy in asymptomatic patients and when neoplasia or other granulomatous diseases have been excluded is somewhat controversial, any patient requiring corticosteroid therapy should have histologic diagnosis. Bronchial, transbronchial, or surgical lung biopsy is the direct way to obtain tissue while video-assisted thoracoscopy permits biopsy of both lung and lymph nodes with precision and minimal trauma. A CD4/CD8 cell ratio of >3.5 in bronchoalveolar lavage is diagnostic with high specificity and is a marker for disease activity. As both restrictive and obstructive abnormalities occur, pulmonary function tests are indicated for all patients. Routine chest x-ray helps in staging and assessing disease progression/therapeutic response. High-resolution computed tomographic (CT) scan or Gallium lung scan obviate the need for invasive procedures but is indicated in limited cases. Suppression of tuberculin and other intradermal responses, elevated serum γ-globulins, calcium and angiotensin converting enzyme (2 x normal) levels, and hypercalciuria support diagnosis in most cases. Kveim-Siltzbach reaction is positive in patients with active disease.

### Therapeutic Principles

In symptomatic and deteriorating pulmonary disease the therapy is aimed at ameliorating symptoms and to prevent fibrosis. Prednisolone 40 mg/day given for 2 weeks initially is tapered off over next 6–8 weeks to maintenance doses of 10–15 mg/day for at least 6 months. Steroid sparing agents (methotrexate, chloroquine, azathioprine, cyclophosphamide, or cyclosporin) are indicated in patients having intolerable corticosteroid side effects, progressive disease despite steroid therapy, or long-term corticosteroid need. Systemic antibiotics or antifungals (itraconazole) are indicated when bronchiectasis is complicated by bacterial infection or aspergilloma. Surgical lung resection may be needed in patients developing fatal hemoptysis while patients with end stage disease may do well with lung transplantation.

## Sarcoma Family Syndrome of Li and Fraumeni

►Li-Fraumeni Syndrome

## Sarcosinemia

C. Ronald Scott
Division of Medical Genetics, University of Washington, Seattle, WA, USA

### Synonyms

Sarcosinuria

### Definition and Characteristics

An autosomal recessive disorder of one-carbon metabolism that results in an accumulation of sarcosine (N-methylglycine) in plasma and the excretion of unmodified sarcosine in urine. There are no recognized physiological consequences from increased plasma sarcosine. Abnormalities of mental development were originally proposed as a consequence of sarcosinemia, but subsequent evaluations have indicated that sarcosinemia is most likely a benign condition unrelated to significant clinical problems [1].

### Prevalence

Sarcosinemia is a rare disorder, with a prevalence in newborns of approximately 1/350,000. A higher prevalence has been identified in Quebec, Canada, 1 of 28,000 newborns, presumably on the basis of a founder effect. The gene for sarcosine dehydrogenase (SARDH)

is located on chromosome 9q34. It is at least 75.3 kb in length and codes for a protein with a predicted mass of 99,505 Da (including bound FAD). The gene is expressed in liver and kidney tissue.

## Genes

The gene for sarcosine dehydrogenase (SARDH) is located on chromosome 9 at 9q34.2. It is 76.36 kb in length, consists of 16 exons, and codes for a protein (EC 1.5.99.1) with a predicted mass of 101,037 Da (including bound FAD). The gene is primarily expressed in lines and kidney tissue [2,3].

## Molecular and Systemic Pathophysiology

Sarcosine is a normal product of the one-carbon cycle and an intermediate in the formation of "active formaldehyde." The active formaldehyde is utilized in the re-circulation of folate between 5-methyltetrahydrofolate and 5,10-methylene tetrahydrofolate. Sarcosine is formed from dimethylglycine via the enzyme dimethylglycine dehydrogenase (EC.1.5.99.2), and in turn is converted to glycine by the enzyme sarcosine dehydrogenase (EC 1.5.99.1). This intermediate step is believed to be the major source of sarcosine in humans. An alternative mechanism for sarcosine formation has been proposed from a glycine methyltransferase (EC2.1.1.20), but probably can account for no more than 10% of the daily synthesis.

The primary metabolic defect associated with sarcosinemia is a deficiency of sarcosine dehydrogenase. The sarcosine dehydrogenase requires covalently bound FAD for activity. The FAD utilized is reoxidized via the mitochondrial electron transport system for regeneration of the sarcosine dehydrogenase. Defects that exist in the electron transfer flavoprotein (ETF) can also result in modest increases in serum sarcosine. This has been observed in patients with glutaric acidemia, type II. In a similar fashion, increased concentrations of sarcosine in plasma have been observed in patients with severe folate deficiency, and corrected when the folate deficiency is corrected.

The relationship of sarcosinemia to mental deficiency remains a nagging problem. Appropriate clinical studies that remove probands from families and only evaluate siblings with sarcosinemia indicate that their intellectual activity is low normal. The observation that glycine and sarcosine share a common glycine transport system, GlyT-1, within the brain suggests that a disturbance in glycine regulation of neurotransmitters offers a theoretical mechanism for cognitive impairment. To date, there has been no confirmation of molecular defects within the sarcosine dehydrogenase gene for patients affected with sarcosinemia.

A disorder similar to sarcosinemia, dimethylglycinuria, has also been identified. A single report of a child with an odor of "fish," similar to what has been observed in trimethylaminuria, was confirmed to have a defect in dimethylglycine dehydrogenase. The child had normal plasma values for folate and sarcosine.

## Diagnostic Principles

Sarcosinemia is confirmed by a marked elevation of sarcosine in blood (50–800 μM) or urine. As a secondary amine, sarcosine reacts poorly with ninhydrin, but is detectable using standard amino acid analysis. Its persistence after the clinical administration of folic acid confirms the diagnosis of this rare disorder.

## Therapeutic Principles

No specific therapeutic intervention is required for sarcosinemia. The levels of sarcosine may be modestly influenced by reducing the protein in the diet, and supplementing with folic acid. Whether this is indicated remains dubious.

### Synonyms

Keloids; Hypertrophic scars

### Definition and Characteristics

Hypertrophic scars are defined as red, raised, sometimes itchy scars confined to the border of the original surgical incision or injury. These scars may increase in size rapidly for 3–6 months, and after a static phase of up to 2 years, begin to regress. By contrast, keloids are large, raised, occasionally painful, and pruritic extending beyond the boundaries of the original wound or injury [1]. Histologically, hypertrophic scars and keloids are composed of excessive collagen deposition, and keloids reveal an increased fibroblast cellularity, a persisting inflammatory infiltrate including most cells and an increased number of partially or totally occluded microvessels. By contrast to hypertrophic scars, keloids reveal a highly increased synthesis and deposition of collagen type III [2] with tightly packed, thickened collagen bundles arranged in parallel pattern to the epidermis.

### Prevalence

There is a higher incidence (4–6%) in individual with skin type V and VI (Fitzpatrick) occurring in the Black population and to a lesser extent in Hispanics and Orientals, when compared with Caucasians [3]. However, more recent data determining the prevalence of hypertrophic scars and keloids are not available. Keloids are found most commonly on the ear lobe, shoulders, upper back, and mid-chest.

### Genes

Most hypertrophic scars occur sporadically, but some cases of keloids are familiar. In a recent study, the genetics of keloid formation has been investigated in 14 pedigrees with familial keloids accounting for 341 family members, of whom 96 displayed keloids. The pattern of inheritance observed in these families is consistent with an autosomal dominant mode with incomplete clinical penetrance and variable expression [4]. Even though involvement of genes of the transforming growth factor-beta family are highly suggestive, all studied single nucleotide polymorphism in genes encoding ligands and receptors of this family so far identified are not causally related to keloid susceptibility.

## Molecular and Systemic Pathophysiology

Trauma, foreign-body reactions, infections, acne, piercing, preceding injury, and in the case of keloids, traction forces have been proposed as precipitating factors. On the molecular level, overexpression of and higher sensitivity to transforming growth factor-beta$_1$ (TGF-beta$_1$) are crucial in the pathogenesis of hypertrophic scars and keloids. Dysregulated TGF-beta$_1$ expression results in excessive increase in collagen synthesis and deposition, enhanced cellularity mainly of alpha-smooth muscle actin-positive myofibroblasts, and enhanced vessel formation, hallmarks in dysregulated scar formation. Apoptosis mediates the decrease in cellularity during transition between granulation tissue and remodeled restoration tissue. Keloid-derived fibroblasts are refractory to Fas-mediated apoptosis, and neutralization of autocrine TGF-beta$_1$ can abrogate this resistance. Interestingly, TGF-beta$_1$ and the antiapoptotic Bcl-2 were significantly upregulated in fibroblasts co-cultured with keloid-derived keratinocytes, suggesting that the overlying keratinocytes of the keloid lesion may play an important role in keloidgenesis by paracrine mechanisms. Whether the observed mutations in p53 in keloids result in decreased apoptosis needs causal proof. In addition, altered levels of immunregulatory cytokines with collagen synthesis reducing effects, such as interferon-gamma, awaits confirmation with a greater number of patients suffering from keloids.

## Diagnostic Principles

Clinical assessment with macroscopic presentation and time course of scar development is diagnostic. Scar classification should follow the Vancouver Scar Scale.

## Therapeutic Principles

Based on a systematic MEDLINE and EMBASE search (1996 to 2001) with evidence-based evaluation of clinical studies, international clinical recommendations on scar management were published [1]. For prevention of hypertrophic scars and keloids after surgery or injury, silicone gel sheeting or hypoallergenic taping is recommended. If the scar is resistant to silicone therapy, monthly corticosteroid injections are indicated. If silicon sheeting, intra-lesional corticosteroid injections, and pressure garments are not successful after 12 months, surgical excision with postoperative applications of silicone sheeting should be considered for hypertrophic scars, and in case of keloids with high recurrence rates, surgical excision may be combined with intra-lesioned corticoid injections or by immediate radiation therapy after surgery. However, the long-term risk of radiation must be carefully considered. Innovative therapies such as bleomycin, 5-fluorouracil, and distinct laser modalities may have a future role, in addition to strategies suppressing the effects of TGF-beta$_1$ or collagen synthesis. In fact, antisense oligonucleotides or neutralizing antibodies against TGF-beta$_1$ have proven to be successful in reducing scar formation and disorganized collagen deposition in rodents. Topical application of imiquimod 5% cream to keloids alters expression of genes associated with apoptosis and induces interferons locally at the site of application to the skin. However, the role of the imiquimod, if any, in the therapy of the keloids requires further investigation [5].

# Scarring Alopecia

Matthew Harries[1], Tobias Fischer[2], Ralf Paus[2]

[1]Dermatology Centre, University of Manchester, Hope Hospital, Manchester, UK

[2]Department of Dermatology, University Hospital Schleswig-Holstein, University of Luebeck, Luebeck, Germany

## Synonyms

Cicatricial alopecia; Permanent alopecia

## Definition and Characteristics

A diverse group of inflammatory hair disorders of often unknown etiology, or the final result of irreversible traumatic, physicochemical or infectious damage to the hair follicle. They are characterized clinically by loss of visible follicular ostia (often along with epidermal atrophy and varying degrees of visible inflammation) and histologically by replacement of the pilosebaceous unit with ill-organized, scar-like fibrous tissue, resulting in permanent hair loss. In primary scarring alopecia the hair follicle is the main target of the disease process whereas in secondary scarring alopecia the follicular damage occurs indirectly from events occurring outside the follicular unit.

## Prevalence

Prevalence of scarring alopecia in the general population is unknown. Two retrospective case series have examined the incidence of scarring alopecia in specialist hair clinics. One study found that 3.2% ($n$ = 112) of hair consultations evaluated over a 5-year period was for a primary scarring alopecia [1]. The other identified 7.3% ($n$ = 427) patients with scarring alopecia over a 10-year period [2].

## Molecular and Systemic Pathophysiology

Main pathologic features include inflammation affecting the upper portion of the follicle, sebaceous gland atrophy and replacement of the follicle with fibrous tissue.

Although the pathogenesis of all primary alopecias is currently unknown, their occurrence invariably implies exhaustion of the regenerative potential of the hair follicle due to an inflammation-based loss of epithelial hair follicle stem cells in the follicle's bulge region, i.e. at the site of the insertion of the arrector pili muscle. However, how and why these stem cells get attacked e.g. by lymphocytes or neutrophils, is essentially unknown (even though the classical "swarm of bees" inflammatory pattern seen in alopecia areata represents a massive inflammatory infiltrate, this alopecia is not scarring, since hair follicle stem cells survive) [3]. The primary scarring alopecias are likely to represent a final common pathway for a number of different disease processes.

Secondary scarring alopecias also result from irreversible hair follicle stem cell damage induced, for example, by ionizing radiation, herpetic infection or chronic traction.

## Diagnostic Principles

Clinically, scarring alopecias typically present as loss of visible follicular ostia (which is best examined and identified using a dermatoscope), often along with epidermal atrophy (presenting as "cigarette paper sign") and varying degrees of visible erythema or even pus. Since lichen planopilaris and its variants (i.e. frontal fibrosing alopecia and Graham-Little syndrome) appear to be the most frequent form of primary scarring alopecia, it is always well-advised to systematically examine the entire integument for other signs of lichen planus (including mucous membranes and nails).

However, the broad spectrum and overlapping clinical features of different conditions that can cause scarring alopecia make disease classification difficult and sometimes, even with the help of histology, impossible. In other cases it remains a matter of contention and debate whether a characteristic clinical entity such as pseudopelade (Brocq) really represents a separate disease entity, or just yet another variant of lichen planopilaris.

Irrespective of these considerations, scalp biopsy is mandatory in all suspected cases of scarring alopecia, particularly when the clinical picture does not allow a firm clinical diagnosis. In fact, due to the essential irreversibility of cicatricial alopecias, it may be claimed that the paramount challenge for every physician during each consultation for a hair loss complaint is to firmly exclude the presence of scarring alopecia.

Ideally two 4 mm punch biopsies from a clinically active, hair-bearing area (outside of the completely scarred lesional skin!) should be taken and submitted for both vertical and horizontal sectioning and staining with hematoxylin and eosin (optimally complemented by Giemsa and PAS histochemistry).

One current recommendation is to classify scarring alopecias histologically primarily on the predominant inflammatory cellular infiltrate. A specific diagnosis may then be suggested by the clinical features (Table 1). Current histopathological techniques are unable to differentiate clinically distinct primary cicatricial alopecias beyond identifying the predominant inflammatory infiltrate [4].

Unless suggested otherwise by the patient's medical history and physical examination, recommended blood tests include: ESR, CRP, differential blood count, ANA, ENA, dsDNA and hepatitis C serology.

**Scarring Alopecia. Table 1** North American Hair Research Society (NAHRS) proposed working classification of primary cicatricial alopecia (Olsen EA et al. (2003) J Am Acad Dermatol 48:103–110). Not listed here are secondary scarring alopecias such as traumatic, traction, radiation-induced and post-herpetic alopecia

| Inflammatory infiltrate | Diagnosis |

## Therapeutic Principles

There is no cure for primary scarring alopecias, and even in secondary alopecia the hair loss may sometimes progress even after removal/discontinuation of the causative agent (e.g. in radiation-induced alopecia). Therefore, currently, symptomatic therapy is all one can offer. An additional major setback is that no fully satisfactory, evidence-based medicine regimens are

**Scarring Alopecia. Table 2** Selection of therapeutic options in the management of scarring alopecia (modified from [5]). Note that much of the currently available treatment guidelines do not yet meet strict standards of evidence-based medicine, i.e. they heavily rely on the personal experience of alopecia authorities and/or reflect clinical trials with insufficient group size/design. [Level of evidence: 1, double-blind studies; 2, clinical series; 3, anecdotal report]

available for the treatment of defined scarring alopecias, whose pathogenesis and effective therapy remain a painfully under investigated area of dermatology.

In general, many practitioners experienced in alopecia management tend to treat the sub-group where lymphocytic infiltrates predominate with immunosuppression (e.g. topical, intralesional or systemic corticosteroids; antimalarials), and the neutrophil-dominated sub-groups with dapsone or other antimicrobials (e.g. tetracyclines; rifampicin and clindamycin) [5]. Table 2 lists a selection of available therapeutic options for distinct forms of primary scarring alopecia.

In the clinical end-stage of scarring alopecia, patients with completely stable and "burned-out" scarring (i.e. without residual inflammatory activity), may profit from hair transplantation or plastic (scalp reduction) surgery, so as to remove or reduce the cosmetically and psychologically disturbing scar. In the future, hair follicle neogenesis from autologous hair follicle cell populations may become an alternative interesting therapeutic option for this subgroup of patients with long-standing and stable scarring alopecia [3].

## Synonyms

SIOD; Morbus Ehrich

## Definition and Characteristics

SIOD, an autosomal recessive panethnic multisystem osteochondrodysplasia, is characterized by dysmorphism and disproportionate short stature, spondyloepiphyseal dysplasia, T-cell immunodeficiency, and steroid resistant nephrotic syndrome [1,2]. Incompletely penetrant features include hypothyroidism, migraine-like headaches, cerebral ischemia, and enteropathy. Strokes from premature atherosclerosis, severe opportunistic infections, bone marrow failure, complications of renal failure, or an undefined pulmonary disease result in premature mortality in most patients during childhood to early adolescence; however, a few patients are alive in their third and fourth decades of life.

## Prevalence

1:3,000,000 in North America.

## Genes

Fifty to sixty percent of patients clinically suspected of having SIOD have biallelic loss-of-function mutations in SMARCAL1 (swi/snf related matrix associated actin dependent regulator of chromatin, subfamily a-like 1, 2q35) [2,3]. SMARCAL1 encodes a protein homologous to the SNF2 family of chromatin remodeling proteins [4]. The reported mutations include deletions of the promoter and first five exons, splice site alterations, small insertions and deletions, and point mutations encoding frameshift, nonsense, and missense alterations [2,3]. Mutations in other genes have not been associated with SIOD.

## Molecular and Systemic Pathophysiology

Most of the disease features of SIOD arise from cell-autonomous loss of functional SMARCAL1 enzyme [5]. Of all the known features of SIOD, none is invariant: specific features range in frequency from 17 to 98% [3]. This suggests that the molecular mechanism underlying SIOD is particularly sensitive to genetic, epigenetic, stochastic, and environmental modifiers.

The SMARCAL1 protein, which is expressed within the nucleus, binds to open chromatin. Deficiency of SMARCAL1 affects the expression of most genes transcribed by RNA polymerase II. In vitro biochemical studies on the SNF2 domain of the SMARCAL1 homologues function as reverse helicases. The human, mouse and drosophila homologues recognize DNA structure and not DNA sequence [4]. This leads to the hypothesis that SMARCAL1 acts as a rheostat modulating RNA polymerase 2-mediated transcription and that the features of SIOD are expressed as manifestations of quantitative alterations in mRNA expression within that tissue (Fig. 1).

## Diagnostic Principles

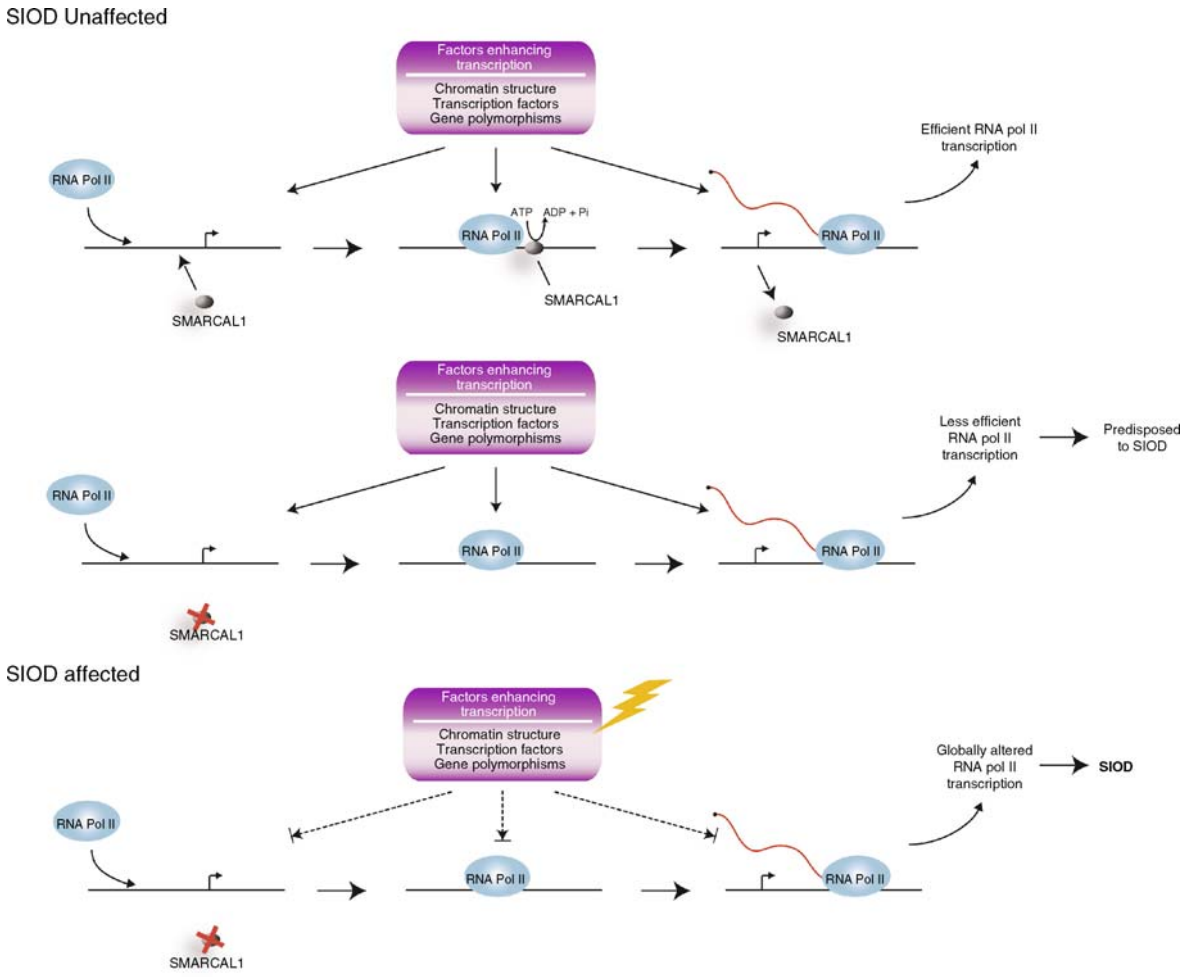
SIOD is diagnosed on the basis of clinical findings (http://www.genereviews.org/). The clinical diagnosis of SIOD is suspected in individuals with:

- Disproportionate short stature (98% of individuals) that manifests as a short neck and trunk with lumbar lordosis and a protruding abdomen.
- Dysmorphism that includes a broad, low nasal bridge (68%) and a bulbous nasal tip (83%).
- Hyperpigmented macules (85%) on the trunk and occasionally extending onto the arms, neck, and legs.
- Spondylo-epiphyseal dysplasia (86%) in which the commonly observed radiological abnormalities are ovoid and mildly flattened vertebral bodies, small deformed capital femoral epiphyses, and shallow dysplastic acetabular fosse. Other bony abnormalities are less common.
- Progressive steroid-resistant glomerulopathy. Most individuals with SIOD have proteinuria; in 64% this evolves into end-stage renal disease (ESRD). The renal pathology has been reported as focal segmental glomerulosclerosis without pathognomonic features in 92% of individuals.
- T cell deficiency (97% of tested individuals). In general, both CD4 and CD8 cells are reduced and the CD4/CD8 ratio is normal.

## Therapeutic Principles

Treatment of manifestations:

- Hip replacement is needed in older individuals
- Symptomatic treatment of nephrotic syndrome. Immunosuppressive regimens are ineffective
- Renal transplantation followed by immunosuppressive therapy as indicated
- Acyclovir for recurrent herpetic infections



**Schimke Immuno-osseous Dysplasia. Figure 1** The SMARCAL1 enzyme modulates global RNA polymerase 2 transcription (*top panel*). Deficiency of SMARCAL1 causes relatively small changes in the mRNA abundance for each expressed gene (*middle panel*) but few or no clinical features of disease in model organisms. However, when global transcription is further compromised via variant epigenetic, genetic, or stochastic factors, model organisms express a disease phenotype (*lower panel*). This suggests that each feature of SIOD is a quantitative trait reflecting alterations in mRNA abundance and that the tissue-specific expression of SIOD disease features is dependent on the underlying efficiency of transcription in the absence of SMARCAL1.

- Imiquimod and cidofovir for severe disseminated cutaneous papilloma virus infections
- Granulocyte colony stimulating factor or granulocyte-macrophage colony stimulating factor for neutropenia
- Agents that improve blood flow or decrease coagulability to moderate transient ischemic attacks or strokes

Prevention of Secondary Complications:
- Prophylaxis against pneumocystis carinii pneumonia

Surveillance:
- Regular monitoring of the hips
- Regular monitoring of renal function
- Annual monitoring of immunological and hematological status

Pitfall:
- Growth hormone supplementation does not improve growth or final height

# Schizophrenia

Markus M. Nöthen, Marcella Rietschel
Department of Genomics, University of Bonn, Bonn, Germany

## Synonyms

Schizophrenic disorder

## Definition and Characteristics

The symptoms of schizophrenia are multiform and cluster into at least three symptom domains: (i) positive symptoms, including hallucinations, delusions, thought disorder and paranoia, (ii) negative symptoms with anhedonia, social withdrawal and poverty of thought, and (iii) cognitive dysfunction, particularly in attention, working memory and executive function [1]. Differing combinations of these symptoms occur in different patients, so that a diagnosis of schizophrenia may be assigned to many varying constellations of symptoms. A history of positive symptoms occurring at least once during a patient's lifetime is common to most patients, however. Differences in the course of the disorder are also observed between patients. Schizophrenia is associated with an increased mortality, which is due in part to an associated suicide rate of 10–15%. There have been increased efforts in recent years to achieve etiological homogeneity through the investigation of endophenotypes. Endophenotypes represent processes underlying clinical symptoms, processes from which a closer, more direct connection with gene function is to be expected [2]. Neurocognitive deficits, neurophysiological measures and neuropathological abnormalities have been proposed as the most promising endophenotypes for the study of schizophrenia.

## Prevalence

The lifetime risk of schizophrenia is ~0.5–1%. Meta-analyses have suggested higher prevalence rates in migrants compared to native-born individuals and lower prevalence rates in developing as compared to developed nations. Study results concerning a difference in the rate of schizophrenia between males and females have been contradictory. Community based studies have usually found an equal distribution across gender, while many hospital based studies have found a higher rate of schizophrenia among males.

## Genes

Family, twin and adoption studies have shown that the risk of developing schizophrenia is significantly increased for the biological relatives of patients and that genetic factors are to a significant degree responsible for this. The risk of illness in children and siblings of patients is around 10%. Heritability has been estimated to be around 80%, although the observation that concordance for monozygotic twins is around 50% indicates the importance of non-genetic factors. Although a single gene may play a major role in some families, the findings of most studies support the view that the majority of cases of schizophrenia have a complex genetic basis.

The pattern of linkage findings in schizophrenia is typical of that for a complex disorder. Levels of statistical significance and estimated effect sizes in individual studies are modest, the chromosomal regions of interest are typically broad and no findings have been replicated in all data sets. Two meta-analyses of linkage studies have implicated loci on various chromosomes (1q, 2q, 3p, 5q, 6p, 8p, 11q, 13q, 14p, 20q and 22q), with the number of loci that meet the aggregate criteria for significance being much greater than the number of loci expected by chance [3]. Candidate genes with positive association findings have been reported for most of these chromosomes, but none have been consistently replicated. Among the genes with best evidence from independent studies are dystobrevin-binding protein 1 (DTNBP1), neuregulin 1 (NRG1), G72/G30 and regulator of G protein signaling 4 (RGS4) [4]. Besides linkage studies, observations of chromosomal characteristics have also provided clues as to the localization of schizophrenia associated genes. Patients with a deletion in region 22q11 have a marked increase in the risk of developing schizophrenia and multiple genes in the deleted region have been reported as being associated, including catecholamine-O-methyl transferase [COMT], proline dehydrogenase [PRODH] and zinc finger and DHHC domain containing protein 8 [ZDHHC8]. Findings for these genes are not fully convincing, however. Two further candidate genes (DISC1 and DISC2) have been identified through breakpoint mapping in an extended family in which a balanced chromosomal translocation (1, 11) (q42; q14.3) co-segregated with psychiatric disorders including schizophrenia. It remains unclear whether or not alterations in these genes account for any significant

proportion of the genetic contribution to schizophrenia in the general population.

### Molecular and Systemic Pathophysiology

A number of studies into schizophrenia have demonstrated disturbances in neurotransmission, in particular in the dopaminergic and glutaminergic systems, with a corresponding hyperstimulation of the mesolimbic pathways and hypostimulation of the mesocortical pathways. The consistent finding of reduced grey matter in the frontal and temporal lobes of schizophrenia patients suggests that neurodevelopmental factors contribute to disease.

Since the majority of schizophrenia susceptibility genes remain unknown and the contribution of those proposed to date is (at best) limited, the future may witness the identification of entirely new pathophysiological mechanisms.

### Diagnostic Principles

The diagnosis of schizophrenia is a purely clinical one, made on the basis of observed and reported symptoms. The use of structured and semi-structured interviews as well as operationalized diagnostic criteria enables the diagnosis of schizophrenia to be assigned more reliably.

### Therapeutic Principles

Predictable, if not reliably effective, means of controlling symptoms have been provided to date by conventional or first generation antipsychotics. These indiscriminately block as much as 80% of D2 dopamine receptors and control mainly the positive symptoms of the disorder. While the effect of antipsychotics on the mesolimbic system reduces psychotic symptoms, their effect on the nigrostriatal system is responsible for the extrapyramidal side effects that are frequently observed in patients undergoing treatment. Newer medications, referred to as atypical or second generation antipsychotics are also effective in the control of schizophrenia symptoms, but are substantially less prone to cause side effects. Compared with first generation antipsychotics, second generation agents have a higher ratio of serotonin type 2 to D2 dopamine receptor blockade and a greater specificity for the mesolimbic than for the striatal dopamine system. It appears that the effectiveness of an individual antipsychotic varies considerably according to the specific characteristics of the patient [5].

## Schizophrenic Disorder

►Schizophrenia

## Schizotypal Personality Disorder

Undine E. Lang
Department of Psychiatry and Psychotherapy, Charité University Medicine Berlin, Berlin, Germany

### Synonyms

Schizotypy; SPD

### Definition and Characteristics

Persons with schizotypal personality disorder are strikingly odd or strange, even to laypersons. Ideas of reference, magical thinking, peculiar notions, illusions and derealization are part of a schizotypal person's everyday world. Schizotypal symptoms are often assessed using a self-report rating scale such as the Schizotypal Personality Questionnaire. Schizotypal persons display the same endophenotypic traits as patients with schizophrenia and therefore schizotypy has been hypothesized to be a genetic variant of schizophrenia, with more subtle attenuated symptoms [1].

### Prevalence

Overall, about 3% of individuals within the community samples suffer from SPD; the sex ratio is unknown. The

disease is very common among biological relatives of those with schizophrenia and a higher incidence has been found in monozygotic versus dizygotic twins with a heritability of about 53%.

### Genes

The neuregulin 1 gene at chromosome 8p22–p12, which has been implicated as a susceptibility gene for schizophrenia has been associated with schizotypal personality features in 905 adolescents [2]. High schizotypal scores have been associated also with the high activity (Val) allele of the catechol-O-methyltransferase (COMT) gene encoding an enzyme involved in the inactivation of catecholamines (dopamine, adrenaline and noradrenaline), which maps to the velocardiofacial syndrome region of chromosome 22q11 (e.g., [3]). Micro-deletions in chromosome 22q11 are 80-fold more common in psychotic patients than in the normal population. The dopamine D4 receptor (DRD4) gene has also been especially related to the social activity trait in schizotypal personality [4].

### Molecular and Systemic Pathophysiology

There are no analyses that have directly examined the biological basis of SPD although several pathological correlates such as electrophysiological findings, somatosensory P50 gating, emotional processing, cognitive tasks or neurological soft signs have been detected.

### Diagnostic Principles

DSM-IV diagnostic criteria of SPD include a pervasive pattern of social and interpersonal deficits marked by discomfort with close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior. SPD's symptomatological hallmarks are ideas of reference, odd beliefs in magical thinking, unusual perceptual experiences including bodily illusions, odd thinking and speech, suspiciousness or paranoid ideation, inappropriate or constricted affect, behavior that is odd, eccentric or peculiar, lack of close friends and excessive social anxiety that tends to be associated with paranoid fears.

*Exclusion criteria*: The pervasive pattern of described behavior does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features or a pervasive developmental disorder. Such traits may be adaptive in certain situations and have even been conceptualized as correlates for creativity and mating success [5], but are maladaptive and diagnosable when individuals incur ongoing significant functional impairment or distress.

### Therapeutic Principles

Symptomatically, antipsychotic medication might be used, but evidence based therapeutic data are lacking.

## Schwartz-Jampel Syndrome

Sophie Nicole, Bertrand Fontaine
Inserm, Université Pierre et Marie Curie, UMR, Paris, France

### Synonyms

Aberfeld syndrome; Chondrodystrophic myotonia; SJS

### Definition and Characteristics

Schwartz-Jampel syndrome (SJS) is characterized by a permanent muscle stiffness, reported as myotonia, recessively inherited and associated to chondrodysplasia. The signs become obvious during the three first years of life. The disease course is slowly progressive until mid-adolescence and then remains stable. The most recognizable feature is a "mask-like face" with blepharospasm, pursed lips, and reduced mobility of the facial muscles. Osteoarticular deformities with pectus carinatum, kyphoscoliosis, lumbar lordosis, bowing of the long bones, and light dwarfism distinguish SJS from other myotonic disorders. However, some cases without obvious bone changes also exist [1]. Radiographic features consist of decreased bone age, platyspondyly with frequent coronal cleft vertebrae, epimetaphyseal dysplasia, bilateral coxa vara and iliac base shortening with acetabular dysplasia, as well as anterior bowing of the diaphyses, metaphyseal widening, and flattening of the epiphyses of the long bones. Electromyographic (EMG) analyses reveal a peculiar muscle hyperactivity whose origin is still unknown. Typical myotonic discharges that wax and wane, and spontaneous sustained discharges which persist for long periods, have been observed. Critical review of the literature indicates that the latter are the more frequent and characteristic findings in SJS. These high-frequency discharges, also reported as pseudo-myotonic or complex repetitive discharges, do not wax and wane in amplitude, are present at rest without any stimulating mechanism, display a relatively constant frequency, and would be neurogenic since they disappeared with a neuromuscular block. The nerve conduction is normal in all cases.

### Prevalence

Undetermined. Over 100 cases reported in the medical literature.

### Genes

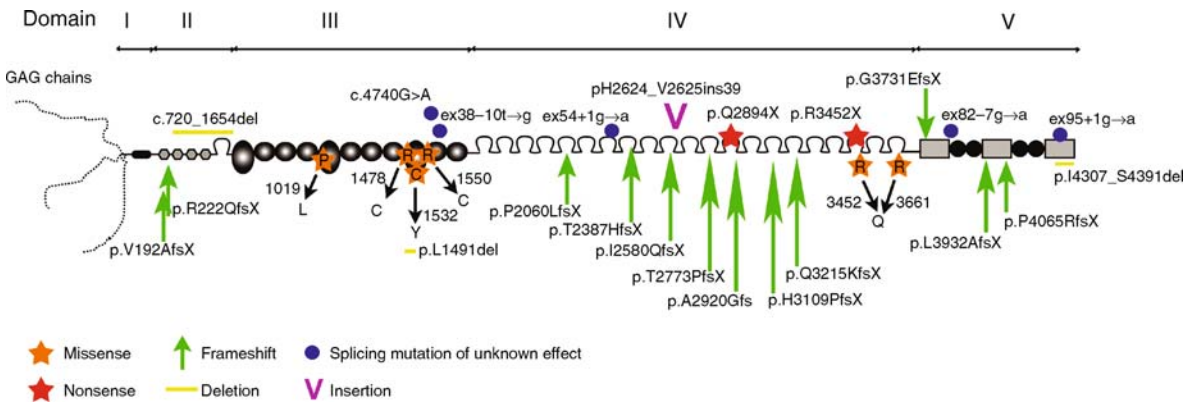
Hypomorphic mutations in HSPG2 (1p35-p36.1) encoding perlecan, the major heparan sulfate proteoglycan of basement membranes (BM) [2]. The core protein consists of five domains (I-V). Thirty mutations, including splicing, nonsense and missense mutations, and large genomic deletions, have been described [1–3]. They are located along the entire gene (Fig. 1).

SJS is allelic to the dyssegmental dysplasia, Silverman-Handmaker type (DDSH), a very rare and autosomal recessive chondrodysplasia with three mutations reported in perlecan [4].

### Molecular and Systemic Pathophysiology

Perlecan is a secreted proteoglycan ubiquitously expressed. SJS mutations are hypomorphic and allow the residual secretion of nearly normal perlecan by cells and tissue from the patients. They assume a residual perlecan function, that rescues the embryonic lethal phenotype observed in humans (DDSH) in the total absence of perlecan. Perlecan plays a role in cell adhesion, growth factor signaling, angiogenesis, and maintenance of BM integrity through interaction with multiple components including laminin, nidogen, collagen type IV, the transmembrane receptors β1-integrin and α-dystroglycan, and growth factors (FGF-2 and 7). Although it lacks a true BM, the developing cartilage undergoing endochondral ossification, the bone development process by which an initial cartilage matrix serves as a template for bone formation, is the tissue displaying the greatest perlecan accumulation. Two hypotheses, not mutually exclusive, are evoked to account for SJS and DDSH chondrodysplasia. The first hypothesis is a slight modification of the fine balance of growth factor signaling, and the second is an excessive degradation of cartilage matrix when perlecan is lacking, both resulting in abnormal organization of growth plate and an altered endochondral ossification.

In the neuromuscular system, perlecan is present in the muscle and nerve BMs. It is accumulated at the neuromuscular junction (NMJ) where it is crucial to the



**Schwartz-Jampel Syndrome. Figure 1** Scheme of perlecan and location of SJS mutations. The mutations associated with SJS are indicated in the one-letter code for amino acids, except those whose effect on the protein was undetermined and that are numbered at the coding nucleotide level (c).

anchorage of acetylcholinesterase (AChE) through its interaction with the ColQ collagenous subunit of this enzyme and α-dystroglycan. Indeed, AChE is decreased at the NMJ in SJS both in human and in a mouse model. Abnormal NMJs with absence of the normal pretzel-like shape and prominent denervation events without gross ultrastructural abnormalities are also seen. How these modifications lead to the abnormal neuromuscular hyperactivity that characterizes SJS remains to be determined.

## Diagnostic Principles

Clinical differential diagnosis for SJS includes myotonic (myotonia congenita and myotonia permanens) and osteochondrodysplasic disorders. SJS cases with mild muscle stiffness may be first diagnosed as another chondrodysplasia such as micromelic chondrodysplasia, kyphomelic dysplasia, or Burton skeletal dysplasia. To establish the diagnosis of SJS, muscle stiffness has to be demonstrated and confirmed by EMG. Chondrodysplasia confirmed by X-ray analysis is a strong argument for eliminating a severe form of myotonia congenita or paramyotonia congenita with a mask-like face, although the absence of abnormalities is not exclusive for SJS diagnosis. The existence of a continuous spectrum of phenotypic severity between DDSH and SJS that depends on the level of residual perlecan expression can be envisaged. The wide spectrum of mutations in the HSPG2 gene and the large size of the gene make mutation screening extremely laborious for molecular diagnosis of these diseases. An attractive approach for their molecular diagnosis is the demonstration of decreased expression of perlecan on primary cell culture of fibroblasts established from patient skin biopsy.

## Therapeutic Principles

Carbamazepine, phenytoin, and procainamide slightly improve muscle stiffness in some cases. Osteoarticular deformities require orthopedic management and often surgery.

# Scleral Melanocytosis

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Synonyms

Ocular melanocytosis; Melanosis oculi; Ocular melanosis

## Definition and Characteristics

Scleral melanocytosis is a congenital hyperpigmentation of the sclera (Fig. 1) [1].

The pigmentation is black or gray-blue, often bilateral, and usually present from birth or early childhood [1,2]. The medial superior quadrant of the conjunctiva is the most frequently affected site and the lateral inferior quadrant is the least frequently affected [1]. The conjunctivae can be moved over the pigmented lesions [3].

## Prevalence

Scleral melanocytosis is found in ~5% of Chinese boys and 4% of Chinese girls under the age of one year [1].

**Scleral Melanocytosis. Figure 1** Scleral melanocytosis in both eyes.

The peak prevalence is around 6 years of age when ~45% of boys and 47% of girls are affected. Thereafter, the lesions tend to be less frequent with time. At 18 years of age, only 11% of boys and 13% of girls are affected. The condition is rare in Caucasian individuals.

## Molecular and Systemic Pathophysiology

Scleral melanocytosis is a racial characteristic of Asian individuals [1,2]. The condition is due to the presence of bipolar or multipolar dendritic melanocytes in the sclera and episclera, rather than in the conjunctival substantia propria [4].

## Diagnostic Principles

Scleral melanocytosis should be distinguished from oculodermal melanocytosis (nevus of Ota). Oculodermal melanocytosis is characterized by scleral melanocytosis and melanocytic hyperpigmentation of the skin in the area supplied by the ophthalmic and maxillary divisions of the trigeminal nerve [1]. In oculodermal melanocytosis, the scleral pigmentation is present at birth or shortly thereafter. The cutaneous pigmentation is present at birth or shortly thereafter in ~50% of affected individuals and in the remainder, the pigmentation appears by the second decade of life. Bilateral skin involvement is seen in ~5% of cases. Ipsilateral scleral melanocytosis is found in approximately two-thirds of cases [1]. Nevus of Ito is a variant of nevus of Ota, in which the skin pigmentation occurs in the acromioclavicular region, and is more diffuse and less mottled [3]. Primary acquired melanosis of the conjunctiva refers to a diffuse, flat, patchy, golden-yellow to brown pigmentation of the bulbar conjunctiva, which usually occurs near the limbus [5]. The pigmentation is almost always unilateral and multifocal, with a course that waxes and wanes over many years [5].

## Therapeutic Principles

In Asian individuals scleral melanocytosis is a benign condition and no treatment is necessary. In Caucasian individuals, scleral melanocytosis is associated with an increased risk of uveal melanoma, and lifetime ophthalmologic monitoring is warranted.

# Scleroderma, Systemic

Thomas Krieg, Julia Weihrauch
Department of Dermatology, University Cologne, Cologne, Germany

## Synonyms

Systemic sclerosis; SSc

## Genes

Scleroderma has a complex genetic background involving many different genes. There are several reports describing polymorphism of genes regulating ECM deposition or the immune system.

## Definition and Characteristics

Scleroderma is a chronic fibrosing disease of unknown etiology characterized by excessive deposition of collagen and other extracellular matrix proteins in skin and internal organs.

## Prevalence

The prevalence of SSc is between 19 and 75 per 100,000 persons, but may be underestimated because patients with early and atypical disease may be overlooked.

## Molecular and Systemic Pathophysiology

The current hypothesis of the development of SSc is based on alterations of the vessels, a disturbed regulation of the immune system and an excessive deposition of extracellular matrix compounds by activated fibroblasts. It is assumed that an initial presently unknown trigger mechanism leads to an early inflammation with the release of a number of cytokines (e.g. TGF-beta, CTGF), which results in an activation of fibroblasts involving autocrine loops. Although not identified in detail, there is evidence for a genetic background predisposing for the development of the autoimmune response and probably also for the perpetuation of the fibrosing process. Infections or the persistence of fetal cells have been postulated to play a role as trigger factors of some subsets of the disease.

## Diagnostic Principles

Typical clinical manifestations are Raynaud's Phenomenon and puffy fingers as the first symptoms in 95% of patients followed by thickening of the skin and variable symptoms like subcutaneous calcinosis, arthralgias, esophageal dysmotility, pulmonary fibrosis, pulmonary hypertension, congestive heart failure and renal crisis depending on the kind of organ involvement. Most patients are also characterized by circulating antibodies against cellular antigens. Identification of their antigens together with typical clinical symptoms is essential for the diagnosis and also to differentiate subsets of the disease. This allows the prediction of certain internal manifestations and determines the prognosis of individual patients.

## Therapeutic Principles

Effectiveness of drug therapy in SSc is difficult to evaluate because of the variable course and severity of the disease. Current therapeutic regimens include the control of vasospasm, improvement of blood flow, immunosuppressive drugs and physical therapy. Even though SSc cannot be cured, treatment of involved organ systems can relieve symptoms and improve function.

# Scleromyxedema

Sergio A. Jimenez
Jefferson Institute of Molecular Medicine and Division of Connective Tissue Diseases, Department of Dermatology and Cutaneous Biology, Thomas Jefferson University, Philadelphia, PA, USA

## Synonyms

Generalized lichen myxedematous; Arndt-Gottron scleromyxedema

## Definition and Characteristics

Scleromyxedema is a rare disease of unknown etiology characterized by the occurrence of either small, firm papular lesions or diffusely indurated and thickened

skin caused by the accumulation of mucin in the dermis in the absence of thyroid disease [1–4]. The course of scleromyxedema is chronic and usually progressive, frequently associated with systemic features, including involvement of the muscles, heart, gastrointestinal tract, and the central nervous system. In most instances there is a monoclonal paraproteinemia most commonly of the IgG lambda class.

## Prevalence

The disease is rare although an accurate estimate of its prevalence is not available. It affects most frequently middle aged adults. Both genders are affected in equal frequency.

## Genes

Scleromyxedema is not a genetic disorder and to date that is no evidence of any gene mutation being responsible on participating in its pathogenesis.

## Molecular and Systemic Pathophysiology

The exact pathogenesis of scleromyxedema is unknown and the mechanisms responsible for the increased accumulation of mucin in the dermis and other affected tissues remain to be elucidated. Dermal mucin is a structural component of the extracellular matrix of the dermis and consists mostly of the acidic glycosaminoglycan, hyaluronic acid. Hyaluronic acid is a long polysaccharide polymer comprised of repeating disaccharide units of glucuronic acid and N-acetyl glucosamine. The size of hyaluronic acid molecules is variable; but most molecules are present as extremely large polymers reaching several million Da in molecular weight. The biosynthesis of hyaluronic acid is complex and unique, since it does not occur in the endoplasmic reticulum but in the cytoplasm just below the cell membrane with the newly synthesized polysaccharide chain being secreted directly into the extracellular space [5]. Three enzymes known as hyaluronan synthases, are responsible for the synthesis of the polysaccharide. Each enzyme is responsible for the synthesis of a specific size of hyaluronic acid. The mechanisms responsible for the increased accumulation of hyaluronic acid and dermal mucin in scleromyxedema remain obscure. However, it has been shown that production of hyaluronic acid can be markedly stimulated by certain cytokines such as interleukin-1, tumor necrosis factor-α, and transforming growth factor-β suggesting the participation of an inflammatory process in the pathogenesis of the disorder. Another important aspect of scleromyxedema pathogenesis is the presence of a monoclonal IgG paraproteinemia. The mechanisms responsible for the production of this monoclonal paraprotein are unknown, and its role in the pathogenesis of the disease is obscure, although some reports have shown that it may cause increased proliferation of cultured fibroblasts, as well as increased prostaglandin and hyaluronic acid production.

## Diagnostic Principles

The diagnosis of scleromyxedema is based on the presence of a diagnostic triad comprised of:

1. Increased deposition of mucinous material accompanied by fibrosis in affected dermis;
2. Presence of circulating monoclonal paraproteinemia; and
3. Absence of thyroid disease.

The histopathological features of scleromyxedema are characteristic with the accumulation of hyaluronic acid, a substantial increase in collagen fibers, and marked proliferation of elongated, spindle-shaped fibroblasts. A monoclonal paraproteinemia is found in essentially all affected individuals although sometimes it appears following the cutaneous lesions. Thyroid disease must be excluded as cutaneous mucinosis related to thyroid dysfunction can closely resemble scleromyxedema.

Nephrogenic fibrosing dermopathy also known as nephrogenic systemic fibrosis (NFD/NSF) is a novel disease entity described in patients with chronic renal insufficiency often undergoing dialysis, which mimics several clinical and histopathological manifestations of scleromyxedema including the exaggerated mucin deposition and fibrosis in affected skin. Patients affected by NFD/NSF, however, in addition to renal insufficiency often have a history of exposure to gadolinium imaging agents and lack the presence of monoclonal paraproteinemia [6,7]. Systemic sclerosis must also be excluded as the clinical appearance of scleromyxedema and its visceral involvement resemble those of systemic sclerosis. Clinically, individuals affected by systemic sclerosis almost always present with Raynaud's phenomenon and harbor antinuclear antibodies, two features absent in scleromyxedema. Skin biopsies are useful for the differential diagnosis showing prominent accumulation of collagen without a prominent increase in tissue mucin and the presence of a perivascular mononuclear cell inflammatry infiltrate in systemic sclerosis.

## Therapeutic Principles

The treatment of scleromyxedema is usually quite difficult and ineffective. Numerous approaches have been described with variable rates of success, including melphalan and other cytotoxic agents, corticosteroids, retinoic acid derivatives, phototherapy, plasmapheresis, extracorporeal photopheresis, thalidomide and bone marrow transplantation. At the present time, there is no universally accepted effective therapy for the disease and it usually has a progressive clinical course. Occasionally, malignancies of the bone marrow or

myelodysplasia occur in association with scleromyxedema. In these instances, the treatment and the prognosis are determined by the underlying disease.

# Scott Syndrome

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Platelet coagulant protein interaction defects.

## Definition and Characteristics

The cause of the platelet defect is still unknown. Normal platelets provide a catalytic surface for procoagulant reactions including formation of the tenase and prothrombinase complexes that amplify generation of factor Xa and thrombin. In Scott syndrome this membrane cofactor function is impaired.

*Animal model*: A novel canine hereditary bleeding disorder with the characteristic features of Scott syndrome has been published [3]. These dogs had a bleeding phenotype not due to thrombocytopenia and platelet function abnormalities other than a defect in platelet dependent prothrombinase assay where washed platelets from these dogs showed twice normal clotting times as compared to normal platelets.

## Prevalence

Extremely rare, only three cases reported.

## Genes

Autosomal recessive trait. Thus far, only three patients have been described [1,2].
*Gene map locus*: OMIM262890

## Molecular and Systemic Pathophysiology

First discovered as an abnormal platelet response, later studies showed that a similar defect is also present in erythrocytes, T-lymphocytes and EBV transformed B-cells, suggesting a stem cell mutation. Main defect is based on impaired lipid scrambling which is most apparent after challenging platelets with calcium ionophore, but also demonstrable after stimulation with collagen plus thrombin [4]. The causal factor in Scott syndrome is unknown. The association between defective Ca2+ -induced lipid scrambling and impairment in tyrosine phosphorylation should be considered an epiphenomenon [4].

*Clinical features*: A moderately severe bleeding disorder that has presented by severe menorrhagic disorder and iron dependent anemia as well as excessive post partum bleeding. Bleeding may also occur after

minor surgery but spontaneous bleeding or bleeding after superficial cuts has not been observed.

### Diagnostic Principles

Scott platelets show no morphological abnormalities and react normally to stimuli of adhesion, secretion and aggregation. Platelet lipid composition is normal. The defect is detected by specific assays devised to test the platelet dependent procoagulant activity after Ca2+ ionophore stimulation.

### Therapeutic Principles

Supportive treatment.

## Secretory Component Deficiency in Human Fetal Pathology

Itshak Zusman[1], Pavel Gurevich[2], Herzl Ben-Hur[2]
[1]Koret School of Veterinary Medicine, Food and Environmental Quality Sciences, Hebrew University of Jerusalem, Rehovot, Israel
[2]Laboratory of Experimental Medicine, Rehovot, Israel

### Definition and Characteristics

The secretory immune system (SIS) participates in the induction and regulation of immune responses in both the mucosal and systemic compartments after antigen exposure [1]. The most important known function of the SIS is immune protection of the mucous membranes, which are in close contact with "symbiotic" microbes and foreign antigens. The SIS is very important in individual development, both normal and pathological caused by acute infectious of the fetal membranes or inflammation of the birth canal. The protein components of the SIS consist of polymeric immunoglobulin receptor (pIgR), also called secretory component (SC), immunoglobulins (Igs) and joining (J) chain [2]. SC, which has been characterized as an epithelial transmembrane glycoprotein, is the most important receptor in the SIS because it is responsible for external transport of locally produced IgA and IgM.

### Prevalence

SC has been detected in all ectoderm and endoderm derived structures from the early embryonic period when Ig-producing lymphocytes and lymphoid organs are absent [3]. This early presence of SC in normal and pathological human embryos/fetuses suggests that it is one of the earliest appearing proteins in developing human organisms. The main function of the SC in human development is Ig exocytosis; the SC is found in cells which are able to perform exocytosis or in structures where Ig exocytosis exists and is reduced or absent in the structures which lose the ability to perform Ig exocytosis during organogenesis. Intracellular localization of the SC in many structures is dependent on the direction of the Ig exocytosis. In the secretory columnar epithelium, the SC is usually situated in the apical part of the cells; in the stratified (multilayer) epithelium, it is found in the superficial layer. In the trophoblast, SC is situated in the basal part of the cytotrophoblast. SC is located in vesicles, endosomes, representing the largest part of the pIgR and containing its antigenic determinants [4]. The smaller cytoplasmic tail of pIgR remains outside the endosome. When an endosome approaches the cytoplasmic membrane, the SC joined to the membrane undergoes proteolytic cleavage from the cytoplasmic tail.

### Molecular and Systemic Pathophysiology

Massive foreign antigenic attacks in embryos or fetuses in pathological cases such as abruptio placentas, placenta previa, acute chorioamnionitis with sepsis, aspiration syndrome or meningitis or in inflammation of the birth canal lead to a decrease in the number of Ig-immunopositive epithelial cells [5]. Prominent changes were found in the amnion, cyto- and syncytiotrophoblast, epithelia of digestive and respiratory tracts and exocrine pancreas. All these structures are in close contact with infected amniotic fluid (aspirated or swallowed by embryos). A decrease in Ig immunostaining in epithelial cells may be a result of Ig hypersecretion, as indicated by the appearance of IgA in fibrin clots in the bronchi. The immunoreactivity of the SC was unchanged in chorioamnionitic and infected fetuses compared to normal embryos.

Immunoreactivity of IgA, IgG and especially IgM was weak or even absent in the epithelium of the skin, respiratory, digestive and urinary tracts, hepatocytes, tubules of kidneys and choroid plexuses of the brain. The number of IgA- and IgM-positive lymphocytes increased in the spleen and lymph nodes, lungs and mucous membranes of the stomach and intestine. Exocytosis of Igs together with the SC and J chain (secretory IgA and IgM complexes) changed in pathological fetuses. A decrease and even disappearance of Ig immunostaining in bronchial, gastric, intestinal and pancreatic epithelium has been described in embryos due to an increase in Ig secretion as a result of massive antigenic attack. The presence of SC immunostaining is unlikely to result from increased synthesis since fetal death occurs in such cases before the onset of the SC synthesis (48 h after antigenic influence).

## Diagnostic Principles

The presence of protein transport and later of cellular components suggests an active role for the SIS not only in mucous membranes, but also in blood–tissue barriers [5]. The SC is widely present in all ectoderm and endoderm derived structures at the beginning of human normal and pathological development. In human ontogeny, the SIS is a very early immune defensive system, which presents and acts before the appearance of the common lymphoid system. Ig exocytosis is a main function of the SC. Loss of morphological contact between epithelial structures and mucous membranes during organogenesis of some organs is followed by the disappearance of the SC as a result of cessation of Ig exocytosis. Under massive foreign antigenic attacks, Ig exocytosis increases sharply in the epithelial cells, as reflected in the decrease and even disappearance of Ig immunostaining. At the same time, no significant changes in immunostaining of the SC and J chain were observed. The further studying of this problem with the methods of molecular biology will allow better understanding of the mechanism of the findings and development of practical approaches for therapy of fetal diseases connected with changes in the development of the SIS.

# Secretory Diarrhea

Jutta Keller
Medical Department, Israelitic Hospital, Academic Hospital of the University of Hamburg, Hamburg, Germany

## Definition and Characteristics

Diarrhea caused by abnormal ion transport in intestinal epithelial cells; clinically characterized by small fecal osmotic gap and persistence during fasting (exceptions possible) [1].

## Prevalence

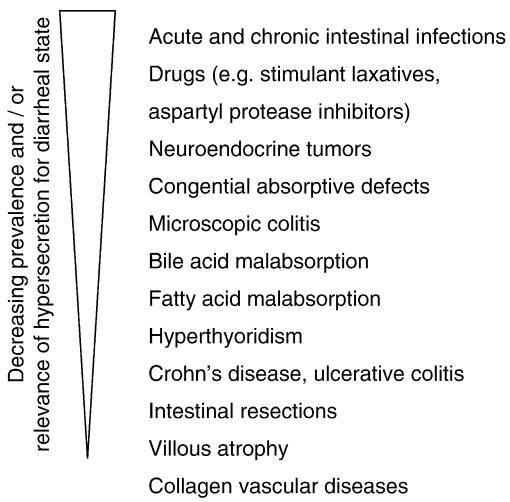
Dependent on the underlying causes, secretory diarrhea comprises very frequent as well as extremely rare disorders (e.g., enteric infections vs. VIPoma). Moreover, in several diseases, intestinal hypersecretion only partly contributes to the diarrheal response (Figure 1).

## Genes

*Congenital chloride diarrhea* is an autosomal dominant disorder caused by mutation of the DRA (down-regulated in adenoma) gene, which encodes the colonic $Cl^-/HCO_3^-$ exchanger. *Congenital sodium diarrhea* is an autosomal recessive disorder of intestinal $Na^+/H^+$ exchange. Neuroendocrine tumours may occur as a consequence of inherited autosomal dominant disorders.

## Molecular and Systemic Pathophysiology

Secretory diarrhea is caused by inhibition of active intestinal absorption of chloride and sodium bicarbon-



**Secretory Diarrhea. Figure 1** Potential causes of secretory diarrhea [1].

ate and/or stimulation of active chloride secretion followed by passive secretion of an equal amount of sodium for maintenance of electrochemical balance. These mechanisms induce an isotonic increase in stool water output.

Secretory diarrhea in infectious diseases is induced by microbial toxins that activate enterocyte signal transduction pathways (compare figs. 1 and 3 of [2]).

Infectious agents stimulating secretion include the pentameric B (binding) subunit of *cholera toxin* (CT), which binds to a membrane receptor, ganglioside GM1. The A (active) subunit acts as a ribosyl transferase and covalently links ADP ribose to Gsα; it thereby upregulates adenylate cyclase activity. The resulting persistent increase in intracellular cAMP causes excessive secretion of isotonic fluid into the intestine. Both phosphorylation of the transmembrane chloride channel protein (cystic fibrosis transmembrane conductance regulator = CFTR) with opening of the channel and chloride secretion and activation of $Na^+$ pumps have been reported to be implicated in hypersecretion. In addition, CT modifies the activity of the enteric nervous system and activates neural secretory pathways.

*E. coli heat-labile toxins* (LT 1 and 2) have a very similar structure (80% homology with CT) and basically the same mode of action.

Binding of *E. coli heat-stable toxins* to the receptor protein guanylate cyclase C activates this enzyme. As a result, intracellular cGMP concentration increases, which stimulates chloride secretion.

*Rota virus* is lethal to mature enterocytes and mainly causes diarrhea by this means. However, its nonstructural protein 4 (NSP4) also acts as an enterotoxin. NSP4 is proposed to elicit anion secretion through an interaction with luminal, age-dependent, $Ca^{2+}$-sensitive anion channels.

High NO production induced by an enterotoxin of *Shigella flexneri* may also act as a secretagogue.

*Stimulant laxatives* (e.g., bisacodyl, senna) block the $Na^+/K^+$-ATPase and thereby decrease sodium and water absorption. Moreover, they elevate secretion of water and electrolytes by increasing permeability of tight junctions.

*Neuroendocrine tumors* (NETs) can secrete excessive amounts of neurohormonal mediators such as gastrin, VIP, and serotonin (5-hydroxytrypamine = 5-HT), which stimulate gastrointestinal secretion [3,4]. Gastrin and VIP receptors are G-protein-coupled receptors with seven transmembrane domains. Binding of gastrin to its receptor on gastric parietal cells activates protein kinase C-dependent signal transduction pathways eventually leading to gastric acid secretion by stimulation of the $H^+/K^+$-ATPase. Binding of VIP to its enterocyte receptor increases intracellular cAMP concentration by activation of adenylate cyclase. This causes phosphorylation of CFTR and chloride secretion as described above. The receptors that mediate the prosecretory effects of 5-HT [5-HT(1P)] are located on submucosal intrinsic primary afferent enteric neurons. Receptor activation elicits secretory reflexes. Moreover, 5-HT3 receptors are implicated in the stimulation of mucosal processes. NETS may be benign or malign and occur sporadically or as a consequence of inherited autosomal dominant disorders (e.g., multiple endocrine neoplasia type 1, MEN 1).

*Gastrinoma:* Excessively high gastrin levels cause hypersecretion of gastric acid with peptic ulcers and diarrhea (Zollinger Ellison syndrome). Acidic denaturation of pancreatic enzymes, bile acid precipitation, and acid-induced damage of the intestinal mucosa may contribute to the diarrheal response.

*VIPoma:* High VIP plasma levels stimulate enteric active chloride and passive sodium, potassium, and water secretion, increase pancreatic water and bicarbonate output and inhibit gastric acid secretion. Clinical consequences are secretory diarrhea (>5 l/day possible), hypokalemia, achlorhydria, and metabolic acidosis (Verner Morrison syndrome).

*Carcinoid syndrome:* High 5-HT levels probably mainly induce diarrhea by stimulation of gastrointestinal motility via 5-HT4 receptors. However, as described above, a secretory component contributes to diarrhea.

Diarrhea in *microscopic colitis* (lymphocytic/collagenous colitis) is not only due to decreased passive permeability of the colonic mucosa caused by collagenous deposits but also hypersecretion. Major pathomechanisms are decreased active sodium absorption in lymphocytic and decreased $Cl^-/HCO_3^-$ exchange rate as well as increased chloride secretion in collagenous colitis [5].

*Congenital chloride diarrhea* is an autosomal dominant disorder caused by defective $Cl^-/HCO_3^-$ exchanger, which is highly expressed in colonic epithelium. Clinical consequences are profound diarrhea with high chloride content and metabolic alkalosis.

*Congenital sodium diarrhea* is an autosomal recessive disorder of intestinal $Na^+/H^+$ exchange, which causes severe diarrhea, hyponatremia, and metabolic acidosis.

## Diagnostic Principles

In general, measurement of stool electrolytes and calculation of the fecal osmotic gap allows differentiation between secretory and osmotic diarrhea. Specific diagnostic approaches differ according to the suspected etiology.

*Infectious diseases:* stool analysis for detection of microorganisms or toxins (in severe cases or prolonged diarrhea).

*NETs:* measurement of hormone plasma levels or of metabolites in urine, somatostatin receptor scintigraphy, CT, MRI, (endo)sonography ± fine needle aspiration,

**Secretory Diarrhea. Table 1** Important therapeutic principles in secretory diarrhea

| | Pharmacotherapy | Dietary therapy | Other treatments |
|---|---|---|---|
| **Infectious diseases** | Antibiotics (if needed/indicated) | Dietary restrictions (light diet, no lactose), supplementation of fluids containing NaCl plus glucose (WHO solution) | Intravenous fluid replacement in severe cases |
| **NETs** | Gastrinoma: proton pump inhibitors Carcinoids: 5-HT antagonists All: somatostatin analogues (e.g., octreotide) Chemotherapy | Dietary supplements only if needed | Surgical resection, arterial (chemo-) embolization, intravenous fluid replacement during episodes of severe diarrhea |

search for associated tumors and affected family members in hereditary syndromes.

*Microscopic colitis:* Colonoscopy including biopsy and histological examination.

## Therapeutic Principles

The therapeutic approach depends on the underlying cause (see Table 1).

## Synonyms

SIgAD

## Definition and Characteristics

Selective IgA deficiency (SIgAD) is a primary immunodeficiency state, characterized by serum IgA levels less than 0.07 g/l, with normal levels of IgG and IgM in patients older than 4 years. All other causes of decreased IgA levels must be excluded. The disease is usually clinically silent, but in some patients, it may lead to increased frequency of respiratory tract infections. Also, the frequency of some autoimmune diseases is increased.

## Prevalence

SIgAD is the most frequent primary antibody deficiency. The incidence in Caucasian populations varies with 1/600 being the approximate average, while in Japan and China population it is much less prevalent (1/18,000 and 1/4,000 respectively) [1].

## Genes

The disease is not caused by mutations in structural IGHA1 and IGHA2 genes. SIgAD is closely related to a much more profound humoral primary immunodeficiency – ►common variable immunodeficiency (CVID), characterized by a decrease of not only IgA but also IgG, and sometimes IgM. Specific antibody production after antigenic challenge is disturbed in patients with CVID (but not in SIgAD). Both diseases can be observed in some kindreds, and progression of SIgAD to CVID was also repeatedly documented. Both CVID and IgAD were associated with several extended HLA haplotypes (most frequently HLA-A1, HLA-B8, HLA-DR3, but also some others: HLA-A28, B14, DR1; HLA-B44, DR7). A significant association of SIgAG was documented with genes located in the HLA-III region including deficient genes at the C4A or 21-hydroxylase (CAP21) loci. Genes responsible for both diseases are still undiscovered. A predisposing gene designated IgAD1 was located onto the telomeric part of the class II region or the centromeric part of class III region; subsequent analysis showed that HLA DQ/DR is the major IGAD1 locus. This is in agreement with previous observations that susceptibility haplotypes had neutral alanine or valine on the DQ chain at position 57, while negatively charged aspartic acid had a protective effect. Recent studies suggest that there are two different predisposing loci, one on HLA class region II, one on class III region, located on different MHC haplotypes [2].

Other studies linked CVID/SIgAD to some other chromosomes. Low levels of IgA were observed in approximately half of the patients with the 18p- or 18q- syndromes or ring chromosome 18, but a study in 83 families did not find any linkage of SIgAD/CVID to any of the loci markers of chromosome 18. Other studies suggested that the disease susceptibility genes can be located to 4q, 16q, and 5p.

A sequence variant of the gene TNFRSF13B, coding for protein TACI, located on 17p, was observed in some persons with IgAD/CVID, usually in a heterozygous form. Recent studies observed the presence of TNFRSF13B sequence variants also in healthy people, and it seems that these gene variants do not markedly predispose the development of SIgAD (but may be involved in CVID).

## Molecular and Systemic Pathophysiology

The mechanisms leading to disturbed IgA production are not elucidated. SIgAD seems to be a stem cell defect as it can be transferred and corrected by hematopoietic stem cell transplantation. IgA-bearing B cells are present in a periphery, although in decreased numbers, and they bear an immature phenotype (expressing surface IgM and IgD). There is a paucity of IgA-bearing plasma cells in submucosal tissues.

Because of the organization of heavy-chain constant gene segments ($C_H$) on chromosome 14, SIgAD should be supposed as a defect of switching of these genes. Indeed, a decrease in Sμ/Sα junction fragments was observed in nonstimulated peripheral blood mononuclear cells (PBMC) of patients with SIgAD, which was consistent with a profound decrease in Cα membrane mRNA expression in nonstimulated PBMC, as well as in

the Cα mRNA levels and IgA production in PWM-stimulated PBMC [3]. A subsequent study showed, besides this mechanism, in other patients, a decreased Cα mRNA level in PBMC despite normal Sμ/Sα recombination, which suggests a blockade of IgA secretion at the level of transcription due to a defect in post-IgA switch differentiation of B cells [4].

The defect in the production of IgA can in vivo be overcome by various stimuli; the combination of anti-CD40, IL-10, and IL-4 was most frequently used. Also, a combination of anti-40, IL-10, and transforming growth factor (TGF)-β led to increased in vitro production of IgA. TGF-β is an important cytokine involved in isotype switching toward IgA production. Interestingly, TGF-β serum levels in IgAD patients were shown to be lower than in healthy controls, but no difference in TGF-β mRNA expression was observed in nonstimulated PBMC.

An increased apoptosis of $IgA^+$ B cells may be involved in the pathogenesis of SIgAD. PBMC of patients with SIgAD showed overexpression of caspase-1. This overexpression was decreased after stimulation of cells by IL-10, CD40L, and Staphylococcus aureus Cowan or tetanus toxoid, which also led to production of IgA [5].

## Diagnostic Principles

The diagnosis is dependent on serum immunoglobulin levels determination. It is necessary to exclude secondary IgA deficiency caused by drugs (sulfasalazine, penicillamine, chloroquine, fenclofenac, gold salts, hydantoin, captopril, carbamazepine, valproate), chromosomal abnormalities (most frequently 18q del syndrome, but also monosomy of chromosome 22 or trisomy of chromosomes 8 or 21). Isolated IgA deficiency can be observed in ataxia telangiectasia or the Nijmegen breakage syndrome. Variable immunoglobulin deficiencies may accompany congenital CMV or rubella infections.

## Therapeutic Principles

The level of IgA cannot be influenced by any current therapeutic approach. Due to a lack of clinical symptoms, treatment is usually not necessary. In rare cases with clinically significant immunodeficiency, intravenous or subcutaneous immunoglobulin treatment can be used.

# Selective IgG Subclass Deficiency

Yaofeng Zhao, Lennart Hammarström
Karolinska Institute, Department of Laboratory Medicine, Karolinska University Hospital Huddinge, Stockholm, Sweden

## Synonym

IgG subclass deficiency

## Definition and Characteristics

There are four human IgG subclasses, IgG1, IgG2, IgG3 and IgG4. Selective IgG subclass deficiency implies that an individual lacks one or several of these subclasses whereas levels of other immunoglobulin classes and subclasses are within the normal range. The deficiencies are most often relative rather than absolute. The total IgG level in patients with selective IgG subclass deficiency is most often normal.

## Prevalence

Selective IgG deficiency is more common than other types of immunodeficiency. However, its frequency varies in different populations. Males and females are equally affected. Generally, selective IgG1 deficiency is very rare. Selective IgG2 and IgG3 deficiencies are more common in children and adults respectively.

## Genes

No determinant gene has yet been identified. In some cases, the deficiencies are found to be due to deletion or mutation of the corresponding γ genes or mutation in the promoter region.

## Molecular and Systemic Pathophysiology

The pathogenesis underlying IgG subclass deficiencies is largely unknown. In a few cases, the deficiencies

have been shown to be caused by homologous deletions or mutations of the corresponding γ genes. Most subclass deficiencies are due to an aberrant regulation of expression of the γ genes where switching to a specific IgG subclass is impaired. The upstream causes may include failure of the signalling process by differentiation factors in activated B cells or insufficient cytokine receptor expression.

### Diagnostic Principles

Patients with selective IgG deficiency may experience recurrent infections of ears, sinuses, bronchi and/or lungs. The total IgG level may be normal or near normal in patients with selective IgG deficiency. Measurement of specific IgG subclasses is needed for diagnosis.

### Therapeutic Principles

Gene or dietary therapies are not available. Pharmacological therapy consists of gamma globulin replacement. Other treatments available are antibiotics.

## Selenium Deficiency

Margherita Bergomi, Carlotta Malagoli, Marco Vinceti
Department of Public Health Sciences, University of Modena and Reggio Emilia, Modena, Italy

### Definition and Characteristics

Whether reduced selenium intake or selenium bioavailability, i.e., daily intake lower than 30 mcg/die, determines selenium deficiency and adverse effects on human health is still a matter of debate in the scientific community [1]. The recommended minimum dietary allowance of selenium in adults varies from 30 mcg/day to 55 mcg/day in different countries [1–3].

### Prevalence

Severe selenium deficiency appears to have occurred in some Chinese areas, where an inadequate supply of this trace element might have favoured the occurrence of cardiomyopathy and osteoarthropathy [1]. It has also been suggested that mild selenium deficiency occurs in several other regions across the world, including some western countries, possibly increasing the risk of chronic diseases such as cancer and cardiovascular disease, but no convincing epidemiologic evidence on this topic has been provided so far [1,2].

### Molecular and Systemic Pathophysiology

Selenium is a non-metallic element naturally occurring in inorganic forms, such as selenite and selenate, and in organic compounds such as dimethyl selenide, selenomethionine, and selenocysteine. Selenium is a trace element of both nutritional and toxicological interest, having an unexpectedly narrow safe range of intake for both humans and animal species. In fact, selenium is an essential micronutrient as a cofactor of enzymes such as the selenium-dependent glutathione peroxidases and thioredoxin reductase, which cooperate with other antioxidants in counteracting oxidative damage. Selenium is also a cofactor of iodothyronine deiodinases, enzymes having a key role in thyroid hormone metabolism. However, selenium, particularly in its inorganic forms and as seleniomethionine, exhibits prooxidants activities even at low levels of exposure, which might explain part of its biological activity, such as its ability to inhibit growth of rapidly proliferating cells including cancer cells [3]. Selenium may also have both beneficial and adverse effects on DNA integrity and on immune system functions, depending on its chemical species and amount of exposure and on the interaction with other dietary factors [3].

By far, the most important way of human exposure to selenium is diet, the major sources of intake being meat (liver in particular), fish, nuts, and less frequently cereals and dairy products. The selenium content in fruit and vegetables is influenced by the natural concentration of this element in the soil in which they grow; however, these food items generally show a limited content of this element. For a limited number of subjects and particularly in occupationally exposed individuals, inhalation and dermal contact may be important sources of selenium exposure [3].

Selenium intake considerably decreases in patients with severe malabsorption syndromes, in subjects undergoing parenteral nutrition and in several statuses of denutrition due to limited food supply or severe systemic disease. Selenium intake is also reduced in people living in areas characterized by low soil selenium content.

Selenium deficiency has been associated with a severe form of dilatative cardiomyopathy, named "Keshan disease," described in the past in regions of China characterized by extremely low selenium intake. Several other

diseases and clinical signs and symptoms have been associated with low selenium status, including increased risk of degenerative diseases such as cancer, cardiovascular disease, and of viral infections, but definitive evidence of such a relation has not yet been provided. In particular, several studies have suggested a link between low selenium intake and excess cancer risk, particularly for some neoplasms such as colon and prostate cancer, but conflicting and even opposite evidence has also been reported, emphasizing the need for further investigation on this issue through well-designed observational or experimental epidemiologic studies [2,4,5]. However, the suggestion of a beneficial effect of selenium in the prevention of chronic diseases has led in some developed countries to widespread use of self-administered supplements, containing selenium and other antioxidant substances, despite the absence of sound evidence about both the lower and the upper safe limits of intake of this element. The molecular mechanisms underlying the anticarcinogenic effect of selenium in its different chemical species, if real, need further clarification.

## Diagnostic Principles

Biomarkers of recent exposure to selenium include blood (serum, plasma, or erythrocyte) element concentration, while hair and nails are long-term indicators of exposure. Plasma levels of selenoproteins (such as selenoprotein P and the selenium-dependent glutathione peroxidase) are also used to assess selenium nutritional status, although several factors apart from selenium appear to influence the levels and the activities of these enzymes. The activity of selenium-dependent glutathione peroxidases might be an indicator of selenium deficiency [1–3].

## Therapeutic Principles

Selenium deficiency is treated by adequate supplementation.

# Selenium Excess

Margherita Bergomi, Carlotta Malagoli, Marco Vinceti
Department of Public Health Sciences, University of Modena and Reggio Emilia, Modena, Italy

## Definition and Characteristics

Exceeding the intake of 300 mcg per day can lead to overt chronic selenium toxicity (selenosis); while intake of considerably higher amounts through dietary intake or by inhalation in occupational settings may induce acute signs of toxicity [1,2].

## Prevalence

Acute selenium overexposure in humans is rare, mainly occuring after occupational exposure and more rarely due to accidental or suicidal dietary intoxication; on the converse, chronic excess exposure to environmental selenium as been described in several ('seleniferous') regions of the world, such as in some areas located in china, the U.S. and Venezuela.

## Molecular and Systemic Pathophysiology

Selenium is a nonmetallic element naturally occurring in inorganic forms (see ▶Selenium deficiency). It is of nutritional and toxicological interest, having an unexpectedly narrow safe range of intake for both the humans and animal species (see selenium deficiency).

By far, the most important way of human exposure to selenium is diet (see selenium deficiency). For a limited number of subjects and, particularly, in occupationally exposed individuals, inhalation and dermal contact may be important sources of selenium exposure [3].

Health effects of excess exposure to selenium include garlic odor on the breath, nausea, vomiting, epigastric pain, diarrhea, anemia, skin depigmentation, hair loss, abnormal fingernails, chronic and acute dermatitis, fatigue, irritability, cephalalgia, and, in most severe cases, various neurological manifestations (paralysis, convulsions, hemiplegia) [1]. Acute

selenium intoxication may lead in the most severe cases to death, generally due to pulmonary edema.

It is not easy to identify the subclinical effects of chronic selenium overexposure, as well as the exact amount of exposure and the chemical forms of the element that may induce mild toxicity. Chronic low-dose selenium toxicity appears to affect initially the endocrine system, interfering with growth hormone and insulin-like growth hormone synthesis and inducing hypothyroidism, and these effects are likely to be the early signs of selenium overexposure in humans [1]. Chronic low-dose selenium overexposure might also induce hepatotoxicity (hepatitis, cirrhosis), eye disease, dental caries, motor neuron disease and diabetes [1,4].

## Diagnostic Principles

If selenium excess is suspected, recent exposure to selenium is apparent from blood (serum, plasma, or erythrocyte) element concentration, while hair and nails are long-term indicators of exposure. Plasma levels of selenoproteins (such as selenoprotein P and the selenium-dependent glutathione peroxidase) are also used to assess selenium nutritional status and deficiency, although several factors apart from selenium appear to influence the levels and the activities of these enzymes. The activity of selenium-dependent glutathione peroxidases might be an indicator not only of selenium deficiency but also of selenium overexposure [3,5].

## Therapeutic Principles

There is currently no established effective treatment or antidotes for selenium overexposure, apart from removal of source of exposure. Therapy of acute intoxication includes treatment of cardiovascular and gastrointestinal alterations and symptoms, and in some cases, haemodialysis, whilst use of effective detoxifying chemicals is still under investigation.

# Self-Starvation

Marie-Estelle Dupont[1], Olivier Guilbaud[1,2]
[1]Département de Psychiatrie de l'Adolescent et du Jeune Adulte, Paris, France
[2]Université René Descartes, Paris, France

## Synonyms

Anorexia nervosa

## Definition and Characteristics

Anorexia nervosa, a form of self-imposed starvation, is a severe pathology of eating behaviors affecting mostly young people. Anorexic behavior consists in a voluntary drastic food restraint, based on the obsessive desire to be thinner and thinner and the pervasive fear of gaining weight, despite hyperactivity and fasting. It is systematically associated with amenorrhea. It is also associated with work overinvestment and hyperactivity and disinvestment of sexuality.

*Clinical Manifestation*:

1. Endocrine troubles (amenorrhea,…)
2. Slowed metabolic activity: bradycardia, blood pressure decrease, hypothermia
3. Skin dryness, hair loss, lanugo
4. Hypokaliema (due to prolonged vomiting…), cardiac arrest
5. Hypophosphoremia
6. Deficiency oedema
7. Osteopenia
8. Growth ceases in preburtal subjects
9. Cachexia

## Prevalence

1% among female teenagers, 0.3% among general population; Incidence rate: 8 out of 100,000; Sex ratio: 1 male/10 females; Mortality: Between 5 and 10% of patients die from cachexy or other complications (notably suicide).

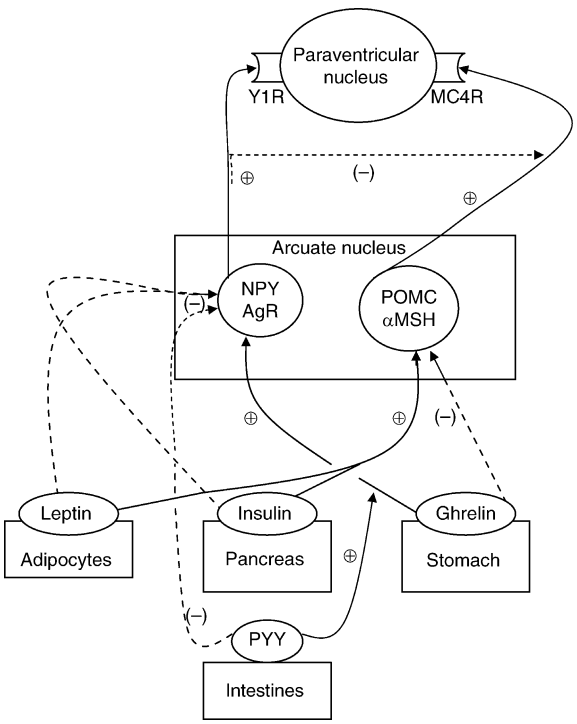
## Genes

Estimated heritabilities of liability to eating disorders, based on twin studies, range from 50 to 70%. First-degree relatives of eating disorder probands have an <3% lifetime risk of AN. Genetic studies and animal models support the participation of the serotoninergic system in the vulnerability to AN. Positive association between anorexia nervosa and the A allele of a -1438 G/A polymorphism in the type 2A serotonin receptor (HTR2A) gene coding serotonin receptor has been

reported. These ever-changing results seem to be more consistent in patients with obsessive-compulsive disorder suffering from restrictive type. More recently, an association between the brain-derived neurotrophic factor (BDNF) gene polymorphism and eating disorders has been observed. Nevertheless, the heterogeneity between the studies performed render this heritability estimation problematic.

## Molecular and Systemic Pathophysiology

The regulation of food intake and energy expenditure imply a complex interplay between peripheral systems (vagal afferent nerve responses, gastrointestinal secretion, gustatory stimulation) and central nervous systems (arcuate nucleus, paraventricular nucleus of hypothalamic area, forebrain,…). Two main neurohumoral systems involved in energy homeostasis have been described (see Fig. 1): the neuropeptide Y and agouti-related peptide circuitry which stimulates food intake via the neuropeptide Y receptor in the paraventricular nucleus of hypothalamic area and the POMC (proopiomelanocortin) circuitry which inhibits food intake through the MC4R (melanocortin 4 receptor). Several neuropeptides and neurohormones are involved in the regulation of feeding behavior by their orexigen effects (grehlin, galanine, orexine A and B, NPY, AgRP…) or their anorexigen effects (leptine, insuline, POMC, cholecystokinin, peptide Y-Y.). Although it has been proposed that neuroendocrine and neuropeptide alterations observed during the course of anorexia nervosa might contribute to the genesis of the disease, in most cases the neuroendocrine alterations tend to normalize after weight recovery. Thus, most of the disturbances are consequences rather than causes of malnutrition and weight loss.



**Self-Starvation. Figure 1** Neuropeptides and neural pathways involved in the regulation of food intake. (Inspired from Korner et Leibel, 2003). Solid lines indicate stimulation effects and dashed lines the inhibitory ones. POMC : proopiomelanocortine; αMSH melanocortine; NPY neuropeptide Y; AgRP agouti-related peptide; PYY peptide YY 3-36; YIR : NPY receptor; MC4R : melanocortin 4 receptor.

A widespread endocrine disorder involving the hypothalamic-pituitary-gonadal axis, with low levels of plasma estradiol and serum gonadotropins, is manifest in women suffering from anorexia nervosa. Usually luteinic hormone (LH) response to gonadotrophin releasing hormone (GnRH) is impaired. Concentrations of growth hormone and cortisol may be raised and changes in the peripheral metabolism of thyroid hormone and abnormalities of insulin secretion may also be seen. Low or normal serum TSH concentration is common in anorexia nervosa. Research supports hypothalamic-pituitary malfunction as secondary to starvation of anorexia nervosa and not an independent hypothalamic-pituitary disturbance.

## Diagnostic Principles

The clinical features of the syndrome are easily recognized, so that diagnosis is reliable with a high level of agreement between clinicians. It is characterized by the association of a weight loss leading to a body weight of less than 85% of the expected weight, amenorrhea and a distorted body image.

According to the ICD 10 (International Statistical Classification of Diseases) or the DSM IV (Diagnostic and Statistical Manual) criteria for anorexia nervosa, all the following are required for a definite diagnostic:

1. Body weight is maintained at least 15% below that expected.
2. Intense fear of gaining weight or becoming fat, even though underweight.
3. Disturbance in the way in which one's body weight or shape is experienced.
4. At least three consecutive menstrual cycles must be missed, if the woman was menstruating previously before the onset of the disorder (a woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen administration).

There are two subgroups of anorexic behavior aimed at reducing caloric intake, including the following:

1. Restricting Type: Severe food restriction without binge-eating or purging behavior.
2. Binge-Eating/Purging Type: Purging practices include self induced vomiting, misuse of laxatives, diuretics, or "slimming medicines."

### Therapeutic Principles

The goals of treatment for anorexia nervosa are to restore patients to a healthy weight, treat the physical complications, enhance the patient's motivation to cooperate with treatment and provide education about healthy nutrition and eating habits. Anorexia Nervosa implies multiple management strategies and involves many health professionals: general practitioner, psychiatrists, nutritionists, …

In the case of severe physical danger, hospitalization is required. Family approaches yielded the best results for teenage patients when associated with an individual psychotherapy.

## Sepsis

Hermann-Josef Gröne, Zoran V. Popovic
Department of Cellular and Molecular Pathology, German Cancer Research Center, University of Heidelberg, Heidelberg, Germany

### Synonyms

Sepsis syndrome; Septicemia

### Definition and Characteristics

Sepsis is an inflammatory condition caused by a severe systemic infection. Sepsis is accompanied by a reaction termed "Systemic Inflammatory Response Syndrome" (SIRS). SIRS describes the acute systemic response to the release of potent inflammatory mediators into the bloodstream. Sepsis has been characterized by the presence of at least two of the following parameters: (i) Body temperature >38°C or <36°C; (ii) Tachycardia (>90 beats/min); (iii) Tachypnoea (>20 breaths/min or $PaCO_2$ < 32 mm Hg); (iv) WBC count >12,000 cells/μl or <4,000 cells/μl [1]. Severe sepsis includes signs of failure of one or more organs. The term septic shock describes severe sepsis in which organ perfusion and normotension fail to be re-established by fluid resuscitation therapy, often leading to a lethal outcome [2].

### Prevalence

Approximately 18 million cases of sepsis occurred in 2006 worldwide. In Europe, prevalence of sepsis is approximately 89 per 100,000. Septic shock is more frequent in neonates, patients over 35 y.o. and pregnant women. Treatment with cytotoxic drugs, invasive diagnostic procedures, aggressive antibiotic and/or corticosteroid

therapy are significant risk factors for development of septic shock [3].

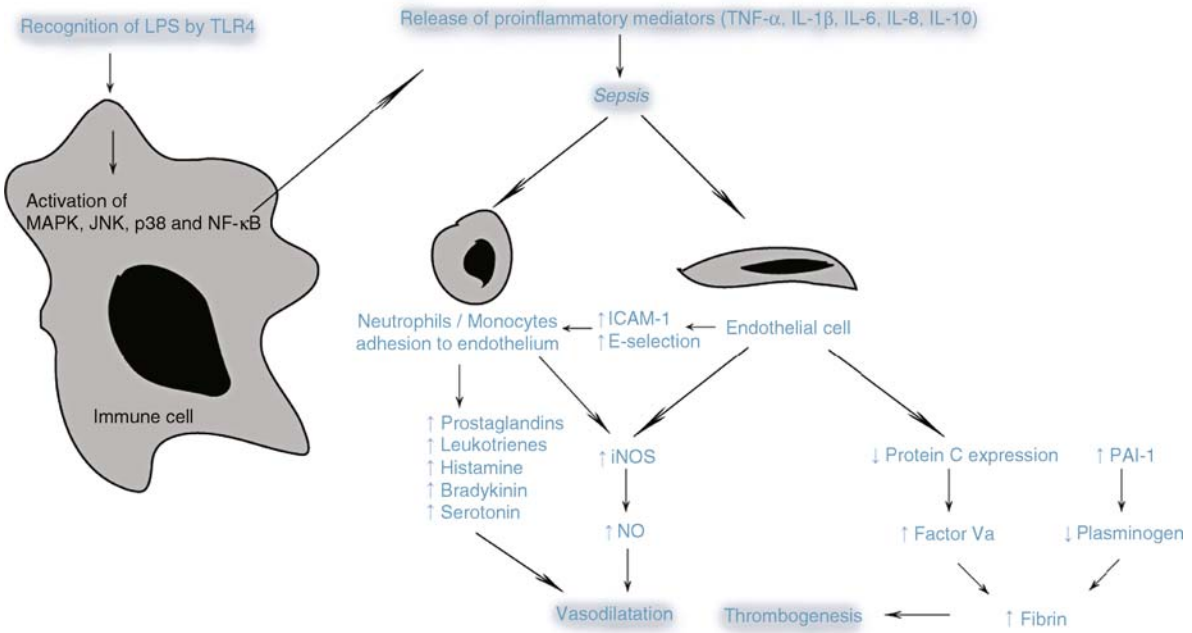
## Genes

A polymorphic region of chromosome 6 has been described as a carrier of the majority of genes that can influence the inflammatory response in sepsis. TNF-α and TNF-β variant alleles have been associated with increased gene transcription and cytokine secretion in response to endotoxin. Other candidate genes include IL-1ra, IL-6, IL-10, CD-14, TLR2 and TLR4 [4].

## Molecular and Systemic Pathophysiology

The mechanisms of sepsis are not completely understood. Central to the pathogenesis of sepsis is an immune response to pathogens that involves "cross-talk" between macrophages, dendritic cells and T cells. Bacteria, fungi or parasites activate pathogen recognition receptors (PRRs) and consecutive transcription of inflammatory genes. Proinflammatory cytokines (TNF; IL-1; IL-6) stimulate endothelial cells to express adhesion molecules (E-selectin; integrins), resulting in increased adhesion of activated neutrophils and mononuclear cells to endothelial cells. In addition, microcirculatory endothelia activate the fibrin clotting cascade with generation of microthrombi. Potent inflammatory mediators such as NO, leukotrienes, histamine, bradykinin, serotonin and IL-2 are released. Anti-inflammatory mediators (IL-4; IL-10) released by mononuclear cells in sepsis seem to provide a negative feedback of the process (Fig. 1) [2,3]. An increase in serum levels of IL-10 has been related to increased mortality. Enhanced apoptosis of CD4 T-cells and follicular dendritic cells contributes to immune anergy and prevents clonal expansion of lymphocytes [5].

As a result of the cytokine storm, vasculatory failure develops. Dilation of arterioles marks the initial phase. Increase in cardiac output compensates for decrease in peripheral arterial resistance. In later stages, cardiac decompensation with arterial hypotension and shock may occur. Bypassing of capillary exchange vessels secondary to release of vasoactive mediators results in poor delivery of $O_2$ and impaired removal of $CO_2$ and



**Sepsis. Figure 1** Molecular mechanisms of vasodilatory and procoagulant response in sepsis.Signaling pathways triggered by the recognition of LPS by TLR4 lead to an activation of MAPK, JNK, p38 and NF-κB. Increase in NF-κB activates transcription of TNF-α, IL-1β, IL-6, IL-8 and IL-10 to contribute to the development of sepsis. Increased expression of ICAM-1 and selectins on endothelial cells causes an enhanced adhesion of monocytes/neutrophils to the vascular endothelium. In sepsis the synthesis of prostaglandins, leukotrienes, histamine, bradykinin serotonin and NO by immune cells is increased, leading to vasodilatation and vascular damage. Sepsis increases the production of PAI-1 and decreases the synthesis of active protein C by endothelial cells, both contributing to an enhanced formation of thrombi. ICAM-1 – intercellular adhesion molecule 1; iNOS – inducible nitric oxide synthase; JNK – c-Jun N-terminal kinase; MAPK – Mitogen-activated protein kinase; PAI-1 – plasminogen-activating inhibitor 1.

waste products. Intravascular coagulation aggravates the decrease in tissue perfusion. Function of one or more vital organs (i.e. lung; heart; kidney) may be affected. However, pronounced organ dysfunction is usually not associated with abundant cell death in the affected organ, as evidenced in autopsies.

### Diagnostic Principles

A diagnosis of sepsis is made clinically. Anamnesis, physical examination and laboratory tests (urine culture; blood culture; body fluid cultures) serve to detect infection. Typical symptoms of sepsis include fever, tachycardia and tachypnoea. Signs of specific infection can accompany general symptoms. Confusion and impaired alertness are common in severe sepsis or septic shock. They are followed by arterial hypotension and hyperthermia. Oliguria is frequent in severe sepsis. Diagnosis may be confirmed by high blood levels of C-reactive protein and procalcitonin. Other blood analyses include complete blood count, arterial blood gases, serum electrolytes and lactate. Initially, hyperventilation causes respiratory alkalosis, compensatory to increased lactic acid load. With advanced septic shock, severe metabolic acidosis evolves. Low levels of serum cortisol may reflect adrenal dysfunction. Other causes of shock should be excluded by physical examination and cardiac functional tests.

### Therapeutic Principles

An early aggressive therapeutic approach (within 6 h of diagnosis) is essential for successful treatment of sepsis patients. Severe metabolic acidosis combined with signs of multiple organ failure is associated with fatal outcome. Monitoring of vital functions and parameters characteristic for sepsis should be continuous. Maintenance of plasma volume is crucial. Left ventricular function should be monitored to prevent fluid overload. If hypotension persists, i.v. dopamine and noradrenaline may be necessary. Supplemental oxygen can be administered by mask or tracheal intubation. Antibiotics are given parenterally, optimally after rapid identification of a potential bacterial cause and antibiogram testing. If the agent cannot be timely identified, high-dose treatment with gentamicin plus a third-generation cephalosporine is the initial therapy of choice. If staphylococci or enterococci are suspected, vancomycin should be added. Antibiotic treatment should be later modified according to culture results. Local abscesses must be treated surgically. Continuous i.v. infusion of insulin (glucose levels 80–100 mg/dl) and replacement doses of corticosteroids improve outcome of severe sepsis. If the patient is diagnosed for significant risk of death, activated protein C may be administered for fibrinolytic and anti-inflammatory effect [3].

# Sertoli Cell Only Syndrome

Mario Mancini
Andrology Unit, San Paolo Hospital, University of Milan, Milan, Italy

## Synonyms

Germ cells aplasia; Del Castillo syndrome; SCOS

## Definition and Characteristics

Sertoli cell only syndrome (SCOS) is a total absence of germinal epithelium in all seminiferous tubules of a single testicular biopsy [1].

## Prevalence

Azoospermia has been reported in 10–20% of infertile males. Prevalence of SCOS in azoospermic patients was 13–16%.

## Genes

Only the complete absence of AZF region of Y chromosome has been associated with complete SCOS.

## Molecular and Systemic Pathophysiology

Sertoli cells increase their number in two main development steps, the fetal period and puberty, respectively. The steps are characterized by differentiation and maturation.

In fetal life, the Sertoli differentiation leads to increased expression of FSH receptors and other genes. Following this, tubular and Leydig cells develop. After birth, the size of tubules and cells increases gradually with progressive involvement of the entire testis. Close to puberty, Sertoli cells express androgen receptor (AR), which are upregulated by thyroid hormones, and seem to prepare the cells for complete maturation. At puberty, Sertoli cells lose their proliferative ability and form tight junctions, making germ cells entirely dependent on their secretory products [2]. An average of 12 Sertoli cells per tubular cross section seems normal. It is directly related to germ cell number and sperm output. Finally, germ cells appear from 9 to 10 years.

Congenital disease can damage step one with abnormal differentiation. This step seems to be mainly under the control of FSH, but no mutations in FSH gene receptor were found in SCOS. Testicular diseases before puberty can impair step two with immature Sertoli cells and persistence of AMH expression; after puberty, germ cells disappear with persistence of mature Sertoli cells.

Based on Sertoli cell maturation, we can distinguish three pictures of SCOS: fetal or dysgenetic, immature, and mature [2]. Although all three types of Sertoli cells were usually found, dysgenetic Sertoli cells are typical in cryptorchid testis that presents with immature nuclei. Immature Sertoli cells are characteristic of androgen insensitivity syndrome (AIS).

Mature Sertoli cells can be primary or secondary, depending on the germ cell absence or their loss after puberty like in complete AZF deletion in Y chromosome and Klinefelter syndrome.

Finally, we can distinguish complete and incomplete SCOS, due to residual germ cells in isolated tubules.

A significant number of Leydig cell micronodules develop in compromised testis with SCOS like Klinefelter syndrome, cryptorchidism, androgen insensitivity syndrome, idiopathic azoospermia. An increased LH/Testosterone ratio, possibly due to an enzymatic defect in steroidogenesis, is still on debate.

Some SCOS, like ►Klinefelter syndrome, Y chromosome abnormalities, ►cryptorchidism, testicular dysgenesis syndrome (TDS), ►androgen insensitivity, and idiopathic azoospermia, are congenital. Acquired causes may be radiation or chemotherapy, bilateral orchitis, bilateral testicular torsion, and ►liver cirrhosis.

Klinefelter syndrome shows tubular fibrosis without germ cells. However, by testicular microdissection, sperms were successfully identified in about 50% of non-mosaic Klinefelter patients.

Cryptorchidism, although managed by orchidopexy, can lead to SCOS in adulthood with degenerated germ and Sertoli cells and collapsed lumen. An increased risk of germ cell tumors and in situ carcinomas was found.

Severe forms of TDS showed tubules with SCOS and mature or undifferentiated Sertoli cells, associated with Leydig clustering, hypospadia, abnormal testis descent, and low sperm count.

In SCOS, the prevalence of testicular nodules and cancer was higher than that in the general population, 26.3% and 10.5%, respectively [3].

In men affected by AIS, Sertoli cells are immature with a few or no spermatogonia and Leydig cells are hyperplastic. Idiopathic azoospermia shows normal or hyperplastic Leydig cells.

Testicular torsion shows several tubules with SCOS and an increased apoptosis.

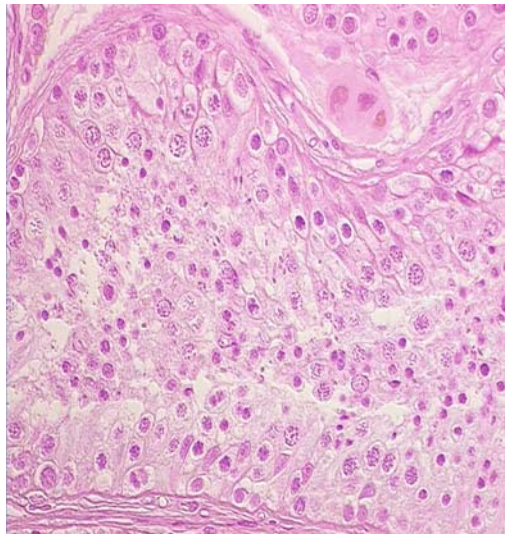
## Diagnostic Principles

When azoospermia occurs, a single testicular biopsy allows the diagnosis of SCOS (Figures 1 and 2) [1].

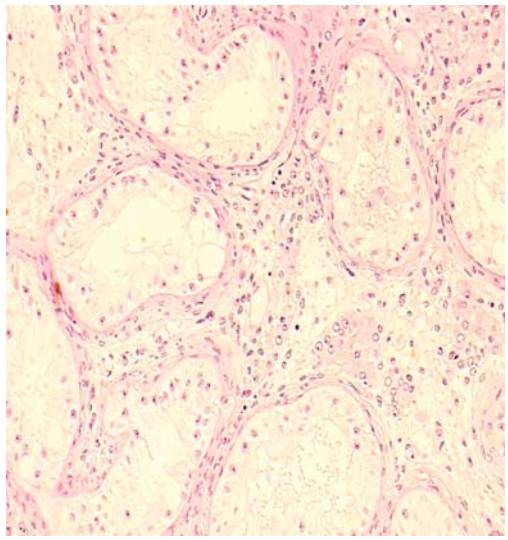
When a small percentage of tubules present with germ cells, SCOS is incomplete.

FSH elevation more than three times is often related to SCOS. Clinical interview and examination and genetic investigations are the most important to identify the pathogenesis.

Gonadotrophin levels are increased in cryptorchidism and in acquired SCOS and very high in Klinefelter syndrome and defective formation or efficacy of testosterone.



**Sertoli Cell Only Syndrome. Figure 1** Normal spermatogenesis.



**Sertoli Cell Only Syndrome. Figure 2** Sertoli cell only syndrome.

Isolated high levels of luteinizing hormone and testosterone occur in AIS.

Gonadotrophins appear normal in SCOS due to Y microdeletions.

The presence of cytocheratin 18 and anti-Mullerian hormone, usually lost at puberty, points to immature Sertoli cells.

## Therapeutic Principles

Early orchidopexy may prevent SCOS.

Varicocelectomy could increase the possibility of sperm retrieval in SCOS but it maybe a temporary result [4].

In Klinefelter syndrome, testicular sperm extraction in younger age increases successful sperm recovery.

In infertile male with SCOS, sperm retrieval rate is increased by microdissection (22.5%) rather than by multiple testicular sperm extraction (13%) [5].

Because a single biopsy explores only about 5% of the entire testis, it should be avoided in SCOS.

# Serum Sickness

Batya B. Davidovici, Batsheva Marcos, Edith Orion, Ronni Wolf
The Dermatology Unit, Kaplan Medical Center, Rechovot, Israel

## Definition and Characteristics

A clinical syndrome resulting from a type III immune complex mediated reaction (circulating immune complexes) that may occur after primary or repetitive exposure to heterologous anti sera or drugs.

## Prevalence

The prevalence of the disease depends on the type of medical treatment used.

## Molecular and Systemic Pathophysiology

Von Pirquet and Schick were the first to describe immune complex disease in humans based on their

experience in the use of horse diphtheria antitoxin in children. They entitled the disease, in a published monograph from 1905, serum sickness. Subsequently, several studies using animal models of serum sickness confirmed that antigen–antibody complexes formed in vivo could produce tissue damage [1]. Detailed clinical and immunochemical analysis were performed prospectively by Lawley et al. [2] on a large series of patients with serum sickness. This study demonstrated the role of circulating immune complexes in human serum sickness. Classically, serum sickness follows parenteral injections of therapeutic sera, the immune complexes consisting of antigen and IgG, usually with antigen excess (type III reaction). As the amount of antibody formed increases, the antigen is eliminated slowly by the mononuclear phagocyte system. The immune complexes cause intravascular complement activation and subsequent immune complex induced necrotizing angiitis, which is responsible for the diverse clinical symptoms of this syndrome. Eventually, the circulating complexes shift to antibody in excess of antigen and the clinical signs subside. Onset is after 1–3 weeks or as quickly as 2–4 days after secondary exposure. Over 70% of patients with serum sickness manifest urticaria, often preceded by pruritus and erythema. Urticarial lesions are persistent, lasting a few days and are sometimes tender or painful with bruising, unlike classical urticaria. Characteristically, a serpiginous, erythematous and purpuric eruption develops on the hands and feet at the borders of palmar and plantar skin, from the dorsa of the extremities (Wallace's line). Systemic features might include fever, joint pain and swelling, lymphadenopathy and occasionally proteinuria, nephritis or endocarditis, with eosinophilia. In minor forms, fever, urticaria and transitory joint tenderness may be the only manifestations.

Sickness-like syndrome refers to adverse reactions that have similar symptoms to serum sickness, however without evidence of the immune complexes.

Serum sickness and serum sickness–like reactions may be produced by exposure to drugs, e.g. penicillin, hydantoins, aminosalicylic acid, streptomycin, thiazides, sulfonamides, streptokinase, tamoxifen, oral contraceptives, anti-influenza vaccine, anti-snake venom and serum [3]. Other causes of serum sickness-like syndrome include radiocontrast media, infections (a serum sickness-like syndrome occurs in about 20–30% of patients with hepatitis B infection [4]) and rarely, foods.

### Diagnostic Principles

The diagnostic principles are based on the time lag between initiating the offending agent and the appearance of the symptoms, the clinical manifestations and the absence of other immunological or infectious causes. Laboratory studies may reveal circulating immune complexes, low serum C4 and C3 levels and elevated plasma C3a anaphylatoxin levels. Direct immunofluorescence reveals the presence of immunoreactants including IgM, C3, IgE and IgA in the walls of dermal blood vessels. An intradermal skin test is positive for the offending agent.

### Therapeutic Principles

Prompt discontinuation of the offending agent and supportive care is the cornerstone of treatment. Aspirin and antihistamines may relieve the symptoms. In case of severe symptoms a short course of high dose corticosteroids may be warranted. However, symptoms are usually self-limited and last for 5–28 days, usually resolving without sequelae. Avoidance of the offending agent is important.

## Shock, Cardiogenic

Jean-Louis Vincent
Department of Intensive Care, Erasme Hospital, Free University of Brussels, Brussels, Belgium

### Synonyms

Acute, life-threatening heart failure

### Definition and Characteristics

Cardiogenic shock is defined as the association of reduced cardiac output with arterial hypotension (a systolic blood pressure less than 90 mmHg or >90 mmHg but needing inotropic support, or a reduction in mean arterial pressure of more than 30 mmHg from baseline) with signs of altered tissue perfusion, including reduced urine output (typically less than 20 ml/h), reduced skin temperature and skin mottling, altered mental status, and raised blood lactate levels (>2 mmoL/l). Cardiogenic shock is typically characterized by elevated cardiac filling pressures and a low mixed venous oxygen saturation ($SvO_2$).

### Prevalence

Cardiogenic shock complicates 7–10% of cases of acute myocardial infarction and carries a mortality rate of some 50–60%.

### Genes

Not yet clearly defined but genetic factors certainly appear to influence the risk of development of, and outcome from, cardiogenic shock. Patients with the tumor necrosis factor (TNF)2 polymorphism appear to have better survival rates from cardiogenic shock [1].

### Molecular and Systemic Pathophysiology

Cardiogenic shock occurs as the result of a weakened heart often due to acute myocardial infarction, but other causes include end-stage cardiomyopathy, severe myocarditis, severe arrhythmia, etc. Classically the damaged myocardium results in reduced cardiac output causing lowered blood pressure that causes further myocardial insufficiency and a vicious downward spiral is created. A complex set of compensatory reflexes is activated to try and reinstate and maintain cardiac output and arterial pressure, including activation of the sympathetic system to increase heart rate and contractility, and the release of catecholamines, angiotensin, vasopressin and endothelins to increase arteriolar and venous tone. Blood flow is also redirected from skeletal muscle, subcutaneous tissue and the splanchnic

circulation to vital organs such as the heart and brain. However, these mechanisms are often inadequate and may actually worsen ischemia and the decreased tissue perfusion results in an imbalance between oxygen demand and delivery resulting in anaerobic metabolism with reduced cellular energy reserves and hyperlactatemia. Activation of the inflammatory system may also be involved in the reaction to cardiogenic shock [2].

## Therapeutic Principles

The main aim of therapy is to restore tissue perfusion, and treatment consists of correcting the primary cause of the cardiogenic shock while supplying ongoing resuscitation and cardiovascular support.

*Correction of the Primary Cause:* In myocardial infarction, thrombolysis is widely used, but longer term outcomes in myocardial infarction complicated by cardiogenic shock are better with emergency surgical revascularization using coronary artery bypass grafting or angioplasty [3]. Intra-aortic balloon pumps and ventricular assist devices can increase coronary blood supply and reduce left ventricular afterload and may be useful to stabilize patients not controlled by inotropic agents while waiting for revascularization [4].

*Resuscitation*: Resuscitation should follow established VIP (ventilation, infusion, pump) principles [5] with oxygen administration (using intubation and mechanical ventilation if needed) to correct hypoxemia and increase oxygen delivery, prudent fluid resuscitation using a fluid challenge technique may be helpful to increase ventricular preload, and vasoactive agents to restore perfusion pressure and increase cardiac output when fluids alone fail to correct the hemodynamic instability.

*Vasoactive Agents*: Vasopressors, such as dopamine or norepinephrine, are used to restore and maintain blood pressure, while inotropic drugs, such as dobutamine, are used to improve cardiac contractility and hence increase cardiac output. As soon as the blood pressure is restored, vasodilators may be considered.

## Synonyms

Septicemia; Blood poisoning

## Definition and Characteristics

Sepsis is a systemic inflammatory response syndrome triggered by a proven or suspected infection. The hallmarks of clinical sepsis are hypothermia or hyperthermia, tachycardia, hyperventilation and usually marked increase in white blood cells at its onset but lower cell counts can also mark its course. When sepsis results in at least one organ failure or dysfunction, it is classified as severe sepsis. Severe sepsis with hypotension unresponsive to fluid resuscitation defines septic shock [1].

## Prevalence

Sepsis syndrome afflicts almost 750,000 patients in the United States each year at a cost of almost $17

billion causing over 200,000 deaths annually. The incidence of sepsis syndrome continues to rise along with the increase in life span and several other important risk factors. Sepsis without organ dysfunction is a relatively benign condition, and spontaneous recovery with conservative measures results in low in-hospital mortality (5–10%). Severe sepsis and septic shock carry high mortality, 30–50%, in spite of all that modern treatment offers [2].

## Genes

Increased susceptibility to death from severe infection appears to be heritable. With the advent of molecular biology, single point mutations or polymorphisms have been demonstrated for cytokines such as tumor necrosis factor-alpha (TNF-a), interleukin-1 (IL-1) and interleukin-6 (IL-6). Most of these polymorphisms, implicated in increasing severity of sepsis, associated with increases in these pro-inflammatory cytokines. Lower levels of Lipopolysaccharide (LPS) binding protein have been reported in males, and abnormalities in toll-like receptor-4 and its signaling kinase IRAK-4 have been associated with worse outcome. Gender appears to play a role, as women under 50 years of age have half the rate of sepsis and death when compared to age-matched men [3,4,5].

## Molecular and Systemic Pathophysiology

*Risk Factors*: With the wider use of immunosuppressive agents, susceptibility to sepsis is all but expected. Advances in medical devices used and invasive procedures especially in the hospital setting provide for opportunistic infections. The alarming increase in pathogens resistant to antibiotics that in the past were very effective in prevention and treatment of sepsis, no doubt contributes to increases in severe sepsis prevalence in the elderly.

*Inflammation*: The key mechanisms that are believed to generate and drive the sepsis syndromes are inflammatory mediators that are elicited by the action of various bacterial (or fungal) toxins. These toxins interact with the host immune system, release of pro-inflammatory polypeptides with pleiotrophic actions. Most prominent among these factors are the cytokines released from monocytes and tissue macrophages, and innate cellular immune defense elements. Tumor Necrosis Factor alpha (TNF) and other pro-inflammatory cytokines, such as IL-1 and IL-6 are released into the systemic circulation. These cytokines trigger numerous additional pro-inflammatory events in all organs leading to widespread organ dysfunction. If untreated, systemic hemodynamic derangements lead to hypotension, failure of essential organ function and loss of their structural integrity. While little doubt exists that these cytokines generate the early clinical syndrome, it has also been recognized that acute inflammatory mediators play a role in compromising host defenses. The emergence of cytokines such as IL-10, IL-13 and TGF-beta, elicit a Compensatory Anti-inflammatory Response Syndrome (CARS) marked by depressed activity of B- and T-cells, macrophages and modulation of numerous genomic and post-transcriptional pathways. The CARS response is believed to contribute to severe cases to dysregulation of immune competencies leading to a compromised host defense condition and increased risk for mortality.

*Hemostasis, and Coagulation Factors*: The hemostasis system no doubt plays a major role in the pathophysiology of sepsis and septic shock. The intrinsic clotting factors, the fibrinolysis cascade, platelets and tissue derived clotting factors (such as Tissue Factor) are rapidly activated and persist along the entire evolution of the syndrome. Consumption coagulopathy defines severe development of the sepsis syndrome where rapid activation and consumption of coagulation factors along with a decrease in platelets lead to bleeding and disseminated intravascular microthrombosis. The dysregulation of the hemostasis system is closely linked to the inflammatory cells and cytokine response. TNF and other factors stimulate Tissue Factor expression in macrophages and endothelium leading to augmented coagulopathy via the extrinsic coagulation pathway, while certain coagulation factors, such as thrombin and Factor Xa, possess pro-inflammatory actions via specific receptors. The importance of the hemostasis system in severe sepsis has recently been validated via the therapeutic utility of activated Protein C (APC), which is now approved by the FDA for treatment of severe sepsis.

## Diagnostic Principles

Sepsis is a systemic inflammatory response syndrome triggered by a proven or suspected infection. Clinical signs and symptoms have been described. In the face of documented or suspected infection, the presence of two or more of the four signs fulfils the diagnosis of sepsis. With development of organ dysfunction or failure, severe sepsis is diagnosed. Septic shock is defined when severe sepsis is accompanied by systemic hypoperfusion resistant to fluid resuscitation.

## Therapeutic Principles

### Non-specific Treatment

The development of drugs for the treatment of sepsis, severe sepsis and septic shock has been a most difficult endeavor. Antibiotic treatment is tailored as much as possible to the infective agent, while palliative treatment of systemic variables and preservation of essential organ function are carefully monitored and balanced. Early goal-directed resuscitation therapy (EGDT) utilizes combinations of crystalloid infusions, vasopressors or vasodilators, transfusion of packed red

blood cells, and dobutamine (an inotrope, vasopressor and renal vasodilator agent). These therapies target a predefined central venous pressure, mean arterial pressure, hematocrit and central venous oxygen saturation of >70%. Early, aggressive volume resuscitation, especially within the first 6 h, remains a foundation of sepsis treatment [1].

## Specific Treatment

*Activated Protein C (APC)*: APC is a human recombinant APC (rhAPC, drotrecogin, Xigris). Protein C is an endogenous factor secreted as a zymogen that is activated by thrombin after binding to the endothelial cell surface factor thrombomodulin. APC serves as a physiological modulator in normal hemostasis by degradation of coagulation factors Va and VIIIa and hence securing a low level of thrombin, anti-coagulation and normal blood flow as well as anti-inflammatory actions. Sepsis leads to depletion of APC, which is also a biomarker for poor outcome. These data underwrote the efforts to supplement APC to patients in severe sepsis. APC infused over 4 days has been shown to decrease 28-day all-cause mortality in patients with severe sepsis. However, administration of rhAPC increases the risk of bleeding, an important consideration in treatment decision. Over the past 5 years since FDA approval of APC, the drug has established itself as a life saving therapeutic in severe sepsis in large clinical studies.

*Corticosteroid Therapy*: In spite of the cardinal role of inflammation in sepsis, contemporary anti-inflammatory agents, such as non-steroidal Anti-Inflammatory Drugs (NSAID, e.g., naproxen, ibuprofen) or adreno-corticosteroids have not faired well as standard treatment in sepsis and septic shock. Corticosteroids are the most potent anti-inflammatory agents known, yet their pleiotrophic activities likely suppress many important protective mechanisms, thereby diminishing their overall therapeutic potential in sepsis. This class of drug may find niche therapeutic utility when given at low doses over prolonged periods in subsets of septic patients that suffer from adrenal insufficiency. However, debate continues in this matter in reference to specific steroid, efficacy parameters, doses, and duration of treatment and patient selection [1].

## Potential New Therapeutic Modalities In Development

*Heparin*, a glycosaminoglycan anticoagulant has recently been shown to also possess anti-inflammatory properties. Heparin binds anti-thrombin III resulting in anticoagulant properties. By blocking, heparin impedes leukocyte adhesion to endothelial cells and their subsequent infiltration into tissue. Heparin inhibits multiple components of the inflammatory cascade, including cytokines (TNF-$\alpha$), integrins, complement activation, P- and L-selectin and platelet-activating factor. This combination of anti-inflammatory and anticoagulant properties, along with its low cost, suggests that heparin might find utility in treatment for sepsis.

*Tissue Factor Pathway Inhibitor (TFPI, Tifacogin)* is a polypeptide that possesses both anticoagulant and anti-inflammatory properties.TFPI inhibits tissue factor (TF), a trans-membrane cell surface receptor that serves as a major initiator of the coagulation cascade. Inhibition of TF decreases the formation of thrombin and clot formation. Reduction in TFPI levels in sepsis, which predisposed patients to fibrin clots, compelled clinical trials in sepsis. Such trials are ongoing.

*High-Mobility Group Box 1 (HMGB1) Protein* is a cytokine, which possesses inflammatory properties. Patients with sepsis-induced organ dysfunction have higher than normal serum levels of HMGB1. HMGB1 is released by LPS and cytokines stimulated macrophages. HMGB1increases inflammation by stimulating pro-inflammatory cytokines, including TNF-α, IL-1, IL-6, IL-8, and macrophage inflammatory protein. Anti-HMGB1 antibodies provided dose-dependent protection against endotoxemia and sepsis models in rodents. Anti-HMGB1 treatments hold the promise for efficacy in treatment sepsis at an extended "therapeutic window."

*Anti-Receptor for Advanced Glycation End Product (RAGE)* is a crucial receptor that mediates multiple inflammatory effects due to multiple RAGE ligands, including HM6B1,which are increased in the plasma of sepsis patients. Multiple experimental studies with various inhibitors of RAGE suggest that blocking the RAGE receptor decreases multiple pro-inflammatory mediators implicated in the sepsis pathophysiology. Furthermore, such inhibitors of RAGE improve short-term survival in rodent models of sepsis. It is expected that clinical testing of such a novel therapeutic will come to fruition in the next few years.

# Shock Syndrome, Toxic

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Streptococcal toxic shock syndrome; Staphylococcal toxic shock syndrome; TSS

## Definition and Characteristics

Toxic shock syndrome (TSS) is an acute onset of illness characterized by fever, rash, hypotension, multiple organ dysfunction that can lead to lethal shock. When cured, it is followed by desquamation [1]. It is caused by bacterial superantigens secreted from Staphylococcus aureus (S. aureus) [2] and group A streptococci, often M type 1 and 3.

## Prevalence

In the United States, annual incidence is 1–2/100,000 in women 15–44 years of age. The incidence of menstrual TSS in the United States peaked in 1980 and has decreased significantly during the past 20 years; 5% of all cases are fatal (CDC http://www.cdc.gov/).

## Genes

TSS may depend on genetic predisposition of the host to respond to some superantigens [3].

## Molecular and Systemic Pathophysiology

There needs to be colonization or infection with a toxigenic strain of. S. aureus or group A streptococcus, most commonly in the female genital tract or in nasal mucosa, but S. aureus found in sinusitis, pharyngitis, tonsillitis, laryngotracheitis, pneumonia, and lung abscess all has been implicated in TSS. In menstrual TSS, proliferation of toxigenic strains under occlusive tampons has been a major cause.

When neutralizing antibody to the toxin is lacking colonization or infection with a toxin-producing bacterial strain initiates a systemic inflammatory response in both menstrual and nonmenstrual disease. The toxins act as superantigens and activate T cells at orders of magnitude above antigen-specific activation, resulting in massive release of cytokines, such as TNF or IL1, which is believed to be responsible for the most severe features of TSS.

TSS toxin-1 (TSST-1) is secreted by strains of S. aureus and belongs to the pyrogenic toxin class of superantigens. Due to its apparently unique ability among this class to cross mucosal surfaces, it is detected in almost all cases of menstrual TSS [1]. However, both menstrual and nonmenstrual TSS can be caused also by other toxins, e.g. by classical staphylococcal enterotoxins B.

The coagulopathy observed in streptococcal TSS has been linked to the capability of M type 1 and 3 strains to induce synthesis of tissue factor in endothelial cells and monocytes independent from cytokine induction [4].

It is surmised that symptoms of TSS not only depend on expression of a certain array of toxins or superantigens, but also on a genetic predisposition of the host to respond to some of these superantigens [3].

Antibodies, which form against the bacterial toxins, have protective function. TSS can recur only among patients who fail to develop a humoral immune response to the implicated staphylococcal toxin.

## Diagnostic Principles

Diagnosis of TSS requires fever, rash, hypotension, multisystem disease, and desquamation 7–14 days after beginning of the illness [1]. Demonstration of toxin production and failure to detect antibodies against toxins support the diagnosis. The diseases caused by the various toxins are indistinguishable clinically.

## Therapeutic Principles

In menstrual TSS, prevention of relapses is achieved by patient education about proper use of tampons and recognition of early signs of the disease. A reduced occurrence was observed due to changes in tampon fiber composition, changes in absorbency, better recognition of early menstrual TSS, and a higher awareness of TSS in clinical situations other than menstruation.

For systemic therapy combinations of flucloxacillin and gentamicin or flucloxacillin and clindamycine have been suggested to inhibit production of TSS toxin 1 or other toxins [5].

# Short Rib-Polydactyly Syndrome Type I

M. Murat Naki[1], Cevahir Tekcan[2]
[1]Göztepe Research and Education Hospital, Department of Obstetrics and Gynecology, Istanbul, Turkey
[2]Barbaros Mh. Başkan Sk. Özlem Sit., Koşuyolu, Istanbul, Turkey

## Synonyms

Saldino-Noonan syndrome; SRPS type I; Polydactyly with neonatal chondrodystrophy, Type I

## Definition and Characteristics

Autosomal recessive lethal skeletal dysplasia characterized by severe thoracic dystrophy with striking micromelia, short and horizontal ribs, postaxial polydactyly, metaphyseal irregularities of long bones, visceral abnormalities, cardiac defects including transposition of the great vessels, polycystic kidneys, hypoplastic penis or ambiguous genitalia, malrotation, and imperforate anus. Pancreatic cyst and dysplasia have also been observed rarely [1].

## Prevalence

This syndrome is an extremely rare type of skeletal dysplasias seen in 0.025–0.033% of births, which probably exceeds the prevalence at birth, because many of the fetuses with this condition do not survive till term. This is associated with a recurrence in 25% of cases [2].

## Genes

GTG banding shows a normal karyotype with a pericentric inversion of chromosome 4 with breakpoints in p16 and q12 or q13, which is observable in all cells at a relatively low resolution level. The fetus in effect, has a hemizygous state for a recessive gene with a tiny deletion around 4p16 or 4q13.2, or through a position effect of the relocated genes. Alternatively, the microdeletion of contiguous genes on an inverted chromosome 4 can also be the mechanism behind SRPS, since contiguous gene syndromes are defined as a group of clinical entities caused by defects of genes located contiguously in the genome. However, at the molecular level, it is not yet clear whether the different phenotypes are the result of allelic heterogeneity or varying deletions in contiguous genes. It has also been suggested that the HOX4 (HOXD10) genes on chromosome 2q31 may be involved in disorders with polydactyly such as the SRPS. The debate as to whether the various forms of SRPS are the result of point mutations at different gene loci, differing mutations at the same locus, or variability in expression of the same mutant gene will not be satisfactorily resolved until the actual biochemical and molecular defects causing the several multiple organ defects in early embryogenesis are identified [3,4].

## Molecular and Systemic Pathophysiology

Saldino-Noonan syndrome is inherited as Mendelian autosomal recessive trait and considered the most lethal condition in the newborn and prenatal period. All result in death from respiratory insufficiency due to hypoplastic thorax cardiac defects, and hydrops fetalis.

## Diagnostic Principles

Prenatal diagnosis of this condition is possible by demonstrating the characteristic triad, which consists of micromelic dwarfism, short and horizontal ribs leading to a narrow thorax and polydactyly in the early second trimester of gestation by ultrasonography [5]. Additionally, demonstration of the pancreatic cyst or hypoplasia is very important, because these conditions are specific for Saldino-Noonan syndrome [2].

## Therapeutic Principles

After counseling geneticists and informing parents of the lethal outcome, termination of pregnancy is justified at any gestation these are diagnosed.

# Short Rib-Polydactyly Syndrome Type II

M. Murat Naki[1], Cevahir Tekcan[2]
[1]Göztepe Research and Education Hospital, Department of Obstetrics and Gynecology, Istanbul, Turkey
[2]Barbaros Mh. Başkan Sk. Özlem Sit., Koşuyolu, Istanbul, Turkey

## Synonyms

Majewski syndrome; SRPS Type II; Polydactyly with neonatal chondrodystrophy, Type II

## Definition and Characteristics

Autosomal recessive lethal skeletal dysplasia characterized by severe thoracic dystrophy with striking micromelia, holoprosencephaly, encephalocele and anencephaly, malformed larynx with hypoplastic epiglottis, low-set ears, cleft lip/palate, short and horizontal ribs, postaxial polydactyly, glomerular and renal tubular cysts, ambiguous genitalia, disproportionate short ovoid tibiae, protuberant abdomen, hydrops fetalis, but cardiac defects are rare [1,2] (Figs. 1 and 2).

**Short Rib-Polydactyly Syndrome Type II.**
**Figure 1** Photograph of a baby at 36 weeks' gestation reveals hydropic appearance, short extrimities, low-set ears, intact lips, and hand and feet hypoplasia.

## Prevalence

This syndrome is an extremely rare type of skeletal dysplasias seen in 0.025–0.033% of births. The real prevalence probably exceeds the prevalence at birth because many of the fetuses with this condition do not survive till term. This is associated with a recurrence in 25% of cases [3].

## Genes

GTG banding shows a normal karyotype with a pericentric inversion of chromosome 4 with breakpoints in p16 and q12 or q13, which is observable in all cells at a relatively low resolution level. The fetus in effect, has a hemizygous state for a recessive gene with a tiny deletion around 4p16 or 4q13.2, or through a position effect of the relocated genes. Alternatively, the microdeletion of contiguous genes on an inverted chromosome 4 can also be the mechanism behind SRPS, since contiguous gene syndromes are defined as a group of clinical entities caused by defects of genes located contiguously in the genome. However, at the molecular level, it is not yet clear whether the different phenotypes are the result of alleles or heterogeneity or varying deletions in contiguous genes. It has also been suggested that the HOX4 (HOXD10) genes on chromosome 2q31 may be involved in disorders with polydactyly such as the SRPS. The debate as to whether the various forms of SRPS are the result of point mutations at different gene loci, differing mutations at the same locus, or variability in expression of the same mutant gene will not be satisfactorily resolved until the actual biochemical and molecular defects causing the several multiple organ defects in early embryogenesis are identified [4,5].

## Molecular and Systemic Pathophysiology

Majewski syndrome is inherited as Mendelian autosomal recessive trait and considered the most lethal condition in the newborn and prenatal period. The primary cause of perinatal death is pulmonary insufficiency secondary to the small thorax [1].

## Diagnostic Principles

Prenatal diagnosis of this condition is possible by demonstrating micromelic dwarfism, short and horizontal ribs leading to a narrow thorax, and polydactyly in the early second trimester of gestation by detailed fetal sonographic scans. The presence of cleft lip/palate and ovoid configuration of the tibias are specific for this condition [1]. An elevated level of AFP in maternal serum is important because of the abnormalities in the central nervous system [2].

**Short Rib-Polydactyly Syndrome Type II. Figure 2** On the babygram hypoplastic scapulal, short ribs, and platyspondyly are seen. In addition there are only II ribs.

### Therapeutic Principles

After counseling geneticists, and informing parents of the lethal outcome, termination of pregnancy is justified when these are diagnosed at any gestation stage [1].

## Shwachman Diamond Syndrome

Amy S. Rawls, Daniel C. Link
Division of Oncology, Department of Medicine, Washington University, St. Louis, MO, USA

### Synonyms

Shwachman-Bodian diamond syndrome; Pancreatic insufficiency and bone marrow dysfunction; Congenital lipomatosis of the pancreas; SDS

## Definition and Characteristics

SDS is an autosomal recessive multisystem disorder characterized by exocrine pancreatic insufficiency, bone marrow dysfunction and skeletal abnormalities. Steatorrhea and low serum trypsinogen levels are present in most patients early in life [1]. Fatty infiltration of the pancreas is typical in patients with SDS and has been used as a diagnostic tool. The pancreatic insufficiency improves with increasing age in most patients. Rib cage abnormalities and/or metaphyseal dysostosis are present in most, if not all, patients [1]. Bone marrow dysfunction is present in nearly all patients with SDS. In the largest series, 86 of 88 patients with SDS displayed chronic or intermittent neutropenia [1]. As with other bone marrow failure syndromes, SDS patients are at a markedly increased risk for developing acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) [2].

## Prevalence

The estimated incidence of SDS is 1 in 100,000 live births.

## Genes

Approximately 90% of SDS patients have mutations in the shwachman bodian diamond syndrome (SBDS) gene [3]. The most common mutations in SBDS (184TA > CT and 258 + 2T > C) encode early truncations that eliminate the majority of the protein, and at least one of these mutant alleles is present in all patients with an identified SBDS mutations. SBDS is a protein of unknown molecular function that has been hypothesized to function in RNA processing and/or transport as well as cell motility [4].

## Molecular and Systemic Pathophysiology

The etiology of the pancreatic and skeletal phenotypes of patients with SDS is currently unclear. The hematopoietic phenotype has been better studied. Cell culture experiments have suggested a cell-intrinsic defect in hematopoietic cell growth and differentiation, as well as a defect in the ability of bone marrow stromal cells from patients with SDS to support hematopoiesis [4]. Though controversial, there also is evidence that hematopoietic progenitors from patients with SDS have an increased susceptibility to apoptosis [4]. Cell motility and chemotaxis defects in circulating neutrophils isolated from SDS patients have also been well documented [4]. Cytogenetic abnormalities and shortened telomeres potentially indicate that genomic instability may play a role in SDS patients that progress to bone marrow failure, AML, or MDS [4]. As noted, most but not all cases of SDS are associated with loss-of-function mutations of the SBDS gene. Ongoing investigations into the function of the SBDS protein should provide important insights into the molecular pathogenesis of SDS.

## Diagnostic Principles

Diagnosis is usually made in the first few years of life and requires documentation of exocrine pancreatic dysfunction and evidence of bone marrow failure (neutrophils < $1{,}500 \times 10^6$/L, hemoglobin < 10 g/dL, or platelets < $150 \times 10^9$/L) [4]. Additional findings that support the diagnosis of SDS include skeletal abnormalities, hepatomegaly, altered liver function, and short stature [4]. Genetic testing for SBDS mutations should be performed in all patients with possible SDS; the presence of SBDS mutations confirms the diagnosis of SDS.

## Therapeutic Principles

Treatment of SDS includes pancreatic enzyme replacement and fat-soluble vitamins for pancreatic insufficiency. Neutropenia, if severe, is usually treated with G-CSF. Annual bone marrow biopsies are recommended by some investigators to monitor for myeloid transformation [4]. Stem cell transplantation is generally reserved for patients with bone marrow failure or who have transformed to AML/MDS. A recent study reported 5-year event free survival of 60% in patients with SDS following stem cell transplantation [5].

## Synonyms

Salla disease (SD); N-acetylneuraminic acid storage disease; SASD

## Definition and Characteristics

Sialic acid storage disease (MIM 269920) is an autosomal recessive, neurodegenerative lysosomal storage disorder. Clinically, it can be differentiated into a slowly progressive adult form, designated Salla disease (SD) and a severe fetal onset-form, the infantile free sialic acid storage disease (ISSD), but intermediate phenotypes also exist. SD is characterized by a normal newborn period, followed by slowly progressive, muscular hypotonia, transient nystagmus, cerebellar ataxia, impaired intelligence and psychomotor delay, but a nearly normal life span. In ISSD, failure to thrive, organomegaly, dysmorphic features, severe mental and motor retardation predominate (Fig. 1), hypopigmentation and ascites can also be present and patients may die in their early years of life. Brain atrophy associated with hypomyelination and corpus callosum hypoplasia is a crucial finding in all clinical subtypes (reviewed in [1]).

## Prevalence

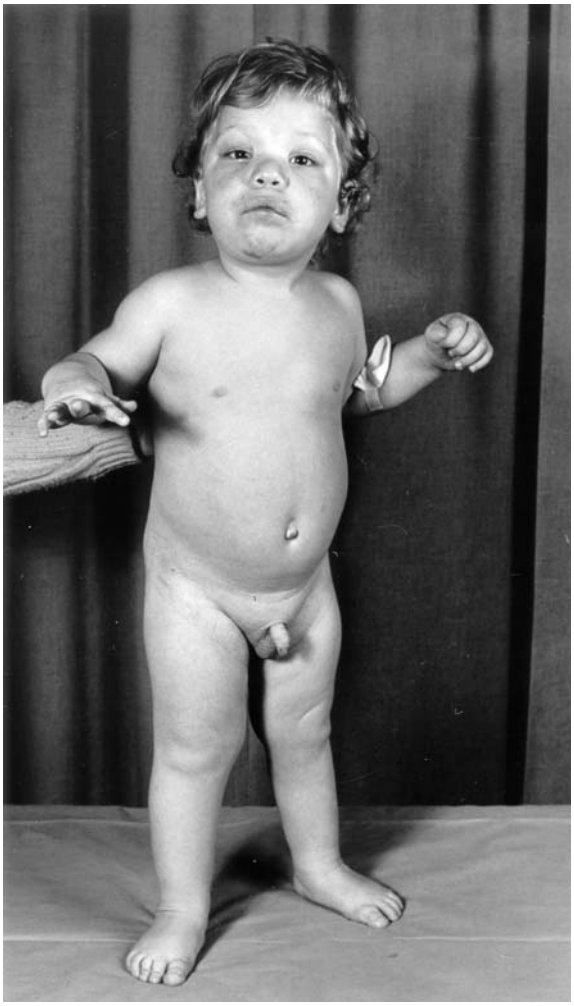
Most patients with Salla disease are of Finnish or Swedish origin whereas there is no ethnic predilection for ISSD, or intermediate forms.

## Genes

SLC17A5 (or AST) coding for an anion sugar transporter protein (sialin), localized on chromosome 16q14–15.

## Molecular and Systemic Pathophysiology

Mutation of the sialin gene leads to defective transport of free sialic acid out of the lysosome and therefore to an accumulation in this compartment and an excessive excretion in the urine. Although the vacuolization and enlargement of cells by storage material leads to dysfunction of whole organs, the precise role of the accumulated sialic acid in the pathogenesis of the disease, especially the severe dysfunction of the brain, is still unknown. Many different mutations have been identified in the SLC17A5 gene, but although there exists some genotype-phenotype correlation [2,3], variations in the phenotypic spectrum despite identical mutations are also possible. This strongly suggests additional genetic or environmental factors being responsible for the clinical manifestation.



**Sialic Acid Storage Disease. Figure 1** Patient with infantile sialic storage disease at the age of four years with coarse facial features, hepatosplenomegaly and psychomotor retardation. Photo courtesy of Prof. Spranger, Sinsheim, Germany.

## Diagnostic Principles

Diagnosis is based on the detection of increased urinary free sialic acid by thin-layer chromatography and demonstration of an elevated ratio of free/bound sialic acid by colorimetric analysis in cultured skin fibroblasts or in urine [4]. MRI studies (brain atrophy and hypomyelination) and electron microscopy (vacuolated cells) additionally confirm the diagnosis. For prenatal diagnosis in mild-type SD uncultured chorionic villi are preferable to amniotic cells. Known mutations of the

index case or parents enable accurate prenatal diagnosis by molecular genetic analysis and corroborate biochemical assays [5]. SASD must be differentiated from other disorders of sialic acid metabolism such as sialuria (increased sialic acid in urine, but not in cultured cells; no cellular vacuolation), sialidosis (lysosomal sialidase deficiency) and galactosialidosis (combined lysosomal sialidase/β-galactosidase deficiency).

## Therapeutic Principles

At present, no specific therapy is available, and treatment rests with amelioration of symptoms.

# Sialidosis

Michael Cantz[1], Johannes Uhl[2], Jürgen Kopitz[1]
[1]Institute of Pathology, University of Heidelberg, Heidelberg, Germany
[2]Scil Proteins Production GmbH, Halle, Germany

## Synonyms

Mucolipidosis I; Cherry-red spot-myoclonus syndrome

## Definition and Characteristics

Sialidosis is a recessively inherited lysosomal storage disease (McKusick classification MIM 256550), that has been grouped in two forms: the milder type I, with myoclonus, ataxia and ocular cherry-red spots (the cherry-red spot-myoclonus syndrome), and the severe or dysmorphic type II (formerly mucolipidosis I; Fig. 1). with psychomotor retardation, cerebral seizures, mildly enlarged liver, skeletal dysplasia, ocular cherry-red spots, occasionally hydrops fetalis, and early death (reviewed in [1]).

## Prevalence

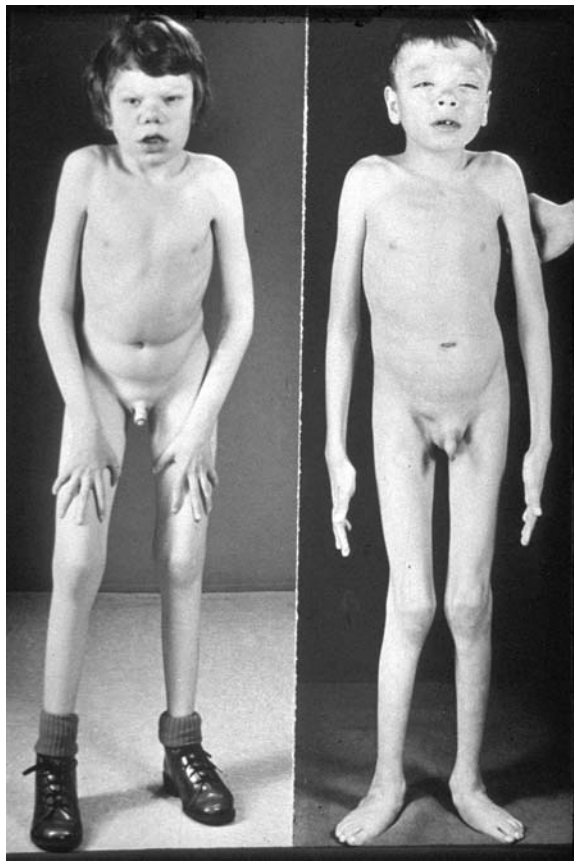
Sialidosis is rare with an estimated frequency of approximately 1 in 4.2 million live births [2].

## Genes

Defective NEU1 gene coding for a lysosomal sialidase (neuraminidase, EC 3.2.1.18), localized on chromosome 6p21.3.

## Molecular and Systemic Pathophysiology

Due to the deficiency of a sialidase involved in the lysosomal catabolism of glycoproteins and glycolipids, there is an excessive accumulation of sialic



**Sialidosis. Figure 1** Two patients with sialidosis type II, aged 12 years, exhibiting the full clinical picture with coarse facial features, depressed nasal bridge, short trunk, barrel shaped chest, and long and thin extremities with muscular wasting. Photographs courtesy of Prof. Jürgen Spranger, Sinsheim, Germany.

acid-containing oligosaccharides and gangliosides in most tissues. This not only leads to an enlargement of lysosomes but also of cells and whole organs, thereby progressively disrupting their function. Because of the defective degradation of glycoprotein-derived oligosaccharides, there is greatly increased urinary excretion of sialyloligosaccharides. Numerous genetic alterations have been reported in NEU1 of sialidosis patients, consisting of many missense and a number of nonsense mutations (reviewed in [1,3]), as well as exon skipping [4] and a large interstitial deletion [5]. So far, the very severe cases exhibiting hydrops fetalis and prenatal or neonatal death were all characterized by genetic lesions expected to cause a complete loss of sialidase activity (nonsense mutations, exon skipping, deletion), whereas patients with clinically less severe forms exhibited missense mutations that presumably resulted in the preservation of some residual activity.

### Diagnostic Principles

The clinical symptoms give some indication of the diagnosis, but must be complemented by laboratory tests. A simple indicator for many lysosomal diseases is the presence of storage granules in lymphocytes in a conventionally stained blood smear. In an oligosaccharidosis like sialidosis, a useful screening test is the demonstration of an abnormal urinary oligosaccharide pattern, e.g. by thin-layer chromatography. For a final diagnosis, however, demonstration of a deficiency of the lysosomal sialidase activity (neuraminidase) in cultured skin fibroblasts obtained from a skin biopsy is necessary (leukocytes must not be used because of the presence of a non-lysosomal sialidase that would mask a deficiency). For prenatal diagnosis, cultured amniotic or chorionic villus cells are used. Molecular genetic analysis should be performed for confirmation of the diagnosis and for genetic counseling. The "isolated" sialidase deficiency in sialidosis must be differentiated from the combined deficiencies of sialidase and β-galactosidase due to the genetic defect of the so-called protective protein/carboxypeptidase A in the disorder galactosialidosis.

### Therapeutic Principles

At present, only symptomatic treatment can be offered. Causal therapeutic attempts such as enzyme replacement or correction of the gene defect have not yet been reported.

## Sickle Cell Disease

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Definition and Characteristics

Hemoglobinopathy affects mainly blacks and is caused by an inherited qualitative disorder of hemoglobin synthesis, resulting in the formation of hemoglobin polymers with rigid sickle-shaped red cells that interfere with normal blood flow and have a shortened life span. This leads to a myriad of vasoocclusive complications with ischemic end organ damage (including painful crises, acute chest syndromes, and strokes), chronic hemolytic anemia, functional asplenism with increased susceptibility to infections. Life expectancy is significantly shortened in patients with SCD [1].

### Prevalence

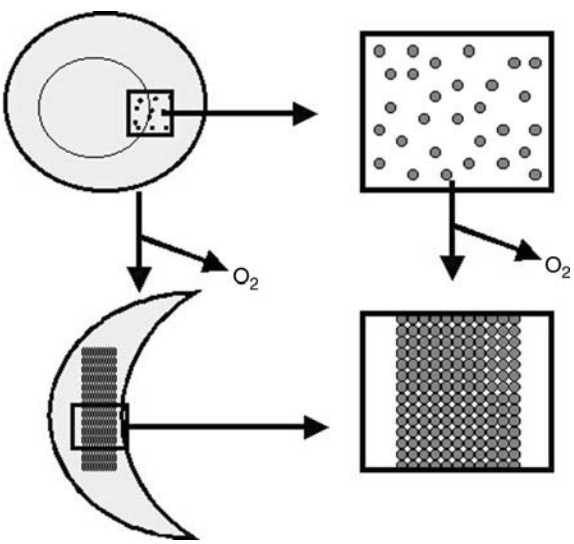
In some parts of Africa, 45% of the population is heterozygous for the $\beta^S$ gene, in the USA and Caribbean about 8% carry one $\beta^S$ gene. Incidence of homozygous sickle cell disease in the USA is 1 in 625 births. Prevalence is lower in the Mediterranean basin, Saudi Arabia, and parts of India [2].

## Genes

11p15.5; due to a single point mutation (thymine substituted for adenine) in the sixth codon of the β gene cluster on chromosome 11 valine is encoded instead of glutamic acid. This leads to the formation of an abnormal β globin; $\beta^s$. Inheritance of SCD follows an autosomal recessive pattern [1,2].

## Molecular and Systemic Pathophysiology

Upon deoxygenation of HbS, hydrophobic interactions occur between the β6 valine replacements, forming deoxyhemoglobin strands and via interactions between adjacent strands a hemoglobin polymer (consisting of seven pairs of strands) is formed. Such polymers lead to the classical sickle shape of red blood cells. Upon reoxygenation, sickled cells "unsickle," but with each sickling sickle, red cells become less pliable and ultimately, irreversibly sickled red cells are formed (Fig. 1). Sickled cells get stuck in the microcirculation, leading to tissue ischemia and damage in almost all organs. This vasoocclusive process is the hallmark of sickle cell disease. Factors that accelerate this polymerization process are the degree of deoxygenation, cellular dehydration and lower pH, and a low content of fetal hemoglobin (HbF, which does not form lateral contacts between deoxyhemoglobin S strands and thereby limits fiber formation). As the delay time ($T_d$; the time required for polymer formation) is longer than the transit time ($T_t$) of red cells through the microcirculation, sickled red cells do usually not form in the microcirculation.



**Sickle Cell Disease. Figure 1** Schematic simplified illustration of the sickling process. *Left upper* figure is an erythrocyte before deoxygenation. After deoxygenation (*left lower*), a sickle-shaped red cell is formed. The *upper right* and *lower right* figures illustrate hemoglobin polymer formation (with hemoglobin depicted as a small circle).

Factors that delay the $T_t$, such as the adhesion of leukocytes and sickle reticulocytes to cytokine-activated vessel wall endothelium, as well as an abnormal vasomotor response, are now considered of importance in the initiation and propagation of sickle cell vasoocclusion. The sequelae of chronic intra-vascular hemolysin, especially mediated via reducing nitric oxide bioavailability, are nowadays also considered of major importance in the pathophysiology of specific SCD related complications, such as pulneonary hypertension [1–3]. The most severe spectrum of disease occurs in patients homozygous for the $\beta^S$ gene mutation (sickle cell anemia; HbSS, $\alpha_2\ \beta^S{}_2$), but co-inheritance of HbS with other β-globin gene mutations, such as HbC (sickle C disease; $\alpha_2\ \beta^S\ \beta^C$) and β-thalassemias, leads to sickle cell syndromes of varying severity. People with one $\beta^S$ gene have the sickle cell trait (HbAS, $\alpha_2\ \beta^S\ \beta$) and are usually asymptomatic. Carriers of the $\beta^S$ gene are less susceptible to lethal malaria infection, explaining the high prevalence in areas where malaria is endemic [1].

## Diagnostic Principles

Detection of HbS can be achieved by inducing the sickling process in a blood film devoid of oxygen, with the presence of sickle cells indicating the presence of at least one $\beta^S$ gene. Hemoglobin electrophoresis, high-performance liquid chromatography, and iso-electric focusing can be used to determine the presence of sickle hemoglobin as well as other abnormal hemoglobins [1].

## Therapeutic Principles

Subjects with sickle cell trait require no specific therapy, but genetic counseling is a must for all carriers of the $\beta^S$ mutation. Specific therapeutics include blood transfusion, folic acid supplementation, vaccination against streptococcus pneumoniae (and haemophilus influenzae) and penicillin prophylaxis during childhood, hydroxyurea (which raises HbF% thereby limiting HbS polymerization), and hematopoetic stem cell transplantation. Acute complications such as painful crises often require hospital admission and treatment with parental opiates [1,4].

►Sudden Infant Death Syndrome

## Siewert Syndrome

Bärbel Schütte
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Katagener syndrome; Primary ciliary dyskinesia; PCD

### Definition and Characteristics

Kartagener syndrome (KS), a subunit of primary ciliary dyskinesia (PCD), is an autosomal recessive disorder with genetic heterogeneity. KS is caused by ciliary immotility or dysmotility due to ultrastructural abnormalities of respiratory cilia and flagella of spermatozoa and Fallopian tube. Clinical characteristic features are situs inversus, respiratory distress of various severity leading to chronic sinusitis and bronchiectasis. Flagella defects of spermatozoa and Fallopian tube results in infertility or subfertility. Situs inversus is probably due to the absence of ciliary motility in Hensen's node in the embryo.

### Prevalence

Estimates of KS prevalence range from 1/32,000 to 1/120,000 live births. Half of all patients with PCD (prevalence 1/16,000 to 1/60,000) are classified as KS.

### Genes

Mutations have been detected in different genes encoding axonemal dyneins, including light (DNAL), intermediate (DNAI) and heavy (DNAH) chains [1,2]. In KS: DNAH5, localized on chromosome 5p15-14 [3] and DNAI1, localized on chromosome 9p21-p13 (6). Recently a KS gene to a 3.5 cM region on chromosome 14q24-25 was identified [4]. In PCD: DNAH5, localized on chromosome 5p15-14 [5], DNAH9, localized on chromosome 17p12 [5] DNAH11, localized on chromosome 7p15 [2–4] and DNAL1, localized on chromosome 14q24.3 [4,5].

### Molecular and Systemic Pathophysiology

Cilia of the respiratory tract and flagella of spermatozoa consist of nine peripheral microtubule doublets surrounding two central microtubules (9 + 2 axoneme). The microtubule core contains a number of multiprotein complexes as outer and inner dynein arms (ODA, IDA), central sheaths, radial spokes and nexin links. The dynein arms are periodically attached to the peripheral microtubules and powers motion by ATP-dependent reactions. ODA and IDA contain several dynein peptides which are classified depending on their molecular weight into heavy (400–500 kDa), intermediate (55–110 kDa) and light (8–45 kDa) chains [2].

Ultramicroscopical studies (TEM) in humans with KS and PCD detected various defects including central sheaths, radial spokes, nexin links and partial or complete absence of dynein arms. Latter are with about 90% most frequent.

### Diagnostic Principles

Transmission electron microscopy (TEM) is the most commonly used method for diagnosis of cilia and flagella defects in KS and PCD.

### Therapeutic Principles

The primary goal of therapy in patients with KS and PCD is the prevention of chronic lung disease by consequent treatment of respiratory infections.

In males with infertility intracytoplasmic spermatozoa injection (ICSI) seems to be the treatment of choice. But so far only a few case reports have been published with varying results of fertilization and pregnancy.

## Silicosis

Samuel J. Arbes, Darryl C. Zeldin
Laboratory of Respiratory Biology, NIH/NIEHS, Research Triangle Park, NC, USA

### Definition and Characteristics

Silicosis is an occupational lung disease caused by the inhalation of crystalline free silica, the major component of sand. Exposure to airborne crystalline silica occurs in a wide variety of industries and occupations including mining, sandblasting, stone cutting, ceramics, and construction. Chronic silicosis, the most common form, usually develops after 10 or more years of relatively low exposure; accelerated silicosis develops 5–10 years after moderate exposure; and acute silicosis typically develops within a year of intense exposure. Acute silicosis progresses rapidly and is often fatal, but fortunately is rare. Silicosis is characterized by pulmonary fibrosis and can also be categorized by the type of fibrotic changes within the lung. In simple nodular silicosis, the fibrosis appears as discrete, small hyalinized nodules throughout the lung. In contrast, conglomerate silicosis (also called progressive massive fibrosis) is characterized by conglomerate fibrotic masses which contract and distort the lung architecture. Individuals with silicosis are at an increased risk for developing pulmonary tuberculosis, lung cancer, and autoimmune diseases, such as rheumatoid arthritis, scleroderma, and systemic lupus erythematosus.

### Prevalence

The National Institute for Occupational Safety and Health (NIOSH) estimates that 1.7 million U.S. workers are potentially exposed to respirable crystalline silica [1]. The prevalence of silicosis in the United States is unknown. From 1984 to 1994, 14,824 silicosis-related deaths were recorded in the United States [2]. Seventy-six percent of the deaths were among persons greater than 65 years of age. The number of silicosis-related deaths has declined from >1,100 in 1968 to <400 annually since 1980; however, among persons aged 15–44 years, the number of deaths due to silicosis has remained relatively constant.

### Genes

The relationship between silicosis and single nucleotide polymorphisms in genes encoding TNF-α, IL-1α, IL-1β, and IL-1 receptor agonist (IL-1RA) was evaluated in a recent study of coal miners [3,4]. The frequencies of polymorphisms in genes encoding TNF-α and IL-1RA were greater in miners with silicosis than in miners without any lung disease. However, silicosis was also present in a large proportion of miners without these polymorphisms, suggesting that other genes may be important in the development of the disease.

### Molecular and Systemic Pathophysiology

Once inhaled, crystalline free silica particles of respirable size (<10 μm) are deposited in the distal airways and engulfed by alveolar macrophages. These macrophages, along with type II epithelial cells, release cytokines that lead to inflammation, cellular proliferation, and fibrosis [5]. Tumor necrosis factor (TNF)-α and interleukin (IL)-1 are perhaps the most important

cytokines involved in the pathophysiology of silicosis. Besides causing the release of proinflammatory and profibrotic cytokines, silica is associated with the production of reactive oxygen species (ROS) in alveolar macrophages. It is believed that silica-induced ROS can lead to activation of the nuclear factor (NF)-κB pathway, which in turn leads to cyclooxygenase-2 induction (and subsequent biosynthesis of proinflammatory eicosanoids) and TNF-α production/release. Silica also activates the activator protein-1 (AP-1) transcription factor through mitogenic-activated protein kinase (MAPK) signal transduction pathways. It is hypothesized that silica-induced activation of NF-κB and AP-1 leads to chronic inflammation and cellular proliferation, which contribute to development of the silicotic nodule, the pathognomonic lesion of silicosis.

## Diagnostic Principles

Diagnosis is based on a history of silica exposure and characteristic changes seen on chest radiographs. Radiographically, simple nodular silicosis appears as multiple, small, rounded opacities, typically in the upper lung zones. The radiographic appearance of simple silicosis is similar to that of other occupational lung diseases; however, the appearance of "eggshell calcifications" in adjacent lymph nodes, if present, distinguishes silicosis from other diseases. Conglomerate silicosis appears as opacities >1 cm in diameter, in conjunction with smaller, nodular opacities. Bilateral symmetry and upper lung zone predominance are typical. The International Labor Office (ILO) classification scheme is used to define and quantify radiographic abnormalities in silicosis as it is in other pneumoconioses. Patients with simple nodular silicosis typically have minimal or no symptoms and little respiratory impairment. Patients with conglomerate silicosis exhibit progressive dyspnea, chronic productive cough, and severe pulmonary functional abnormalities (restrictive lung disease with reduced lung volumes and diffusing capacity). When the fibrotic masses become extensive, weight loss, general disability and death can result. Physical findings vary with the state of the disease.

## Therapeutic Principles

No effective treatment is available for silicosis. Because of this, limiting workplace exposure to silica is important. NIOSH recommends limiting respirable crystalline silica exposure to $\leq 0.05$ mg/m$^3$ as a time-weighted average for a 10-h workday, substituting less hazardous materials for silica when possible, using respiratory protection, and making regular medical examinations available to exposed workers [1]. Complicating infections should be treated with appropriate antimicrobials. Patients with silicosis should receive immunizations against pneumococci and influenza. In patients with associated autoimmune disease, anti-inflammatory drugs may be effective.

# Silver-Russell Syndrome

Alessandra Baumer
Institute of Medical Genetics, University Zurich, Scherzenbach, Switzerland

## Synonyms

SRS (MIM 180860); Russell-Silver syndrome; Maternal uniparental disomy for chromosome 7; UPD(7)mat

## Definition and Characteristics

SRS is a rare disorder associated with features such as small stature, low birth weight, characteristic "triangular" facies and clinodactyly of the fifth fingers. A maternal uniparental disomy 7 (matUPD7) is detected in about 10% of patients [1], thus imprinted genes appear to be involved in the disorder.

## Prevalence

The Silver-Russell syndrome is a rare mostly sporadic disorder. The incidence of SRS is not very clear: estimates range from 1 in 3,000 to 1 in 100,000 newborns.

## Genes

Two distinct regions on chromosome 7 are thought to be associated with SRS: 7p13-p11.2 [2,3] and 7q31-qter [4]. Although several genes are considered to be good candidate genes, no SRS causative gene has been detected to date.

## Molecular and Systemic Pathophysiology

The only SRS causative genetic defect known to date is the presence of a matUPD7 in 10% of SRS patients. UPDs often occur through trisomy rescue and theoretically the SRS phenotype could be due to residual cells with a trisomy 7. However, because the UPD is always of maternal origin and other familiar cases also show maternal transmission, it is believed that the SRS phenotype is due to the disruption of imprinted genes and not to confined placental mosaicism.

## Diagnostic Principles

The main criteria for the clinical diagnosis of SRS are pre- and postnatal growth retardation, characteristic facies with broad forehead and narrow chin, wide mouth and thin lips; and clinodactyly of the fifth fingers. [5–7]. The molecular investigations are to date limited to the detection of the approximately 10% of cases with a matUPD7. Such analyses are performed by haplotype analysis at the critical regions on chromosome 7.

## Therapeutic Principles

No specific therapy is available. It is not clear whether growth hormone therapy can improve final height.

# Sinusitis, Chronic

Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Definition and Characteristics

The term chronic sinusitis summarizes a group of heterogeneous clinical conditions that are characterized by a chronic inflammatory response of the nasal sinus mucosa, which frequently involves the nose [1,2,4] (chronic rhinosinusitis, CRS). The precise etiology and pathogenesis is enigmatic in many individual cases. It often represents a multifactorial clinical condition that entails varying involvement of impaired ostial patency, disruption of mucociliary clearance [1], allergic [3] bacterial or fungal afflictions [2,5] and immunocompromized states as well as environmental and genetic factors that are either associated or present as risk factors [4].

The clinical definition of a CRS is based on the symptomatology, duration and severity of the disease as well as on endoscopic findings and findings from imaging procedures. A subgroup of CRS is formed by nasal polyposis [3], which originates in the nasal sinuses.

## Prevalence

CRS is characterized by a significant morbidity, which entails considerable socio-economic costs. A precise measurement of the prevalence of CRS is not possible. In the United States prevalences varying between 2 and 15% have been reported, depending on how the CRS is defined.

## Molecular and Systemic Pathophysiology

Anatomical variations in the osteomeatal complex with subsequent disruption in the aeration of the nasal sinuses play a key role in the pathophysiology [4]. In addition, disorders in mucociliary competence with impairment of ciliary clearance [1] in the nasal sinuses can also occur. In some cases a pre-disposition towards

an IgE mediated type I allergy can exist. The frequent occurrence of CRS amongst patients with a compromised immune status (immunoglobulin deficiency, HIV, immunosuppressive therapy) suggests that an immunocompromized status represents a risk factor for the establishment of a CRS [4].

### Diagnostic Principles

1. Anterior and posterior rhinoscopy
2. Nasal endoscopy
3. CT scan

### Therapeutic Principles

*Conservative Therapy*: With non-polypous CRS the pharmaceutical treatment of a disease inducing bacterium or fungus is of major importance if its etiological involvement can be proven upon cultivation. For an IgE-associated immediate-type allergy, the condition itself is treated. In the vast majority of cases, however, the demonstration of the etiology is not possible so that conservative therapy is usually restricted to the application of topical corticoids [4].

*Surgical Therapy*: Surgical therapy comes to the fore if an anatomical constriction in the osteomeatal complex is diagnosed as the cause for the CRS. Surgical therapy is almost always indicated if one is dealing with the polypous form of a chronic rhinosinusitis. Surgical therapy characteristically consists of a FESS (functional endoscopic sinus surgery), which is then followed by a conservative therapy using topical corticosteroids.

## Sitosterolemia

Brandy J. Harvey, Jyh-Yeuan Lee, Ina L. Urbatsch
Department of Cell Biology and Biochemistry, Texas Tech University Health Sciences Center, Lubbock, TX, USA

### Synonyms

Phytosterolemia

### Definition and Characteristics

Sitosterolemia [MIM 210250] is a rare inherited sterol metabolism disorder first described in 1974 by Bhattacharyya and Connor [reviewed in 1]. The disease is manifested by significantly elevated plasma levels of plant sterols (phytosterols) in the form of sitosterol (hence the name), campesterol, stigmasterol, and their 5-alpha derivatives. The defect is caused by intestinal hyperabsorption and decreased biliary excretion of dietary sterols, especially plant and shellfish sterols [1,2]. Hyperabsorption and inefficient secretion of cholesterol also occurs; however, in 50% of cases, plasma levels appear normal due to downregulation of enzymes in the cholesterol biosynthetic pathway. Patients develop tendon and tuberous xanthomas, which are often associated with arthritis, hemolytic episodes, and they also have a strong propensity towards developing premature coronary atherosclerosis.

### Prevalence

Sitosterolemia is a rare autosomal recessive disease with only ~45 cases reported worldwide; some founder mutations are seen in Amish, Scandinavian and Japanese populations [3]. Most likely, sitosterolemia is significantly underdiagnosed and probably misdiagnosed as hyperlipidemia or hypercholesterolemia.

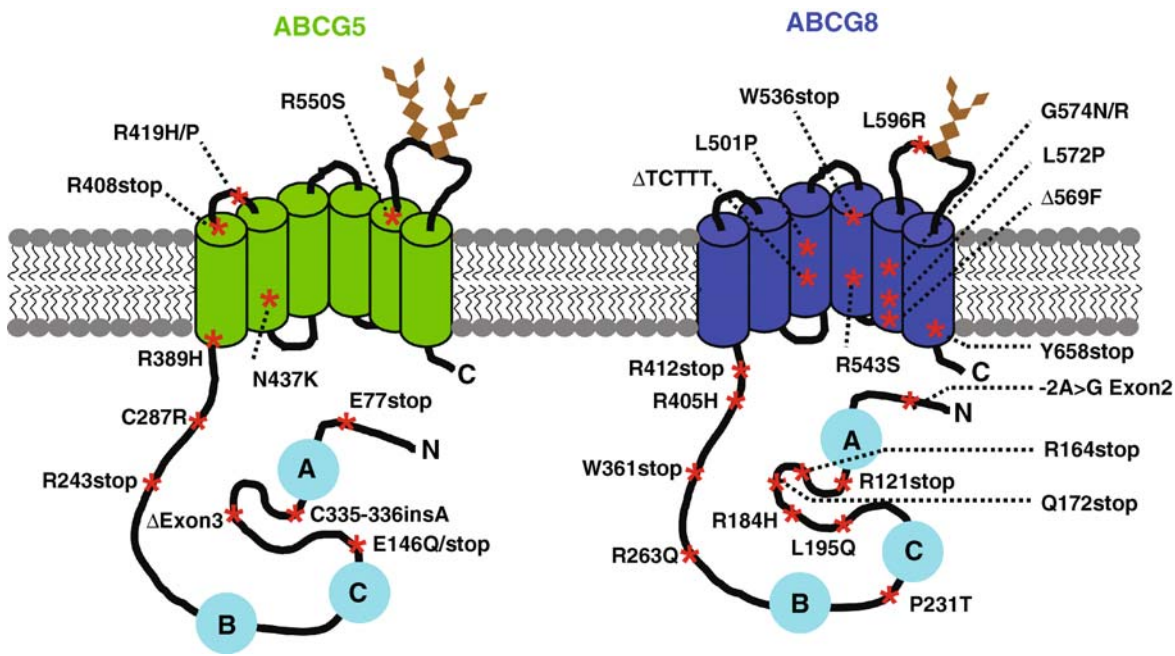
### Genes

The genetic defect in sitosterolemia was localized to chromosome 2p21 by two independent groups [2,3]. This locus (STSL) contains two adjacent homologous

genes, ABCG5 and ABCG8, which are organized in a head-to-head orientation spanning ~80 kb of the locus with a very small intergenic region (<160 bases), and likely share common regulatory elements. Each gene contains 13 exons encoding half-size ATP-binding cassette (ABC) transporter with molecular weights of ~75 kDa that are expressed in the plasma membrane of the intestines, liver and gallbladder [3]. Mutations in either of the two genes result in an identical phenotype indicating that they function as heterodimers (Fig. 1). Mutations in ABCG5, most commonly R389H, seem to occur in Asian probands, while mutations in ABCG8 are mainly present in Caucasian patients, with W361stop being the most prominent [3]. Considerably more polymorphisms have been identified in ABCG8 than in ABCG5, and interestingly, some polymorphisms, including D19H and T400K in ABCG8, have been associated with lower serum plant sterol levels in healthy individuals [2].

## Molecular and Systemic Pathophysiology

In normal individuals, about 50% of the dietary cholesterol is absorbed while plant sterols are poorly absorbed (<5%), and those that do reach the blood stream are rapidly excreted through the liver. Thus, only trace amounts of plant sterols are found in the blood (<0.5% of total plasma sterols). In sitosterolemia, plant sterols reach levels up to 20% of total plasma sterols, sometimes higher [4]. Plant sterols, in contrast to cholesterol, are not synthesized in the human body and are exclusively derived from the diet. Thus, identification of the genes defective in sitosterolemia, ABCG5 and ABCG8, has lead to major insights into plant sterol/cholesterol homeostasis. Initial uptake of sterols across the intestinal mucosa is facilitated by Nieman Pick C-Like1 protein (NPC-L1) and then, after esterification, sterols are packaged into chylomicrons for transport into the lymph [1]. ABCG5 and ABCG8 are sterol pumps co-expressed at the apical membrane of enterocytes where they function as heterodimers (ABCG5/G8) [5] as a first line defense against dietary sterol input and pump plant sterols and excess cholesterol back out into the intestinal lumen. In the liver, they are co-expressed at the apical surface of hepatocytes lining the bile duct where they regulate sterol homeostasis by pumping excess amounts into the bile. Mutations in ABCG5 and ABCG8 that cause sitosterolemia result in truncated proteins, protein trafficking defects, or inactive pumps [1]. Defective ABCG5/G8 causes hyperabsorption of



**Sitosterolemia. Figure 1** Putative topology of ABCG5 and ABCG8 with mutations known to cause sitosterolemia. ABCG5 and ABCG8 are half-size ABC transporter each containing six transmembrane α-helices (green and blue cylinders) and a cytoplasmic nucleotide binding domain (NBD). They function as heterodimer to pump sterols out of the plasma membrane powered by ATP hydrolysis in the NBDs. Mutations that cause sitosterolemia [3,4] are indicated by a red asterix (stop, premature termination; ins, insertion; Δ, deletion). The conserved Walker A, Walker B, and C motifs are shown in cyan circles, and N-glycosylation sites in brown diamonds. Based on Swiss-Prot entries Q9H222 and Q9H221.

sterols in the intestine and decreased excretion of sterols from the liver into the bile. This has been confirmed in transgenic mouse models where disruption of Abcg8 or Abcg5/g8 caused phenotypes similar to patients with sitosterolemia [1,5]. Sitosterol in particular is the most hyperabsorbed sterol in sitosterolemic patients and mouse models followed by stigmasterol, sitosterol, campesterol and cholesterol. As a result, these plant sterols are found in the plasma, lipoproteins, red blood cells, xanthoma, adipose tissue, and skin surface lipids. If untreated, patients develop coronary heart disease that is responsible for most morbidity and mortality.

### Diagnostic Principles

Diagnosis requires either capillary gas liquid, high pressure liquid chromatography (HPLC), or gas chromatography/mass spectrometry (GC/MS) to detect elevated plant sterols in the blood because many common assays for cholesterol levels do not differentiate between cholesterol and plant sterols [4]. Many cases of sitosterolemia may be misdiagnosed due to the need for this specialized assay. Clinically, symptoms of sitosterolemia may include xanthomas at any age, even in childhood, arthritis, particularly in the knee and ankle joints, and signs of coronary vascular disease. Hemolytic anemia (chronic or episodic) may be expected as plant sterols in the erythrocyte membrane may render them more rigid and prone to rupture. Platelet abnormalities or angina may occur.

### Therapeutic Principles

Dietary therapy strictly limiting the intake of plant and shellfish sterols (e.g. vegetable oils, olives, avocados) is the first line of treatment. If changes in diet alone are not sufficient, bile acid-binding resins that stimulate the conversion of cholesterol into bile acids, another pathway for removal of cholesterol from the body, and/or a new cholesterol absorption inhibitor, ezetimibe, that targets NPC-L1 are often administered [4].

## Sleep Apnea

Jan Rémi, Soheyl Noachtar
Section of Sleep, Department of Neurology, University of Munich, Munich, Germany

### Synonyms

Obstructive sleep apnea; Central sleep apnea

### Definition and Characteristics

Sleep apnea is defined as a cessation of breathing during sleep lasting at least 10 s with a decline in blood oxygen saturation. There are two forms: obstructive sleep apnea and central sleep apnea, and overlaps are possible (mixed sleep apnea). The former is characterized by a collapse of the upper or middle airway with a consecutive obstruction of the air passage. The latter is characterized by a loss of central sleep drive [1].

### Prevalence

8–25% of the adult population.

### Genes

Obstructive sleep apnea has a polygenic hereditary component, but its genetic base remains elusive. Indirectly, mutation of genes that affect metabolism may provoke or worsen an obstructive sleep apena syndrome through weight gain, like the leptin receptor gene [2].

In central sleep apnea, good andidates for revelant genes are those that encode central nervous chemoreceptors involved in the generation of the breathing drive. One example is a mutation in Phox2b which, next to other phenotypical features, is a possible cause of central hypoventilation syndrome in humans. The

physiological mechanism could be shown in Phox2b mutant mice, which do not respond to hypercapnia [3].

## Molecular and Systemic Pathophysiology

Obstructive sleep apnea is thought to result from a decrease of pharyngeal muscle tone during sleep, a loss that can be compensated during waking. The airway collapses and is only reopened after an arousal in sleep, which is most likely induced by the drop in blood oxygenation. These arousals cause a fragmented sleep, which is most likely the reason for excessive daytime somnolence. The pathophysiological concept of altered muscle tone would make obstructive sleep apnea a neurological disorder at core [4].

There is epidemiological evidence, that obstructive sleep apnea contributes to cardiovascular and cerebrovascular morbidity. Causes may be changes in endothelial and thrombocyte function and changes in blood pressure regulation [5].

In central sleep apnea, the central sleep drive is disturbed, which can be caused by many underlying disorders, making the etiology of central apnea very heterogenic. The most important chemical inducer of respiratory drive is hypercapnia, which can be lost in apneic intervals, when tidal volumes are high enough to keep the pCO2 at lower levels than those needed for a continuous respiratory drive. Furthermore, the modulation of excitatory and inhibitory factors for the respiratory oscillations is finely tuned, and minimal disturbances by small-scale neuronal loss or intoxications can disrupt the neuronal network.

## Diagnostic Principles

Excessive daytime sleepiness combined with a subjectively good sleep should be highly suspicious for sleep apnea. Also the history of any bed partner is helpful.

The diagnosis should be secured with a polysomnography, the decisive parameter being the AHI (apnea hypopnea index), also allowing to rate the apnea syndrome as mild (5–15 apneas/hypopneas per hour of sleep), moderate (15–30), or severe (>30) [1]. Polysomnography also allows the distinction of obstructive and central sleep apnea, the former still showing excursions of thorax and abdomen. Central sleep apnea warrants further neurological workup (CNS imaging).

## Therapeutic Principles

Depending on the form of sleep apnea, several therapeutic principles can be applied. Obstructive sleep apnea can be treated surgically in selected patients, if the obstructive part of the airway can be well defined. Rarely orthodontic devices can show a benefit, if the dental malocclusion is a major contributing factor. Simple treatment options include changes in sleep position (avoiding the supine position, rather sleeping on the side) and avoidance of medication and alcohol that may deteriorate obstructive sleep apnea by further relaxing the airways leading to a collapse. Nightly hyperbaric insufflation is a very effective treatment option, which shows a direct effect on the AHI. It can be delivered as CPAP (continuous positive airway pressure), BiPAP (biphasic PAP), or adaptive PAP, the latter changing pressure in predefined limits to adapt to changing pressure demands during the night. Another very effective treatment option is weight loss, but compliance is typically low [1].

Central sleep apnea is best treated medically: Acetazolamide and theophylline both increase respiratory drive by increasing carbon dioxide concentration and stimulating respiratory drive, respectively [1].

# Sleepwalking

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Somnambulism

## Definition and Characteristics

Sleepwalking, a common childhood parasomnia, is an arousal disorder that arises from stage three or four non-rapid eye movement (NREM) sleep [1]. The behavior actually takes place during a transition from deep sleep to waking, usually at the end of a sleep cycle. Typically,

it begins 1–3 h after the onset of sleep [1]. The patient suddenly awakens, sits up, rises out of bed and walks about in a slow, clumsy automatic manner. The patient may appear confused, detached, and unresponsive. Although consciousness is clouded, the eyes are mostly open, and obstacles are usually avoided. Hearing is not impaired, but efforts to communicate with the sleepwalker usually elicit mumbled and slurred speech and monosyllabic answers. Sometimes, the patient may be involved in more complex activities, such as dressing, taking toys apart and reassembling them, eating, or urinating. Doors and drawers may be opened, and furniture skirted. In the young child, the walking is often limited to the child's bedroom. The child may, however, wander about the house or even away from home. In adolescents and adults, fatal accidents, violent behavior, and even homicide have occurred during somnambulistic episodes [1]. Typically, the sleepwalker does not awaken from sleepwalking. The total duration of the episode usually ranges from 15 to 30 s when sitting in bed, to 5–30 min or more, when actual walking occurs. The child usually recalls nothing of the event the following morning. There is rarely more than one episode per night.

## Prevalence

The prevalence is estimated to be 2–14% in children and 1.6–2.4% in adults [2]. Sleepwalking is more common in males than in females [1].

## Genes

Specific DQB1 genes have been implicated in the genetic susceptibility of sleepwalking [3]. In one study, DQB1*501 was present in 35% of sleepwalkers, compared with 13% of controls [3].

## Molecular and Systemic Pathophysiology

Genetic factors play an important role in sleepwalking. Prevalence of sleepwalking in the first degree relatives of an affected individual is at least ten times greater than that in the general population [1]. The condition is six times more common in monozygotic than in dizygotic twins [1]. Sleepwalking typically begins in childhood and is usually outgrown by late adolescence, suggesting that a delay in maturation of the central nervous system may have a role to play in the pathogenesis of this disorder. Sleepwalking may be a cortical reaction to brain activation [4]. Psychological factors are not prominent in children with sleepwalking but are common in adults with this disorder. Sleepwalkers have a high incidence of other sleep arousal disorders such as night terror, sleeptalking, and nocturnal enuresis. Patients with Tourette syndrome or migraine headache have an increased incidence of sleepwalking. Fever, sleep deprivation, and alcohol may precipitate sleepwalking. Factors which may disturb the patient's sleep or half waken the patient may initiate a somnambulistic episode. Sleepwalking can be induced by standing the patient up 1–2 h after the patients fall asleep. Rarely, medication such as chlorpromazine, lithium, amitriptyline, beta blockers, and anticholinergics can precipitate sleepwalking.

## Diagnostic Principles

The diagnosis is clinical and no laboratory test is usually necessary. EEG during a somnambulistic episode often shows diffuse rhythmic delta with intermixed faster frequencies in the theta and alpha range, or prominent alpha and beta activity [4]. Polysomnographic studies may disclose an association with upper airway resistance syndrome, restless leg syndrome, and periodic limb movement syndrome [5].

## Therapeutic Principles

In children, sleepwalking is usually a benign, self-limited condition which usually disappears by adolescence. Sleepwalkers may, on occasion, injure themselves. Prophylactic measures such as locking windows and doors, putting gates across stairs, having the patient sleep on the ground floor if possible, and removing dangerous objects from the area are essential. Attempts to interrupt sleepwalking episodes should be avoided as such an intervention may confuse and frighten the patient even more. Consideration should also be given to factors that may disturb sleep or half awaken the patient: the discomfort of a distended bladder, pets jumping on the patient's bed, the noise of shouting in the neighborhood; any of these factors may initiate a sleepwalking episode. In the occasional case when the sleepwalking is frequent and severe, drugs such as benzodiazepines, particularly clonazepam may be tried on a short-term basis. Treatment of upper airway resistance syndrome, restless leg syndrome, and periodic limb syndromes may eliminate or significantly decrease sleepwalking episodes.

# Smith-Magenis Syndrome

Sarah H. Elsea, Santhosh Girirajan
Departments of Pediatrics and Human Genetics, Medical College of Virginia Campus, Virginia Commonwealth University, Richmond, VA, USA

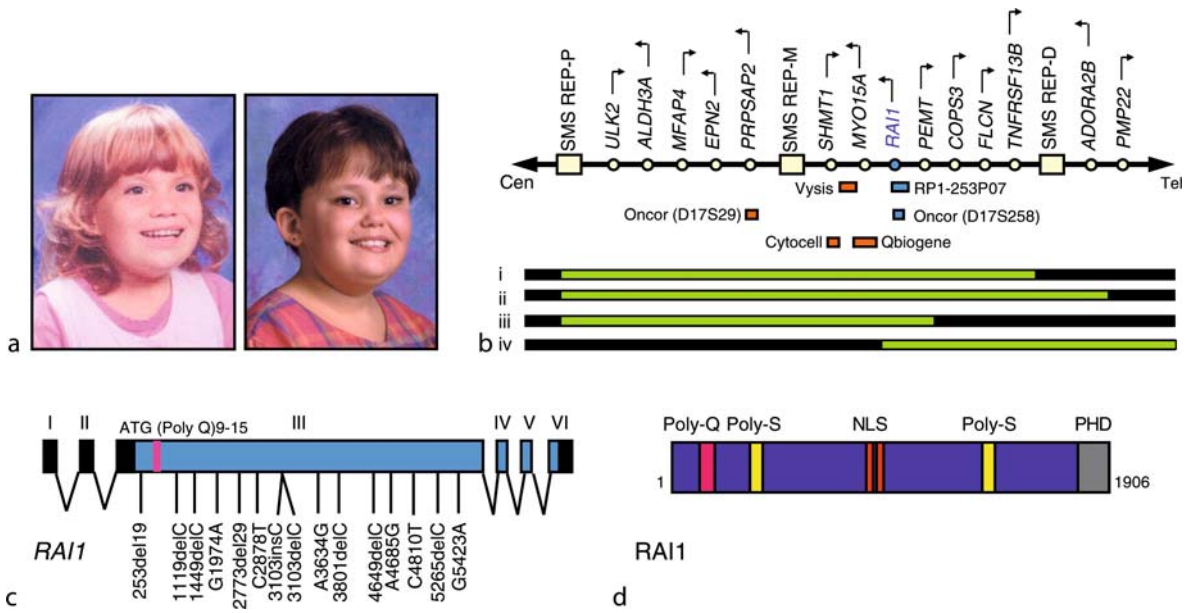
## Synonyms

SMS; del(17)p11.2; del(17)(p11.2p11.2); RAI1 mutation

## Definition and Characteristics

Smith-Magenis syndrome is a complex neurobehavioral disorder that includes mild to moderate mental retardation, sleep disturbance due to inverted circadian rhythm of melatonin, infantile hypotonia and feeding difficulties. Craniofacial and skeletal abnormalities are common, including brachycephaly, broad nasal bridge, flat midface, tented upper lip, synophrys, hypertelorism, abnormally shaped or low-set ears, and brachydactyly. Hearing loss (both conductive and sensorineural), speech delay (expressive language >> receptive language), motor delay, and hypercholesterolemia are also common. Eye findings include myopia, strabismus, microcornea, nystagmus, cataracts, retinal detachment, and iris anomalies. With age, prognathism, scoliosis, and a hoarse, deep voice become more apparent [1]. Other features include cardiac defects (ventricular septal defect, atrial septal defect, aortic stenosis, pulmonary stenosis, mitral valve prolapse, and tetralogy of fallot), renal abnormalities (enlarged kidneys, urinary tract infections, reflux), enlarged ventricles of the brain, cleft lip/palate, velopharyngeal insufficiency (VPI), hypothyroidism, decreased immunoglobulin levels, fifth-finger clinodactyly, two three toe syndactyly, and decreased sensitivity to pain (Fig. 1).

The neurobehavioral phenotype, including self-injury and sleep disturbance, defines the disorder. Self-injurious behaviors are common including head banging, polyembolokoilamania (insertion of objects into body orifices), onychotillomania (pulling out finger-nails and toenails), skin-picking, and self-hitting. Temper tantrums, explosive and aggressive actions, and obsessive and compulsive behaviors are common and typically worsen with sleep deficit.



**Smith-Magenis Syndrome. Figure 1** (a) Representative photos of SMS patients with a 17p11.2 deletion (*left*) and a mutation in *RAI1* (*right*) are shown. (b) *Top,* a map of the SMS region on 17p11.2 showing representative genes and the proximal, middle, and distal SMS repeats. FISH probes to diagnose the 17p11.2 deletion, containing *RAI1* (*blue*) or not containing *RAI1* (*orange*), are depicted. *Bottom*, to illustrate the variety of deletions identified in SMS cases, a representation of different sized SMS deletions is shown. The *black* bars indicate 17p11.2 regions that are not deleted, while the g*reen* regions denote the SMS-associated deletions: (i) common deletion, (ii) large deletion, (iii) small deletion, and (iv) atypical deletion. Note that all deletions contain the *RAI1* gene. (c) The genomic structure of the *RAI1* gene with coding (*blue*) and non-coding (*black*) exons is shown. All *RAI1* mutations identified are represented. (d) A schematic of the RAI1 protein containing polyglutamine repeats (*pink*), polyserine repeats (*yellow*), bipartite nuclear localization signal (*red*), and a C-terminal plant homeo-domain (PHD) (*gray*) is illustrated.

S

## Prevalence

Smith-Magenis syndrome is a sporadic disorder with minimum prevalence of 1:25,000 live births [1]. Cases of parental mosaicism, with or without phenotypic effect, range from ~1 to 5%.

## Genes

Smith-Magenis syndrome is typically considered a genomic disorder caused by heterozygous deletion or mutation of retinoic acid induced 1 (RAI1) gene [2,3]. Approximately 90% of cases are due to a chromosome 17p11.2 deletion, while ~10% are due to mutation of RAI1.

## Molecular and Systemic Pathophysiology

The chromosome 17p11.2 deletions result from both non-homologous mechanisms and non-allelic homologous recombination mediated either by SMS-repeat cluster or low-copy repeats during maternal or paternal gametogenesis (Fig. 1) [4]. Approximately 65% of SMS patients have a common 3.5 Mb deletion, while ~25% have larger, smaller or atypical 17p11.2 deletions [3]. About 10% of SMS patients have mutations in RAI1 (Fig. 1). RAI1 is a putative transcription factor that likely affects multiple developmental pathways, explaining the pleiotropic effects seen in this disorder. Haploinsufficiency leading to functional abrogation of RAI1 is responsible for the major diagnostic features of SMS including variable mental retardation, sleep disorder, behavioral and neurological abnormalities, and craniofacial and skeletal abnormalities [5]. Patients with 17p11.2 deletions are more likely to exhibit, in addition to the diagnostic features, short stature, infantile hypotonia, frequent ear infections, hearing loss, and renal and cardiovascular defects, which are likely due to reduced dosage of gene(s) in the 17p11.2 deletion region other than RAI1 [5].

## Diagnostic Principles

Suspected cases of SMS should first have high resolution chromosomes followed by FISH for 17p11.2 deletion. Alternative methods for identifying the 17p11.2 deletion include MLPA and CGH. All methods must include probes that represent the RAI1 gene (Fig. 1). Due to phenotypic overlap, other disorders should also be considered on a case-by-case basis, including Prader-Willi syndrome and 9q- syndrome. In cases negative for 17p11.2 deletion, RAI1 sequencing should be pursued.

## Therapeutic Principles

There is no cure for Smith-Magenis syndrome. All treatments are to alleviate symptoms on a per case basis. Recommended strategies include early diagnosis with subsequent early intervention to include hearing, eye, and speech evaluations and subsequent therapies, sign language in infancy prior to acquiring speech, occupational and physical therapy, and behavioral modification. Therapeutic management of sleep disorder is important for the patient and family. Behavioral modifications and/or pharmacological treatment using melatonin (2.5–5 mg) and acetbutolol (10 mg/kg) have been successful for some. Ongoing treatment, management, and monitoring of systemic abnormalities and psychosocial support for the family are recommended.

# Smokers' Lung

Chee-Keong Toh
Department of Medical Oncology, National Cancer Centre, Singapore, Singapore

## Synonyms

Chronic obstructive pulmonary disease; COPD; Chronic obstructive lung disease; COLD; Chronic bronchitis; Emphysema

## Definition and Characteristics

Smokers' lung refers to a group of disorders characterized by symptoms of dypsnea, cough, sputum production and airflow limitation which are a result of structural and functional changes in the lungs caused by cigarette smoke [1]. These disorders can occasionally be caused by inhaled gases and particles due to occupational exposure and air pollution. Chronic airflow limitation, a major underlying cause of morbidity and mortality in smokers' lung, is the most studied and often referred to as COPD. The airflow limitation in COPD is a result of

structural and inflammatory changes in the airways, lung parenchyma and pulmonary vasculature, and is often progressive and not fully reversible. Chronic bronchitis is a clinical description for the presence of cough and sputum production for at least 3 months in two consecutive years. Not all patients with chronic bronchitis will develop COPD and not all patients with COPD have preceding chronic bronchitis. Emphysema, on the other hand, is a pathological description of the destruction of lung alveoli that can contribute to COPD.

## Prevalence

The prevalence of COPD varies across countries and mirrors that of tobacco smoking. It is the fifth leading cause of death in the world. In addition, it is a major cause of morbidity and contributes to significant utilization of health care resources [2].

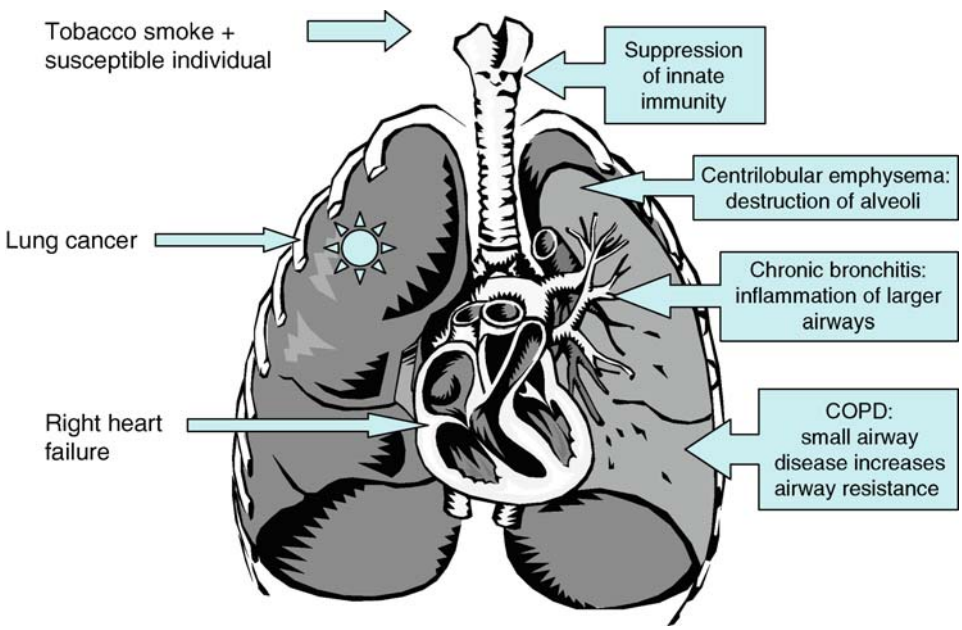
## Genes

The most important risk factor for developing COPD is tobacco smoke. Other contributing factors include air pollution, occupational dusts, severe childhood respiratory illness and genetic susceptibility [3]. Not all smokers develop COPD, with the susceptible group estimated at 15–20% of smokers. A known genetic factor is alpha-1-antitrypsin deficiency. Other possible genetic associations include polymorphisms in alpha-1-antichymotrypsin, tissue inhibitor of metalloproteinase-2, heme oxygenase-1, glutathione S-transferase M1 and P1, cytochrome P450, microsomal epoxide hydrolase, tumor necrosis factor (TNF)-α, interleukin (IL)-13 gene promoter and the vitamin D binding protein gene.

## Molecular and Systemic Pathophysiology

The pathology seen in smokers' lung is a combination of insult from inhaled toxic substances as well as the inflammatory response of the susceptible individual. Cigarette smoke suppresses the innate immunity in the lungs and allows invasion of microorganisms in the lower airways. In addition, epithelial insult by toxic particles induces an acute inflammatory response with recruitment of inflammatory cells, such as polymorphonuclear cells, eosinophils, macrophages. It activates the cellular and humoral arms of the adaptive immunity [4]. Orchestrating the immune responses are the cytokines that include TNF-α, IL-1β and transforming growth factor (TGF)-β. In the attempt to restore integrity of the epithelium and surrounding structures, there is deposition of connective tissue matrix which contributes to peribronchiolar fibrosis. All these inflammatory responses, cytokine effects and repair processes contribute to the pathogenesis of diseases seen in smokers' lung. The inflammatory response is amplified in susceptible smokers who develop emphysema, although the mechanisms are not yet fully understood. Fig. 1 summarizes the pathologies seen in smokers' lung.

In chronic bronchitis, pathology is seen in the larger airways where there is inflammation on mucosal surfaces of bronchi larger than 2 mm luminal diameter and



**Smokers' Lung. Figure 1** Pathophysiological changes seen in smokers' lung.

also around glands and gland ducts in bronchi larger than 4 mm diameter. In the smaller airways, structural abnormalities include thickening of the airway wall and its components, accumulation of mucus exudates in the lumen as well as increased numbers of inflammatory cells organized into follicles surrounding the airway. All these changes in the small airways increase the resistance of the lungs. In emphysema, there is pathological destruction of lung tissue beyond the terminal bronchiole which results in a decrease in capillary exchange area and a reduction in the elastic recoil force required to expel air out of the lungs. The centrilobular emphysema seen with tobacco smoke damage affects the upper lobes predominantly and targets the centrilobular region which is made up of a respiratory bronchiole, alveolar duct and adjacent alveolar structures. The exact cause of destruction in emphysema is not known but two hypotheses have been proposed: the protease/anti-protease imbalance and the oxidant/anti-oxidant theory.

### Diagnostic Principles

Smokers' lung should be considered in any patient with cough, sputum production or dypsnea and a history of tobacco smoking. Physical signs are usually not present in early COPD. The gold standard for diagnosis of COPD is spirometry, with a post-bronchodilator FEV1/FVC <0.7 confirming the presence of airflow limitation [1].

### Therapeutic Principles

1. Smoking cessation and reduction of other risk factors
2. Patient education
3. Pharmacological treatment. Although none of the medications have been shown to modify the long-term decline of lung function, it can help control symptoms, minimize exacerbations, and improve general health status. Mainstays are bronchodilators, anticholinergics, methylxanthines and glucocorticosteroids
4. Regular assessment and monitoring
5. Pulmonary rehabilitation
6. Others, such as influenza vaccination, long term oxygen therapy for chronic respiratory failure and surgery (bullectomy, lung volume reduction surgery or lung transplantation) for highly selected individuals

## SMS

►Smith-Magenis Syndrome
►Stiff Man Syndrome

## Sneddon's Syndrome

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Definition and Characteristics

A systemic syndrome characterized by livedo reticularis and ischemic cerebrovascular disease with multiple ischemic infarcts, often associated with antiphospholipid antibodies [1].

### Prevalence

It occurs sporadically, but a few familial cases of Sneddon's syndrome (SS) have been reported.

### Molecular and Systemic Pathophysiology

Sneddon's syndrome is not a vasculitis of small blood vessels, but is due to impairment of blood flow in the brain, the skin, and other organs. Histology of cutaneous vessels reveals detachment of endothelial cells of small and medium-sized arteries, infiltration of neutrophils and monocytes, and subendothelial proliferation of fibroblasts and myocytes. Similarly, in the brain small leptomeningeal venous vessels show intimal hyperplasia as well as micronecrosis of grey and white matter.

Fishnet reticular livedo pattern in the skin reflects irregular deoxygenation of blood at sites of impaired blood flow. Insufficient arterial blood flow results in ulcers of the skin and in infarcts of the brain with subsequent transitory ischemic attacks, epilepsy, or progressive reduction of cognitive functions. The cause of vasculopathy and multiple ischemic infarcts has been related to the presence of antiphospholipid antibodies (see corresponding chapter), but it occurs also in absence of antiphospholipid antibodies. The pathomechanisms of the latter are unknown, but should prompt search for parameters known to be associated with other coagulopathies. Inefficacy of immunotherapies argues against a primary inflammatory vascular process.

### Diagnostic Principles

Livedo reticularis and the clinical symptoms or signs of ischemic cerebrovascular disease (transitory ischemic attacks, stroke, epilepsy, progressive reduction of

cognitive functions) are the hallmark of Sneddon's syndrome. They can be supplemented by the symptoms of antiphospholipid syndrome, such as deep vein thrombosis and a history of miscarriages by women as well as presence of antiphospholipid antibodies. Mitral regurgitation and thrombocytopenia are more prevalent at presence of antiphospholipid antibodies [2].

In addition to skin biopsy, cranial magnetic resonance imaging needs to be performed to detect diffuse atrophy, multiple small white matter infarcts, and leptomeningeal enhancement.

Microemboli can be monitored by continuous transcranial Doppler ultrasonography.

### Therapeutic Principles

If Sneddon's syndrome is associated with antiphospholipid syndrome, then therapy should be conducted accordingly. If there are other causes for coagulopathy, then these should be treated. In any case, intensified antiplatelet therapy appeared to be as effective as high-dose warfarin in aPL-negative patients [2,3]. Immunosuppression with steroids and azathioprine is ineffective [4], and steroids may even worsen the disease as they are thrombogenic.

# Spastic Paraplegia, Hereditary

Rebecca Schüle, Ludger Schöls
Department for Neurodegenerative Diseases, Hertie-Institute for Clinical Brain Research and Centre for Neurology, Tuebingen, Germany

## Synonyms

Familial spastic paraplegia; FSP; Spinal spastic paraplegia; SSP; HSP

## Definition and Characteristics

Hereditary spastic paraplegias (HSP) comprise a group of neurodegenerative disorders characterized by lower limb spasticity and weakness due to degeneration of the corticospinal tract. HSPs can be classified (i) by clinical features (pure vs. complicated HSP), (ii) by mode of inheritance (autosomal dominant vs. autosomal recessive vs. x-linked), and (iii) by genetic locus (SPG1–41) [1].

In pure HSP, symptoms are mainly restricted to pyramidal motor system malfunction of the lower limbs. In complicated HSP, the degenerative process affects multiple parts of the nervous system and presents clinically with additional features like neuropathy, ataxia, cognitive impairment, seizures, optic atrophy, amyotrophy, or extrapyramidal involvement.

Age of onset is widely variable and ranges from early childhood until late adulthood. Progression rate varies between different HSP subtypes but also even within families. Apart from rare aggressive subtypes (i.e., SPG12), the course of HSP is slowly progressive with about one-third of patients ultimately depending on a wheelchair after several years or decades. Life expectancy is not limited due to pure forms of HSP.

## Prevalence

The prevalence of HSP has been estimated to range from about 1.2–9.6 per 100,000.

## Genes

HSP is genetically highly heterogeneous. Presently 37 loci, termed SPG1–41, have been described, among them 16 loci for autosomal dominant, 18 loci for autosomal recessive, and 3 loci for x-linked disease [2,3]. Sixteen HSP genes were cloned, eight of them causing autosomal dominant, six recessive, and two x-linked disease. By far, the most common form of HSP is SPG4 that accounts for ~50% of autosomal dominant HSP and is caused by mutations in the spastin gene. The most common autosomal recessive HSP seems to be SPG11; recently mutations in the spatacsin gene have been identified to cause SPGII (Table 1).

## Molecular and Systemic Pathophysiology

Cellular processes that appear to be primarily impaired in the majority of HSP subtypes include (i) axonal transport defects, (ii) mitochondrial dysfunction, and (iii) myelinization defects. Furthermore, impairment of axonal transport leading to axon degeneration seems to be the common pathway most HSPs ultimately follow [4,5].

Neuropathological analyses in HSP patients show distal degeneration of corticospinal tracts, fasciculus gracilis, and spinocerebellar tracts. These fiber tracts contain the longest axons of the nervous system. Because of their length and polarized architecture, these axons highly depend on an efficient transportation system that supplies the cellular periphery with proteins, RNAs, and membranous organelles and transports cellular waste as well as neurotrophic factors back toward the cell body. Long-range axonal transport is powered by molecular motor proteins – kinesins for anterograde transport and dyneins for retrograde transport – that move along microtubule tracks. The microtubule-severing protein spastin that influences microtubule stability is mutated in SPG4. In a Drosophila model, mutant spastin as well as knockdown of spastin lead to excessive stabilization and accumulation of microtubules. Microtubule-destabilizing drugs like vinblastin were able to ameliorate the mutant phenotype in this model system. In a transgene mouse model expressing truncated spastin, hyperstabilization of microtubules at the growth cone was shown to cause axonal transport defects.

Mutations in kinesin heavy chain KIF5A, the neuronal motor of fast anterograde axonal transport, cause SPG10. Drosophila kinesin heavy chain mutants develop focal axonal swellings, packed with fast axonal transport cargos and do not survive the third larval instar. Similarly, KIF5A null mutant mice are not viable. Conditional KIF5A knockout develop age-dependent sensory neuron degeneration and impairment of kinesin-dependent slow axonal transport with accumulation of neurofilaments.

SPG2 is caused by mutations in proteolipid protein (PLP1), the major component of CNS myelin. Mutations of PLP1 also cause Pelizaeus-Merzbacher disease that is characterized by severe hypomyelination of the CNS. Mice expressing SPG2-related mutant PLP1, however, assemble compact myelin sheaths; the pathological myelin leads by, as yet, unknown mechanisms to regional disturbances of axonal transport.

Mitochondrial dysfunction is the primary pathomechanism in at least two forms of HSP: SPG7 and SPG13. The SPG7 gene, paraplegin, encodes a mitochondrial AAA protein. Muscle biopsies from SPG7 patients show typical signs of mitochondrial

**Spastic Paraplegia, Hereditary. Table 1** HSP loci and genes

| Locus/gene | Chromosomal position | Protein function | Clinical description |
|---|---|---|---|
| *Autosomal dominant HSP* | | | |
| SPG3A/ SPG3A | 14q12 | *Atlastin*: Golgi-localized integral membrane protein GTPase, interacts with *spastin*. Loss of atlastin impairs axon elongation | Pure HSP |
| SPG4/ SPAST | 2p22.3 | *Spastin*: cytosolic AAA ATPase that severs microtubules; *spastin* mutants lead to hyperstabilization of microtubules and secondary axonal transport disturbances | Usually pure HSP, rarely complicated with dementia, cerebellar ataxia, thin corpus callosum |
| SPG6/NIPA1 | 15q11.2 | Function unknown; ubiquitously expressed, neuronally enriched. Predicted function: transmembrane protein, transporter, or receptor | Pure HSP |
| SPG8/ KIAA0196 | 8q23-q24 | *Strumpellin*: function unknown, contains conserved spectrin-domain | Pure HSP |
| SPG9/– | 10q23.3-q24.2 | – | Complicated HSP: bilateral cataracts, gastroesophageal reflux, motor neuronopathy |
| SPG10/ KIF5A | 12q13.13 | Neuronal kinesin heavy chain; molecular motor of anterograde axonal transport | Pure HSP |
| SPG12/– | 19q13 | – | Pure HSP |
| SPG13/ HSP60 | 2q33.1 | Human homologue to E. coli chaperone GroEL; implicated in mitochondrial protein import and correct folding of imported proteins | Pure HSP |
| SPG17/ BSCL2 | 11q13 | *Seipin*: unknown function; integral membrane protein of endoplasmatic reticulum, highest expression brain and testis | Complicated HSP: lower motor neuron involvement |
| | | N88S and S90L – mutation: abnormal *N*-glycosylation, impaired protein folding | *Silver syndrome*: amyotrophy of small hand muscles |
| | | | Allelic to Berardinelli-Seip congenital lipodystrophy type 2 and dSMA type V |
| SPG19/– | 9q33-q34 | – | Pure HSP |
| SPG29/– | 1p31.1-p21.1 | – | Complicated HSP: sensory hearing impairment, persistent vomiting |
| SPG31/ REEP1 | 2p11.2 | Promotes expression of G-protein coupled odorant-receptor proteins at the cell surface, localizes to mitochondria. Predicted: HVA22 domain, present in stress-induced genes like heat shock proteins | Pure HSP |
| SPG3/7– | 8p21.1-q13.3 | – | Pure HSP |
| SPG38/– | 4p16-p15 | – | Silver syndrome: amyotrophy of small hand muscles |
| SPG41/– | 11p14.1-p11.2 | – | Complicated HSP, peripheral nerve involvement |
| SAX/1– | 12p13 | – | Complicated HSP, cerebellar ataxia |
| *Autosomal recessive HSP* | | | |
| SPG5/ CYP7B1 | 8p12-q13 | Oxysterol-7α-hydroxylase involved in cholesterol degradation | Pure or complicated HSP-mild cerebellar signs HSP |

disease, including ragged-red fibers, succinate-dehydrogenase-stained areas, and cytochrome-oxidase-negative fibers. Paraplegin-deficient mice develop mitochondrial pathology long before disturbances of axonal transport are observed, suggesting that mitochondrial failure might secondarily impair transport processes via energy depletion. Intramuscular viral delivery of wild-type paraplegin delayed onset and progression of symptoms in paraplegin-deficient mice.

Albeit the remarkable genetic heterogeneity of HSP, impairment of axonal transport seems to be a common pathophysiological pathway into which many HSPs converge.

## Diagnostic Principles

Diagnosis of HSP is mostly by exclusion. In a patient presenting with progressive spastic paraplegia, structural spinal cord abnormalities, inflammatory diseases, metabolic disorders, and other hereditary movement disorders have to be considered. These patients, therefore, should receive MRI of the complete neuroaxis, spinal tab, measurement of vitamin B12 and folate levels, and, if signs of demyelination are present, screening for leucodystrophies.

Presently, gene testing is commercially available for only a subset of HSP genes, several other genes can be examined on a research basis. Because of its high frequency, SPG4 diagnostic is reasonable in autosomal dominant as well as in sporadic HSP. SPG31 and SPG3 are the second most common forms of dominant HSP and should be considered in cases with dominant family history, the latter especially in patients with an early onset. SPG11 should be tested in autosomal recessive or sporadic HSP with thin corpus callosom. SPG17 sequencing is suggestive if muscle wasting especially of small hand muscles is present.

## Therapeutic Principles

Presently no curative treatment is available for HSP. Physical therapy should start early in the course of the disease and be carried out on a regular basis to prevent secondary damage like contractures and maintain walking function as long as possible. Oral antispastic drugs like baclofen, tizadidn, tolperisone or memantine decrease muscle tone, and can improve lower limb function especially in cases where spasticity exceeds weakness. Baclofen can also be applied intrathecally. Intramuscular injections of botulinumtoxin are particularly useful in treatment of hip adductor spasticity and pes equinus. Urinary urgency can be reduced through anticholinergics like oxybutynin or tolterodin. Ankle–foot orthotic devices can sometimes reduce foot dragging in HSP.

►Schizotypal Personality Disorder

# Specific Granule Deficiency

Niels Borregaard, Jack B. Cowland
Department of Hematology, Rigshospitalet University of Copenhagen, Copenhagen, Denmark

## Synonyms

SGD

## Definition and Characteristics

Specific granule deficiency (SGD) is a rare autosomal disorder, that has been described in fewer than ten patients worldwide [1]. It is defined by lack of the granule proteins that normally fill the lumen of two of the three granule populations in neutrophils, specific granules and gelatinase granules. The more prominent of these are the antibacterial proteins lactoferrin, NGAL, hCAP18, arginase 1, pentraxin 3, gelatinase, collagenase and haptocorrin. In addition, two antibacterial proteins, α-defensins and BPI (bactericidal permeability increasing protein) normally located in the other major class of neutrophil granules, the azurophil granules, are also lacking in SGD. The proteins lacking in SGD are all critically dependent on the transcription factor C/EBP-ε for transcription, which occurs during the late promyelocytic stage and the myelocyte metamyelocyte stage when C/EBP-ε itself is induced and specific and gelatinase granules are formed [2,3] (Fig. 1).

Most proteins that normally localize to the membrane of specific and gelatinase granules are not dependent on C/EBP-ε, for example the $\beta_2$-integrin $\alpha_M\beta_2$, which is needed for firm adhesion and for phagocytosis of complement opsonized particles and the flavocytochrome b complex $p22^{phox}$/$gp91^{phox}$ that constitutes the NADPH oxidase. These are transcribed normally or near normally but localize to the plasma membrane or intracellular vesicles and not to granules [4].

The neutrophils thus contain only the peroxidase positive granules. The nucleus has the Pelger-Huet anomaly (bilobed "pince-nez form").

## Prevalence

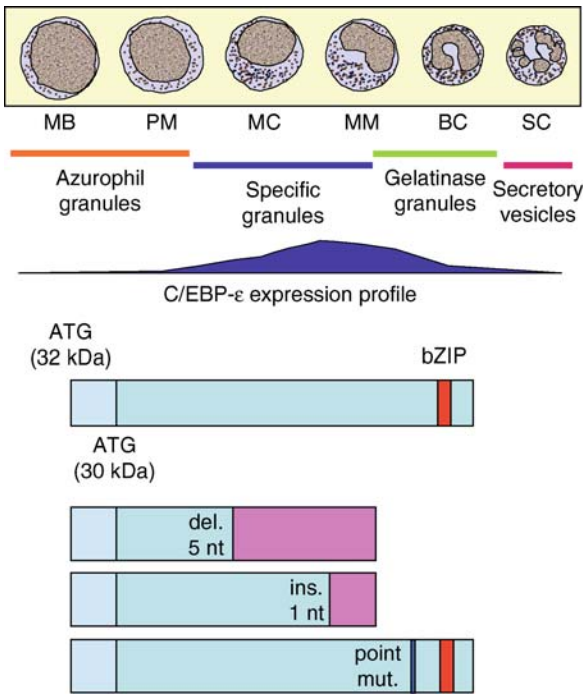
Very rare.

## Genes

The C/EBP-ε gene encodes three exons with the open reading frame contained in exon 2. Mutation of the C/EBP-ε gene has been described for three patients. Patient 1 has a five bp deletion in exon 2 causeing a frameshift mutation and premature termination. Patient 2 has a single A insertion in exon 2 causing a frameshift mutation and premature termination. Patient 3 has a point mutation resulting a valine to alanine mutation of amino acid 218. Targeted disruption of the C/EBP-ε gene in mice results in a SGD-like phenotype.

## Molecular and Systemic Pathophysiology

Specific granule deficiency is charactized by a propensity for bacterial infections primarily of the skin and respiratory tract. Staphylococcus aureus and Pseudomonas aeruginosa are the most commonly observed pathogens, although Candida albicans has also been isolated. This propensity for infections is largely explaind by a deficiency in chemotaxis and a reduced capacity for killing of microorganisms. While the latter is well explained by the lack of the antibactericidal proteins of granules, defensins, BPI, hCAP18, lactoferrin, and NGAL, the reduced chemotaxis is less well explained but may be due to reduced or mistargeted $\beta_2$ integrin. Some discrepancy exists regarding the capacity for generation of microbicidal oxygen species from the NADPH oxidase. Certainly,



**Specific Granule Deficiency. Figure 1** Expression of C/EBP-ε during granulopoiesis and the structure of the C/EBP-ε protein and mutants. *Top:* During granulopoiesis, C/EBP-ε is absent in the early stages of neutrophil differention (myeloblasts (*MB*) and promyelocytes (*PM*)) and emerges when the cells enter the myelocyte (*MC*) stage. Following exit from the metamyelocyte (*MM*) stage, expression of C/EBP-ε begins to be down-regulated and eventually disappears during the band cell (*BC*) stage. C/EBP-ε is not present in segmented neutrophils (*SC*) and peripheral blood neutrophils. The window of C/EBP-ε expression during granulopoiesis precisely coincides with the stage where specific granule proteins (*SGP*) and gelatinase granule proteins (*GGP*) are synthesized and their cognate granules are formed. A direct link between C/EBP-ε and SGP-gene expression has been demonstrated and C/EBP-ε is important for the coordinate activation of SGP gene transcription. *Bottom:* Two major forms of C/EBP-ε of 32 kD and 30 kD, respectively, are found in the bone marrow as a result of the use of two different translational initiation sites (ATG). The C-terminal part of the protein contains a DNA binding element, the transactivating region and a sequence (bZIP) required for dimerization. Genetic analysis has demonstrated a mutation in the C/EBP-ε gene of three SGD patients. In two of the patients, the mutation resulted in a frame shift mutation that resulted in a truncated protein with an erroneous C-terminal amino acid sequence. In the third case, a point mutation led to an inefficient interaction between C/EBP-ε and another transcription factor required for SGP and GGP gene expression.

the oxidase components are present but the flavocytochrome may be reduced in quantity, like the $\beta_2$-integrin. A possible reason for these deficiencies in membrane proteins may be that their window of biosynthesis is shortened during myelopoiesis.

## Diagnostic Principles

Morphological examination of a blood smear with demonstration of the nuclear anomaly and lack of specific granules is suggestive for the disease. For diagnosis, lack of lactoferrin, hCAP18 and NGAL and presense of normal amounts of myeloperoxidase in leukocytes isolated from peripheral blood must be established.

*Differential Diagnosis*: The condition must be distinguished from cases of myelodysplastic syndrome, which often have the Pelger-Huet nuclear anomaly and a deficiency of granules, but do not lack specific granule proteins totally. MDS is also characterized by anemia and thrombocytopenia and carries a high risk of developing to acute myeloid leukemia, all of which distinguishes MDS from specific granule deficiency.

## Therapeutic Principles

Bone marrow transplantation is curative, but the short and long term risks must be weighed against the clinical severity of the condition. Prophylactic antibiotic therapy with penicillin or Sulphotrim and aggressive antibiotic treatment of established infections may permit patients to enjoy near normal life, but the clinical spectrum of reported patients varies from rapidly fatal due to infections in infancy to nearly normal life.

## Definition and Characteristics

Most common hereditable disorder of red cell membrane resulting in hemolytic anemia, gallstones and splenomegaly [1].

## Prevalence

Estimated incidence in Northern Europe 1 per 2,000, 1 per 5,000 in the United States, more common in Caucasians than in people of African descent [1].

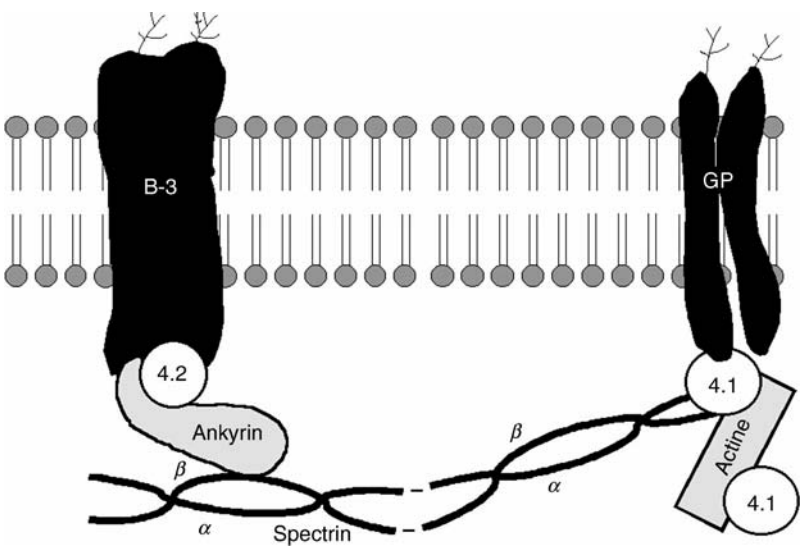
## Genes

Hereditary spherocytosis (HS) results from qualitative and/or quantitative protein defects in either ankyrin (8p11.2), band 3 (anion exchanger, 17q21–q22), α (1q21) and β (14q22–q23.2) spectrin heterodimers or band 4.2 (pallidin, 15q15) [1–3].

## Molecular and Systemic Pathophysiology

The red cell membrane consists of a lipid bilayer to which a cytoskeleton is anchored via direct vertical interactions with several proteins, resulting in membrane stability as well as the deformability required to traverse the microcirculation (Fig. 1).

Red cells in patients with HS have progressive loss of membrane microvesicles leading to a reduced membrane surface area without loss of volume. This leads to the spherocytic shape. Spherocytes have an increased mean cellular hemoglobin concentration (MCHC) and the mean corpuscular volume (MCV) is reduced. They are prematurely destroyed in the spleen, leading to clinical manifestations including hemolytic anemia with jaundice, splenomegaly and often bilirubin gallstones. Inheritance is mostly dominant (75%), with about 25% following a recessive inheritance pattern. Multiple gene loci are implicated and many different abnormalities, including deletions, frame shifts and nonsense gene mutations, have been described. The most frequent cause is ankyrin deficiency (50%). Ankyrin interacts with spectrin to form an important vertical interaction between the lipid bilayer and the cytoskeleton, and hence, ankyrin deficiency is associated a concomitant reduced spectrin incorporation on the red cell membrane. Less frequently, spectrin deficiency results from α or β spectrin gene mutations. β spectrin synthesis is rate limiting for spectrin assembly and thus a single mutation results in HS (dominant inheritance), whereas two α gene mutations are required for a HS phenotype (recessive inheritance). Band three defects mostly result in HS without a change in cytoskeletal structure as band 3 is mainly involved in maintaining intracellular homeostasis. However, as Pallidin is associated with Band 3, there is usually also



**Spherocytosis, Hereditary. Figure 1** Schematic representation of the red blood cell lipid bilayer with its cytoskeleton. Interactions of band 3 with ankyrin, ankyrin with spectrin, glycophorin C with band 4.1, and band 4.2 with band 3 are vertical interactions that anchore the cytoskeleton to the lipid bilayer. Horizontal interactions warrant lateral deformability of the cytoskeleton and these occur mainly between spectrin heterodimers and between spectrin heterodimers with actin.B-3: band 3, GP: glycoprotein-C.

a reduced Pallidin content. Pallidin mutations occur mainly in Japanese people [1–3].

### Diagnostic Principles

Due to the decreased surface/volume ratio, spherocytes are unable to withstand volume expansion in a hypotonic solution. Therefore, the cornerstone of diagnosis is the identification of increased susceptibility to osmotic stress of red cells in a patient clinically suspected of HS. Identification of specific genetic defects, as well as osmotic gradient ektacytometry remains limited to specialized laboratories [2,3].

### Therapeutic Principles

Management is largely supportive consisting of RBC transfusion for patients with profound anemia, folic acid supplementation, and cholecystectomy for symptomatic gallstones. Splenectomy is indicated in severe cases, which markedly reduces hemolysis (at the cost of an increased risk of sepsis with encapsulated bacteria) despite persistence of the red cell abnormality [3].

## Spilus Nevus

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital
The University of Calgary, Calgary, AB, Canada

### Synonyms

Nevus spilus; Speckled lentiginous nevus; Multiple agminate Spitz nevi; Nevus sur nevus

### Definition and Characteristics

Classically, spilus nevus presents as a light-brown circumscribed pigmentation that is stippled with dark-brown punctate macules or papules (Fig. 1).

Although spilus nevus can be congenital, most lesions develop in the first year of life, and some during childhood or adolescence [1]. The lesion often starts as an evenly pigmented light-brown macule with few or no speckles. The speckles appear or increase during childhood or even adulthood [1]). In the macular type of spilus nevus, the speckles are evenly distributed within the background macule [2]. In contrast, the papular type shows a more scattered and uneven distribution of the speckles within the background macule [2]. The dimension of the lesion is variable, ranging from 1 cm to more than 20 cm in diameter [3]. In most cases, the lesion is small [1]. Sites of predilection include the abdomen and back [3]. Spilus nevus usually

**Spilus Nevus. Figure 1** A giant spilus nevus on the right side of the abdomen and lateral right upper chest.

presents as an isolated finding. Sometimes, it may occur as part of phacomatosis spilorosea, phacomatosis pigmentokeratosis, or spilus nevus syndrome [2].

## Prevalence

Spilus nevus occurs in less than 0.2% of all newborns, 1.2% of white schoolchildren, and 2% of white adults [3,4]. Both sexes are affected equally.

## Genes

There is no evidence of a Mendelian mode of inheritance.

## Molecular and Systemic Pathophysiology

A spilus nevus may represent a localized defect in neural crest melanoblasts that is influenced by genetic and environmental factors. Histologic examination of a macule reveals an increase in melanin deposition in keratinocytes and an increase in the number of melanocytes along the basal cell layer of the epidermis. A papule, on the other hand, consists of melanocytic nests in the papillar and reticular dermis [2].

## Diagnostic Principles

Spilus nevus should be differentiated from segmental lentiginosis, Becker's nevus, and a café au lait spot. In segmental lentiginosis, the background pigmentation is absent. Becker's nevus consists of a sharply demarcated, irregular area of hyperpigmentation that does not have a speckled pattern; hypertrichosis commonly develops in the lesion. A café au lait spot presents as an ovoid, uniformly brown macule that is found in almost all children with neurofibromatosis. Occasionally, a café au lait spot in an individual with segmental neurofibromatosis may simulate a spilus nevus.

## Therapeutic Principles

Although nevi spili are generally benign, they must be followed closely so that any changes that are suspicious for malignancy can be detected; atypical melanocytic proliferations can lead to melanoma formation. This is especially true for dysplastic giant congenital nevi and those with an atypical appearance [5].

# Spina Bifida

Laura E. Mitchell[1], Analee J. Etheredge[1], Denise S. Hill[2], Richard H. Finnell[1]
[1]Institute of Biosciences and Technology, Texas A&M University System Health Science Center, Houston, TX, USA
[2]Interdisciplinary Faculty of Toxicology, Texas A&M University, College Station, TX, USA

## Synonyms

Spina bifida cystica; Open spina bifida; Meningomyelocele; Myelocele

## Definition and Characteristics

The term spina bifida (SB) is used to describe a range of conditions involving the spinal cord and/or vertebral arches. For the purpose of this review, the term spina bifida is restricted to include only those conditions that are thought to result from abnormalities of primary neurulation. SB is a congenital malformation characterized by an open lesion involving the spinal cord, vertebrae and skin. The primary developmental defect in SB is failure of neural tube closure. Defects of the overlying vertebrae and skin are secondary to the neural tube closure defect. These malformations are often described as being open because the neural tissue is either directly exposed to the body surface or covered by only a thin membrane. SB may occur in the cervical or thoracic regions, but is most commonly located in the lumbar-lumbosacral region. Morbidity and mortality are directly related to the location of the lesion. SB is commonly associated with bowel, bladder, motor and sensory dysfunction and anomalies of the central nervous system (e.g. Chiari II malformations and hydrocephalus).

## Prevalence

The prevalence of SB ranges from 0.5–1/1000 births and varies with geographic location, time period, race and ethnicity. The birth prevalence of SB is also influenced by the availability of prenatal diagnosis and elective pregnancy termination [1]. Maternal periconceptional folic acid supplementation has been shown to reduce the risk of having a child with SB by up to 70%, and mandatory folic acid fortification of the food supply has been associated with a 30–50% reduction in the prevalence of SB. Preliminary data also suggest that mandatory folic acid fortification may be associated with a modest decrease in the first-year mortality rates for SB, suggesting that fortification may be associated with a shift towards less severe defects [2].

## Molecular and Systemic Pathophysiology

SB is a defect of primary neurulation that results from failure of fusion in the caudal region of the neural tube

during gestational days 26–28. Failure of fusion in the cranial region of the neural tube results in a distinct but related condition called anencephaly. Work in animal models suggests that defects of primary neural tube closure can result from abnormalities in the shape of the neural plate, elevation and bending of the neural folds or cell shape/adhesion, which prevent the proper apposition and/or fusion of the neural folds.

The familial recurrence pattern for SB indicates that multiple genes and environmental factors, which may interact with each other, influence susceptibility. Confirmed environmental risk factors for SB include inadequate maternal intake of folic acid, pregestational diabetes and use of valproic acid and carbamazepine [1,3]. Additional maternal factors for which there is strong evidence of an association with spina bifida include vitamin B12 status, obesity and hyperthermia [1,3].

While the genes that contribute to SB susceptibility have not been elucidated, candidate genes fall into two groups, genes involved in embryonic development and genes involved in selected metabolic pathways.

*Embryonic Development*: During primary neurulation the neural plate elongates via convergent extension. Following elongation, the neural folds elevate through proliferation of the underlying mesenchyme and production of hyaluronic acid. Subsequent bending at the medial and paired lateral hinge points permits apposition of the apical edges. Shaping and folding of the hinge points requires apical constriction and basal expansion of the neural cells, which involves placement of microfilaments and microtubules and changes in mitotic rate. Upon apposition of the neural folds, cell processes extend from one fold to the other, glycoproteins are deposited to stabilize the tube, neurectoderm cells reorganize to form the roof of the neural tube, and the overlying epidermal cells form the ectodermal layer of the skin. Genes that are thought to play a role in these developmental processes include the dishevelled gene of the non-canonical Wnt signaling pathway, planar cell polarity genes, sonic hedgehog and other genes involved in neural tube pattern formation, and both HOX and PAX genes [1,4,5].

*Metabolic Pathways*: The association between maternal folic acid intake and SB provides a strong rationale for considering genes involved in folate-homocysteine metabolism and transport as candidate genes for SB. Other candidates include genes that influence the risk of maternal conditions associated with an increased risk of SB in offspring (e.g. diabetes), genes that are involved in the metabolism of potential teratogens (e.g. valproic acid) and genes that encode factors that are necessary for embryonic development (e.g. cholesterol). Genes in this group may exert their influence on the risk of SB via the maternal and/or the fetal genotype.

### Diagnostic Principles

Prenatal screening procedures for SB include evaluation of maternal serum alpha fetoprotein (AFP) levels and/or screening ultrasound (US). Diagnostic procedures include evaluation of amniotic fluid AFP and acetyl cholinesterase and/or diagnostic US.

### Therapeutic Principles

Surgical closure of the lesion generally takes place within 48 h after birth. Additional surgeries may be required to treat hydrocephalus and secondary complications (e.g. tethered cord). Intrauterine repair of SB has been suggested to improve outcome, and lower both the incidence of hindbrain herniation and hydrocephalus requiring shunting, relative to post-natal treatment [1]. However, in utero repair of SB is not widely available and in the US is currently only conducted as part of an ongoing clinical trial.

### Synonyms

Sqamous cell carcinoma; Spinalioma; SCC

### Definition and Characteristics

Malignant tumor of epidermal keratinocytes, which grows locally destructively and which does metastasize, albeit infrequently (5%). Predilection in sun-exposed areas (face).

### Prevalence

Fifteen percent in men, 7% in women. Squamous cell carcinoma (SCC) is the second most common type of skin cancer (after basal cell carcinoma): Incidence differs in various regions depending on the degree of sun exposure. The number of patients with SCC is increasing dramatically (in the Netherlands approximately by 80% until 2015) [1].

### Genes

Functional loss of p53 tumor suppressor gene, mutations of ras, and certain chromosomal aberrations (e.g., gain of 3q, 9q, and 11q, or loss of 3p and 9p).

### Molecular and Systemic Pathophysiology

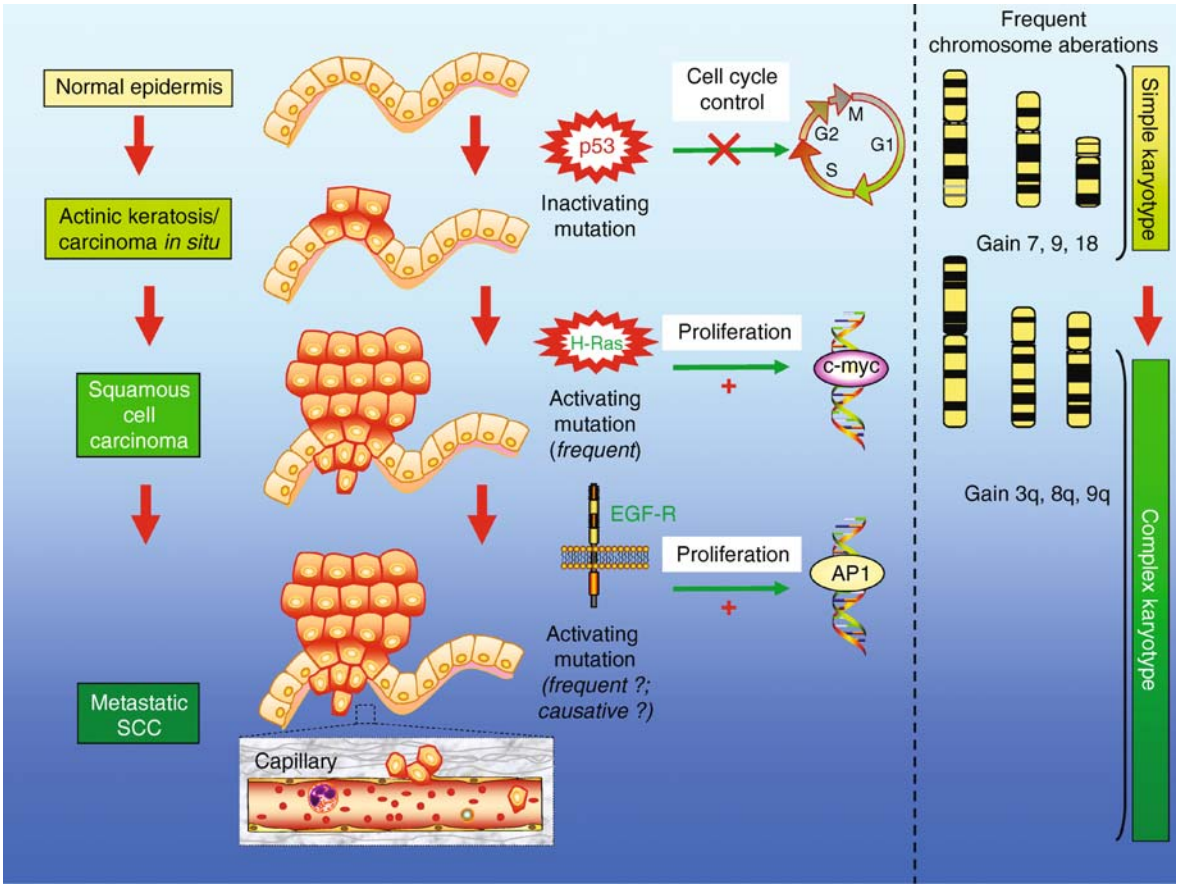
SCC of the skin probably develops through a multistep process (Fig. 1). SSC at least partially develops from precursor lesions and accumulates a highly complex geno- and karyotype en route to invasive SSC. It encompasses several chromosomal aberrations featuring gains, losses, and translocations, in particular, e.g., gain of 3q, 9q, and 11q, or loss of 3p and 9p. For development of full malignancy, certain combinations of these aberrations appear to be required, making genomic instability a prerequisite in SCC carcinogenesis.

The major carcinogenic agent in skin carcinogenesis is cumulative life-time exposure to ultraviolet (UV) radiation. Other risk factors include race, age, gender, and DNA repair capacity. Chronic UV radiation causes (i) mutations in cellular DNA and (ii) relative immunosuppression in the cutaneous immune system (e.g., dendritic cells), thus impairing immunological tumor rejection. The combination of immunosuppressive drugs with UV radiation (e.g., in patients after organ transplantation) increases the risk for SCC 65–250-fold. The UV-A spectrum may also be involved by generating oxidative stress, which may participate in the mentioned chromosomal changes, thus inducing genomic instability. UVB is absorbed in DNA with the formation of UV-specific dipyrimidine photoproducts, which, if insufficiently repaired and erroneously replicated, lead to characteristic mutations in dipyrimidine sequences (C→T and CC→TT transition mutations).

In SCC, these mutations are often found in the p53 tumor suppressor gene and may present the initial event in skin carcinogenesis. They are frequently found in actinic keratoses which, like Bowen's disease, are in situ carcinoma and present a preinvasive stage of SCC (5–10% will develop into invasive SCC). Upon stress, p53 alters expression of genes, leading to cell cycle arrest for repair of DNA damage. Mutations in the p53 gene prevent UVB-induced apoptosis and deletion of DNA-damaged cells, resulting in clonal expansion of mutated cells, which become targets to further mutations. Function of p53 can also be abolished by the so-called high-risk human papilloma virus types (HPV-16, 18, 31, 33, 35, and 58) whose E6 gene product induces rapid proteasomal degradation of p53. This is relevant in cervix carcinoma, but although the prevalence of HPV infection is high in immunocompetent patients (47%) and higher in immunosuppressed patients (75%), it does not include the high-risk HPV types [2]. So far, no definite statement can be made about the role of HPV in SSC.

Another gene likely to be mutated in SSC by UV radiation (10–20%) is the ras oncogene [3]. Its exact role in the carcinogenic cascade is not clear yet, but it appears to be important in SSC especially in Xeroderma pigmentosum (Fig. 1).

For complete tumorigenic conversion, functional loss of p53, mutations of ras, and certain chromosomal aberrations (e.g., gain of 3p and loss of 9p) are not yet



**Spinocellular Carcinoma. Figure 1** Multistep process of SCC development.

sufficient, but need to be complemented by additional chromosomal aberrations. Those can be provoked by an oxidative damage response (induced, e.g., by UV-A). Another factor adding to genomic instability is chromosomal gain of 8q with continued amplification of c-myc (located at 8q24 9), present in about 50% of SSC in transplant patients [4].

Contributing to the high number of aberrations in the complex karyotype and to genomic instability are telomere dysfunctions, and breaks of centromers and DNA double strands.

One of the consequences of the aberrations in SCC is increased expression of epidermal growth factor receptor or its ligand. They have been suggested to contribute to tumor growth and metastasis [5] (Fig. 1).

## Diagnostic Principles

The diagnosis is usually made clinically, but needs histological confirmation. Actinic keratosis as a precursor lesion presents as hyperkeratotic papule, plaque, or even horn. Early invasive SCC is usually a small but distinctly firm, skin colored and sometimes somewhat erythematous papule or nodule with a verrucous, sometimes with only smooth surface. Ulceration, usually around the center of the tumor may occur early or late.

## Therapeutic Principles

Standard procedure is surgical excision with histological control. If this is not possible due to anatomical location or the patient's general health, radiotherapy, if required in combination with chemotherapy, or immunotherapy presents an alternative. Almost 50% of patients with one nonmelanoma skin cancer develop another one within 5 years. An integrated program of skin cancer awareness, sun protection, and prophylactic approaches is critical.

Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Splenic enlargement; Hypersplenism

## Definition and Characteristics

In most cases of relevant splenomegaly, the tip of the spleen can be detected below the right costal margin by palpation or percussion. In adult splenomegaly, the weight of the spleen generally exceeds 250 mg and its length is above 11 cm in the craniocaudal extension.

Splenomegaly is classified as "moderate" if the largest dimension is 11–20 cm and "severe" if the largest dimension is greater than 20 cm.

Apart from numerous pathological affections, the spleen may also enlarge as it performs its normal functions. The most important functions include the synthesis of antibodies, removal of antibody-coated bacteria, clearance of defective red blood cells and extramedullary hematopoesis in certain diseases [1].

## Prevalence

Please refer to the corresponding underlying disease entity for further details.

## Genes

Please refer to the corresponding underlying disease entity for further details.

## Molecular and Systemic Pathophysiology

More than 50 underlying disease entities are accompanied by splenomegaly. These entities can be grouped (a–g) according to the basic pathophysiologic mechanism. Major underlying diseases are:

a) Hyperplasia caused by immune response
   - Infections of bacterial, viral, fungal or parasitic origin
   - Systemic lupus erythematosus (SLE)
   - Collagen vascular diseases
   - Felty's syndrome
   - Drug reactions
   - Interleukin 2 therapy
   - Sarcoidosis
   - Serum sickness
   - Immune hemolytic anemias
   - Immune thrombocytopenias
   - Immune neutropenias
   - Angioimmunoblastic lymphadenopathy
   - Benign lymphoid hypertrophy

b) Hyperplasia of the reticuloendothelial system for red blood cell removal
   - Hemoglobinopathies
   - Thalassemia major
   - Sickle cell anemia
   - Spherocytosis, elliptocytosis
   - Pyruvate kinase or glucose-6-phosphate dehydrogenase deficiency
   - Paroxysmal nocturnal hemoglobinuria
   - Nutritional anemias

c) Congestive enlargement
   – Portal hypertension
   – Cavernous transformation of the portal vein
   – Portal vein obstruction
   – Cirrhosis
   – Hepatic vein obstruction/thrombosis
   – Splenic vein obstruction/thrombosis
   – Splenic artery aneurysm
   – Congestive heart failure
d) Myeloproliferative enlargement (extramedullary hematopoesis)
   – Myelofibrosis
   – Marrow damage by radiation or toxins
   – Marrow infiltration by tumor or leukemia
e) Storage diseases
   – Hyperlipidemias
   – Amyloidosis
   – Gaucher's disease
   – Niemann-Pick disease
f) Benign and malignant tumors
   – Hodgkin's lymphoma
   – Non-Hodgkin's lymphoma
   – Leukemia
   – Myeloproliferative syndromes
   – Metastatic tumors
   – Angiosarcoma
   – Hamartoma
   – Histiocytosis X
   – Eosinophilic granuloma
   – Hemangioma
   – Fibroma
   – Lymphangioma
   – Splenic cyst
g) Miscellaneous
   – Berylliosis
   – Iron-deficiency anemia
   – Idiopathic splenomegaly

## Diagnostic Principles

In general, the presence of splenomegaly requires the identification of the underlying causative mechanism. In the majority of cases, the spleen is not the primary site of the underlying disease [2]. Many of the diseases causing splenomegaly are listed above and their diagnosis is beyond the scope of this chapter. In cases of diagnostic uncertainty, diagnostic puncture or diagnostic splenectomy may be indicated [3].

A massively enlarged spleen exceeds 20 cm in the craniocaudal diameter and its lower margin is located more than 8 cm below the left costal margin. The differential diagnosis in patients with massive splenomegaly is mostly restricted to an underlying hematological malignancy, including chronic lymphocytic leukemia, non-Hodgkin's lymphoma, hairy cell leukemia, chronic myelogenous leukemia, myelofibrosis or polycythemia vera.

Splenomegaly is diagnosed either by physical examination and/or imaging techniques, e.g. ultrasound, computerized tomography or magnetic resonance imaging [4].

Most laboratory abnormalities in splenomegaly are determined by the underlying systemic illness. The erythrocyte count may be decreased in thalassemia major, SLE or cirrhosis with portal hypertension, and it may be increased in polycythemia vera. Granulocyte counts may be decreased in congestive splenomegaly, leukemias or Felty's syndrome, and it may be increased in infections, inflammatory disease or myeloproliferative disorders. The platelet count is usually decreased in congestive splenomegaly, Gaucher's disease or immune thrombocytopenia, and it may be increased in myeloproliferative disorders. Cytopenias are mostly caused by increased destruction of cells secondary to reduced blood flow through congested cords or secondary to immune-mediated mechanisms.

## Therapeutic Principles

In the majority of cases splenomegaly is the consequence of an underlying disease. Thus, treatment of the underlying disease is of utmost importance.

Splenectomy: Indications that may require splenectomy include splenic trauma, splenic cysts, splenic tumors, vascular lesions, sickle cell anemia with splenic sequestration crisis. In order to reduce the risk of bacterial sepsis, an attempt should be made to conserve splenic tissue.

Splenectomy may also be indicated in severe cytopenia caused by hypersplenism.

Patients with functional or anatomical splenectomy are prone to fulminant bacterial infections, mainly caused by streptococcus pneumoniae, haemophilus influenzae and neisseria meningitidis. Vaccination against these bacteria should accompany splenectomy, preferably at least 10 days prior to surgery or in functional splenectomy (severe hypersplenism).

Antibiotic prophylaxis with Penicillin V is recommended for patients who cannot be vaccinated due to either severe immunosuppression or severe hemorrhagic diathesis.

# Spondylo-Epi-Metaphyseal Dysplasia

David Geneviève[1], Valérie Cormier-Daire[1,2]
[1]Département de Génétique, Hôpital Necker Enfants Malades, Paris, France
[2]INSERM, Paris, France

## Synonyms

SEMD; Spondyloepiphyseal dysplasia; SED; Spondyloepiphyseal dysplasia congenita; SEDC; Wolkott-Rallison; Dyggre-Melchior-Clausen; DMC

## Definition and Characteristics

Spondylo-epi-metaphyseal dysplasias (SEMD) are a heterogeneous group of disorders defined by the combination of vertebral, epiphyseal, and metaphyseal anomalies. The International classification recognizes at least 18 distinct entities within this group [1]. The majority of these entities are rare with less than 15 reported cases, and some of them have been described in unique family like SEMD Pakistani type or SEMD matrilin type. Table 1 summarizes the most frequent forms of SEMD with their mode of inheritance. The majority of them are still purely defined on clinical and radiological features. The presenting symptom of SEMD patients is usually disproportionate short stature. Several SEMD are also classified in the spondyloepiphyseal dysplasia (SED) group such as SEMD handigodu type, Schimke immuno-osseous dysplasia, the dyssegmental dysplasia Silverman-Handmaker type, or Wolcott-Rallison syndrome (WR), suggesting a variability in the presenting phenotype.

The most frequent forms of SEMD are represented by pseudoachondroplasia, SEMD Strudwick type, DMC syndrome, and Morquio syndrome type IV.

**Spondylo-Epi-Metaphyseal Dysplasia. Figure 1** Skeletal anomalies observed in pseudoachondroplasia. Note (a) small, fragmented and irregular epiphyses, (b) anterior tonguing of vertebral bodies and (c) metaphyseal widening.

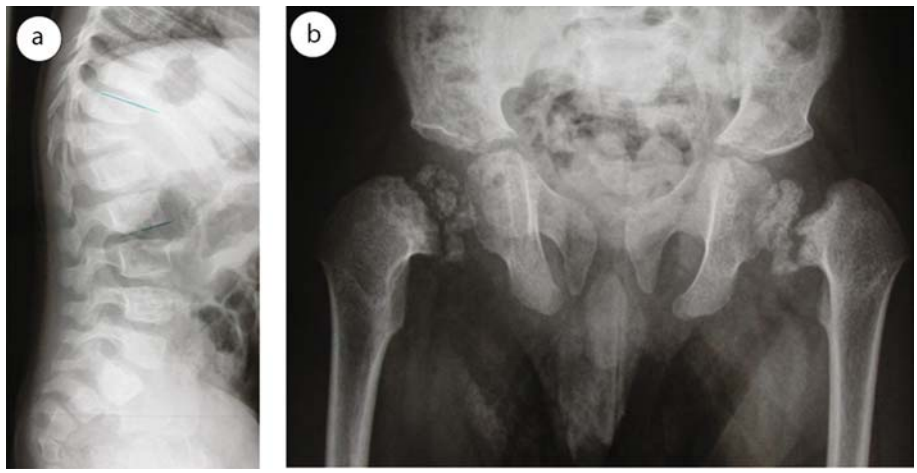
Pseudoachondroplasia is characterized by normal size at birth and normal growth curves until the second to four years of life. Patients present with marked shortness of hands and feet, bowing of long bones, and scoliosis. Skeletal X-rays reveal very small, fragmented, and irregular epiphyses, anterior tonguing of vertebral bodies and metaphyseal anomalies (Fig. 1).

Mutations in the cartilage oligomeric matrix protein gene (COMP), located at 19p13.1, are responsible for this condition. Mutations in this gene have also been identified in multiple epiphyseal dysplasia of Fairbanks type. COMP is a member of the thrombospondin gene family and is highly expressed in the extracellular matrix (ECM) of chondrocytes. Mutations observed in pseudoachondroplasia alter the type III, calmodulin-like repeats that possess a high affinity to bind collagen I, II and IX. This anomaly is responsible for the accumulation of the abnormal COMP within the rough endoplasmic reticulum. The presence of amorphous aggregates formed by mutant COMP lead to an abnormal organization of collagen fibers within the ECM with secondary retention of type IX collagen, aggregan and link proteins. This anomaly increased the cell death of growth plate chondrocytes by a dominant effect manner.

SEMD Strudwick type was identified initially as a variant form of SED congenital (SEDC). Both skeletal dysplasias are due to mutations in COL2A1 located at 12q13. Among the structural proteins, collagen type II is one of the most abundant protein. Mutations in COL2A1 have also been observed in a wide variety of mild to perinatal chondrodysplasia including Stickler syndrome, Kniest, SEDC, achondogenesis type II, and hypochondrogenesis. Myopia, deafness, and cleft palate are certainly helpful for the diagnosis of SEMD Strudwick type. Mutations identified in SEMD Strudwick type are glycine substitutions leading to incorporation of abnormal collagen chains into the ECM as observed in hypochondrogenesis and SEDC. Precise correlation between clinical severity and the relative amount of abnormal type II procollagen (which are retained intracellularly rather than secreted and incorporated in the ECM) remains speculative. At birth, patients present with short limbs and short trunk. Myopia leading to retinal detachment may be observed in the course of the disease. Skeletal X-rays are characterized by generalized platyspondyly with mild posterior constriction and rounded anterior borders of vertebral bodies. Flocculated dappled metaphyses, which define Strudwick type as a distinct entity, are present only in the course of the disease (Fig. 2).

DMC syndrome is a progressive autosomal recessive SEMD associated with mental retardation. Clinical manifestations are short trunk dwarfism with a barrel-shaped chest, rhizomelic limb shortening, microcephaly, a coarse face, and variable mental retardation (MR). Radiological features include misaligned spine, markedly flattened vertebral bodies with a double-humped appearance, metaphyseal irregularities, laterally displaced capital femoral epiphyses, and small pelvis with thickened and lacy iliac crests (Fig. 3).

DMC is a progressive disorder and the first manifestations are usually recognized between 1 and 18 months of age. The double-humped appearance of the vertebral bodies and the very specific aspect of iliac



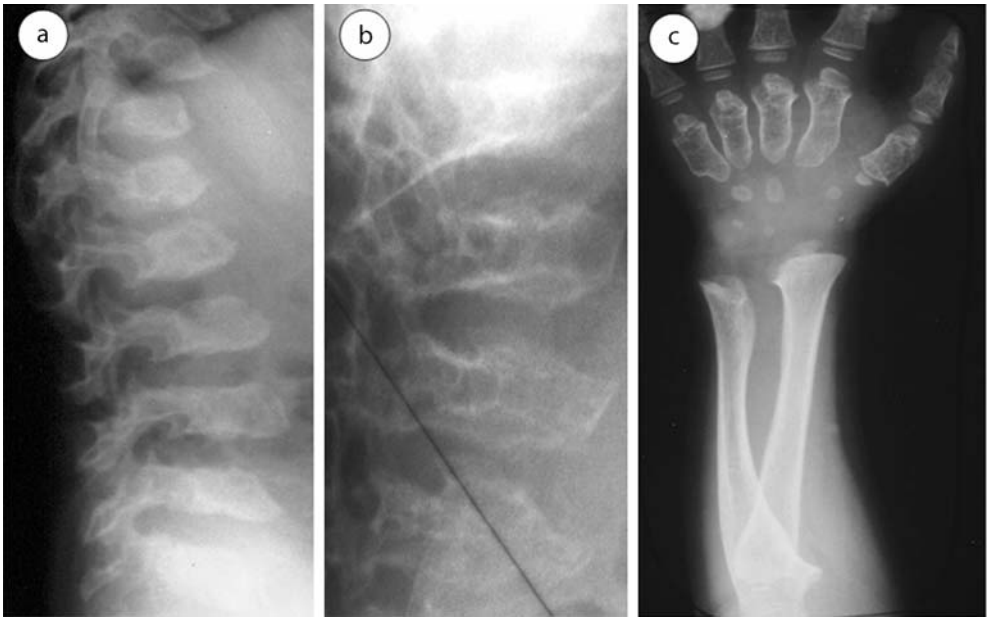
**Spondylo-Epi-Metaphyseal Dysplasia. Figure 2** Skeletal anomalies observed in SEMD Strudwick type. Note (a) generalized platyspondyly with mild posterior constriction and rounded anterior borders of vertebral bodies. Note also (b) flocculated dappled metaphyses.

**Spondylo-Epi-Metaphyseal Dysplasia. Figure 3** Skeletal anomalies observed in Dyggve-Melchior-Clausen syndrome. Note (a) double vertebral humps and (b) lacy pelvis iliac crest in a 4-year old patient.

crests become evident by 3–4 years of age. Orthopedic complications include the following: possible spinal cord compression due to atlantoaxial instability, lumbar lordosis, scoliosis, thoracic kyphosis, subluxation of the hips, deformations of the knees, and restricted joint mobility. MR is also a progressive feature and is quite variable in severity.

DMC is allelic to Smith-McCort dysplasia, which is distinct by the absence of MR. Mutations in the dymeclin gene (DYM) located at 18q21 and encoding a protein of unknown function have been identified in both disorders.

Finally, the mucopolysaccharidosis IV (MPS IV) also named Morquio syndrome is a lysosomal storage disease characterized by severe kyphoscoliosis, pectus carinatum, corneal opacifications, mild sensorineural deafness, mildly coarse facial features, and sometimes valvular heart disease. In the classical form, bone



**Spondylo-Epi-Metaphyseal Dysplasia. Figure 4** Skeletal anomalies observed in Morquio syndrome. Note (a) central beak protruding from the vertebral bodies, and (b) magnified view (c) small and irregular carpal bones and pointed distal end of the middle and distal phalanges.

X-rays showed spondyloepimetaphyseal dysplasia with central beak protruding from the vertebral bodies, small and irregular carpal bones and pointed distal end of the middle and distal phalanges (Fig. 4).

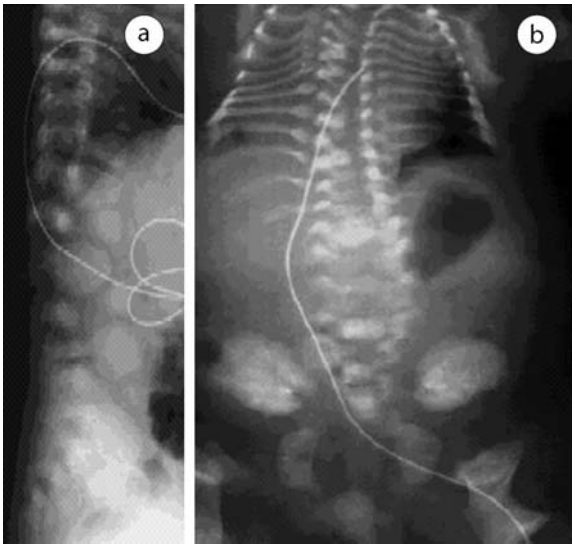
The main complication is spinal cord compression by atlantoaxial dislocation, due to hypoplasia of the odontoid. Two genes are responsible for this condition: galactosamine-6-sulfatase gene (GALNS), located at 16q24.3, responsible for Morquio type A and beta-galactosidase gene (GLBI) located at 3p21.33, responsible for Morquio type B.

## Prevalence

SEMD are rare conditions and the frequency of each entity is lower than 1/100,000 affected patients.

## Genes

Several genes involved in SEMD have been identified these last years (Table 1), namely collagen type II chain alpha-1 (COL2A1 – SEMD Strudwick type), COMP (pseudoachondroplasia), 3-prime-phosphoadenosine 5-prime-phosphosulfate synthase 2 (PAPSS2 – SEMD Pakistani type), carbohydrate sulfotransferase 3 (CHST3 – SEMD Omani type), matrix metalloproteinase 13 (MMP13 – SEMD Missouri type), DYM (DMC syndrome), matrilin 3 (MATN3 – SEMD Matrilin type), swi/snf-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a-like protein 1 (SMARCAL1 – Schimke immuno-osseous dysplasia), mitochondrial RNA-processing endoribonuclease (RMRP – SEMD anauxetic type or Menger type), eukaryotic translation initiation factor 2-alpha kinase 3 (EIF2AK3 – WR syndrome), and GALNS and GLBI (Morquio syndrome type A and B, respectively).



**Spondylo-Epi-Metaphyseal Dysplasia.**
**Figure 5** Skeletal anomalies observed in dyssegmental dysplasia, Rolland-Desbuquois type. Note vertebral segmentation defects with irregular ossification centers ((a) lateral view, (b) front view).

DEO, delayed epiphyseal ossification.

## Molecular and Systemic Pathophysiology

It is difficult to define among all the SEMD a common molecular pathway. Regarding the molecular-pathogenic classification of the genetic disorders of the skeleton proposed by Superti-Furga et al. [2], SEMD belongs within groups 1, 2, 3, 5 and 7 corresponding to defects in extracellular structural proteins (COL2A1, COMP, and MATN3), defect in metabolic pathways (PAPSS2, CHST3), defects in foldings and degradation of macromolecules (GALNS and GLBI), defects in nuclear proteins and transcription factors (EIF2AK3 and SMARCAL1), and defects in RNA and DNA processing and metabolism (RMRP), respectively.

## Diagnostic Principles

Many isolated SEMD cases have been reported and a precise diagnosis is often difficult. Skeletal manifestations can be characteristic, i.e., vertebral segmentation defects with irregular ossification centers or anisospondyly in dyssegmental dysplasia (Rolland-Desbuquois type, Fig. 5), major delay in epiphyseal ossification in opsismodysplasia or lacy pelvis iliac crest and double vertebral humps in DMC.

Extraskeletal features, which may appear in the course of the disease, highlighting the importance of the follow up of SEMD patients, are often a clue for the final diagnosis, i.e., joint laxity in SEMD with joint laxity (SEMD-JL), diabetes in WR, immunodeficiency and renal insufficiency in Schimke dysplasia, myopia and deafness in COL2A1 group, or mental retardation in DMC. Table 2 summarizes the discriminating clinical and skeletal features of the SEMD.

## Therapeutic Principles

No specific treatment is available for the SEMD. Orthopedic management is often required with a particular attention to odontoid hypoplasia as well as atlantoaxial instability. Depending on the specific diagnosis, the management will include ophthalmological, immunological, renal, cardiac, and endocrine follow-up.

## Synonyms

SEDL; SEDT [MIM 313400]

## Definition and Characteristics

X-linked recessive osteochondrodysplasia affecting epiphyses (especially at the hips) and vertebral morphology.

## Prevalence

The prevalence of SEDL has been estimated to be at least 1.7/1,000,000 [1].

## Genes

The SEDL gene is localized on chromosome Xp22.2. There are at least seven SEDL pseudogenes in the human genome, among them one, SEDLP1 (retropseudogene), on chromosome 19q13.4 is transcribed and has potential to encode a 100% identical protein to that of the SEDL gene. The remaining pseudogenes, one on chromosome 8q13.3 (retropseudogene) and at least six on chromosome Yq11.23 (duplicated copies), are not transcribed and thus highly likely non-functional [2].

## Molecular and Systemic Pathophysiology

The function of the SEDL protein (or sedlin) is not deciphered yet. Preliminary data show that sedlin, as a member of a highly conserved multiprotein complex TRAPP – Transport Protein Particle, likely participates in vesicular transport and docking along the ER-Golgi membrane compartments ([3] and references therein). In yeast, saccharomyces cerevisiae, the function of TRS20 (yeast ortholog of sedlin) is essential. Yeast TRS20 knockout (KO) mutants, which are not viable, can be rescued using human recombinant sedlin thus further confirming the high conservation of sedlin function [3]. Interestingly, while some naturally occurring human SEDL gene mutants are unable to rescue yeast TRS20 KO phenotype, others are. This suggests that in human, and vertebrate cells in general, sedlin may have acquired novel function(s). It is also clear that the function of sedlin is redundant in human cells as SEDL patients with large SEDL gene deletions (and thus complete absence of the SEDL mRNA and protein) survive and have only tissue specific (epiphyses of hips and vertebrae) phenotype. There is little clinical phenotype variability among SEDL patients with various truncating, splice or missense SEDL gene mutations. It has been proposed that all SEDL gene mutations behave highly likely as loss of function mutations. This hypothesis is also supported by the single domain crystal structure of sedlin [4]. To date there have been 35 different SEDL gene mutations identified in 46 SEDL families and isolated cases. The most common mutations identified have been deletions (14/46) and splice site mutations (12/46), with these accounting for over 50% of the types of mutations identified (total 19/35). The splice site mutation IVS3 + 5G>A is the most prevalent (5/46) SEDL mutation to date ([5] and references therein).

## Diagnostic Principles

Diagnosis is clinically suggested by the presence of disproportionate (short-trunk) short stature in a male (typically aged 8–15 years), and confirmed by the characteristic vertebral morphology on a lateral radiograph of the thoraco-lumbar spine; comprising generalized platyspondyly, narrowing of intervertebral disc spaces, and pathognomonic superior and inferior "humps" involving the posterior two-thirds of the flattened vertebral bodies. Full radiographic survey of the skeletal features may also reveal small and irregular epiphyses in childhood and evidence of osteoarthritic change in later life. The most important diagnostic "tools" are a three-generation family history (suggestive of X-linked inheritance) and radiographic skeletal survey. Diagnosis can now also be verified by the finding of a mutation in the SEDL gene.

## Therapeutic Principles

There is no currently available therapy for SEDL apart from symptomatic management of complications and prevention of premature joint disease by diet and exercise. Hip dysplasia may necessitate replacement surgery. No data exists on growth hormone therapy to increase final height. Genetic counseling and psychosocial support of the family is important.

# Staphylococcal Food Poisoning

Yves Le Loir, Michel Gautier
Laboratoire de Microbiologie, UMR STLO, INRA, Rennes, France

### Synonyms

Staphyloenterotoxemia; Staphyloenterotoxicosis

### Definition and Characteristics

Staphylococcus aureus is a Gram-positive bacterium considered as a potent opportunistic pathogen. Some S. aureus strains are able to produce staphylococcal enterotoxins (SEs) and are the causative agents of staphylococcal food poisonings (SFP). The symptoms of SFP are abdominal cramps, nausea, vomiting, sometimes followed by diarrhea (never diarrhea alone). The onset of symptoms is rapid (from 30 min to 8 h), and usually a spontaneous remission is observed after 24 h [1].

### Prevalence

S. aureus is a major cause of food borne disease (FBD) because it may contaminate manipulated foodstuff during the process [1]. S. aureus is indeed found in nostrils, on skin and hair of humans and warm-blooded animals. S. aureus is able to grow in a wide range of temperatures (7–48.5°C), pH (4.2–9.3), sodium chloride concentrations (up to 15% NaCl) [2]. These characteristics enable S. aureus to grow in a wide variety of foods. Thus, SFP incidence is rather high in foodstuffs that require manipulations during process. In many countries, low contaminations by S. aureus are tolerated in most of the foodstuffs, as they are not considered as a risk for public health.

### Genes

The genes encoding SEs are carried by mobile genetic elements including a family of temperate phages (for sea), a 750-kb plasmid (for seb), a pathogenicity island ($sec_{bovine}$), or a defective phage (see). The main regulatory system controlling the gene expression of virulence factors in S. aureus is the accessory gene regulator (agr; 3). Some SE genes (e.g., seb, sec, and sed) have been demonstrated to be agr-dependent whereas others (e.g., sea and sej) are agr-independent. As agr expression is tightly linked to the quorum sensing [3], the production of the agr-controlled SEs in foodstuffs is dependant on the S. aureus ability to grow up to a high cell density (estimated as $10^6$ cfu/g) in the foodstuffs. Environmental factors also play an important role in SE gene expression [1,2].

## Molecular and Systemic Pathophysiology

To date, 17 different SE types have been identified. They belong to a family of so-called superantigens that share structure and sequence similarities [4]. The SEs are short proteins secreted in the medium. Most of them possess a cystine loop required for proper conformation and probably involved in the emetic activity. They are highly heat stable, resist most proteolytic enzymes, and thus keep their activity after pasteurization, and or ingestion, in the digestive tract. SEs were discovered when studying S. aureus strains implicated in FBD outbreaks, and they were classified in distinct serological types. Thus, SEA to E and SEH have been clearly demonstrated as being able of more or less potent emetic activity. Recently, data resulting from genome sequence analysis allowed the identification of several new SE types, first identified based on similarities with existing SEs. When performed, experiments demonstrated their superantigenic but rarely their emetic activity.

Among superantigens, only SEs have an emetic activity. Superantigen and emetic activity of the SEs are two separate functions localized on separate domains. The emetic activity is not precisely localized. One common feature of the SEs is a cystine loop, thought to be important for emetic activity. However, SEI lacks the cystine loop structure and is both superantigenic and emetic. SEI emetic activity is nevertheless significantly lower compared with other SEs. Sequence analysis of the recently identified SEK and SEL reveals the absence of the cystine loop. These SEs were not tested for their emetic activity.

Emetic activity is uniquely characterized by the SEs ability to cause emetic responses when administered orally to monkeys whereas other superantigens are not emetic. Little is known about how SEs cause symptoms of food poisoning. SEs may have a direct action on intestinal epithelium and an action on the vagus nerve causing stimulation of the emetic center and stimulation of gut transit. The infective dose required to induce SFP in humans is estimated around 0.1 μg, and it may vary with patient sensitiveness.

## Diagnostic Principles

Interviews with the patients and collecting epidemiologic data are essential in the diagnosis of SFP. SFP symptoms may be similar to those of other types of food poisoning (e.g., poisoning caused by Bacillus cereus toxin), thus leading to a misdiagnosis of the illness. Incriminated foods should be examined for enterotoxigenic staphylococci. The most conclusive test is the detection of the SE in the food sample(s). If the food has been heat-treated (pasteurization), serological methods for the detection of the SEs in foods can be used successfully for the diagnosis.

## Therapeutic Principles

Usually a spontaneous remission is observed after 24 h.

# Staphylococcal Scalded Skin Syndrome

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Morbus Ritter von Rittershain (1878) (obsolete); Staphylogene Lyell syndrome (misnomer, not to be used anymore); SSSS

## Definition and Characteristics

Widespread superficial blistering of the skin caused by release of exfoliative toxins A or B from Staph aureus into systemic circulation; these toxin-producing Staph aureus can be found as colonizing or infecting agents on several parts of the body such as the skin, the nose, or the pharynx.

## Prevalence

Not common anymore under good standards of hygiene. More frequent in newborns or infants, but also occurring in adults in cases of predisposing conditions such as renal insufficiency, alcohol abuse, immunosuppression, malignancy, or under bad socioeconomic conditions.

## Molecular and Systemic Pathophysiology

There needs to be (i) focal colonization or infection with staph aureus (often phage group II), (ii) expression of exfoliative toxin A or exfoliative toxin B (ETA or ETB) by these staph aureus (the eta gene is acquired by horizontal gene transfer and located on chromosome, etb is located on a plasmid [1], and (iii) release of sufficient amounts of these toxins into the circulation.

This systemic release distinguishes SSSS from bullous impetigo where toxins are only released locally.

ETA or ETB both specifically cleave desmoglein 1, a desmosomal adhesion molecule, whose inactivation results in loss of adhesion between keratinocytes below the stratum corneum and in formation of subcorneal blisters. They act as serine proteases with highly focused molecular specificity. They cleave desmoglein 1 once after glutamic acid residue 381 between extracellular domains 3 and 4. This pathogenetic mechanism has marked resemblance to pemphigus foliaceus. In this autoimmune blistering disease, autoantibodies are directed against desmoglein 1.

Although desmoglein 1 is found throughout the epidermis and in mucous membranes, the blister occurs only in the superficial epidermis. The reason is that in areas of epithelium where both desmoglein 3 and desmoglein 1 are expressed, the former can compensate for desmoglein 1. This is the case in mucous membranes where both desmogleins are found throughout the epithelia. However, if like in skin only Dsg1 is present throughout and desmoglein 3 only in the deep epidermis, a superficial blister will form because there desmoglein 1 is not compensated for by desmoglein 3 [2].

Children usually recover from the disease while adults reveal a higher mortality rate due to the increased presence of predisposing conditions. Antibodies against the exfoliative toxins are supposed to have protective effects.

### Diagnostic Principles

Staphylococcal scalded skin syndrome (SSSS) starts with a widespread erythematous eruption progressing rapidly within 48 h into flaccid bullae and scaling of skin. The flexures are usually always affected, followed by large areas of the skin, but not the mucous membranes. The skin and superficial erosions are tender and sometimes very painful.

Healing occurs after 1–2 weeks. Sparing of mucous membranes, superficial location of blisters, and the relatively good general condition of the patient are decisive clinical criteria to distinguish this syndrome from toxic epidermal necrosis. In addition, histological analysis of the margin of a lesion or even only of the roof of blisters will also guide to the correct diagnosis by detection. Pemphigus foliaceus will be recognized by detecting the corresponding antibodies on immunofluorescence microscopy.

Detection of antibodies against exfoliative toxin A or exfoliative toxin B is not a routine measure. The toxins can be identified after the producing strain of staph aureus has been detected and isolated.

### Therapeutic Principles

Parenteral antibiotics effective against staph aureus such as isoxazolyl-penicillines (oxacilline, fluloxacilline) are required. The addition of clindamycine is sometimes recommended as it interferes with production of the toxin by its inhibition of intracellular protein synthesis [3].

# Stargardt Disease

Jean-Michel Rozet, Josseline Kaplan
Unité de Recherches Génétique et Epigénétique des Maladies Métaboliques, Neurosensorielles et du Développement, INSERM, Hôpital des Enfants Malades, Paris, France

## Synonyms

Juvenile macular degeneration (early Stargardt); Macular dystrophy with flecks; Fundus flavimaculatus (late Stargardt); STGD

## Definition and Characteristics

Stargardt disease (STGD) is the most common hereditary macular dystrophy. This autosomal recessive (ar) condition is usually characterized by a sudden loss of visual acuity in late childhood or early teenage and a rapidly progressive course leading to legal blindness in a few years. The onset of the visual loss can however occur later and progress over several years. These later forms, referred as fundus flavimaculatus (FFM), are not uncommon. The age at onset of FFM is highly variable even within families (second to sixth decades).

Rare autosomal dominant cases resembling STGD, referred as STGD-like, have been reported. These forms which are due to mutations in ELOVL4 are not considered here.

## Prevalence

1:10,000 in STGD, not precise in FFM.

## Genes

STGD/FFM due to mutations in the retinal-specific ATP-binging cassette (ABCA4) gene (1p22.1) [1,2] – ABCA4 mutations also involved in ar-retinitis pigmentosa (ar-RP; uncommon) and ar-cone-rod dystrophies (20% of ar-CRD) [3] – strong correlations between the ABCA4 genotype and the phenotype [3].

Wide allelic heterogeneity: approximately 500 different mutations – vast majority of point mutations or micro-rearrangements – several complex alleles – one frequent hypomorphic allele (c. 2588G>C).

ABCA4 heterozygous carriers estimated to 1:50–1:30.

## Molecular and Systemic Pathophysiology

Vision begins with the isomerization of the 11-*cis*-retinal (RAL) of visual pigments in rod and cone photoreceptors. This light-dependent conversion triggers conformational changes of pigments and subsequent activation of a G-protein-coupled cascade that ultimately produces transient changes in the membrane potential of photoreceptors. Changes in membrane potentials provide the sensory signal to the photoreceptor synapse and the central nervous system.

When isomerized, the RAL is released into the photoreceptor disc interior where it reacts with phosphatidylethanolamine (PE) to form N-retinylidene-PE (N-RPE). ABCA4 in the disc of photoreceptor is an N-RPE flippase, effecting ATP-dependent translocation of N-RPE to the outer leaflet of the disc membrane [4]. Upon translocation, N-RPE is hydrolyzed to release all-trans-RAL, which is then reduced to all-trans-retinol that diffuses, or is translocated across the outer segment plasma membrane, where it is taken up in the retinal pigment epithelium (RPE) to be regenerated into 11-cis-RAL.

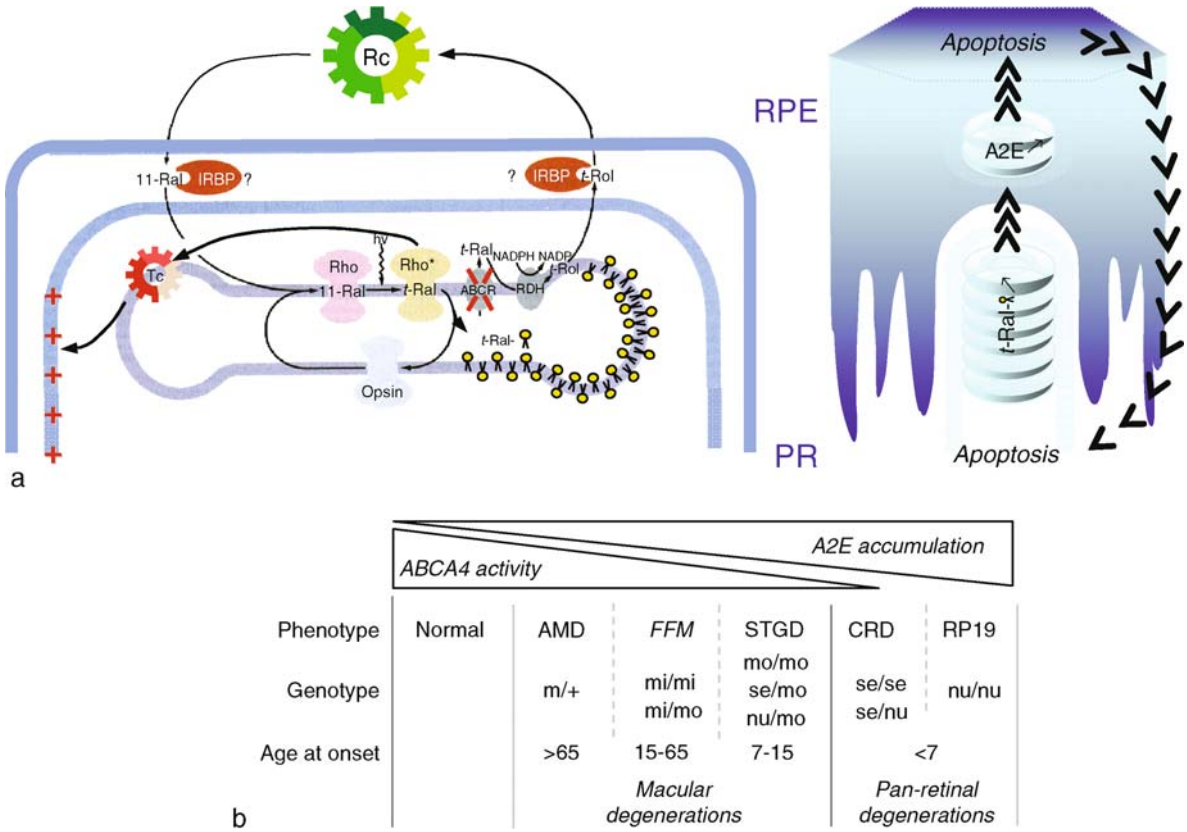
In addition to the synthesis/regeneration of visual chromophore, RPE is required for the shedding of photoreceptor outer segments. Lipofuscin arises in the RPE from incomplete digestion of these retinaldehyde-rich outer segment fragments. The major fluorophore of lipofuscin is the bis-retinoid, N-retinylidene-N-retinylethanolamine (A2E). By preventing from eliminating N-RPE from the disc interior of photoreceptors, the loss of ABCA4 function results in an acceleration of light-dependent deposition of A2E in the RPE. Abnormally increased A2E levels trigger RPE cell apoptosis and thus deprive photoreceptors from their support (Fig. 1a).

An inverse relationship between the residual ABCA4 function and the retinal cell death may exist. This notion results from the analyses of the nature of mutations identified on both ABCA4 alleles in patients affected with retinal dystrophy [3]. Approximately 500 different ABCA4 mutations are reported, which can be classified as mild, moderate, severe, null mutations on the basis of their nature and the severity of the phenotype with which they are associated. It is worth noting that homozygosity/compound heterozygosity for severe and/or null mutations is consistently responsible for panretinal degenerations including RP and CRD [3] (Fig. 1b).

## Diagnostic Principles

The visual loss in STGD/FFM precedes macular changes; early changes include high autofluorescence seen under confocol scanning laser Ophthalmoscope, calmacular beaten-bronze reflect, snail's slim aspect, whitish-yellowish perimacular flecks. Advanced changes may include a bull's eye aspect of the macula and choriocapilary atrophy. Silent choroid at the fluorescein angiography is a hallmark of STGD and FFM. ERG and EOG recordings are normal in early stages of the disease. The follow-up of patients is essential to confirm the diagnosis as some CRD can be confused with STGD in early stages.

STGD/FFM is genetically homogeneous. However, owing to the high frequency of ABCA4 heterozygous



**Stargardt Disease. Figure 1** ABCA4 (ABCR) deficiency. (a) Isomerization of the chromophore (11-RAL) by light (hn) activates photopigments (Rho) which in turn stimulate the visual transduction cascade (Tc) and ultimately results in the hyperpolarization (+++) of the plasma membrane of the photoreceptor (PR) cells. Isomerized chromophore, all-*trans* retinal (t-RAL), is released in the interior of the disc of PRs, where it binds to membrane phosphatidylethanolamine (PE, ♀) to form N-retinylidene-PE (N-RPE, t-Ral-♀ ABCA4 translocates N-RPE in the outer leaflet of the disc, at-RAL is released from PE, reduced into all-*trans* retinol (t-ROL) by a retinol dehydrogenase (RDH), and transported by the interstitial-retinol-binding protein (IRBP) to the retinal pigment epithelium (RPE) to re-enter the retinoid cycle (Rc). Alterations of ABCA4 (X) are responsible for an accumulation of N-RPE (↗) and upon shedding of outer segments of PR of an accumulation of N-retinylidene-N-retinylethanolamine (A2) that triggers RPE apoptosis and ultimately PR cell death. (b) ABCA4 genotype–phenotype correlations. The severity of the phenotype is directly correlated to the severity of ABCA4 mutations and inversely correlated to the residual activity of the transporter. Homozygosity or compound heterozygosity for null mutations (nu) are responsible for RP while the association of null/severe (se) or severe/severe mutations causes CRD; STGD is accounted for by the association of null/severe or moderate (mo)/moderate mutations; FFM is caused by the association of moderate/mild (mi) or mild/mild mutations.

carriers in the general population and the existence of complex alleles, molecular testing must be interpreted with care when the diagnosis is ambiguous.

## Therapeutic Principles

To date, no treatment allows preventing fast deposition of A2E in the RPE. However, it has been shown that the synthetic vitamin A analogue, N-(4-hydroxyphenyl) retinamide (HPR, fenretinide), can reduce serum retinol and consequently the accumulation of the toxic vitamin A-based A2E fluorophore in the RPE of ABCA4-deficient mice [5].

Because fenretinide can also trigger apoptosis, it has been extensively used in cancer chemoprevention phase II trials that have demonstrated a favorable toxicological profile of the molecule. Thus, fenretinide is currently used in a clinical trial in patients affected with atrophic age-related macular degeneration that, similarly to STGD/FFM, is characterized by an A2E accumulation in the RPE.

# Status Epilepticus

Katarzyna Lukasiuk[1], Asla Pitkänen[2]
[1]The Nencki Institute of Experimental Biology, Polish Academy of Sciences, Warsaw, Poland
[2]Department of Neurobiology, A.I.Virtanen Institute for Molecular Sciences, University of Kuopio, Kuopio, Finland

## Definitions and Characteristics

Status epilepticus (SE) is defined as at least two seizures without regaining consciousness or continuous seizure activity between seizures lasting for at least 30 min. SE can be *convulsive* (with tonic-clonic or myoclonic seizures) or *non-convulsive* (with absence or complex partial seizures). SE is a life threatening condition and requires hospitalization. The overall mortality is about 20%. If SE lasts more than 4 h, the mortality rate rises to 50% and for SE longer than 12 h reaches 80%. The most frequent precipitating factors are poor compliance with antiepileptic medication regimens, alcohol withdrawal, cerebrovascular accidents, meningitis, sepsis, encephalitis, brain tumor, head trauma, extremely high fever, low glucose levels or exposure to toxins.

## Prevalence

The incidence of SE is estimated to be 10–41 cases per 100,000 per year. Approximately 50% of new cases of SE occur in young children. The incidence is two times higher in the elderly than in the general population.

## Genes

Populational data indicate that genetic factors contribute to the risk of SE.

## Molecular and Systemic Pathophysiology

SE is a result of either increased neuronal excitation or impaired inhibition, which results in lack of control of seizure activity. SE causes extensive physiological and biochemical changes in the brain. One of the characteristic features of SE is induction of progressive benzodiazepine pharmacoresistance. Factors contributing to the decrease in sensitivity to GABA inhibition are alterations in subunit composition and endocytosis of inhibitory GABA-A receptors and/or accumulation of intracellular chloride or $HCO_3^-$. In addition, an increase in excitation is also observed during the course of SE. Translocation of AMPA and NMDA receptor subunits to the synapse enables the introduction of additional excitatory receptors. Moreover, an increase in glutamate release from the presynaptic side is also observed. During SE, a decrease in expression of inhibitory peptides such as dynorphin, galanin, somatostatin or neuropeptide Y occurs, while proconvulsive substance P and neurokinin B expression are increased. Finally, alterations in gene expression that are induced by SE can result in long term changes in brain function. SE induces profound, widespread neuronal loss in animal models. In human subjects, brain damage was observed in patients with SE both at autopsy and when using imaging methods.

## Diagnostic Principles

SE is diagnosed according to its characteristic symptoms. In convulsive SE, prolonged tonic or clonic activity of the extremities is present. It is often associated with a loss of consciousness. With time, seizures can evolve into more subtle ones. In the case of nonconvulsive SE, diagnosis can be difficult. Symptoms can include agitation, confusion or bizarre behavior. It is diagnosed on the basis of electroencephalography (EEG).

## Therapeutic Principles

Treatment of SE relies on early termination of seizures by rapid administration of anticonvulsants. Several protocols are used in practice and treatments vary among different centers. Usually treatment regimens involve sequential application of benzodiazepines (lorazepam or diazepam), phenytoin (or phosphophenytoin) and phenobarbital. As a second-line drug, midazolam, profolol, pentobarbital, or valproate can also be used. In the most severe cases, anesthesia is used to stop SE. Treatment is considered to be successful if both motor and electroencephalographic activity stop and do not resume.

# Steatohepatitis, Alcoholic

Stephan Haas[1], Sören Siegmund[2], Manfred V. Singer[1]
[1]Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg, Mannheim, Germany
[2]Department of Medicine, College of Physicians and Surgeons, New York, NY, USA

## Synonyms

ASH; Alcoholic hepatitis; Alcohol-induced hepatitis

## Definition and Characteristics

Alcoholic steatohepatitis (ASH) is a syndrome of inflammatory liver injury in conjunction with chronic heavy alcohol consumption. Characteristic symptoms and signs are moderate fever, hepatomegaly, jaundice and anorexia. While a significant proportion of patients is asymptomatic severe forms coincide with encephalopathy and liver failure. Obligatory histological findings include liver cell necrosis, Mallory bodies, infiltration of neutrophils and perivenular distribution of the inflammatory infiltrate. Steatosis, fibrosis and cholestasis are not a prerequisite.

Alcoholic hepatitis can be found in alcoholics with underlying steatosis or even with liver cirrhosis.

In hospitalized patients overall 30-day mortality is 15%, 1-year mortality is 40%. In severe forms of ASH 30-day mortality is 50%. Cirrhosis is present in approximately 90% of severe cases. Encephalopathy, hyperbilirubinemia, impaired renal function and leucocytosis are negative prognostic factors. The Maddrey-score and the Mayo-End-Stage Liver Disease (MELD) score are used to assess prognosis.

## Prevalence

The precise prevalance of alcoholic steatohepatitis is unknown as (i) patients with milder forms may be asymptomatic; (ii) a minority of alcoholics seeks medical attention; (iii) histological diagnosis by liver biopsy is rarely available. Up to 25% of alcohol abusers are estimated to have ASH.

## Genes

Gender is an established risk factor for ASH. Woman develop ASH more rapidly and have a worse course. Epidemiological studies link the risk for alcohol-induced liver injury to racial genetic factors. Non-white individuals have a higher prevalence of ASH and a higher progression rate to cirrhosis (see ►Liver cirrhosis, alcoholic).

## Molecular and Systemic Pathophysiology

Conversion of ethanol to acetaldehyde by aldehyde dehydrogenase (ADH) results in a shift of the hepatocellular redox-potential leading to steatosis by inhibiting beta-oxidation of fatty acids.

Hypermetabolism leads to centrilobular hypoxia. Impaired gut barrier function results in endotoxinemia thus activating Kupffer cells. Secreted tumor necrosis factor (TNF) induces apoptosis and activates cytokine expresssion (IL-1, IL-6, IL-8). Metabolism of ethanol by cytochrome P405 2E1 (CYP2E1), activation of Kupffer cells and infiltrating leukocytes contribute to oxidative stress with subsequent peroxidation of phospholipids. Acetaldehyde damages proteins, cell membranes and DNA. Acetaldehyde-protein adducts serve as antigens inducing immune-mediated cell toxicity.

## Diagnostic Principles

A history of alcoholism in combination with elevated liver enzymes is indicative for ASH. Characteristically AST/ALT ratio is greater than 2. Both AST and ALT almost never exceed 500 U/L. Moderate anemia, increased mean corpuscular volume and elevated GGT serum levels are frequently found in alcoholics. Neutrophilic leukocytosis is a characteristic feature of ASH. Infections resulting in leukocytosis like spontaneous bacterial peritonitis and pneumonia have to bee ruled out. In more advanced forms of ASH hypoalbuminemia and pathologic coagulation parameters reflect impaired hepatic synthetic function. Laboratory screening tests should always exclude other disease entities

(e.g. viral hepatitis, cholangitis, hemochromatosis). Elevated serum levels of laminin, collagen IV, IL-1, IL-6 and IL-8 are found in ASH patients. These parameters play no significant role for the clinician.

Transabdominal ultrasound detects hepatic steatosis and with less sensitivity liver cirrhosis in patients with ASH and has the potential to rule out other hepatic diseases. The role of liver biopsy is still controversial. In all cases in whom the diagnosis remains uncertain liver biopsy should be performed. In patients developing liver failure liver biopsy might be helpful to determine the severity of liver pathology. Transvenous liver biopsy is an alternative method with a lower bleeding risk compared to the standard ultrasound-guided procedure.

### Therapeutic Principles

Cessasation of alcohol consumption is essential and reduces long-term mortality and progression to liver cirrhosis. Most alcohol abusers exhibit protein-calorie malnutrition and proper nutrition has to be ensured [1]. 1–1.5 g/kg BW and a minimum of 30 kcal/kg BW per day are required. In the critically ill patient oral supplementation via nasogastric or nasojejunal tubes is necessary. Only patients with marked encephalopathy require additional branched-chain amino acids. Vitamin deficiencies should be corrected (thiamine, folate, pyridoxine).

Based on two metaanalyses glucocorticoids reduce short-term mortality only in severe ASH [2,3]. Approximately seven patients have to be treated to prevent one death. Acute infections might represent a contraindication. Generally 40 mg/day predinisolone is given for 1 month followed by a taper. Oral administration of pentoxifylline (400 mg PO TID) appears to be a promising new therapy. In one study mortality reduction resulted from a decrease in the frequency of hepatorenal syndrome. Further studies have to confirm positive effects of infliximab, a chimeric mouse–human anti-TNF monoclonal antibody and of extracorporal liver support systems (e.g. MARS). Propylthiouracil, colchicine, insulin–glucagon infusions, calcium-channel blockers and anabolic steroids (oxandrolone) did not prove to be effective. Most transplantation units exclude patients with ongoing alcoholism from liver transplantation. For long-term therapy see ►Liver cirrhosis, alcoholic.

## Steatohepatitis, Nonalcoholic

Henryk Dancygier
Department of Internal Medicine II, Klinikum Offenbach GmbH, Offenbach, Germany

### Synonyms

NASH

### Definition and Characteristics

Nonalcoholic steatohepatitis (NASH) is part of the spectrum of nonalcoholic fatty liver disease (NAFLD). NAFLD encompasses hepatic lesions such as steatosis, steatohepatitis, fibrosis, cirrhosis, and in some cases hepatocellular carcinoma. NASH mimics alcoholic hepatitis and is defined histologically by the presence of hepatocellular injury (steatosis, ballooning, cell death), inflammation (intralobular neutrophils > mononuclear cells), and fibrosis in patients consuming up to 20–25 g ethanol daily.

### Prevalence

The prevalence of NAFLD in industrialized western countries is estimated to be 20–25%. The incidence has increased from 4.2 per $10^5$ inhabitants per year in 1980–1985 to 38 per $10^5$ inhabitants per year in 1995–1999 [1]. 70–95% of obese patients with a long-standing BMI > 30 kg/m$^2$ have a steatotic liver, 9–30% have NASH, and 7–16% have a cirrhosis. Approximately 70% of cases of cryptogenic cirrhosis are thought to represent the end stage of the NAFLD/NASH pathway. The growing obesity epidemic in children has led to an increase in prevalence of NASH in this age group.

### Genes

Genetic influences in NASH are poorly understood. Available data suggest that genes may be involved in determining the susceptibility to NASH. Polymorphisms of microsomal triglyceride transfer protein (MTP) gene and manganese superoxide dismutase (MnSOD) gene have been described [2]. The former leads to decreased MTP transcription, less export of triglyceride from

hepatocytes, and greater intracellular triglyceride accumulation, the latter results in less transport of MnSOD to mitochondria. Using microarray technology genes for maintaining mitochondrial function (copper/zinc superoxide dismutase, aldehyde oxidase, and catalase) were found to be underexpressed whereas genes for complement component C3 and hepatocyte-derived fibrinogen-related protein were overexpressed in NASH. Genes related to lipid metabolism and extracellular matrix remodeling were significantly dysregulated in NASH. In general, genes related to detoxifying enzymes are underexpressed whereas genes related to the activation of stellate cells and fibrinogenesis are overexpressed [3].

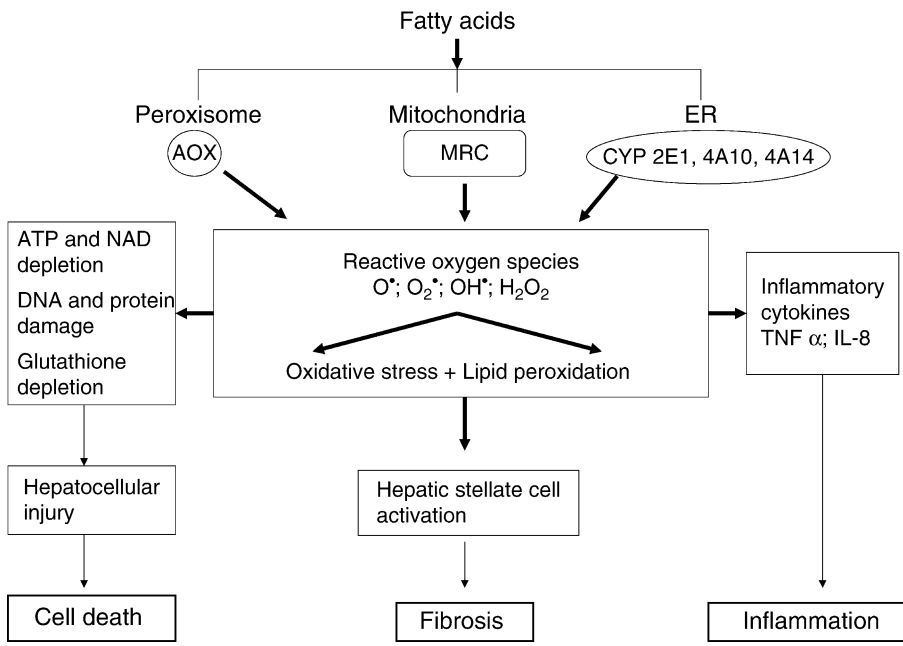
## Molecular and Systemic Pathophysiology

Central to the pathophysiology of NASH is insulin resistance (IR) and mitochondrial dysfunction. Increased visceral adipose tissue mass coupled with IR-mediated enhanced activity of hormone-sensitive lipase lead to increased hydrolysis of triglycerides with increased levels of free fatty acids (FFA) in portal venous blood. IR of skeletal muscle inhibits the muscular uptake of glucose thereby contributing to hyperglycemia. Consequently, in insulin-resistant states the amount of glucose and FFA taken up by the hepatocytes is increased, creating a new balance between the expanding intracellular pool of FFA, glucose, and hepatic triglycerides. In patients with NAFLD/NASH, the liver is less resistant to insulin than adipose tissue and skeletal muscle, and hepatic lipogenesis remains relatively insulin sensitive. In addition, chronic hyperinsulinemia reduces the synthesis of apolipoprotein B 100 thereby reducing the VLDL-associated lipid export from the hepatocytes. The final outcome of IR is an accumulation of hepatic triglycerides with a concomitant inhibition of their excretion as VLDL (steatosis). The pathway from steatosis to steatohepatitis involves lipid peroxidation and reactive oxygen species generating oxidative stress, which leads to hepatocellular injury through peroxidation of membrane lipids and damage of DNA. Cytokines such as tumor necrosis factor α (TNF α), interleukin-6, and interleukin-8 injure mitochondria and promote apoptotic, necroinflammatory, and fibrogenic processes (Fig. 1) [4,5].

Structural and functional mitochondrial alterations in patients with NASH affect the synthesis of ATP and cause dysregulation of energy-homeostasis, thus contributing to liver damage. The role of the adipokines leptin and adiponectin in the pathogenesis of NASH is currently under investigation.

## Diagnostic Principles

Obesity (BMI ≥ 30 kg/m$^2$), hyperglycemia (≥110 mg/dL), hyperinsulinemia, hypertriglyceridemia (≥150 mg/dL), and systolic blood pressure >130 mmHg are risk factors for the development of NAFLD. About two thirds of patients with elevations of aminotransferase levels of unknown etiology display NAFLD/NASH lesions on liver histology. Most patients with NASH are asymptomatic with only mild elevations of aminotransferases (ALT > AST; 2–4 × ULN), but ALT is no marker for NAFLD, and patients with normal aminotransferases



**Steatohepatitis, Nonalcoholic. Figure 1** Mechanism of lipid-induced hepatocellular injury in NAFLD/NASH (adapted from [4]).

may have NASH lesions on liver histology. Ferritin is increased in every other patient and up to 25% of patients with NAFLD/NASH have low titer elevations (≤ 1: 320) of antinuclear antibodies. Hepatomegaly is present in 50% of patients with NASH. On ultrasound, the liver is bright with a homogeneous hyperechogenicity. The diagnostic gold standard is liver biopsy, only histology being able to grade inflammatory activity and stage fibrosis.

## Therapeutic Principles

The therapy of NAFLD/NASH is the therapy of the metabolic syndrome. The mainstay of management is strict blood glucose control and cautious weight reduction. So-called crash diets should be avoided since they can trigger acute necroinflammatory flares. In morbidly obese patients, bariatric surgery with gastric bypass yields promising results. Insulin sensitizing agents such as thiazolidinediones and biguanides represent a rational pharmacological approach based on pathophysiology of NASH. However, the data-based evidence for prescribing these drugs to patients with NAFLD/NASH is still small.

# Steatorrhea

Mark Oette
Clinic for Gastroenterology, Hepatology, and Infectious Diseases, University Clinic Duesseldorf, Duesseldorf, Germany

## Synonyms

Fat malabsorption

## Definition and Characteristics

Steatorrhea is characterized by increased stool fat exceeding the normal 7 g/day. Patients complain about greasy pale diarrhea with offensive smell and enlarged stool volume. Weight loss and malabsorption of essential nutrients may be present.

## Prevalence

Due to heterogeneous etiological background of the symptom steatorrhea, no information on the prevalence exists.

## Molecular and Systemic Pathophysiology

The process of digestion and absorption of food may be divided into three major phases. In the luminal phase, dietary fats, proteins, and carbohydrates are hydrolyzed and solubilized by secreted digestive enzymes and bile. The absorption of digested food into the mucosal cells is the luminal phase, which depends on the integrity of the intestinal surface. In the third phase, reassembled lipids and other nutrients are transported via lymphatic vessels and portal blood. Pathological conditions of the first phase result in maldigestion, of the second phase in malabsorption, and of the third phase in defects of transportation into the circulation (Table 1).

Most dietary lipids are absorbed in the proximal two-thirds of the jejunum. The basic mechanism for this is the generation of an emulsion of triglycerides and phospholipids in an aqueous environment. Lingual and pancreatic lipase is necessary for fat hydrolysis and degradation of triglycerides; pancreatic bicarbo nate produces the optimal pH for digestion, and bile salts enhance fat solubilization. The aggregates called micelles may pass the mucosal membranes leaving the bile salts in the lumen for later reabsorption. The major transport protein enhancing fatty acid absorption is FATP4 [1]. The aggregation of triglycerides, cholesterol esters, phospholipids, and apoproteins leaves the mucosal cell to enter the hepatic lipid metabolism.

Etiological conditions of steatorrhea are shown in Table 1. In the first section, different disorders that result in impaired fat degradation and micelle formation are listed. The underlying diseases affect the pancreas, the biliary tree, and the bacterial flora of the small intestine. Furthermore, tumor secretion products may interfere with food digestion. Disorders of the mucosal surface and absorptive capacity are shown in the second section. Here, the pathology is caused by drugs, inflammatory diseases, immunological processes, ischemia, anatomical changes, and infections. In the third section, disorders that affect transportation of absorbed lipids are listed. Congenital and acquired disturbances of lymphatic and venous flow, infections, and inborn defects of chylomicron formation may be present. The

**Steatorrhea. Table 1** Causes of steatorrhea

| Pathophysiology | Diseases |
|---|---|
| Maldigestion | Exocrine pancreatic insufficiency, bile duct obstruction, pancreatic duct obstruction, cystic fibrosis, bacterial overgrowth, primary sclerosing cholangitis, Zollinger Ellison syndrome, somatostatinoma |
| Malabsorption | Drugs, inflammatory bowel disease, coeliac disease, tropical sprue, chronic ischemia, short bowel syndrome (chologenic diarrhea), Mycobacterium avium infection in immunocompromised hosts, Giardiasis |
| Transport into the circulation | Congenital intestinal lymphangiectasia, Whipple's disease, abetalipoproteinemia, lymphatic obstruction induced by infection, trauma, tumors, and others |

underlying molecular mechanisms of the heterogeneous list are diverse.

In cases with small intestine disease, stool fat ranges between 15 and 25 g/day. It may rise to more than 40 g/day in patients with pancreatic exocrine deficiency. Complications of steatorrhea consist of weight loss and fatigue, flatulence and abdominal distention, hypoalbuminemia, loss of other nutrients such as vitamins, edema, anemia, bleeding disorders due to vitamin K deficiency, osteopenia due to vitamin D deficiency, night blindness due to vitamin A deficiency, neurological signs due to thiamine deficiency, and dermatological manifestations like pale skin, dermatitis herpetiformis, aphthous ulcers of the mouth, and alopecia.

## Diagnostic Principles

Tests of fat malabsorption and a 24-h fecal fat collection are considered as standard. D-Xylose test is used to test the general integrity of the small intestine. Stool cultures and selected antigen tests to exclude pathological microorganisms are necessary for differential diagnosis. Laboratory studies should consist of hematological tests, serum iron, vitamin B-12, folate concentration, prothrombin time, electrolytes, protein, albumin, triglycerides, cholesterol, antigliadin and anti-transglutaminase antibodies, serum IgA, and fecal pancreatic elastase. Imaging should consist of ultrasound of the abdomen, complete endoscopy including biopsies, plain abdominal X-ray, small bowel barium studies, and CT-scan in defined situations. ERCP should be applied in cases with suspected duct obstruction. Finally, lactose breath test and Schilling test may be applied.

## Therapeutic Principles

Two basic principles underlie the management of patients with malabsorption. These are the correction of nutritional deficiencies and the treatment of causative diseases. Supplementing various minerals, such as calcium, magnesium, iron, and vitamins, is important. Caloric and protein replacement also is essential. Oral medium-chain triglycerides can be used as fat substitutes because they do not require micelle formation for absorption, and their route of transport is rather portal than lymphatic. A restriction of daily fat intake to <40 g may be useful in patients who are able to maintain weight with this method. In severe intestinal diseases, such as massive resection and extensive regional enteritis, parenteral nutrition may become necessary. Treatment of causative diseases is necessary, although most of these conditions cannot be controlled completely. For example, a gluten-free diet helps treat celiac disease; protease and lipase supplements are the therapy for pancreatic insufficiency [2]; antibiotic treatment is used for bacterial overgrowth; cholestyramin therapy is indicated for chologenic diarrhea, and corticosteroids or other anti-inflammatory agents may be applied to treat regional enteritis.

# Steele-Richardson-Olzewski Syndrome

►Progressive Supranuclear Palsy

# Stenocardia

►Angina Pectoris

# Stent Restenosis

Vicente Andrés[1], Rainer Wessely[2,3]
[1]Vascular Biology Unit, Instituto de Biomedicina de Valencia (IBV-CSIC), Spanish Council for Scientific Research, Valencia, Spain
[2]Deutsches Herzzentrum and 1st Department of Medicine, University of Technology, Munich, Germany
[3]Heart Center, Marienhospital, Osnabrueck, Germany

## Synonyms

In-stent restenosis; ISR

## Definition and Characteristics

Restenosis is the recurrent arterial narrowing following a percutaneous coronary intervention (PCI) performed to dilate atherosclerotic vessels to treat vascular stenosis or revascularize the infarcted myocardium. Compared with native atheromas, which normally have high lipid content and develop over years, restenotic lesions lack lipid deposits and typically grow during 4–6 months post PCI [1]. In some patients, excessive restenosis results in a recurrence of clinical symptoms that forces target-vessel revascularization. The first percutaneous transluminal coronary angioplasty (PTCA) was performed in 1977 using the Grüntzig balloon catheter. Nowadays, >90% PCIs use metallic prostheses, so called stents, which increase the safety of the interventional procedure and decrease restenosis rates [1]. Prevention of negative arterial remodeling, the major cause of PTCA restenosis, is a key determinant of the superior outcome of coronary stents (Fig. 1).

It is well accepted that neointimal hyperplasia is the main cause of ISR (Fig. 2). Thus, ISR is a proliferative disease.

The economic impact of ISR is significant; the estimated annual costs in the western world exceed US $1,000,000,000. Per PCI, costs for possible restenosis in the bare-metal stent era were attributed to approximately US $2,500.

## Prevalence

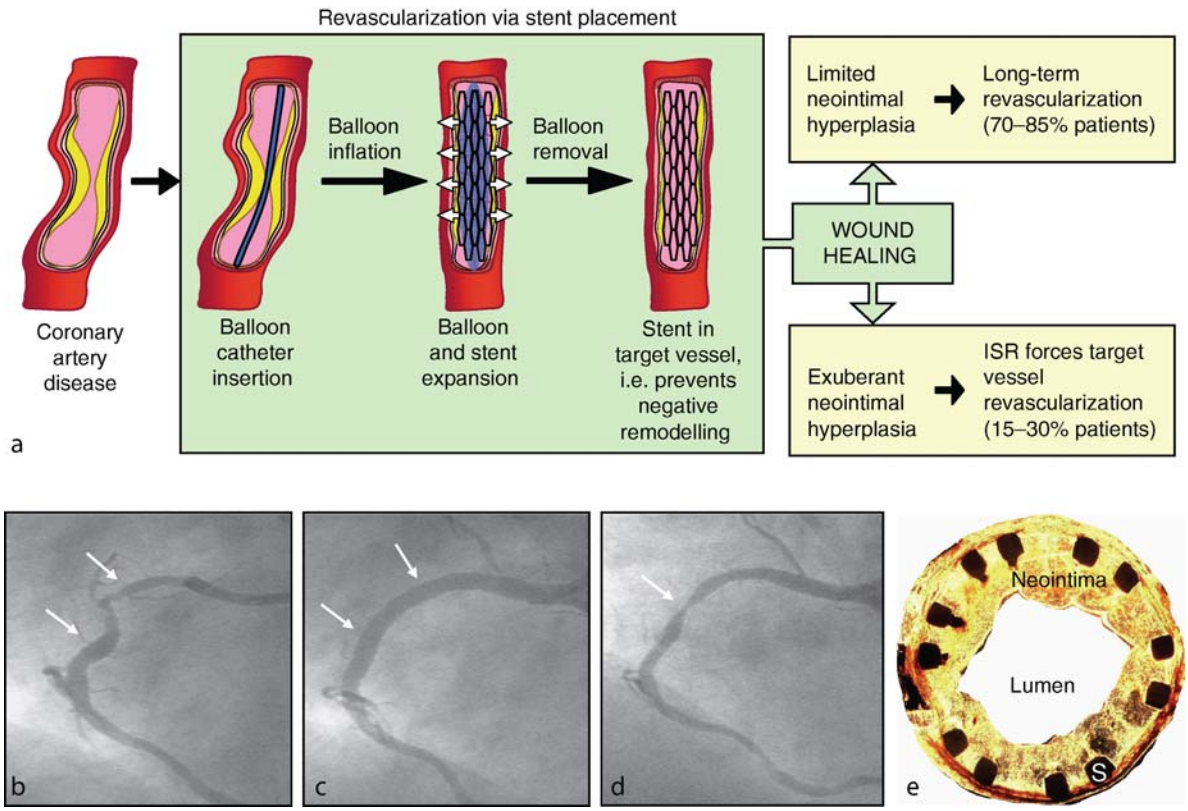
The rates of restenosis after PCI, which depend on lesion and patient characteristics, have diminished from 25–50% typically observed after conventional PTCA to 15–30% using bare-metal stents [1]. ISR is further reduced using drug-eluting stents (see below).

## Genes

Human studies are being conducted to assess whether a patient's susceptibility to develop restenosis may be, at least in part, genetically determined. In particular, pilot studies have identified the association between the risk of restenosis and single nucleotide polymorphisms (SNPs)/haplotypes in genes considered involved in the disease (e.g., TLR-2, ADRB2, CD14, CSF2, CCL11, p22-PHOX, PON1, FABP2, THBD). Replication of these preliminary findings in other studies, as well as high-throughput screening for additional SNPs – millions of SNPs exist across the human genome – may identify useful markers for improved stratification of patients to individually tailored treatment for ISR.

## Molecular and Systemic Pathophysiology

Neointimal hyperplasia following stenting can be viewed as the arterial wall's healing response to acute mechanical injury (e.g., endothelial cell damage and denudation) [2] (Fig. 2). The acute early phase of ISR involves localized platelet activation and thrombosis accompanied by recruitment of circulating monocytes, neutrophils, and lymphocytes into the intimal area. These cell types trigger a chronic inflammatory response characterized by the activation of smooth muscle cells (SMCs) within the tunica media. Unlike medial SMCs in normal adult arteries, which are fusiform and exhibit a differentiated contractile phenotype characterized by the expression of contractile proteins and reduced proliferative and migratory activity, medial SMCs within the injured vessel wall display a less (un) differentiated synthetic phenotype featuring broader and flatter shape, expression of embryonic isoforms of contractile proteins, high responsiveness to growth and chemotactic stimuli, and abundant extracellular matrix (ECM) synthesis. A plethora of mitogenic and chemotactic factors produced by neointimal cells provoke a first proliferative "wave" of medial SMCs and their migration toward the intimal area, which is followed by a second hyperplastic response of neointimal SMCs [2,3]. Evidence is mounting that recruitment of adventitial myofibroblasts and bone marrow-derived and adventitial SMC progenitors also contribute to neointimal SMC accumulation [2]; however, the relative role in restenosis of the different sources of neointimal SMCs remains unclear. Candidate regulators of neointimal hyperplasia identified in animal and human studies include thrombogenic factors (e.g., tissue factor, thrombin receptor), cell adhesion molecules (e.g., VCAM, ICAM, LFA-1, Mac-1), signal transducers (e.g., PI 3-kinase, MEK/ERK), transcription factors (e.g., NF-κB, E2F, AP-1, c-myc, c-myb, YY1, Gax), cell cycle regulatory proteins (e.g., pRb, p21, p27, CDK2, CDC2, cyclin B1, PCNA), growth factors (e.g., PDGF-BB, TGFβ, FGF, IGF, EGF, VEGF), inflammatory cytokines (e.g., TNFα), chemotactic factors (e.g., CCR2, MCP-1), and metalloproteases (e.g., MMP-2, MMP-9). Resolution of inflammation and wound healing at later stages post PCI is accompanied by



**Stent Restenosis. Figure 1** PCI using stent and visual appearance of in-stent restenosis. (a) The image on the left side depicts a tight coronary artery stenosis in need for PCI. A balloon catheter is advanced into the stenotic artery via a previously inserted guidewire. Subsequently, the balloon that can also carry a crimped stent is inflated and retracted. In case of stent placement, the stent remains within the target vessel, thus preventing negative remodeling. The amount of neointimal hyperplasia, which develops consistently as the result of complex wound healing processes (see Fig. 2), determines the clinical outcome. Renarrowing of the vascular segment of more than 50–75% leads to clinical restenosis, which may require repeated revascularization. (b–d) depict coronary angiograms of a right human coronary artery. (b) Tight symptomatic atherosclerotic lesion (arrows) requiring coronary stenting. (c) Coronary angiogram demonstrating successful revascularization immediately after stent placement (arrows). (d) Six months later, the patient presented again with chest pain on exertion. Renarrowing of the artery within the stented segment and thus ISR is apparent angiographically. (e) Cross-sectional area of a stent explanted from an animal model with neointima formation, the pathoanatomical correlate of ISR. S, stent strut.

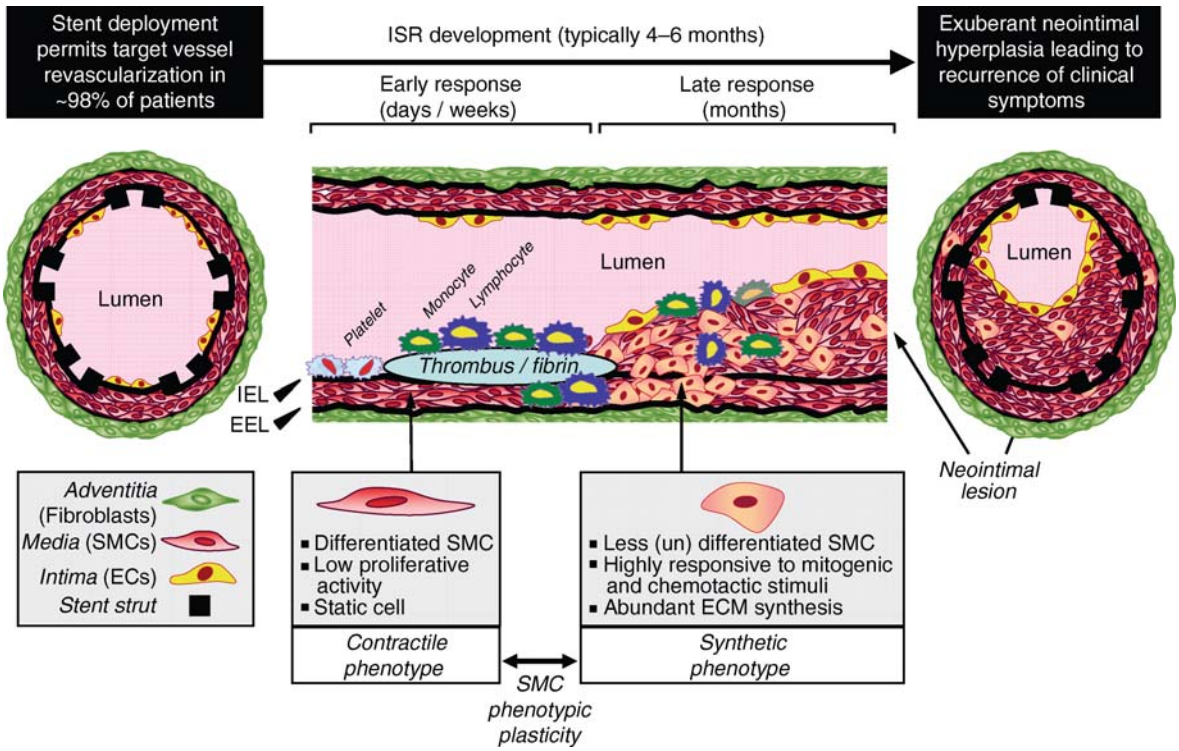
restoration of the contractile phenotype of neointimal SMCs and changes in ECM composition to more closely resemble the uninjured arterial wall.

## Diagnostic Principles

Predictors of ISR include lesion length and complexity, stent length, number of stents per lesion, small vessel diameter (≤2.75 mm), residual diameter stenosis, and certain clinical scenarios, such as diabetes mellitus or previous ISR. Besides typical clinical symptoms such as stable and unstable angina pectoris, about 25% of patients with ISR even present with an acute coronary syndrome. The diagnostic gold standard is coronary angiography; noninvasive diagnostic tools including novel imaging techniques such as coronary CT (computerized tomography) are at the current stage associated with lower sensitivity and specificity.

## Therapeutic Principles

Countless systemic therapeutic approaches to prevent or treat ISR failed in clinical trials despite encouraging preclinical data derived from various animal models. However, after shifting the paradigm to local, stent-based therapy [4], the recent introduction of drug-eluting stents has revolutionized interventional cardiology by a robust decrease of restenosis of up to 80%. The therapeutic principle is derived from the pathophysiological evidence that ISR can be regarded as a proliferative disease. Lipophilic drugs that target the final common pathway of cellular proliferation, the eukaryotic cell cycle, such as sirolimus and paclitaxel,



**Stent Restenosis. Figure 2** Mechanisms of in-stent restenosis. The images on both sides schematize cross sections through stented arteries immediately after intervention (left) and at a late time point with excessive neointimal lesion development (right). The scheme in the middle corresponds to a longitudinal section through the vessel wall illustrating the temporal pattern of the main events that occur during the early and late response to injury. For simplicity, the process is shown only in one side of the artery wall and the stent struts are not depicted. Moreover, none of the cartoons shows the native atherosclerotic plaque that compromised blood flow before performing PCI. Stenting causes endothelial cell damage and denudation. The early restenostic lesion features fibrinogen deposition, platelet adhesion/activation, and thrombus formation. Circulating leukocytes adhere to thrombi via selectins and integrins, and migrate across the fibrin–platelet layer toward the intimal area driven by locally produced chemokines. A plethora of mitogenic and chemotactic factors produced by platelets and leukocytes act on medial differentiated SMCs exhibiting a *contractile* phenotype, which revert to a *synthetic* less (un)differentiated phenotype characterized by high responsiveness to mitogenic and migratory stimuli and abundant ECM protein synthesis. Activated SMCs proliferate very actively and migrate toward the intimal area, where a second proliferative response of neointimal SMCs contributes to neointimal growth. Alterations in ECM protein synthesis and ECM degradation distort the normal arterial architecture. Cessation of inflammation at later stages leads to wound healing, accompanied by total or partial reendothelialization of the stented artery and restoration of the contractile phenotype of neointimal SMCs. Moreover, the ECM composition of the healed artery resembles that of the uninjured vessel wall. EC, endothelial cell; ECM, extracellular matrix; EEL, external elastic lamina; IEL, internal elastic lamina; SMC, smooth muscle cell.

are locally delivered at high dosage via the stent surface into the adjacent vascular wall, thus attenuating cell proliferation and consequently ISR [2,5]. Yet, the prolonged healing phase that is apparent in these particular stents has to be bridged by a longer-lasting dual antiplatelet therapy to avoid stent thrombosis that is associated with a high mortality rate.

Most novel therapeutic developments follow the principle of local stent or device-based therapy and focus on coatings that improve the healing process while maintaining antirestenotic efficacy or they concentrate on biodegradable stent platforms as drug carriers that dissolve over time.

# Sternocleidomastoid Tumor of Infancy

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Fibromatosis colli

## Definition and Characteristics

A sternocleidomastoid tumor presents in the first few weeks of life as a firm, nontender, discrete, fusiform or spindle-shaped mass within the sternocleidomastoid muscle (Fig. 1) [1].

The size varies from 1 to 3 cm in diameter. The mass is not fixed to the skin and is movable in the horizontal plane. The tumor is usually found in the middle or inferior portions of the sternocleidomastoid muscle. Both heads of the sternocleidomastoid muscle are often affected. There is a slight propensity for the lesion to be on the right side. Bilaterality is rare. Shortening of the sternocleidomastoid muscle pulls the head toward the side of the lesion; this results in ipsilateral head tilt and contralateral chin deviation. Torticollis is aggravated by the inability of the affected muscle to grow normally and to keep pace with the normal muscle. The degree of torticollis is related to the ratio of the fibrosis to the remaining functional muscle. Other complications include restricted neck motion, plagiocephaly, and facial asymmetry.

## Prevalence

The incidence is approximately 0.05–0.4% of live births [2]. There is no predilection of sex or race.

**Sternocleidomastoid Tumor of Infancy.**
**Figure 1** Sternocleidomastoid tumor presenting as a discrete, fusiform mass in the right sternocleidomastoid muscle.

Sternocleidomastoid tumor is more common in infants born to primiparous mothers. Approximately 60% of affected infants have had a complicated birth [1]. The reported incidence of breech delivery in affected infants is much higher than usual (20–30%) [1].

## Molecular and Systemic Pathophysiology

The precise cause is not known. Birth trauma might result in muscle stretching and hematoma formation, which might be followed by fibrosis and muscle contraction [3]. However, a clinical hematoma is not present within the sternocleidomastoid muscle and hemosiderin is not present in pathological specimens.

Another popular hypothesis is that the tumor is the sequela of an intrauterine or perinatal compartment syndrome. Since the tumor can develop following cesarean section and in association with other congenital lesions (such as hip dysplasia and talipes equinovarus), an intrauterine influence is considered operative in at least some cases. The localized increase in pressure within the muscular compartment contained by the sternocleidomastoid fascia is thought to lead to focal ischemia and fibrosis. The main objection to this hypothesis is that a sternocleidomastoid tumor, although relatively common, has never been detected by antenatal ultrasonography. Heredity might play a role in a small percentage of cases. Sternocleidomastoid tumor has been reported in twins and siblings [1].

## Diagnostic Principles

The differential diagnosis includes branchial cleft cyst, dermoid cyst, ectopic thyroid, lymphadenopathy, cystic hygroma, branchial cleft cyst, lipoma, lymphangioma, hemangioma, sebaceous cyst, neuroblastoma, rhadomyosarcoma, and fibrosarcoma.

A clinical diagnosis can be established by palpation of the mass within the sternocleidomastoid muscle. Usually, no diagnostic test is necessary. If there is any doubt about the clinical diagnosis, the typical histology can be confirmed with a fine-needle aspiration of tissue. Ultrasonography and MRI can be used to demonstrate the fibrotic lesion within the sternocleidomastoid muscle.

## Therapeutic Principles

Up to 70% of sternocleidomastoid tumors resolve spontaneously without treatment [1]. Initial therapy consists of physiotherapy, with passive and active stretching of the sternocleidomastoid tumor on the affected side. The success rate from physiotherapy ranges from 90 to 95% [4]. Poor prognostic factors include the presence of facial asymmetry at diagnosis and limitation of neck rotation over 30° [5]. Surgical intervention is reserved for patients with a tumor or

an associated contraction that persists beyond 1 year of age, and for those in whom craniofacial abnormalities develop [2].

# Steroid 21-Hydroxylase Deficiency

Deborah P. Merke
Warren Grant Magnuson Clinical Center and The Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA

## Synonyms

Congenital adrenal hyperplasia; CAH; Virilizing congenital adrenal hyperplasia; Adrenogenital syndrome

## Definition and Characteristics

21-Hydroxylase deficiency is responsible for over 95% of cases of congenital adrenal hyperplasia (CAH), a group of inherited autosomal recessive disorders in which there is an enzymatic defect in cortisol biosynthesis. There is a wide spectrum of clinical variants; classic refers to the severely affected form and nonclassic (also referred to as "late-onset") refers to the mild form. Classic CAH is subcategorized as salt-losing or nonsalt-losing (simple-virilizing), reflecting the degree of aldosterone deficiency.

Females with classic CAH present at birth with ambiguous genitalia due to exposure to high levels of androgens in utero. The age at diagnosis in males varies according to the severity of aldosterone deficiency. Salt-losing males typically present at 7–14 days of life with vomiting, weight loss, lethargy, hyponatremia, and hyperkalemia. Nonsalt-losing males present with precocious puberty, characterized by pubic hair and accelerated growth velocity at 2–4 years of age. The nonclassic form presents in late childhood or early adulthood with mild hyperandrogenism, and is an important consideration in the differential diagnosis of the female with symptoms or signs of hyperandrogenism. Males with nonclassic CAH are often asymptomatic, but may present with early puberty and rarely have infertility.

## Prevalence

The highest incidence of the classic form occurs in two geographically isolated populations: the Yupic Eskimos of Alaska (1:280) and the French island of La Reunion in the Indian Ocean (1:4,100) [1]. The overall incidence worldwide is 1:15,000 live births for the classic form, giving a carrier frequency of 1 in 60 persons [1]. The nonclassic form is more common and accounts for approximately 5–10% of women with hirsutism. The carrier frequency of the nonclassic form ranges from 1 in 5 to 1 in 50, depending on the ethnic group. It is most common in Hispanic, Italian and Ashkenazi Jewish populations.

## Genes

The gene for 21-hydroxylase lies on chromosome 6 within the HLA locus of the major histocompatibility system [2]. There are two homologous genes resulting from ancestral duplication; CYP21B, the active gene, and CYP21A, an inactive pseudogene. The proximity of these genes and their location within the HLA region, which has a high rate of recombination, makes CYP21B vulnerable to genomic DNA exchanges. The majority of mutations result from gene conversion, the transfer of sequences between the pseudo and active genes. The degree of impairment of 21-hydroxylase activity based on in vitro studies of individual mutations usually predicts the clinical severity (Fig. 1).

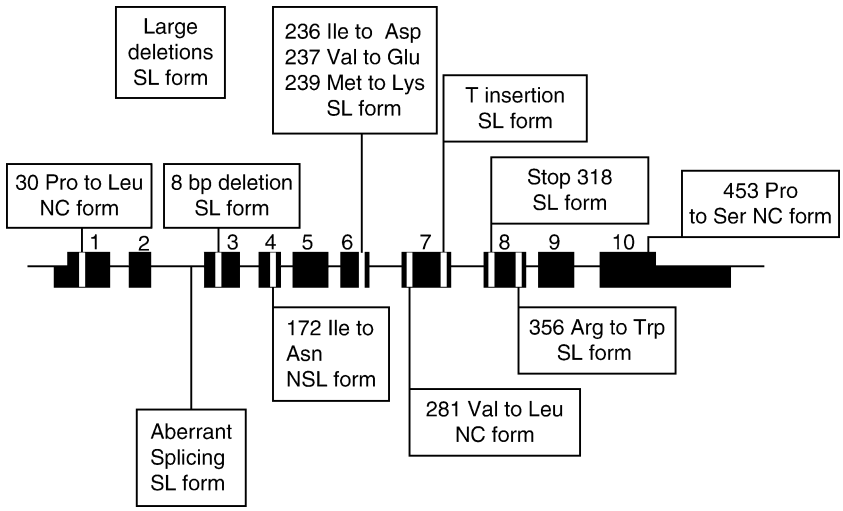
Most patients are compound heterozygotes and the severity of the disease is determined by the activity of the less severely affected allele. However, genotype-phenotype discrepancies have been described [2].

## Molecular and Systemic Pathophysiology

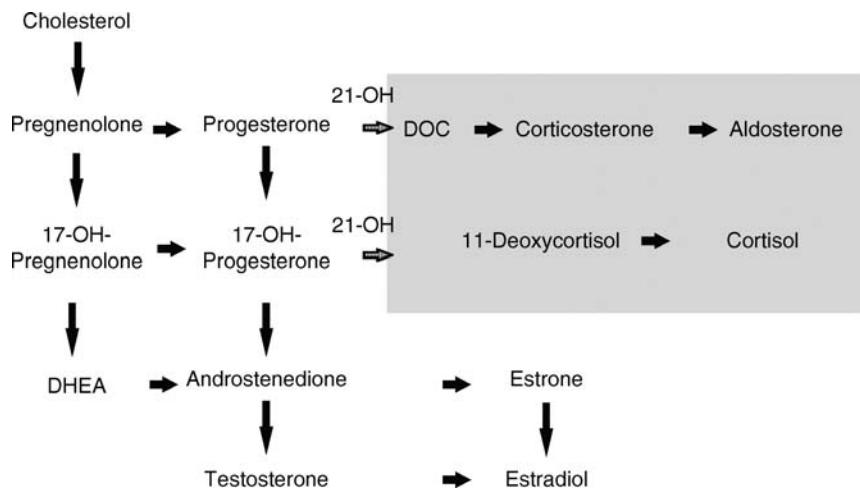
Several endocrine systems are disturbed in 21-hydroxylase deficiency. In the untreated patient with classic CAH, a block in cortisol biosynthesis leads to a build-up of cortisol precursors (Fig. 2).

A lack of negative feedback on the hypothalamus and pituitary results in increases in corticotropin (ACTH) and adrenal gland enlargement. The combination of accumulated cortisol precursors and increased corticotropin results in massive androgen production (Fig. 3).

A deficit in aldosterone synthesis leads to salt loss and hypovolemia, stimulates the renin-angiotensin axis, antidiuretic hormone (ADH) and angiotensin II, and



**Steroid 21-Hydroxylase Deficiency. Figure 1** The location and nature of the most common genetic mutations found in 21-hydroxylase deficiency and the expected clinical phenotype (SL, salt-losing; NSL, non-salt-losing; NC, nonclassic) are shown. The ten exons and nine introns of CYP21B are drawn to scale. (Arg = Arginine; Asn = Asparagine; Asp = Aspartate; Glu = Glutamate; Ile = Isoleucine; Leu = Leucine; Lys = Lysine; Met = Methionine; Pro = Proline; Trp = Tryptophan; Val = Valine).

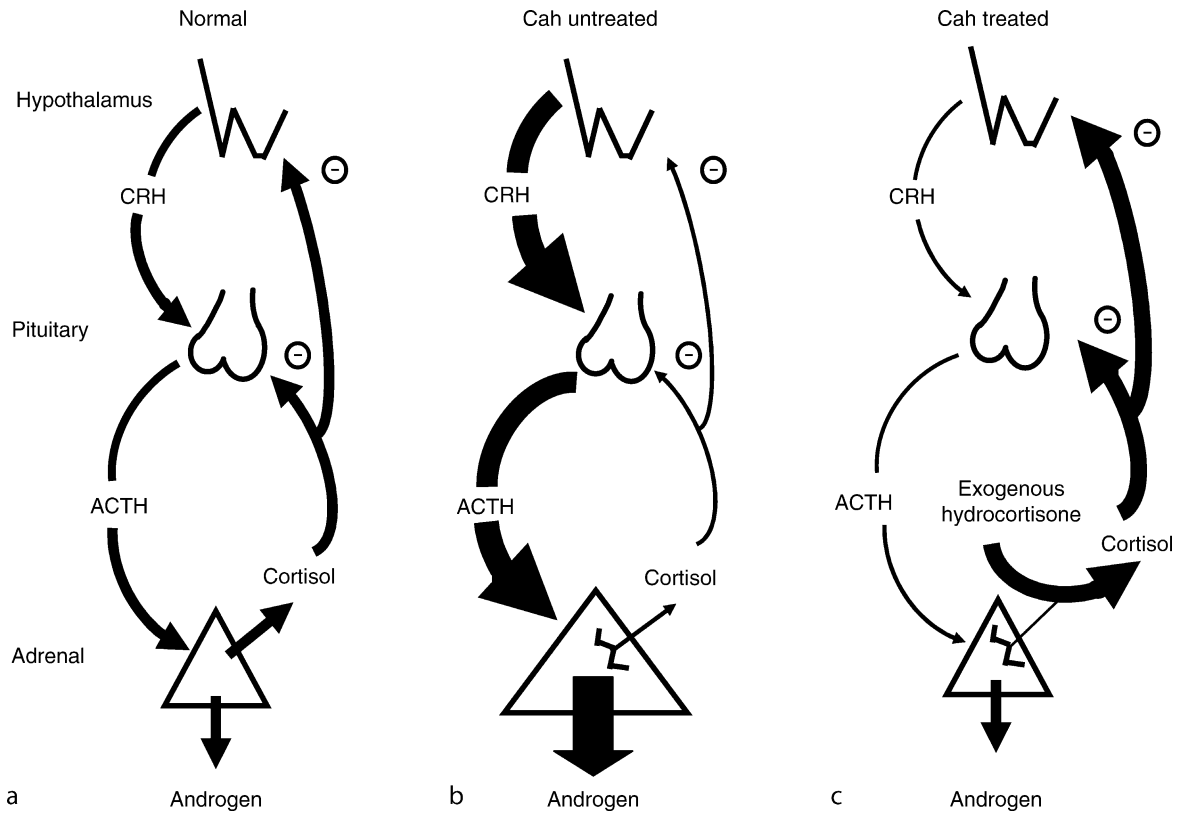


**Steroid 21-Hydroxylase Deficiency. Figure 2** Pathway of adrenal steroid biosynthesis. The shaded area represents steroids whose synthesis is impaired by a defect in the 21-hydroxylase enzyme (21-OH). 21-hydroxylase deficiency leads to accumulation of the precursor 17-hydroxyprogesterone, which results in increased androgen production.

also stimulates the hypothalamic-pituitary-adrenal axis. Both variants of classic CAH, the salt-losing and nonsalt-losing forms, are associated with impairment of aldosterone biosynthesis, but are distinguished by the severity of the defect. Glucocorticoids are also important in the development and regulation of the adrenal medulla, and the adrenomedullary endocrine system has been shown to be impaired in severely affected cases [3].

## Diagnostic Principles

A markedly elevated random 17-hydroxyprogesterone level of greater than 8,000 ng/dL or 242 nmol/L (normal < 295 ng/dL or 9 nmol/L) is diagnostic of classic 21-hydroxylase-deficiency. Typically, salt-losers have higher 17-hydroxyprogesterone levels than nonsalt-losers. Patients with nonclassic CAH may have normal 17-hydroxyprogesterone levels. A 17-hydroxyprogesterone level > 1,500 ng/dL or 45 nmol/L at either 30 or



**Steroid 21-Hydroxylase Deficiency. Figure 3** (a) Normally the adrenal gland produces both cortisol and androgen. The hypothalamic-pituitary-adrenal axis is controlled by negative feedback. (b) In the untreated patient with CAH, a block in cortisol biosynthesis leads to a buildup of cortisol precursors and lack of negative feedback. The combination of accumulated cortisol precursors and increased ACTH results in massive androgen production. (c) Exogenous hydrocortisone replacement reduces androgen production. Supraphysiologic doses of hydrocortisone are often necessary to adequately suppress androgen production. (CRH = corticotropin-releasing hormone).

60 minutes following a corticotropin stimulation test (250 μg of cosyntropin [tetracosactide]) is diagnostic [4].

## Therapeutic Principles

Treatment of classic CAH is intended to reduce excessive ACTH secretion and replace both glucocorticoid and mineralocorticoid hormones [1]. The majority of patients have satisfactory control of androgens with doses of hydrocortisone of 12–20 mg/m$^2$/day in two or three divided doses. Longer-acting glucocorticoids, such as prednisone or dexamethasone, may be used in adults, but they are usually avoided in children because of growth suppression. The goal is to maintain satisfactory control of androgens without total suppression of the hypothalamic-pituitary-adrenal axis in order to avoid iatrogenic Cushing's syndrome. Patients with classic CAH cannot mount a sufficient cortisol response to physical stress and require pharmacological doses of hydrocortisone with significant illness. Mineralocorticoid replacement is accomplished with fludrocortisone (100–200 μg/day) and the dose should be adjusted to maintain plasma renin activity in the mid-normal range. Many patients, especially males, with nonclassic CAH do not require treatment. A glucocorticoid, and/or a combination of the birth control pill and an antiandrogen may be used to treat adult females with nonclassic CAH with signs or symptoms of hyperandrogenism. Patients with nonclassic CAH usually have adequate cortisol and aldosterone production and do not require stress doses of glucocorticoid unless they have iatrogenic suppression of their adrenals due to therapy.

Novel treatment approaches are being investigated for classic CAH. The National Institutes of Health is testing a new treatment regimen consisting of reduced hydrocortisone dose, an antiandrogen and an aromatase inhibitor in a long-term randomized clinical trial. Bilateral adrenalectomy is being performed on select cases. Other promising new treatment approaches include: LHRH-agonist-induced pubertal delay with or without growth hormone therapy, alternative glucocorticoid preparations or dose schedules, CRH antagonist treatment, and gene therapy [5].

[2]Department of Pediatrics, Prince of Wales Hospital, The Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region, People's Republic of China

## Definition and Characteristics

Stevens-Johnson syndrome is characterized by a sudden onset of inflammatory bullous lesions on the skin with epidermal detachment involving <10% of the total body surface area accompanied by involvement of two or more mucosal surfaces [1]. According to a consensus classification, patients with epidermal detachment area >30% are classified as having toxic epidermal necrolysis whereas between 10 and 30% as having Stevens-Johnson syndrome-toxic epidermal necrolysis overlap [2]. Some patients have a prodromal period of 1–14 days. During the prodromal period, affected patients may have fever, malaise, headache, myalgia, and arthralgia. Skin lesions are often symmetrical and consist initially of erythematous macules with purpuric centers (targetoid lesions) on the face, trunk, and extensor surfaces of the extremities [1]. These macules rapidly develop central necrosis to form vesicles, bullae, and areas of denudation. New lesions appear in crops. The affected skin is tender. In response to gentle shear pressure, the affected skin becomes wrinkled and peels off like wet tissue paper (Nikolsky sign). The oral mucosa is almost always affected. Sore throat and a burning sensation and erythema of the lips are often the presenting sign, followed by the development of bullae, ulceration and hemorrhagic crusting of the lips (Fig. 1).

Ocular involvement occurs in ~70% of patients and consists of purulent conjunctivitis, pseudomembrane formation, corneal ulceration, keratitis, anterior uveitis, and panophthalmitis. Mucosal involvement may also occur on the anogenital, esophageal, gastrointestinal,

**Stevens-Johnson Syndrome. Figure 1** A 2-year-old boy with Stevens-Johnson syndrome. Note the erythematous macules on the face and hemorrhagic crusting of the lips.

and tracheobronchial mucosa. Generalized lymphadenopathy is usually present and hepatosplenomegaly may occur. Complications include sepsis, dehydration, electrolyte imbalance, pneumonia, bronchiolitis obliterans, myocarditis, hepatitis, pancreatitis, enterocolitis, cutaneous dyschromia, cutaneous scarring, nail dystrophy, ocular scarring, joint contractures, and strictures of the urethra, anus, vagina, and esophagus. The mortality is about 5% for Stevens-Johnson syndrome and 10–15% for Stevens-Johnson syndrome-toxic epidermal necrolysis overlap.

### Prevalence

The incidence is approximately one to six cases per million persons per year [1]. The peak incidence is in the second decade of life. Immunocompromized patients and individuals with antigens HLA-B*1502, HLA-B*5801, HLA-Bw44 and HLA-DQB1*0601 and those who have a decreased capacity to detoxify reactive intermediate drug metabolites are more susceptible [3].

### Genes

No specific gene has been identified.

### Molecular and Systemic Pathophysiology

Stevens-Johnson syndrome represents a severe hypersensitivity reaction to drugs (e.g. sulfonamides, lamotrigine, aromatic anticonvulsants, or non-steroidal anti-inflammatory agents) or less commonly, infectious agents (e.g. mycoplasma pneumoniae, herpes species) [4]. The typical interval between onset of drug therapy and Stevens-Johnson syndrome is between 1 and 3 weeks [4]. Activated T lymphocytes and macrophages are the main triggers of mucocutaneous damage [5]. These triggers could activate CD95 (fas) ligand. Binding of this ligand to a CD95 (fas) apoptotic receptor located on the surface of keratinocytes may lead to apoptosis which causes separation of the epidermis from dermis [2,4]. Activated T lymphocytes could also lead to massive necrolysis by secreting perforin, granzyme B, and cytokines such as interleukin-6 and tumor necrosis factor-α [5].

### Diagnostic Principles

The diagnosis is mainly clinical. Nonspecific laboratory abnormalities include leukocytosis, eosinophilia, proteinuria, hematuria, elevated erythrocyte sedimentation rate, and elevated C-reactive protein. Differential diagnoses include erythema multiforme, toxic epidermal necrosis, staphylococcal scalded skin syndrome, pemphigus vulgaris, Kawasaki disease, herpangina, and Behçet syndrome. In case of doubt, a skin biopsy can be performed which typically shows necrosis of the lower epidermal cells and interface dermatitis.

### Therapeutic Principles

Treatment is mainly symptomatic and supportive. If an offending drug is suspected, it should be discontinued as soon as possible. Careful attention to fluid balance, nutritional support, meticulous skin and eye care, pain control, and treatment of secondary bacterial infection are the mainstays of care. Recently, intravenous immunoglobulin 0.5–1 g/kg/day for 3–4 days, given within 4 days of the eruption of the skin lesions, has been shown to be an effective treatment modality [2]. It is suggested that intravenous immunoglobulin works by inhibiting fas and fas ligand, thereby preventing apoptosis of keratinocytes.

## STGD

►Stargardt Disease

## Stickler Syndrome

Jutta Engel
Institute of Physiology, Department II and Tuebingen Hearing Research Center, University Tuebingen, Tuebingen, Germany

### Synonyms

Hereditary arthro-ophthalmopathy; Otospondylomegaepiphyseal dysplasia (only STL2)

### Definition and Characteristics

Autosomal dominant (STL1–3) with variable expressivity and nearly 100% penetrance, characterized by vitreoretinopathy, chondrodysplasia, sensorineural hearing loss; a new form has autosomal recessive inheritance.

### Prevalence
One in 10,000 births.

### Genes
COL2A1 coding for type II procollagen located on 12q13.11–q13.2 (STL1; 1), COL11A1 coding for type α XI procollagen located on 1p21 (STL2; 2), COL11A2 coding for type α2 XI procallagen located at 6p21.3 (STL3; 3), COL9A1 coding for type IX collagen located at 6q13 [1,2].

### Molecular and Systemic Pathophysiology
The classic phenotype (STL1) is caused by mutations in COL2A1, e.g., by premature stop codons [2,3]. Haploinsufficiency in type II collagen results in a membranous anomaly of the vitreous. Characteristics of STL1 are myopia, vitreoretinal degeneration, premature joint degeneration, abnormal epiphyseal development, midface hypoplasia, cleft palate deformity, and variable sensorineural hearing loss. The fibrillar collagen COLXI is a minor cartilage constituent that is a trimer built of three different proteins α1, α2, and α3. STL2 is caused by mutations in COL11A1; affected individuals have the characteristic ocular, auditory, and orofacial features of STL1 [2,4]. Mutations in COL11A2 cause STL3 characterized by the typical facial features of STL, hearing impairment, cleft palate, and mild arthropathy, but ocular defects are absent [2,5].

### Diagnostic Principles
Characteristic features are congenital anomaly of vitreous body (initially optically empty vitreous, followed by fibrillar degeneration and liquefaction), myopia (onset <6 years of age, typical range of 8–18 diopters), radial perivascular retinal degeneration, retinal detachment, cataract, glaucoma. Extraocular features are joint hypermobility, sensorineural hearing loss, midline clefting.

### Therapeutic Principles
Neither gene therapy, pharmacological therapy nor dietary therapy is available. Other treatments are prophylactic: prevention of retinal detachment (laser photocoagulation or cryotherapy depending on the size, number, and location of breaks) or symptomatic: cleft palate repair; cataract extraction; glasses; hearing aid.

►Arthro-Ophtalmopathy, Hereditary
►Hearing Impairment, Syndromal

## Stickers Disease

►Fifth Disease

## Stiff-Baby Syndrome

►Hyperekplexia, Hereditary

## Stiff Esophagus

►Esophagitis, Eosinophilic

## Stiff Man Syndrome

Hans-Michael Meinck
Department of Neurology, University of Heidelberg, Heidelberg, Germany

### Synonyms
Stiff person syndrome; SMS

## Definition and Characteristics

SMS is a sporadic neurological disorder of adulthood comprising fluctuating symmetric muscle rigidity, superimposed spasms, disturbance of gait and exaggerated startle. Psychiatric (task specific phobia), autonomic (diaphoresis, tachycardia, arterial hypertension) and orthopedic (skeletal deformities, particularly kyphoscoliosis) symptoms and signs may associate. SMS develops insidiously over months and remains stable over years or even decades thereafter. Firm neurological signs are usually absent, but some 70% of patients harbor serum autoantibodies against glutamic acid decarboxylase (GAD-abs) [1].

*Variants of SMS*: (i) Stiffness and spasms confined to one limb (stiff limb syndrome, SLS). (ii) SMS in company with firm neurological signs such as myoclonus, ocular motor disturbance, ataxia or epilepsy (progressive encephalomyelitis with rigidity and myoclonus, PERM). (iii) SMS associated with both, malignancies (mainly breast cancer) and autoantibodies against the synaptic vesicle protein, amphiphysin (paraneoplastic SMS, pSMS) [1].

## Prevalence

SMS is uncommon, and its variants PERM, SLS and pSMS are even rare. Exact figures on the prevalence are not available [1].

## Genes

SMS is a sporadic disorder that is however frequently associated with the HLA haplotypes $DR_3$ and $DQB_{1*0201}$ [2].

## Molecular and Systemic Pathophysiology

The majority of patients with GAD-abs develop endocrine autoimmune disorders such as type 1 diabetes mellitus (IDDM) or Hashimoto thyroiditis [1]. Autoimmune endocrinopathies as independent diseases, particularly IDDM are likewise associated with GAD-Ab. However, both subclasses of GAD-abs and their epitope recognition differ between SMS and IDDM [2]. Moreover, most patients with SMS and its variants have alterations in the cerebrospinal fluid including intrathecal de novo synthesis of GAD-abs, suggesting autoimmune mediated encephalomyelitis [1].

*Molecular Pathophysiology*: The exact role of GAD-abs in the pathogenesis of SMS is poorly understood including the development of anti-GAD autoimmunity and its spread into the CNS and the antibody-antigen reaction with GAD, a cytosolic target. GAD is the rate-limiting enzyme in the synthesis of the major inhibitory transmitter, GABA. In the presence of GAD-abs, the in vitro synthesis of GABA is reduced in a dose dependent manner [3] and GABAergic synaptic transmission is attenuated [4]. Correspondingly, many authors believe that the symptoms of SMS reflect an immune mediated attenuation of GABAergic inhibition. Moreover, injection of serum from a pSMS patient into rats caused transient neurological symptoms resembling SMS [5].

*Systemic Pathophysiology*: Involuntary continuous motor unit activity is the electromyographic correlate of muscle rigidity and suggests that the central drive onto the spinal α-motoneurons is increased. Proprioceptive stimulation reveals normal results whereas exteroceptive stimulation causes massive and long-lasting spasms, often with a hypersynchronous (i.e. myoclonic) onset. A variety of neurophysiological alterations such as abnormal brainstem reflexes often lack a clinical correlate, but suggest widespread affection of the CNS even in cases with a seemingly circumscribed movement disorder [1].

## Diagnostic Principles

Ancillary tests diagnostic for SMS are not available. The unique combination of characteristic clinical symptoms and signs, abnormal electromyography and the presence of GAD-abs or amphiphysin-abs support diagnosis. Cerebrospinal fluid analysis (IgG index, oligoclonal bands, GAD-abs) specifically confirms autoimmune encephalomyelitis [1].

The most frequent differential diagnosis is psychogenic movement disturbance. Paraneoplastic encephalomyelitis and other uncommon causes of symmetric axial rigidity such as spinal arteriovenous malformation, axial dystonia or atypical multiple sclerosis must be excluded. Cases with the tentative diagnosis PERM require extensive ancillary tests to rule out other diagnoses.

## Therapeutic Principles

Gene therapy or dietary treatments are not available. Symptomatic treatment with anti-spastic drugs, benzodiazepines or anticonvulsants aims at attenuating both excess motor activity (stiffness, spasms, hyperekplexia) and task specific phobia.

Immunomodulation with repeated high dose i.v. immunoglobulins or with front-loaded long term p.o. prednisolone attempts to suppress the enhanced immune response [1].

## Stomatitis

Amei Ludwig, Hartmut Hengel
Institute for Virology, Heinrich-Heine-University Duesseldorf, Germany

### Synonyms

Acute inflammation of the oral cavity (Gingivostomatitis acuta)

### Definition and Characteristics

Stomatitis manifests as a local inflammation due to viral, bacterial, or fungal infection or as the symptom of a broad range of dermal and systemic diseases, such as infectious, autoimmune, and neoplastic diseases. In addition, traumatic or thermic injury as well as chemical burn and oral toxicity of chemotherapy and radiotherapy frequently leads to stomatitis. Rare causes of stomatitis are intoxication with metals, such as thallium or mercury. Autoimmune-mediated stomatitis should be considered as differential diagnosis and includes diseases such as ►Behcet's syndrome, ►systemic lupus erythematodes, ►bullous pemphigoid, or ►pemphigus vulgaris. Stomatitis is further associated with erythema multiforme and other drug-induced systemic blistering diseases.

Stomatitis shows the classical features of inflammation (redness, swelling, bleeding) and manifests with foetor ex ore, hypersalivation, and sometimes blisters. Ulcerations are often seen and can be divided into aphthous lesions, aphthoid lesions, and ulcers of heterogenous origin. Aphthoses are painful oral lesions, which appear as shallow, round to ovoid ulcers with a grayish base surrounded by an erythematous halo. A "benign" type of aphthosis is clinically differentiated from a "pernicious" type, such as Behçet disease. Morphological features of aphthoid lesions resemble those of real aphthous erosions, but, in contrast to these, often show a grouped distribution [1].

### Prevalence

The most frequent inflammatory lesion of the oral mucosa is benign recurrent aphthae with approximately 10–15% of the population afflicted.

### Molecular and Systemic Pathophysiology

*Recurrent Aphthous Stomatitis*: Benign recurrent aphthae ("recurrent aphthous stomatitis" or "canker sores") is typically painful, making eating and speaking difficult. There are three clinical forms including aphthous minor, aphthous major, and herpetiform aphthous. The most important differential diagnosis is recurrent herpes (cold sores). The etiology of recurrent aphthous stomatitis (RAS) remains unknown, although an immunpathogenesis involving production of TNF-α by T cells has been proposed. An elevated cytotoxicity of lymphocytes for epithelium suggests a strong role for these cells in the pathogenesis of recurrent aphthous stomatitis. A possible cross-reactivity between the 60-kDa heat shock protein (hsp60) of oral streptococci (Streptococcus sangui) and oral mucosal hsp60 has been suggested, and reactivity to hsp-derived peptides has been observed in gamma-delta T cells and cytotoxic CD8+ lymphocytes [2]. Triggers that may excite the development of RAS include stress, hormonal factors, infections, vitamin, and trace element deficiencies.

*Infectious Stomatitis*: Numerous infectious agents can present with intraoral manifestations [2]. Important causes include HSV (recurrent herpes and herpetic gingivostomatitis as primary infection), coxsackievirus (herpangina and hand-foot-mouth disease), HIV (primary HIV infection may demonstrate with painful mucocutaneous ulcerations), syphilis, bacterial pharyngitis (i.e., steptococci infections and Plaut-Vincent's angina), EBV, and VZV. Oropharyngeal candidiasis (thrush) is a common condition in immunocompromised patients or diabetics. A pseudomembraneous form is clinically distinguished from an atrophic form. According to the CDC Classification System for HIV-infected adults and adolescents, thrush is one of the

**Stomatitis. Table 1** Mucositis/Stomatitis

| Grade | Clinical examination | Functional/symptomatic |

category B symptomatic conditions. Noma or gangraenous stomatitis is an acute, fulminating infection of the oral and facial tissue in the presence of severe malnutrition and often associated with measles, typhus, and HIV infection or AIDS. Fusospirochetal bacteria are often cultured from noma lesions, although the cause of the disease still remains unknown [2]. Without antibiotic treatment, noma is a life-threatening disease.

*Stomatitis in the Immuncomprised Host*: The severity of stomatitis due to chemotherapy (i.e., Methotrexat) or radiotherapy can be classified by using the National Cancer Institute Common Toxicity Criteria (NCI-CTC v3.0) of the year 2003 (see table 1).

The pathophysiology of oral mucositis due to cytotoxic therapy has been proposed to take place in a series of phases: 1. initiation (damage of cells with a high mitotic index by cytotoxic therapy); 2. inflammatory phase (production of proinflammatory cytokines, such as IL-1, TNF-α, on response to cytotoxic therapy); 3. epithelial phase (accelerated apoptosis and diminished cell renewal); 4. ulcerative phase (overt mucositis with clinical painful lesions); 5. healing phase (recurrent cell regeneration) [3]. Together with neutropenia, mucositis facilitates secondary infection, which can lead to blood-stream invasion and systemic infection.

## Diagnostic Principles

Diagnostic principles include anamnestic and clinical investigation. Laboratory diagnostics should cover microbiological, viral, and serological diagnostics, including diagnosis by culture, PCR, antigen detection, or histopathological techniques if required. Tests for HSV, HIV, EBV, VZV, and treponema pallidum as well as smears of scrapings for candida pseudohyphae may be performed.

## Therapeutic Principles

Recurrent aphthous stomatitis normally shows spontaneous healing within 2 weeks, but may demand symptomatic relief. Caution must be exercised in the administration of topical or systemic steroids, which might be beneficial in patients with extensive disease.

Gingivostomatitis herpetica often requires local pain relief with anesthetic applications. In the initial stage, aciclovir may be indicated.

Management of stomatitis in the immunocompromised patient includes frequent saline rinses and the use of mucosal coating agents. Topical antiseptic and anesthetic applications are usually prescribed. To manage pain associated with mucositis, both topical and systemic approaches might be performed. Severe cases may require parenteral nutrition therapy. The finding of infectious agents may justify the use of anti-infectious substances. To prevent oral mucositis during myelotoxic therapy, Palifermin (Kepivance), a recombinant keratinocyte growth factor (KGF), can be administered. KGF binds to the KGF receptor resulting in proliferation, differentiation, and migration of epithelial cells.

## Definition and Characteristics

Uniconcave erythrocytes giving the appearance of a "stoma" in the center of the cell on the peripheral blood smear, either congenital or acquired, mostly with decreased surface to volume ratio due to increased cell volume (overhydration), producing varying degrees of hemolysis as well as vasoocclusive manifestations. Some variant stomatocytic disorders are characterized by cell dehydration [1,2].

## Prevalence

Acquired forms are rare with data limited to case reports.

## Genes

Hereditary stomatocytosis (HS) with overhydration refers to an autosomal dominant hemolytic anemia associated with absence of band 7.2 which has been, a protein of unknown function on the cytoplasmatic red cell membrane [1]. Band 7.2 absence alone does not account for stonratocytosis with overhydration and its molecular basis is not elucidated [1–3]. Variants (such as hereditary xerocytosis [HX] and pseudohyperkalemia) associated with cell dehydration are linked to 16q23–q24 [3].

## Molecular and Systemic Pathophysiology

Erythrocyte membranes are permeable to water. Control of cell volume is regulated via intracellular monovalent cation content. Passive membrane leaks of sodium ($Na^+$) inward and potassium ($K^+$) outward are compensated by active, ATP-dependent ([$Na^+$] outward and [$K^+$] inward) pumps. These active pumps have limited capacity to compensate increments in passive cation leaks. In HS, intracellular $Na^+$ content is increased due to an altered sodium permeability of the red cell membrane. The concomitant increment of water leads to a decrease in surface to volume ratio with macrocytosis and variable hemolysis. Even though it has been suggested that deficiency of band 7.2 leads to HS in some patients, this is not supported in animal studies. In HX there is an increased $K^+$ loss with subsequent cellular dehydration and moderate to severe hemolysis. Two other variants, cryohydrocytosis and pseudohyperkalemic syndrome, are characterized by overhydration and dehydration, respectively. In the latter, erythrocytes exhibit a net loss of $K^+$ at temperatures below 22°C, which leads to the laboratory artifact of hyperkalemia. Acquired forms of stomatocytosis are associated with Rh-null disease, Tangier disease, in patients receiving vinka alkaloids, and in acute alcoholic disease. Interestingly, stomatocytes show increased endothelial adherence, which can lead to manifest vasoocclusive thrombotic complications analogous to sickle cell syndromes [2]. Such events seem to occur more frequently in splenectomized individuals, due to a larger number of circulating stomatocytes [1,4].

## Diagnostic Principles

Suspect in individuals with hemolysis and stomatocytes in the peripheral blood smear. A high mean corpuscular volume (MCV) with low mean cellular hemoglobin concentration (MCHC) is suggestive of overhydrated forms, whereas a normal MCV with increased MCHC would suggest dehydrated forms. In specialized laboratories, cellular $Na^+$ and $K^+$ can be measured. Osmotic fragility is increased in overhydrated forms [1].

## Therapeutic Principles

Often symptoms are mild, and general supportive measures (folic acid supplementation) suffice. As thrombotic events seem to occur especially after splenectomy, the decision to undertake such a measure with the goal of reducing transfusion requirement should be taken with extreme caution [4].

## Stress and Cardiovascular Risk

Giora Z. Feuerstein, Xinkang Wang
Wyeth Research, Discovery Translational Medicine, Collegeville, PA, USA

### Definition and Characteristics

Stress is defined as a condition of extended and exaggerated physiological, mental or emotional functions due to unusual circumstance. Stress conditions are associated with hormonal, neural and psychogenic factors and carry genetic predisposing factors. Stress conditions can be acute (short lasting) to adjust transient conditions or chronic situations leading to diverse diseases. Chronic stress is a key risk factor for cardiovascular diseases, such as heart attack and stroke, immune disease (infections and autoimmune diseases) and neuropsychiatric disorders.

### Prevalence

Statistical data on the prevalence of chronic stress related diseases are not available. Epidemiological studies estimated lifetime prevalence rates for anxiety/panic disorder (2.3–2.7%), generalized anxiety disorder (4.1–6.6%), obsessive compulsive disorder (2.3–2.6%), posttraumatic stress disorder (1–9.3%), and social phobia (2.6–13.3%) in USA [1]. Sufficient clinical and epidemiological data suggest that various psychological and social stressors promote the development or worsening of heart disease. The combination of preexisting vulnerability and major stressors (e.g., under acute setting) is believed to result in cardiac death due to arrhythmias and atherosclerosis [2].

### Molecular and Systemic Pathophysiology

Two main neurohormonal systems have been emphasized as key mediators of the stress syndrome. The first system that was identified is the hypothalamic-pituitary-adrenocortical (HPA) axis and the second, the sympatho-adrenomedullary system (SAS). These two systems provide effective adaptation to acute stress condition such as acute physical and mental conflicts. Under chronic stress conditions, however, the balance and regulation of the HPA axis and the SAS are disrupted, resulting in harmful effects on human health due to deregulated levels of steroids such as glucocorticoids (GCs), mineralocorticoids (MCs) and other hormones such as estrogen (ER) [3]. These steroid hormones play an important role in regulation of the cardiovascular system by affecting fluid volume, blood pressure and cardiac function. GCs, MCs and ER achieve their action through binding to their respective nuclear receptors, the glucocorticoid receptor, mineralocorticoid receptor and estrogen receptor resulting in stress-related gene expression, stress-activated signaling pathways (e.g., phosphoprotein kinases), stress-activated heat shock proteins and redox (oxidative stress systems) enzymes that are essential in maintaining multi-organ homeostasis [4].

### Diagnostic Principles

The diagnostics of stress and its association with cardiovascular risk is complicated. No diagnostic

laboratory tests are available for diagnosis of major depressive disorder. Currently, psychiatric exam and psychological tests (e.g., Minnesota Multiple Personality Inventory) are used to assess the psychological component of stress. Neuro-imaging technologies are being developed (such as functional magnetic resonance imaging (fMRI)) to objectively evaluate brain responses to stress. The chemical, physical and biological biomarkers of stress can be diagnosed based on laboratory analytical technologies, e.g., blood levels of pituitary hormones (ACTH), adrenal gland hormones (cortisol, adrenaline), and thyroid gland hormones (thyroxine). The diagnostics of cardiovascular risk factors associated with chronic stress are being developed using various imaging modalities (e.g., intravascular ultrasound and magnetic resonance imaging) and/or circulating blood biomarkers (e.g., C-reactive protein) for high-risk atherosclerotic plaques and patients.

### Therapeutic Principles

Life style modifiers and psychotherapy are important factors in reducing stress-associated emotional, mental and physical disorders. Behavioral modifiers of attitudes leading to productive changes in perceptions and perspectives of self and its contextual social framework usually require skilled psychotherapy support. Pharmacological agents that reduce anxiety, mitigate depression and alleviate exaggerated reactive tendencies are available via psychiatric consultations. Such agents include drugs that modulate brain neurotransmitters function- selective serotonin/norepinephrine reuptake inhibitors (SSRI or SNRI), GABA (diazepines) and dopamine (phenothiazines). Combination of behavioral, social and pharmacological modalities are often needed to effectively intervene with stress associated disorders.

## Subaortic Stenosis

Ivor L. Gerber
Department of Cardiology, Green Lane Cardiovascular Service, Auckland City Hospital, Auckland, New Zealand

### Synonyms

Membranous, discrete, or fibromuscular "tunnel" subaortic stenosis; SAS

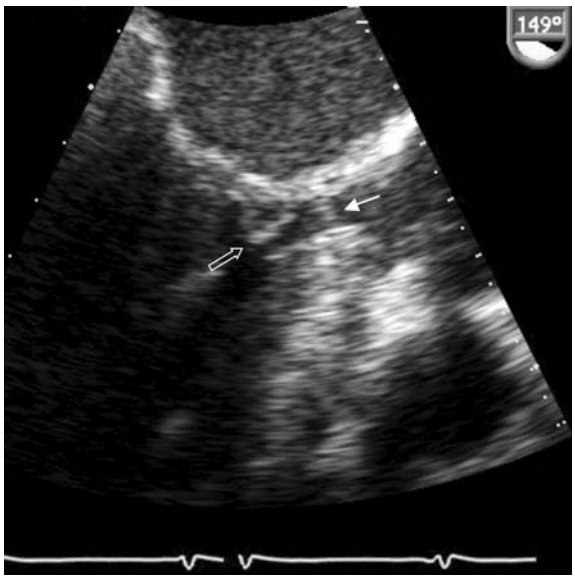
### Definition and Characteristics

Subvalvar aortic stenosis (SAS) spans a spectrum of anomalies in the left ventricular outflow tract (LVOT). In the majority of cases (~80%), a fibrous crescent or ring completely encircles the LVOT, producing a discrete obstructive lesion. In its less common but more severe form, a fibromuscular band involving the whole length of the LVOT produces a diffuse, tunnel-like narrowing. Additional subaortic anomalies may also occur and contribute to LVOT obstruction including abnormal septal insertion of the mitral valve, accessory mitral apparatus tissue, anomalous papillary muscle, anomalous muscular bands in the LVOT, muscularization of the anterior mitral leaflet, and posterior displacement of the infundibular septum (Fig. 1) [1].

Other associated congenital cardiac anomalies occur in ~50% of cases, most commonly a ventricular septal defect, coarctation of the aorta, patent ductus arteriosus, atrioventricular septal defect, and a bicuspid aortic valve. In most cases, SAS occurs as a secondary lesion years after the surgical repair of the associated cardiac anomaly. Aortic regurgitation (AR) is a common consequence of SAS but it is usually mild. The AR is due to thick fibrous tissue on the LV surface of the valve leaflets. The fibrosis is caused by repetitive trauma from a jet of blood through the SAS or by the proliferation of the fibroelastic membrane itself. Infective endocarditis may complicate the condition.

### Prevalence

SAS accounts for 8–30% of cases of congenital LVOT obstruction and has an estimated prevalence of 6.5% in adults with congenital heart disease.



**Subaortic Stenosis. Figure 1** A transesophageal echocardiographic image showing a severely crowded left ventricular outflow tract due to a combination of a subaortic membrane (*solid arrow*), systolic anterior motion of a thickened mitral chord (*open arrow*) and septal hypertrophy (27 mm).

### Genes

SAS is considered an acquired cardiac defect of postnatal development, as it does not appear during embryologic development of the heart and occurs very rarely in the neonatal period. Familial cases suggesting autosomal dominant and autosomal recessive inheritance have rarely been reported implying a genetic predisposition, although no specific genetic defect has been identified [2]. A genetic predisposition to the development of SAS has been documented in Newfoundland dogs, although the results of breeding experiments were not consistent with any simple genetic hypothesis, and indicate that SAS is inherited as a polygenic trait or as an autosomal dominant trait with modifiers.

### Molecular and Systemic Pathophysiology

The etiology and pathophysiology of SAS has not been clearly defined. The progressive nature of SAS is hypothesized to be related to the complex relationship between genetic predisposition, anatomic substrate, local shear stress, and the response to injury. It is likely that the events begin with an underlying morphological abnormality, such as a steep aortoseptal angle, which is associated with a genetic predisposition and results in cellular proliferation when exposed to altered septal shear stresses. Mechanical stresses have been shown to alter the structural and functional properties of cells by mechanotransduction. The stresses are converted to

electrophysiological and biochemical responses in the sensing cell and this is followed by adaptation of the cells to external forces by altered gene expression [3]. SAS has a variable rate of progression. Progression can be very rapid in infants and small children, while the obstruction progresses much more slowly in adults.

### Diagnostic Principles

Diagnosis is usually confirmed by echocardiography. The severity is determined by the 2-D appearance of the lesion and the measurement of a gradient. Cardiac catheterization with direct measurement of the gradient is rarely required. Associated cardiac anomalies should also be looked for.

### Therapeutic Principles

The timing of intervention and choice of surgical technique is controversial. Some authorities advocate an early operation even in the absence of symptoms to prevent aortic valve damage, while others adopt a more conservative "wait and see" approach. Surgery should be considered when a resting gradient by cardiac catheter or a mean gradient by echocardiography >50 mmHg is demonstrated, symptoms develop, or if combined with progressive AR which is more than mild. The type of operation depends on the nature of the obstructive lesion but the usual procedure is a membranectomy with a myomectomy. The myomectomy has been shown in some studies to reduce the recurrence rate of SAS. Tunnel-type SAS may require augmentation of the LVOT using the Kono procedure (aortoventriculopasty with aortic valve replacement) or other modifications for enlargement of the LVOT. In general, there is a high postoperative recurrence rate of SAS, occurring in 15–27% of cases that often leads to reoperation. The average time to recurrence is 4–5 years. The completeness of the initial relief of obstruction is the main determinant of recurrence and the recurrence rates are also higher and more rapidly progressive in those with diffuse tunnel-type obstruction. Surgical complications include complete atrioventricular block necessitating a permanent pacemaker, perforation of the interventricular septum, or damage to the mitral valve apparatus causing mitral regurgitation. The development of progressive AR is also seen in 25–40% of cases even after successful relief of obstruction and aortic valve replacement is occasionally required. All patients are at increased risk for infective endocarditis and should receive antibiotic prophylaxis.

## Sucrase-Isomaltase Deficiency

►Sucrose Intolerance

# Sucrose Intolerance

Eric Sibley
Division of Pediatric Gastroenterology, Stanford University School of Medicine, Stanford, CA, USA

## Synonyms

Sucrase-isomaltase deficiency; Congenital sucrose intolerance; Congenital sucrose-isomaltose malabsorption

## Definition and Characteristics

Clinical deficiency of sucrase-isomaltase results in the inability to digest and absorb dietary sucrose. The condition becomes manifest during infancy upon the introduction of sucrose in fruits and juices or glucose polymers in formula. A late onset deficiency has also been described in adults. The inability to digest sucrose results in signs and symptoms of malabsorption including diarrhea, increased gas production, and abdominal distension.

## Prevalence

Sucrase-isomaltase deficiency has been reported to be present with a frequency of 0.2% in North Americans and greater than 10% in Greenland and Alaskan Eskimos. Genetic studies support autosomal recessive inheritance.

## Genes

Sucrase-isomaltase, SI, gene localized on chromosome 3q25-q26.

## Molecular and Systemic Pathophysiology

Sucrase-isomaltase is an intestinal disaccharidase expressed on the apical brush-border membrane of the epithelial cells lining the mucosa of small intestine. The enzyme activity allows for hydrolysis of the disaccharide sucrose to yield the monosaccharides glucose and fructose. Intestinal epithelial cells cannot readily absorb sucrose, the major carbohydrate in most fruits, until the sugar has been hydrolyzed. Sucrase-isomaltase deficiency, therefore, results in intestinal sucrose malabsorption. Several different mutations in the sucrase-isomaltase gene have been described that lead to the synthesis of a transport-incompetent or functionally altered enzyme in patients with sucrose-isomaltase deficiency [1].

## Diagnostic Principles

Diagnosis of sucrose intolerance relies on clinical suspicion in infants and toddlers with severe diarrhea upon ingestion of sucrose in fruits and juices or ingestion of formula that contains glucose polymers. In patients with clinical suspicion of sucrose intolerance, symptoms resolve on a sucrose-free diet and return upon rechallenge. Breath hydrogen testing and determination of sucrase enzyme activity in intestinal biopsies are used in establishing a diagnosis of sucrose intolerance.

## Therapeutic Principles

Treatment for congenital sucrase-isomaltase deficiency consists of avoidance of sucrose in the diet. Sacrosidase, produced from saccharomyces cerevisiae, is a β-fructofuranoside fructohydrolase that hydrolyzes sucrose and has been used in preventing symptoms of intolerance in patients with sucrase-isomaltase deficiency [2].

# Sucrose Intolerance, Congenital

►Isomaltose Intolerance

# Sudden Cardiac Death

►Cardiac Arrest

# Sudden Infant Death Syndrome

Akihiro Takatsu
Department of Forensic Medicine, Jikei University School of Medicine, Tokyo, Japan

## Synonyms

Sudden unexpected death in infancy; SUDI; Cot death; Crib death; SIDS

## Definition and Characteristics

Sudden infant death syndrome (SIDS) is defined as "the sudden death of an infant under one year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history" [1]. Therefore, SIDS is a diagnosis of exclusion. SIDS is not likely a specific disease with a single cause, but is more likely attributable to heterogeneous causes [2]. SIDS is always categorized as natural death. However, it is difficult to exclude unnatural deaths, even when all of the conditions of the SIDS definition are met [3].

## Prevalence

After SIDS was first defined in 1969, the rates of mortality attributed to it have dramatically increased and then declined in western countries, where SIDS currently accounts for about 25% of all infant deaths, in spite of recent declines in SIDS rates of more than 50% [2]. However, the diagnostic ambiguity attributable to changes in the classification and the concept of SIDS, shifting diagnostic preferences of pathologists, and low autopsy rates result in different prevalence rates among these countries.

## Genes

Genetic studies have identified several mutations and polymorphisms pertinent to lethal genetic disorders or possible genetic predispositions in SIDS cases. Extensive research into the A985G mutation in the medium-chain acyl-CoA dehydrogenase (MCAD) gene has been done; however, this mutation was found in less than 1% of SIDS cases. The long QT syndrome (LQTS) is associated with mutations in cardiac ion channel genes (KVLQT1, SCN5A, HERG). These mutations have been identified in 5–10% of SIDS cases [2], suggesting that mutations in cardiac ion channel genes may be the cause of a lethal arrhythmia in some infants. Polymorphisms in the promoter region of the serotonin transporter (5-HTT) gene have been identified in SIDS cases. Serotonin (5-HT), a neurotransmitter, affects a wide range of autonomic functions, such as the regulation of breathing, circulation, temperature, and circadian rhythm. SIDS victims are more likely to have a higher frequency of long (L) alleles of the 5-HTT gene [4]. Mutations in genes pertinent to autonomic nervous system (ANS) dysregulation (PHOX2a, TLX3, RET, ECE1, EN1) and polymorphisms in the interleukin-10 (IL-10) and complement (C4) gene have been identified in SIDS cases. However, these genetic alterations have been identified in only a small percentage of all cases diagnosed as SIDS, and therefore, it is highly improbable that one is common to all SIDS cases [4]. It is clear that cases in which a genetic disorder is found to be the cause of death should not be diagnosed as SIDS, but as an explained sudden infant death.

## Molecular and Systemic Pathophysiology

SIDS cases have no pathognomonic or diagnostic findings at routine autopsy and are often difficult to distinguish from accidental suffocation during sleep. Discussion of various triple-risk hypotheses [5], such as the model proposed by Filiano and Kinney in which the three converging factors resulting in a greater risk for SIDS are a pathophysiologically vulnerable infant in a critical stage in the development of homeostatic control and subjected to one or more environmental stressors, led to the conclusion that SIDS is a complex disorder in which the intersection of biological, developmental, and environmental factors play a crucial role [4]. The most well known are the environmental factors, particularly infant sleeping position, such as the prone facedown sleep position, environments, such as soft bedding, and bed sharing. It is important to note that these factors, singly or in combination, are also potential risks for mechanical suffocation [3]. Biological risk factors, or predisposing factors, including neuropathological abnormalities or ANS dysfunction, such as astrogliosis of the brainstem, neurotransmitter deficiencies, hypoplasia of the arcuate nucleus, and arousal deficiencies, have also been identified in separate SIDS cases. Therefore, pathophysiological factors, mechanisms, and responses differ among SIDS infants.

## Diagnostic Principles

Reliable diagnoses of SIDS according to the current definition are essential to clarify its epidemiology, etiology, research, and prevention [3]. A significant number of accidental or intentional infant deaths as well as those caused by genetic disorders have been misdiagnosed as SIDS. To avoid misclassification of the cause of death as SIDS, all of the following are minimum essentials for a SIDS diagnosis: a complete autopsy, including at least microscopic and toxicological examinations, no evidence of trauma, significant disease or other causes of death, a thorough death scene investigation, and review of the clinical history. The diagnosis of the cause and manner of death has a strong relation to the realization and protection of human rights, and the dignity of the deceased infant and guardian in the legal framework.

## Therapeutic Principles

There is no clinical intervention at present, because it is impossible to identify future SIDS cases at birth. The current achievable goal is to reduce the risk of SIDS. As evidenced by the recent dramatic decline in SIDS mortality in the USA due to the "Back to Sleep" campaign by the National Institute of Child Health and Human Development, the avoidance of environmental risk factors, particularly hazardous sleeping positions and environments, may prevent sudden unexpected

infant death during sleep, including SIDS and accidental mechanical suffocation.

## Suicide

Brigitta Bondy
Section Psychiatric Genetics and Neurochemistry, Psychiatric Hospital of University Munich, Munich, Germany

### Synonyms

Suicidal behavior; Suicidality; Completed suicide; Attempted suicide

### Definition and Characteristics

Suicidal behavior covers a wide spectrum from low lethality usually impulsive, triggered events, to highly lethal but failed suicide attempts and at the extreme to fatal acts (completed suicide). Suicidal ideation, which comprises suicidal thoughts or threats but no action is more common. Its prevalence varies widely, being twice as common in females as in males. Although the exact clinical definition of suicidal behavior remains unsatisfactory and is a source of confusion, the phenomenon of suicidality is often viewed as a continuum of increasing severity ranging from ideation, to attempts, to completed suicide and may be classified according to intent to die, method and lethality (violent or non-violent), cognitive impairments (impulsivity, aggressiveness) or mitigating circumstances. For example, violent methods, assessed with a higher level of lifetime aggression and a higher level of impulsivity, are more often applied by males than by females and are often associated with lifetime substance abuse or dependence [1].

### Prevalence

Suicide is a major cause of death worldwide (2% of the world's death according to the WHO) with the highest annual rates in Eastern European countries, such as Estonia, Latvia, Lithuania, Finland and Hungary and the Russian federation. Completed suicide rates are predominant in males with the exception of China, where suicide rates are higher in females. Attempted suicide has a life time prevalence of about 3.5% and it is estimated that up to 10% of suicide attempters will commit suicide within the following 10 years. Suicide rates are increasing with age for both men and women, but numerically more suicides are committed by younger

people and recent evidence suggests that suicide rates of young people are increasing in many geographic areas. Several explanations have been considered for national and regional variations, including climate, religion and social and political systems, but a more likely scenario is that the genetic contributions to suicide are composed of the small sized effects of many gene variants associated with processes involved in suicidal behavior and by interaction of these genetic factors with environmental ones [2].

## Genes

Genes of the serotonergic system have especially been investigated as possible candidate genes for suicidal behavior. The SCL6A4 gene, coding for the serotonin transporter has a functionally active, 44 bp insertion\deletion polymorphism in its promoter region (5-HTTLPR), resulting in long [l] or short (s) alleles. The s-allele of the 5-HTTLPR seems not to be involved in general suicidal behavior, but in violent and repeated suicide attempts.

Intronic polymorphisms (A218C and A779C) of the tryptophan hydroxylase 1 (TPH1) gene were suggested as a quantitative risk factor for suicidal behavior. Concerning the recently identified, brain specific TPH2 gene, there are positive results for several SNPs indicating a predisposition for suicide, mainly in depression. This however is waiting for confirmation.

The data have further shown that the MAO-A gene, which is consistently associated with impulsive aggressive personality traits, is not related to suicide but might induce violent methods in subjects with other suicide risk factors [3].

## Molecular and Systemic Pathophysiology

Although suicidal behavior might be seen as a disorder on its own, psychiatric disturbances, especially mood disorders are major contributing factors. Further, it is increasingly recognized that a certain individual predisposition, especially impulsive-aggressive personality traits, neuroticism, anxiety and anger related traits are intermediary phenotypes and risk factors for suicidal behavior. As personality traits themselves are partly under genetic control, this may contribute to the well-known familial loading of suicidality. The contribution of susceptibility genes was underlined in twin studies, with monozygotic twin pairs having higher concordance rates (about 14%) for suicidal behavior than dizygotic ones (<1%).

Suicidal behavior is a complex phenomenon involving psychological and biological characteristics. Perspectives on the neurobiological basis of suicidal behavior are now converging on several key areas. The most important among them is a dysfunction within the serotonergic system, which is involved in regulation of mood, anxiety, cognition, impulsivity and aggression and decreased serotonergic tone has repeatedly been correlated with suicide risk in depression. Of further importance are alterations in the hypothalamic-pituitary-adrenal axis (HPA) and an excess activity of the noradrenergic system, which are both involved in the response to stressful life events and in the pathophysiology of depression and might thus have an impact on suicide risk [4,5]. Thus, on the assumption that anxiety and stress response are involved in suicidal behavior, several mechanisms modulating these effects are gaining importance. However, multiple systems play a role in regulating the risk of suicide. From this perspective, the identification of new candidate genes is gaining interest, possibly among those coding for lipid metabolism, as they are demonstrating essential roles for cholesterol in brain synaptogenesis.

## Therapeutic Principles

The management of suicidal behavior involves three principles, primarily the diagnosis and effective treatment of a possibly underlying psychiatric disorder, secondly limited access to the most lethal methods for suicide and thirdly recent efforts to develop a more specific treatment to reduce diathesis or propensity to attempt suicide, involving prophylactic treatment with lithium ions, which seems to reduce suicidal behavior independently from its mood stabilizing effect [4].

# Sulfaturia

Daniel Markovich
School of Biomedical Sciences, University of Queensland, Brisbane, QLD, Australia

## Synonyms

Hypersulfaturia

## Definition and Characteristics

Sulfur is the seventh most abundant element in the tissues of higher vertebrates and its oxidized form, sulfate, is the fourth most abundant anion in blood, with a mean $SO_4^{2-}$ serum concentration of 0.3–0.4 mM, which is finely regulated by renal transport mechanisms [1]. The major sources of sulfate to the body are inorganic sulfate or sulfur-containing amino acids cysteine and methionine, present in ingested food. Dietary $SO_4^{2-}$ is completely and rapidly absorbed by the intestinal tract and fecal losses are negligible [2]. On normal diets, the majority of filtered $SO_4^{2-}$ is reabsorbed, whereas after oral $SO_4^{2-}$ loading (i.e. high protein diets), plasma $SO_4^{2-}$ can increase up to twice normal levels, with excess $SO_4^{2-}$ quickly excreted, leading to sulfaturia [1]. Since sulfate is not extensively bound to serum proteins and the majority of filtered sulfate is reabsorbed, it is believed that sulfate is not secreted to any significant extent in humans. Metabolic acidosis, Vitamin D deficiency, $K^+$ deficiency and the use of NSAIDs, all decrease renal sulfate reabsorption and increase fractional excretion of sulfate, leading to sulfaturia [1].

## Prevalence

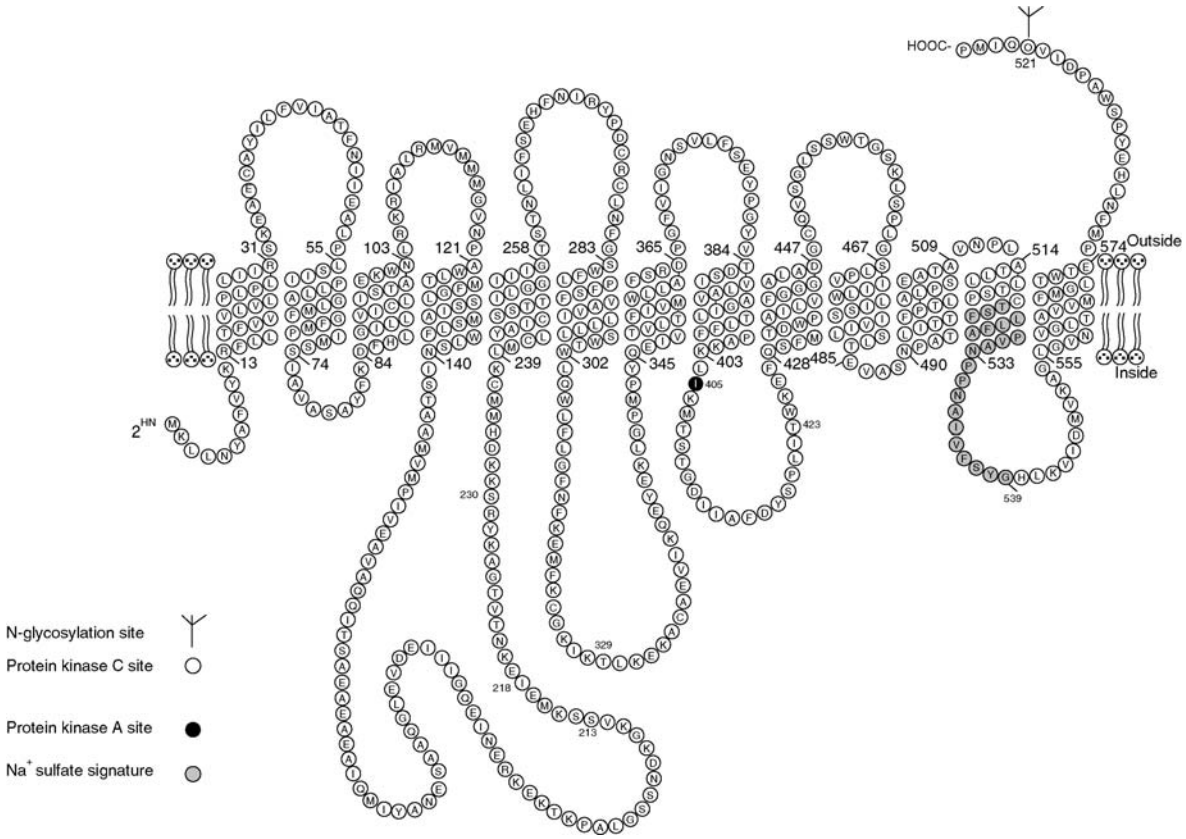
Presently unknown.

## Genes

SLC13A1 or NaS1 ($NaS_i$-1) encodes $Na^+$-sulfate cotransporter localized on human chromosome 7q31 [3].

## Molecular and Systemic Pathophysiology

NaS1 encodes an 66kD plasma membrane protein, which contains 13 putative transmembrane spanning domains [1,3]. Figure 1 shows the predicted secondary structure of NaS1 [1]. NaS1 functions as a sodium-dependent sulfate transporter [1,3], which is competitively



**Sulfaturia. Figure 1** The predicted model for the NaS1 protein.

inhibited by molybdate and tungstate [1,3]. It is mainly expressed on the apical brush border membrane of the renal proximal tubule and additionally in the intestine (mainly ileum and colon) in rodents [1,3]. Due to its location in the renal proximal tubule, NaS1 facilitates renal sulfate reabsorption and thereby regulates plasma sulfate levels [1,4]. Despite no human disorder yet to be linked to NaS1, the loss of the NaS1 protein in the mouse (NaS1 null mouse) leads to hypersulfaturia [4]. The sulfaturia in the NaS1 null mouse arises due to the loss of the NaS1 protein in renal proximal tubule, which results in hyposulfatemia, growth retardation, reduced fertility and seizures [4]. The etiology and mechanisms by which these latter pathologies arise still needs to be determined.

### Diagnostic Principles

Increased urinary sulfate levels (sulfaturia) have been detected in patients with autism, Parkinson's, Alzheimers and Motor Neurone Disease [5]. Blood and urinary sulfate levels are rarely measured in clinical setting, thus the prevalence of sulfaturia in the human population is currently unknown. Ion chromatography or turbidometric assays are used to measure sulfate levels [4,5]. Recently, single nucleotide polymorphisms have been identified in the NaS1 gene, with two SNPs (R12X and N174S) characterized to be loss of function mutations [5], which would lead to sulfaturia.

### Therapeutic Principles

Electrolyte repletion by primarily sulfate supplementation, including cysteine and methionine, would be the main therapy, which will serve to normalize plasma sulfate levels.

### Synonyms

SOD defects

### Definition and Characteristics

There are three types of superoxide dismutase (SOD) in human tissues: CuZnSOD, MnSOD and EC-SOD. CuZnSOD, which is most abundant in liver, kidney, heart, and brain, is located in the cytoplasm, nucleus, and intermembranous spaces (IMS) of mitochondria; the active enzyme is present as a dimer and requires Cu and Zn as cofactors. MnSOD, which is most abundant in heart and brain, is located in the matrix of mitochondria; the

active enzyme is present as a tetramer and requires Mn as the cofactor. EC-SOD, which is most abundant in the vasculature and the airway of the lung, is located extracellularly; the active enzyme is present as a tetramer and requires Cu and Zn as cofactors.

SOD mediates the conversion of superoxide radicals ($O_2^-$) into hydrogen peroxide ($H_2O_2$) and oxygen (eq 1). The resulting $H_2O_2$ is then converted into $H_2O$ by catalase and peroxidases. During the catalytic process, the electron transfer to and from $O_2^-$ is mediated through Cu or Mn. The rate constant for SODs at the physiological pH is in the order of $10^9$/M/s.

## Prevalence

SOD1 mutations are found in ~20% of individuals with familial amyotrophic lateral sclerosis (ALS) and ~3% with sporadic ALS. Since the incidence of ALS is $\sim 2 \times 10^{-5}$ and 5–10% of ALS is familial, the incidence of causative SOD1 mutations is $\sim 0.2–0.4 \times 10^{-6}$ per year.

## Genes

The gene designations and chromosomal locations of human CuZnSOD, MnSOD, and EC-SOD are SOD1, SOD2, and SOD3, and chromosome 16, 17, and 4, respectively.

## Molecular and Systemic Pathophysiology

*Human Disorders Resulting from SOD1 Mutations*: Mutations in SOD1 have been associated with a familial form of motor neuron disease, amyotrophic lateral sclerosis. The mutations are usually missense mutations in the coding region. It is generally accepted that the mutations result in a gain-of-function, which leads to a selective degeneration of motor neurons. To date, more than 130 mutations in SOD1 associated with ALS have been identified, but patients with SOD1 mutations account for only 1–2% of the total ALS population. Mutations and polymorphisms in SOD2 and SOD3 have not been associated with ALS.

*SOD2 and SOD3 Polymorphisms and Associations with Human Disease*: A few polymorphisms have been identified in SOD2 and SOD3. Most notable is the Ala(-9)Val polymorphism in the mitochondrial targeting sequence of MnSOD, which would affect the trafficking of MnSOD into mitochondria. Whereas the presence of the Ala allele has been associated with increased risk for breast cancer [1], the presence of Val allele is correlated with higher frequencies of diabetic nephropathy and diabetic neuropathy [2,3]. The Ile58Thr polymorphism affects the tetrameric interface stability of MnSOD. However, no specific human disease has been associated with this polymorphism. A change of Arg213 to Gly in EC-SOD leads to a tenfold increase in the serum level of EC-SOD. Whereas the presence of Gly allele has been associated with increased risk for ischemic heart disease (IHD) in the Copenhagen City Heart Study, the presence of Gly allele has also been shown to protect against the development of chronic obstructive pulmonary disease (COPD) in cigarette smokers [4].

*Disorders Associated with SOD Null Mutations in Mice*: Null mutations of the SODs have not been identified in the human population. However, mouse models with null mutations have been created for each of the SOD genes. The Sod2 null mutation leads to an early demise with a phenotype that includes dilated cardiomyopathy, fatty liver, neurodegeneration, and mitochondrial defects. Sod1 and Sod3 null mice, on the other hand, have no overt phenotype during development and for the majority of their adult lives. However, mice lacking CuZnSOD have an increased incidence of hepatocellular carcinoma and accelerated muscle atrophy as they age, and the females have reduced fertility. Mice lacking EC-SOD, on the other hand, have impaired learning and memory and reduced neurogenesis in the subgranular zone of hippocampus.

*Effects of Altered SOD Activities on Resistance to Oxidative Stress*: Increased sensitivity to oxidative stress is a common theme among all types of SOD deficient mice. Whereas CuZnSOD and MnSOD deficient mice (Sod1−/−, Sod1−/+, and Sod2−/+) have been shown to be more sensitive to brain ischemia-reperfusion injury, EC-SOD deficient mice (Sod3−/−) are more sensitive to hyperoxia. On the other hand, transgenic mice with increased levels of SOD are usually more resistant to acute oxidative insults. However, certain aspects of Down syndrome phenotype have been attributed to the long-term effects of elevated levels of CuZnSOD. In addition, although elevated levels of EC-SOD in young SOD3 transgenic mice cause an impairment of long-term potentiation and associative memory, aged SOD3 transgenic mice are protected against age-related decline in spatial memory.

*Relationship of SOD Activities to Aging/Longevity*: Although increased levels of SOD in non-mammalian organisms have been shown to correlate with extended lifespans, the relationship between SOD activity and mammalian longevity and aging has been more difficult to interpret. Whereas increasing the level of CuZnSOD in transgenic mice does not lead to an extension of lifespan, increasing the level of CuZnSOD in transgenic rats significantly extends their lifespan. Furthermore, although the early demise of mice lacking MnSOD supports the importance of MnSOD in maintaining the viability, a 50% reduction in MnSOD activity (in Sod2−/+mice) does not lead to a reduced lifespan despite an increase in oxidative injury.

### Diagnostic Principles

Testing for SOD1 mutations is performed in familial cases of ALS and may be performed in sporadic cases, with mutations detected in 20 and 3%, respectively. Testing for SOD1 mutations by sequence analysis in available in several clinical laboratories, but no testing is available for SOD2 or SOD3 variants (and would not be clinically useful if it were).

### Therapeutic Principles

No specific therapies are available for ALS caused by SOD1 mutations. However, a variety of experimental therapies are being tested in animal model systems, the most promising of which employ siRNAs directed against the mutant SOD1 [5].

### Synonyms

Neurosyphilis; Neurolues; Tabetic, paretic, and meningovascular neurosyphilis; Syphilitic meningitis (primosecondary stage); Syphilis cerebrospinalis

### Definition and Characteristics

Infection by Treponema pallidum (T.p.) induces syphilis – a multistage complaint with varying organ manifestations und courses. Syphilitic involvement of central nervous structures may occur in all stages after infection. Syphilitic meningitis in the primosecondary stage results in headache, nausea, vomiting, and stiff neck, at times combined with cranial nerve alterations (predominantly nerves II, VII, and VIII). Patients are usually afebrile. Laboratory indicators of inflammation such as increased sedimentation rate or C-reactive protein are mostly absent as are intrathecally synthesized antibodies against T.p.

CNS manifestations of tertiary syphilis are meningovascular neurosyphilis (syphilis cerebrospinalis), general paresis, and tabes dosalis. Meningovascular neurosyphilis usually occurs 4–7 years after infection. The inflammatory process subacutely takes place on meningeal and vascular tissues of the CNS, in some cases mainly cerebral while in others mainly spinal. Meningovascular neurosyphilis is extraordinarily variable. Early symptoms are vision impairment, vertigo, mono- or hemipareses (with stroke-like onset), headache, hearing loss, gait disturbances, and behavioral deviations. In progressed stages, syndromes of brain stem/cranial nerves (e.g., eighth cranial nerve), hemisyndromes, syndrome of chronic meningitis, spinal syndromes, epilepsy, and dementia may exist.

Tabetic neurosyphilis (tabes dorsalis) presents with a well-defined syndrome, characterized by episodic lightning pains, absent ankle and knee jerks, abnormal pupils (up to 66%), hyperflexibility of the hip joints, pallhypesthesia, gait disturbances, atonic bladder, and optic nerve atrophy. Most frequent initial symptoms are lightning pains, impairment of the vision, "locomotor" ataxia, gastric and visceral crises, paraesthesias, and vertigo.

Paretic neurosyphilis (general paresis, dementia paralytica) develops as a result of a chronic progressive meningoencephalitis about 10–20 years after T.p. infection. Initially, there are slight behavioral changes, subtle deterioration in cognitive functions, dysarthria, complaints of headache, and vertigo. Progressed complaint presents with organic brain syndrome, psychotic episodes, abnormal pupils, tremor of the tongue and hands, epileptic fits, eventually speech destruction, tetraparesis as well as loss of bowel, and bladder control. If untreated, general paresis is fatal in 3–5 years.

### Prevalence

According to the WHO global estimates, over 12 million cases of syphilis exist worldwide. For Germany, the Robert Koch Institute reported in July 2005 an incidence of syphilis infections with 3,450 cases annually (4.1 per 100,000); 5–9% of untreated patients develop CNS involvement. Because most of the infected are treated with antibiotics during the early stage, at present the prevalence of neurosyphilis is low. However, male homosexuals represent a group at increased risk. With them, co-infection of syphilis and HIV are not infrequent, resulting in a special disposition to treponemal CNS infections.

### Genes

A genetic disposition to syphilitic CNS involvement is not known so far. Yet, the genome of T.p. was clarified. The organism contains a single circular chromosome with 113,806 bp, an average G + C content of 52.8%, and no extrachromosomal elements. Lipoprotein genes comprise 2.1% of the open reading frames. There are observations suggesting that lipoproteins are involved in the host–pathogen interactions. Interestingly, in the genome of T.p., a gene family with 12 members, termed tpr, has been discovered. Although a consensus lipoprotein sequence is missing, three members (tprF, tprI, and tprK) may be associated with the outer membrane of T.p. Some findings suggest that tprK has the capacity to undergo recombination with generation of new alleles or gene variants [1]. This could provide an explanation for the ability of T.p. to evade the host defense system, surviving in the host, and inducing multistage protean clinical manifestations.

### Molecular and Systemic Pathophysiology

Treponemal lipoproteins may be involved in the initial inflammatory processes that occur in the primary lesion after infection. Signal transduction in host phagocytes is mediated by toll-like receptor-2, which reacts with the lipoproteins inducing an intracellular signal cascade. This process ends in the expression of genes designated for infection defense. Besides the activation of transcription factors NF-kappaB and AP-1 in the antigen

presenting cells, co-stimulating molecules like B7 and MHC are upregulated and the pro-inflammatory cytokines Il-6, Il-12, and TNF-alpha are released. An additional role may play an initial signaling or binding event with the CD-14 receptor activating the production of Il-6, Il-8, and PAF.

In the dermal lesion of primary syphilis, the local defense of the host is characterized by predominating T cell infiltrates, preferentially T helper/inducer cells. In secondary syphilis lesions, the ratio of T helper/inducer and suppressor/cytotoxic cells is approximately equal with tendency in favor of the latter [2]. The increased count of T-suppressor cells in these lesions is thought to result in the natural shutdown of the early vigorous immune response following clearance of most of the organisms from the lesions, ushering in the latent stage of syphilis. In this stage, intermittent bacteremia occurs enabling T.p. to penetrate parenchymatous organs like the CNS. Additional virulence factors may be the bacterial phosphodiesterase neutralizing antibodies and the deposition of host`s MHC class I molecules onto surface of T.p., probably resulting in an impairment of regulation processes between immune cells [3]. Tertiary stage organ manifestations are characterized by plasma cell infiltrations and obliterative endarteritis reflecting an (hyperergic) immunological reaction.

## Diagnostic Principles

Syphilis of the central nervous system is to be verified by serologic tests (TPPH-, FTA-, and VDRL-test) and CSF analysis. In the early stage of syphilis, T.p. can be demonstrated in CSF using fluorescent or darkfield microscopy. T.p. PCR is an alternative option with undefined sensitivity so far. Further CSF analysis, carried out in all stages of syphilis, includes cell counts, determination of total protein, albumin, and IgG (IgM and IgA) concentrations, and isoelectric focusing for oligoclonal IgG bands. Albumin and immunoglobulin determination as well as oligoclonal antibody detection should be performed simultaneously in serum and CSF samples to obtain CSF/serum quotients. CSF/serum quotients of IgG, IgM, and IgA as compared with the albumin quotient can give indications to intrathecal immunoglobulin synthesis. By this means, an IgG-index calculated >0.69 substantiates a local humoral immune response within the CNS. To verify the syphilitic cause of the latter, the local production of antitreponemal antibodies must be proven by calculating an antibody index (CSF/serum quotient of antibody concentrations divided by IgG quotient). Antibody index >2 points to syphilitic CNS involvement with probability; index >3 proves neurosyphilis with specificity of 100 and sensitivity of 84% [4].

The activity of the syphilitic CNS process can be ascertained by CSF pleocytosis, proof of antitreponemal IgM antibodies in serum (T.p. IgM-ELISA, 19S-(IgM) FTA-ABS test) and positive VDRL test. However, in later stages, pleocytosis is absent in about 1/3 of cases with untreated neurosyphilis.

## Therapeutic Principles

Therapy of the first choice is penicillin G in high doses; ceftriaxone represents an equivalent alternative. These beta-lactam antibiotics inhibit the treponemal transpeptidase by irreversibly binding at the C7 atom of the beta lactam circle. Thus, the peptidoglycan structure of bacterial wall ruptures.

In vitro concentrations that immobilize 50% of the treponemes are 0.002 µg penicillin G/ml and 0.01 µg ceftriaxone/ml. These concentrations should be exceeded tenfold in vivo. Doses of penicillin G of 20 million IU/day and 2 g ceftriaxone/day (initial 4 g) are adequate to achieve corresponding CSF concentrations [5]. In patients allergic to beta-lactam antibiotics alternatively doxycyclin can be administrated (at least 200 mg daily for 28 days).

### Synonyms

Catecholaminergic polymorphic ventricular tachycardia; Catecholaminergic bidirectional ventricular tachycardia; Familial polymorphic ventricular tachycardia; Ryanodine receptor mediated ventricular tachycardia

### Definition and Characteristics

Stress or exertion induces syncope, premature ventricular contractions, and polymorphic or bidirectional ventricular tachycardia in children and young adults in the absence of structural heart disease (and with a normal QT interval on electrocardiography).

### Prevalence

Mutations of the RYR2 gene are rare in a general Italian population. However, a mutation in RYR2 was found in 14 of 30 probands with exertion induced polymorphic ventricular tachycardia in the absence of structural heart disease [1]. To date, more than 40 RyR2 mutations have now been found to be associated with stress-induced ventricular tachycardia [1–4].

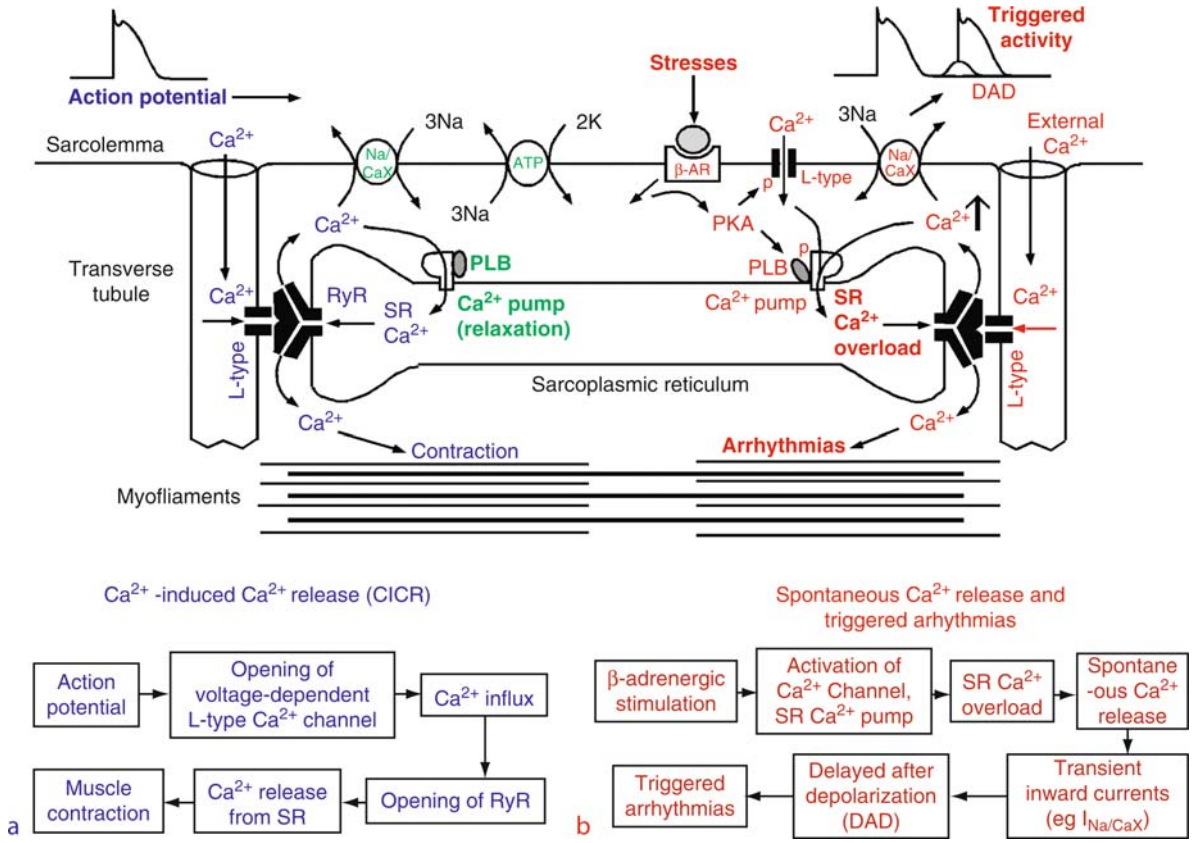
### Genes

RYR2 gene coding for the cardiac ryanodine receptor, localized on chromosome 1q43.

### Molecular and Systemic Pathophysiology

The ryanodine receptor is located in the sarcoplasmic reticulum (SR). This calcium-gated calcium channel provides the primary source of the calcium required for cardiac muscle excitation-contraction coupling (Fig. 1).

The ryanodine receptor is a homotetrameric channel associated with numerous binding proteins. Most of the disease-linked RyR2 mutations are clustered in the NH2-terminal, central, and COOH-terminal regions. Recent investigations reveal that RyR2 mutations from each of these regions enhance the sensitivity of the channel to activation by luminal calcium and reduce the threshold for spontaneous calcium release during SR calcium overload, a process referred to as store-overload-induced-calcium release (SOICR) [5]. Since SOICR is linked to delayed after depolarizations (DADs) and triggered arrhythmias (Fig. 1), the reduced threshold for SOICR as a result of enhanced luminal calcium activation of RyR2 likely underlies a common



**Tachycardia, Polymorphic Ventricular, Stress-induced. Figure 1** (a) $Ca^{2+}$-induced release, (b) spontaneous $Ca^{2+}$ release and triggered arrhythmias.

arrhythmogenic mechanism of RyR2-associated cardiac arrhythmias and sudden death [5].

## Diagnostic Principles

Stress induced ventricular tachycardia classically occurs in the absence of structural heart disease with a clinical onset in childhood or as an early adult. The presentation is usually one of recurrent exercise-induced syncope. During exercise testing with electrocardiographic monitoring, syncope is associated with bidirectional (or polymorphic) ventricular tachycardia in the setting of a normal QT interval. The ventricular tachycardia can be induced by isoproterenol infusion, but not by programmed electrical stimulation. A family history of sudden death or stress-induced syncope is present in ~1/3 of cases.

## Therapeutic Principles

Given the risk of ventricular fibrillation in this condition, the placement of an implantable cardioverter defibrillator is an appropriate therapy. Beta-adrenergic receptor blockers have been reported to prevent syncope and ventricular dysrhythmias in several patients [2,4], and can be used cautiously as primary therapy or as an adjunct to the implantable cardioverter defibrillator.

# Tachycardia, Supraventricular

Arti N. Shah[1], Bharat K. Kantharia[2]
[1]Division of Cardiac Electrophysiology, Mount Sinai School of Medicine, Elmhurst Hospital Center, Elmhurst, NY, USA
[2]Division of Cardiac Electrophysiology, The University of Texas Health Science Center, Houston, TX, USA

## Synonyms

Paroxysmal supraventricular tachycardia; PSVT; SVT; Wolff-Parkinson-White (WPW) syndrome

## Definition and Characteristics

Supraventricular tachycardias (SVTs) are defined as paroxysmal tachyarrhythmias that are initiated, maintained by, or confined to the tissue above the ventricles i.e. the atria or the atrioventricular node (AVN) tissue, or both. Conventionally the term SVT includes (i) atrioventricular nodal (AVN) reentrant tachycardia (AVNRT), (ii) atrioventricular (AV) reentrant tachycardia (AVRT) that utilizes accessory bypass tracts that are either "concealed" with only retrograde conduction from the ventricles to atria or "manifest" with anterograde conduction properties in which case the term Wolff-Parkinson-White (WPW) syndrome is used, and (iii) atrial tachycardia (AT) (Fig. 1). However, technically many different arrhythmias including atrial fibrillation may be included within the broader definition of "supraventricular arrhythmias." Although, "genetic"/"familial" atrial fibrillation with various genetic mutation of different domains including KCNQ1 and KCNE2 have been described, in this chapter we have focused on genetic and molecular basis of AVNRT, AVRT and AT.

## Prevalence

Although difficult to assess correctly, the incidence of SVT is considered to be about 35 cases per 100,000 persons per year, and the prevalence is about 2.25 per 1,000. Given mostly sporadic rather than familial nature of most SVTs, it is even more difficult to assess the exact prevalence and incidence of "familial" or "genetic" SVTs. Nonetheless, all three forms i.e. AVNRT, WPW syndromes and AVRT, and AT that have familial or genetic basis have been described [1–5]. The prevalence of "familial WPW" is significantly higher at 0.55% compared to 0.15% of sporadic WPW found in the general population ( $p < 0.0001$) [2]. Furthermore, there is a higher prevalence (1.7%) of WPW syndrome in relatives of patients with multiple accessory pathways than with single pathways (0.43%) or the general population ( $p < 0.05$ and $<0.001$ respectively) [2].

## Genes

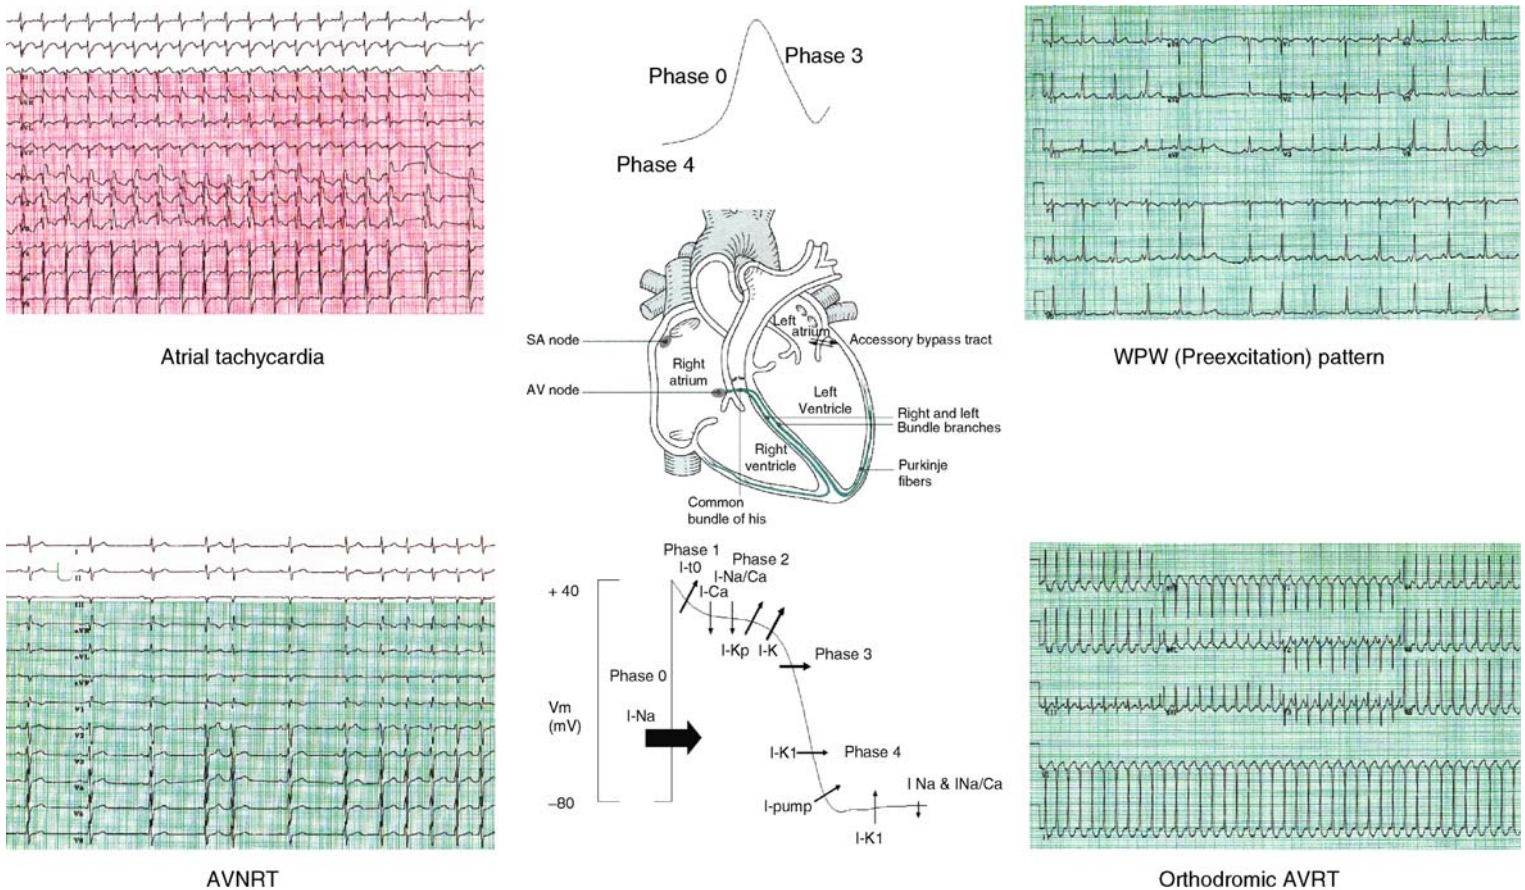
For the most part, SVT result from sporadic errors during cardiogenesis, rather than genetic malfunction. No particular genes have been identified for AVNRT and AT. In 2001, the gene responsible for "familial WPW" was identified by Gollob et al. [3]. The gene, PRKAG2, located on chromosome 7q36 encodes for the gamma 2 subunit of the enzyme adenosine monophosphate-activated protein kinase (AMPK). The gene is inherited in an autosomal dominant pattern. Single nucleotide change resulting in missense mutations consisting of a substitution of glutamine for arginine at residue 302 has been identified. Six such mutations have been identified. Familial WPW syndrome is also linked in association with hypertrophied cardiomyopathy and Leber's hereditary optic neuropathy [1].

## Molecular and Systemic Pathophysiology

Excitability of cardiac cells with the resultant different phases of action potential (Fig. 1) is dependent upon and controlled by exchanges of various ions ($Na^+$, $Ca^{++}$, $K^+$ and $Cl^-$) across cell membranes through ion channels which are integral membrane proteins.

Spatial heterogeneity of ion channel expression underlies the different action potential morphology of the different parts of the heart which in turn ensures a coordinated contraction. For example, the sinus node and the Purkinje cells possess property of spontaneous phase 4 depolarization from hyperpolarization through $I_f$ channels that are modulated by autonomic neurotransmitters. Besides ion conduction, the ion channels by their property of voltage, ligand or receptor (including adrenergic, cholinergic and purinergic receptors) dependent gating are responsible for switching between different conduction states. The maintenance of normal cardiac rhythm is dependent on the proper movement of ions mediating the action potential in each cardiac compartment. Inherited mutations in ion channel genes can cause channel dysfunction and consequently cardiac arrhythmia.

From the arrhythmia mechanism standpoint, AVNRT and AVRT result from reentry of electrical impulses in a defined circuit in which the AV node is a critical component for both arrhythmias. For AVNRT, differences in the conduction and refractoriness of different pathways of the longitudinally dissociated AV node allow electrical reentry that results from a critically timed premature extra atrial or ventricular beat. As seen in Fig. 1, typical slow-fast AVNRT starts after a premature atrial beat that is blocked anterogradely in an otherwise fast pathway but conducts through the slow



**Tachycardia, Supraventricular. Figure 1** In the center, the components of cardiac conduction system are schematically shown. Schematics of ion currents during action potential of sinus node, typical pacemaker cell, and the ventricular myocyte are shown on middle-top and middle-bottom panel respectively. The ECGs of atrial tachycardia, typical atrioventricular (AV) nodal reentrant tachycardia (AVNRT) on the top and bottom panels on the left; and preexcitation pattern of Wolff-Parkinson-White (WPW) syndrome and orthodromic AV reentrant tachycardia on the top and bottom panels on the right. In the ECG of atrial tachycardia P waves are seen before each QRS complexes; the last two complexes show resumption of sinus rhythm upon termination of SVT. The ECG of AVNRT shows a narrow complex SVT (last five beats) that is initiated by a premature atrial complex (preceding beat) that conducts with long PR interval. In the ECG of WPW syndrome, delta waves which are negative in leads I and aVL, and positive in the precordial leads indicate presence of a left lateral accessory bypass tract. Interestingly, the fifth beat (better seen in the rhythm strips) shows normal narrow QRS complex without preexcitation. This occurs as the premature atrial complex (seen on the preceding T wave) blocks in the accessory bypass tract and conducts normally through the AV node. Similar mechanism of conduction anterogradely through the AV node and returning via the accessory bypass tract initiates orthodromic AVRT, the ECG of which (the bottom right panel) shows *P* waves that follow QRS complexes, better seen in leads I, aVL and the lateral precordial leads.

pathway thus causing a long PR interval on ECG, and then returns via the fast pathway that has recovered retrogradely. In case of accessory bypass tract mediated reentrant tachycardia, in similar causative mechanism, the atria, AV node, His-Purkinje system, ventricles and the bypass tract form critical components of the reentrant circuit. While in orthodromic AVRT, the AV node and infranodal structures form the antegrade limb and the bypass tract constitutes the retrograde limb, the circuit is reversed in antidromic AVRT. Both AVNRT and AVRT could therefore be treated by adenosine, betablockers, calcium channel blockers and sodium channel blockers which may be targeted to alter properties of different components of the reentrant circuit. In case of AT, in addition to reentry, automaticity of atrial myocytes, triggered activity from either early or delayed after depolarizations (EADs and DADs) may also be causative.

## Diagnostic Principles

While careful history and physical examination is warranted, ECG recording and invasive electrophysiology study remain the mainstay to diagnose various forms of SVT that are encountered in the general population. Currently there is no single genetic test that is available which could be utilized universally to identify genetic or familial SVT.

## Therapeutic Principles

Similarly, there is no unique "gene therapy" available currently to treat genetic or familial SVT. Given a very high curative rate by nonpharmacological therapy i.e. ablation, and various antiarrhythmics, the therapeutic approach to genetic or familial SVT is similar to all other forms of SVT.

# TACI Deficiency

Ulrich Salzer[1], Bodo Grimbacher[2]
[1]Department of Medicine, Division of Rheumatology and Clinical Immunology, University Hospital Freiburg, Freiburg, Germany
[2]Department of Immunology and Molecular Pathology, Royal Free Hospital and University College Medical School, London, UK

## Definition and Characteristics

Common variable immunodeficiency (CVID) summarizes a heterogeneous group of diseases characterized by significant hypogammaglobulinemia of unknown cause, failure to produce specific antibodies after immunization and typically recurrent upper respiratory tract infections [1,2]. A subgroup of patients with CVID carries mutations in the gene TNFRSF13b encoding TACI.

## Prevalence

The prevalence of CVID ranges from 1:25,000 among Caucasians to 1:100,000 in the Japanese population and affects men and women equally [3]. Genetic alterations in TNFRSF13b/TACI may be observed in up to 8% of the CVID patients [4]. TACI deficiency thus represents to date the most common genetic defect observed in CVID and has an estimated prevalence of 1: 250,000 to 1: 1,000,000.

## Genes

The human protein TACI is encoded by the gene TNFRSF13B, which has five exons spanning 30 kb on human chromosome 17p11.2 (the mouse syntenic region is chromosome 11). Both heterozygous and homozygous sequence variants have been observed in TNFRSF13b [4]. Heterozygous TNFRSF13b sequence variants observed in CVID patients are also found in the healthy population, but at significantly lower frequencies [5]. These heterozygous sequence variants show a variable clinical penetrance and incomplete segregation in familial CVID cases, classifying them as disease modifiers. Biallelic TNFRSF13b mutation have so far been exclusively found in CVID patients and are considered as disease causing in these individuals.

## Molecular and Systemic Pathophysiology

TACI, together with BAFFR and BCMA, forms a triad of specialized TNFR superfamily members involved in the regulation and differentiation of humoral immunity. All three receptors bind the ligand BAFF, while only BCMA and TACI bind a second ligand, APRIL. Mouse

models suggest that TACI acts as a manifold regulator of B-cell homeostasis and activation as evidenced by the B-cell expansion, lymphoproliferation, autoimmune disease and impaired T-cell independent antibody responses observed in TACI knockout mice. TACI expression is restricted to the B-cell lineage in humans; higher levels of expression are found on the CD27+ memory B-cell subset and after activation.

TACI deficient humans show a humoral immunodeficiency of variable degree ranging from asymptomatic hypogammaglobulinemia to full blown CVID presenting with nearly agammaglobulinemic Ig levels [6,4]. While T cell numbers and function are normal in TACI deficient individuals, the B-cell compartment shows an often pronounced reduction of CD27+ memory B-cells [4]. TACI deficient individuals may initially present with a history of recurrent upper and/or lower respiratory tract infections, gastrointestinal complaints like chronic diarrhea or malabsorption or with other manifestations of CVID-like autoimmune phenomena such as immune thrombocytopenic purpura or autoimmune hemolytic anemia [7]. Signs of lymphoproliferation are observed at a high frequency in TACI deficient humans [4,7].

## Therapeutic Principles

[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Carman and Ann Adams Department of Pediatrics, Institute of Medical Education, Children's Hospital of Michigan, Detroit, MI, USA

## Synonyms

Taenosis; Adult tapeworm infection

## Definition and Characteristics

Taeniasis in humans results from intestinal infection with the adult stage of tapeworm of the genus Taenia. The most common are Taenia saginata (beef tapeworm) and T. solium (pork tapeworm). The adult tapeworm has a head (scolex), a short neck, and a ribbon-like body (strobila) consisting of segments (proglottids). T. saginata usually measures 4–10 m, with 1,000–2,000 proglottids whereas T. solium usually measures 2–8 m, with 800–900 proglottids. The scolex of T. saginata measures 1–2 mm in diameter, has four suckers and no hooks. The scolex of T. solium is about 1 mm in diameter, possesses four suckers, and is armed with a double row of hooklets. Each proglottid contains male and female reproductive system. The gravid proglottids each are packed with 50,000–100,000 eggs [1]. The proglottids of T. saginata usually have more than 20 uterine branches from a central uterine structure, whereas those of T. solium have 12 or fewer [1]. In addition, a vaginal sphincter is seen only in T. saginata and a third ovarian lobe in T. solium. The proglottids of T. saginata are motile, whereas those of T. solium are not. Taeniasis is acquired by ingestion of the larval forms in infected insufficiently cooked beef or pork. Most patients are asymptomatic. Some may present with abdominal discomfort, hunger pain, nausea, weight loss, and pruritus ani. Rarely, taeniasis may lead to cholangitis, appendicitis, and intestinal obstruction. With T. saginata, there may be discomfort and embarrassment caused by the migration of

proglottids from the anus. On the other hand, T. solium may be complicated by cysticercosis.

### Prevalence

The prevalence is well below 1% except in endemic areas where the prevalence may exceed 10%. These endemic areas include Africa, Central America, and Southeast Asia [1].

### Molecular and Systemic Pathophysiology

Taenia eggs passed out in human faeces remain viable for days to weeks. After ingestion by cattle or pigs, they hatch in the intestine of the intermediate host to release oncospheres that penetrate the intestinal mucosa to reach the bloodstream. Hatching is facilitated by the action of gastric juice, intestinal enzymes, and bile on the eggs. Some of the oncospheres are filtered out in striated muscles of the respective animal where they develop into mature cysticerci. When humans eat raw or undercooked beef or pork containing the viable cysticerus, the scolex evaginates from the cysticerus and attaches to the intestinal (usually jejunal) mucosa. Development into the adult tapeworm then begins. The maturation process takes 84–120 days. The presence of tapeworm in the intestine might lead to reduced nutrient absorption and alteration in intestinal motility [2]. An immune response might result in eosinophilia and hyperimmunoglobulinaemia E [2].

### Diagnostic Principles

The diagnosis is based on the demonstration of ova or proglottids in faeces. The eggs of T. saginata are indistinguishable from those of T. solium morphologically. Detection of coproantigen in faeces by enzyme-linked immunosorbent assay is more sensitive, but the coproantigen is only genus specific, making it impossible to differentiate T. saginata from T. solium infection. Various techniques to improve species identification have been developed, including mitochondrial DNA analysis, polymerase chain reaction (PCR) coupled to restriction fragment length polymorphism, PCR-amplified DNA sequences, and random amplified polymorphic DNA-PCR [3]. T. asiatica has been reported primarily in Taiwan, Korea, Indonesia, Vietnam, and China. DNA and morphological characteristics show that T. asiatica is a subspecies of T. saginata [4].

### Therapeutic Principles

Praziquantel, 5–10 mg in a single oral dose, is highly effective. An alternative is niclosamide, 50 mg/kg (2 g in adults), in a single oral dose. Taeniasis can be prevented by adequate cooking of beef and pork prior to consumption.

# Tangier Disease

Genovefa D. Kolovou,
Katherine K. Anagnostopoulou,
Dennis V. Cokkinos
First Cardiology Department, Onassis Cardiac Surgery Center, Athens, Greece

## Synonyms

Familial hypoalphalipoproteinemia; High density lipoprotein deficiency

## Definition and Characteristics

Tangier disease (TD) is a familial disorder characterized by a deficiency of high-density lipoproteins in the blood serum, with storage of cholesteryl esters in tissues.

Lipid abnormalities of TD patients involve impaired cholesterol efflux, low serum high density lipoprotein cholesterol (HDL-C), low serum apolipoprotein (apo) A-I levels, low total and low density lipoprotein cholesterol (LDL-C) levels and normal or high triglyceride levels. Regarding the clinical manifestations, cholesteryl ester deposits are typically found in reticuloendothelial cells, such as: tonsils or pharyngeal lymph follicles, lymph nodes, thymus, spleen, liver, bone marrow, cornea, lungs, skin and gall bladder [1,2]. Neurological abnormalities are described in more than half of the reported cases of TD including peripheral, symmetric or asymmetric, mono- or poly-neuropathy with diminished or absent reflexes and sensory abnormalities. The sensory abnormalities consist of widespread dissociated loss of pain and temperature sensation, paresthesia and rarely, attacks of stabbing pain. Additionally, motor abnormalities may be present (e.g. progressive focal muscle weakness). Thrombocytopenia is another clinical feature observed in TD. Tangier platelets are characterized by reduced number of dense bodies and by the presence of giant granules typically encountered in platelets form Chediak-Higashi syndrome. The clinical manifestations may vary from subclinical and transient to quite disabling. Thus, the first symptoms usually involve enlarged tonsils, neuropathy, splenomegaly and atherosclerotic complications.

## Prevalence

It is a very rare disease with few cases; approximately 60 identified worldwide [Online Mendelian Inheritance in Man (OMIM) 205400]. Both genders are equally affected.

## Genes

In 1999, three independent groups simultaneously reported that mutations in the gene encoding the ATP-binding cassette transporter A1 (ABCA1) were the genetic basis of TD [3].

## Molecular and Systemic Pathophysiology

The genetically determined disease with an autosomal recessive mode of inheritance is called "Tangier disease" after the community of origin of the fist two cases (Tangier Island, Virginia, USA). ABCA1 is a member of the ABC transporter family. These proteins, found in all species, are integral membrane proteins and use adenosine triphosphate (ATP) as a source of energy to transport a wide assortment of molecules, such as ions, sugars, vitamins, lipids, amino acids, peptides, proteins and a large number of hydrophobic compounds and metabolites across intracellular and plasma membranes [4,5]. The transmembrane domains form a pathway across the membrane through which substrates pass. Upon ATP binding and hydrolysis, ABC transporters undergo conformational change altering the affinity and orientation of the substrate binding sites. ABC proteins of both eukaryotic and prokaryotic origins are implicated in the transport of lipids. The action of ABCA1 on cholesterol efflux is represented in Fig. 1.

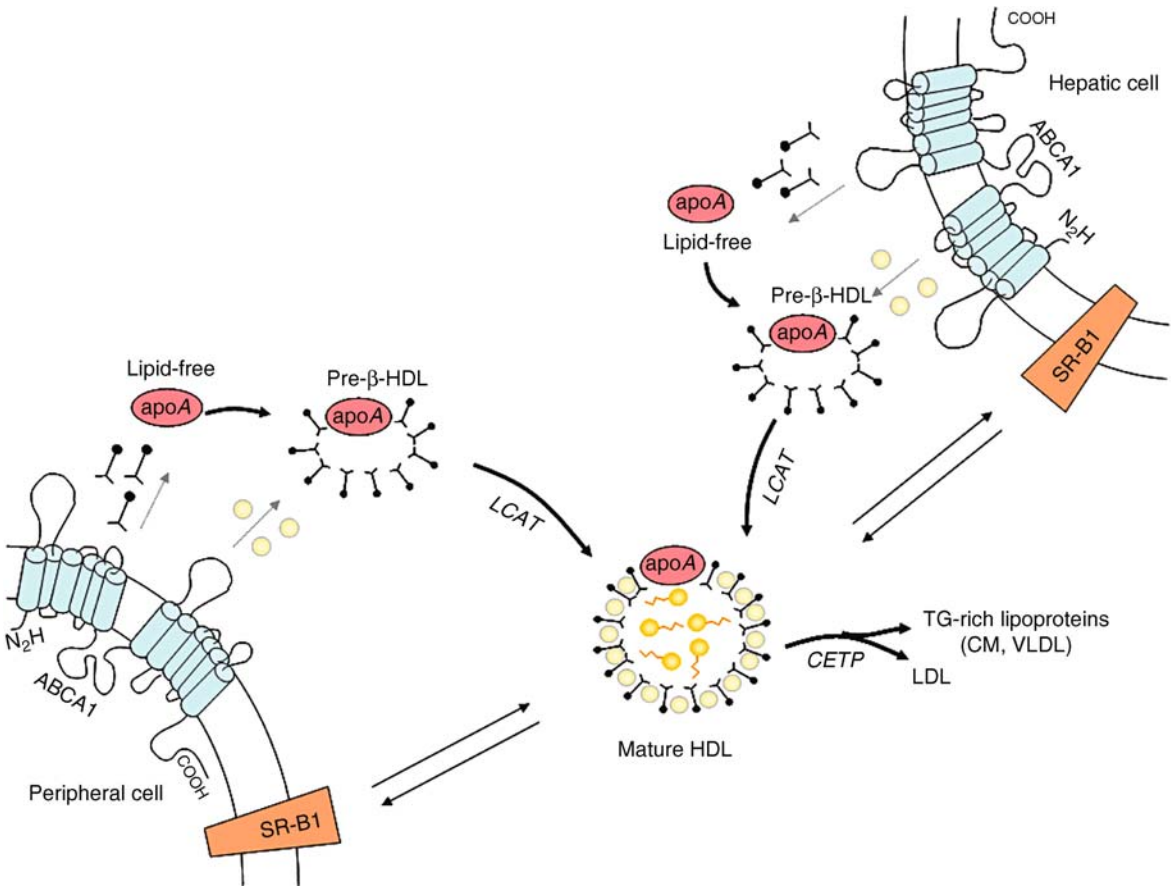
At least 50 ABCA1 gene mutations have been identified, leading to the allelic disorders TD and familial hypoalphalipoproteinemia. Familial hypoalphalipoproteinemia is associated with moderately low HDL-C and predilection toward premature coronary heart disease. Sequence variants in ABCA1 may also contribute to variations in plasma HDL-C levels in the general population. The biochemical hallmark of TD plasma is the absence of α-migrating HDL and apoA-I-containing lipoproteins. In the absence of other lipid components, apoA-I and phospholipids form a stable discoidal particle, termed pre-β HDL. This process is dependent on functional ABCA1. The increased abundance of pre-β HDL (in certain HDL deficiency states) provides evidence that this particle reflects the first step in the life cycle of an HDL particle [5].

## Diagnostic Principles

The plasma lipid profile is very characteristic, nearly zero HDL-C, very low LDL cholesterol and normal or increased triglyceride levels.

## Therapeutic Principles

The treatment of TD patients is still not established since there are very few data and great variability between cases to provide a credible meta-analysis. Usually in TD patients with CHD who are on low-fat diet and estrogen replacement therapy or lipid lowering drugs (niacin, gemfibrozil and lovastatin), serum HDL-C levels are not raised above 5 mg/dl (0.13 mmol/l) and no significant effects on triglyceride or LDL-C



**Tangier Disease. Figure 1** Role of ABCA1 in cholesterol efflux and HDL formation. After lipid-free apoA-I binds to the ABCA1 protein, phospholipid efflux takes place. ApoA-I binds to phospholipids to form disk-like HDL particles (pre-ß-HDL). Free cholesterol from peripheral cells effluxes to pre-ß-HDL. SR-B1 may also promote cholesterol efflux from cells when there is a favorable cholesterol gradient. Free cholesterol is then, esterified by LCAT forming spherical HDL molecules. The cholesterol ester is transported back to the liver for catabolism either directly by HDL through SR-B1 or by the apoB-containing lipoproteins by the action of CETP. In addition, hepatic ABCA1 is able to efflux excess cholesterol in order to maintain intracellular homeostasis. The newly formed HDL particles can be remodeled by LCAT into mature HDL particles following cholesterol esterification. The cholesterol carried in liver-derived mature HDL particles can be either transported to peripheral cells or removed by the hepatic SR-B1. ABCA1: ATP-binding cassette transporter A1, ApoA-I: apolipoprotein A-I, CETP: cholesteryl ester transfer protein, CM, chylomicron, HDL: high density lipoprotein cholesterol, I, LCAT: lecithin cholesterol acyltransferase, SR-B1: scavenger receptor class B type 1, TG: triglyceride, VLDL: very low density lipoprotein. From [5], reprinted by permission from Bentham Science Publishers Ltd.

levels are noted. In patients with isolated low HDL-C and CHD, bezafibrate treatment improves endothelial function of brachial arteries, increases HDL-C and apoA-I and lowers fibrinogen concentrations [5].

Treatment with antioxidants such as vitamin C, E, beta carotene does not significantly improve neurological symptoms. The effect of propranolol to enhance cholesterol efflux in TD fibroblasts to almost normal values seems a theoretically promising alternative [5]. In an attempt to identify mechanisms enhancing ABCA1-mediated lipid release, plasma has been treated by dimyristoyl phosphatidylcholine multilamellar vesicles and generated prebeta[1]-apoA-I-containing lipoproteins (LpA-I)-like particles similar to those of native plasma. Dimyristoyl phosphatidylcholine treatment of plasma resulted in the redistribution of apoA-I from α-HDL to pre-β-HDL and increased both phospholipid and free cholesterol efflux. Therefore, increasing the plasma prebeta-1-LpA-I level by either pharmacological agents or direct infusions might prevent foam cell formation and reduce atherosclerotic vascular disease. Thus, ABCA1 could be considered a major therapeutic target for the treatment of low HDL syndromes and atherosclerosis.

# TAPVC

►Totally Anomalous Pulmonary Venous Connection

# TAR Syndrome

►Thrombocytopenia with Absent Radii Syndrome

# Tardive Dyskinesia

Takahiro Shinkai
Department of Psychiatry, University of Occupational and Environmental Health, Kitakyushu, Japan

## Synonyms

Tardive stereotypy; Rhythmical chorea; Oral-buccal-lingual dyskinesias; Classical tardive dyskinesia; Persistent oral dyskinesia; Orofacial dyskinesia

## Definition and Characteristics

Tardive dyskinesia (TD) is a movement disorder that is essentially caused by the long-term use of antipsychotic medication. The syndrome may develop after 3 months up to several years after continuous exposure to antipsychotic drugs or upon sudden withdrawal from treatment. The abnormal movements may persist with or without continued use of antipsychotics (a potentially irreversible adverse effect) or may diminish or disappear over time. The disorder consists of hyperkinetic involuntary movements characterized by choreiform (rapid, jerky, non-repetitive), athetoid (slow, sinuous, continual), and/or rhythmic (stereotypical) movements, or a combination of these. The abnormal movements are most commonly seen in the orofacial area (especially in the tongue, lips, and jaw) and less frequently in the limbs and trunk.

## Prevalence

A meta-analysis including 76 studies on 39,187 patients with chronic antipsychotic treatment reported TD rates ranging from 3 to 70% and overall prevalence of 24.2% [1]. The atypical (second-generation) antipsychotics have a decreased liability for TD: approximately 1% annually, compared with 5% for typical (first-generation) agents [2].

Among several variables suggested to increase the likelihood of developing TD, advanced age is the single most significant risk factor in terms of prevalence, severity, and persistence, with a TD incidence of approximately 25–30% per year in elderly patients.

## Genes

No definite conclusions have been drawn regarding the degree to which genes account for TD risk. The disorder is considered to arise from complex gene–environment interplay. Possible risk genes for TD which have been reported in association studies include the genes coding for cytochrome P450 (CYP) 2D6, CYP1A2, CYP17, dopamine $D_2$ receptor (DRD2), DRD3, serotonin $(5\text{-HT})_{2C}$ receptor, $5\text{-HT}_{2A}$ receptor, human leukocyte antigen, manganese superoxide dismutase, and mu opioid receptor [3,4]. In terms of the pharmacokinetics candidates, mutations in the CYP2D6 (a primarily important degradation enzyme for antipsychotics) gene, which accounts for the interindividual difference of the enzyme activity (i.e., poor metabolizer, extensive metabolizer, and ultrarapid metabolizer), have been associated with TD risk. On the other hand, in terms of the pharmacodynamics candidates, a single nucleotide polymorphism (SNP) in exon 1 of the DRD3 (Ser9Gly), which may lead to the altered affinity of D3 dopamine, has been associated with the development of TD.

## Molecular and Systemic Pathophysiology

The precise mechanism for the pathophysiology of TD, however, has yet to be adequately understood. The main hypothesis is the dopamine supersensitivity theory. The vast majority of antipsychotics have potent dopamine receptor blockade properties (primarily to D2). Chronic use of dopamine receptor blocking agents may cause an increase in post-synaptic dopamine receptors (up-regulation), which eventually leads to dopaminergic supersensitivity. The excess dopaminergic neurotransmission in the nigrostriatal system, a pathway particularly associated with motor regulation, is believed to result in TD outcome. This hypothesis is supported by

evidence from an animal model showing that sustained $D_2$ occupancy may influence risk of TD [5]. This hypothesis is in line with the observation that atypical antipsychotics, which have relatively lower affinity for D2 (and/or fast dissociation from D2), have lower risk for the development of TD compared to typical antipsychotics.

Other neurotransmitter hypotheses borne out of antipsychotic pharmacology include norepinephrine, 5-HT, acetylcholine, and gamma-aminobutyric acid models. Free radical-mediated neuronal damage (i.e., oxidative stress) has also been offered as a possible basis for the development of TD.

### Diagnostic Principles

The diagnosis of TD should principally be based on the antipsychotic medication history (and/or other dopamine receptor blocking agents) as well as neuropsychiatric history and the nature of the movement disorder. TD criteria based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) can be used to make a standardized diagnosis. The use of the Abnormal Involuntary Movement Scale (AIMS) is also recommended to evaluate the severity of the symptoms.

Occasionally, a full blood test, serum electrolyte level, thyroid function, serum ceruloplasmin level, brain imaging, and connective tissue disease screening are necessary to rule out differential diagnosis such as neuroacanthocytosis, hyperthyroidism, Wilson's disease, Huntington's disease, or other complications.

### Therapeutic Principles

Although numerous drugs, including vitamin E (a free radical scavenger with an advantage of carrying virtually no risk), have been used in an attempt to treat TD, no marked treatment has been currently established. The principal strategy in its management thus remains preventative. In this context, medication doses should be kept at the minimum level needed to achieve the desired antipsychotic effect and should be withdrawn at the earliest opportunity. The use of atypical antipsychotics may decrease, if not prevent or cure, the risk for TD compared with typical antipsychotics.

## Tardive Stereotypy

►Tardive Dyskinesia

## Tarui's Disease

Rosaline C. M. Quinlivan[1], Robert Beynon[2]
[1]Children's Unit, Robert Jones District and Orthopedic NHS Trust, Oswestry, UK
[2]Department of Veterinary Preclinical Sciences, University of Liverpool, Liverpool, UK

### Synonyms

Phosphofructokinase; PFK deficiency; Glycogenosis type VII; GSD VII; OMIM 232800

### Definition and Characteristics

Autosomal recessive disorder of glycogen metabolism resulting in exercise intolerance, myalgia, myoglobinuria, hemolytic anemia and gout. Associated insulin intolerance is reported [1], recurrent hemolysis may lead to gall stones. Classically, the onset is in childhood or early adulthood, although late onset cases with progressive weakness have been reported. A severe multi-system neonatal onset with arthrogryposis, cardiomyopathy, developmental delay and cataracts has been described and is thought to reflect absence of an unknown activator common to all PFK isoforms [2].

### Prevalence

This is a rare disorder, over 40 cases reported world wide, in the USA, there is a predominance of Ashkenazi Jews affected, Japanese and Italian cases have also been reported. An animal model is known in Springer Spaniels.

### Genes

The PFK-M locus was originally assigned to 1cen-q32 by somatic cell hybridization, however, subsequently the gene was demonstrated to map to 12q13.3. PCR analysis with a somatic cell hybrid mapping panel using primers derived from intron 6 and exon 18 of the PFKM gene showed consistent amplification of cell lines to chromosome 12 (concordance 100%). Fluorescence in

situ hybridization with a CEPH YAC, isolated with exon 18 primers indicated that this clone maps to 12q13.3 [3]. In Ashkenazi Jews, the two most common mutations are: G to A substitution at 5′ splice donor site of intron 5 (leading to a splicing defect complete deletion of the preceeding exon in mRNA) and a deletion of a single base (C) at position 2079 in mRNA, both mutations account for 95% of those found in this patient group.

## Molecular and Systemic Pathophysiology

Phosphofructokinase (PFK) irreversibly catalyzes the conversion of fructose-6-phosphate to fructose-1, 6-biphosphate in the glycolytic pathway. Muscle tissue deficient in PFK is unable to utilize free or glycogen derived glucose as a fuel source. Glycogen accumulation in skeletal muscle is a consequence of impaired degradation or excess synthesis. Accumulation of hexose monophosphates, as a consequence of the glycogen block, activate glycogen synthetase. Raised levels of glucose-6-phosphate also activate the hexose monophosphate shunt, enhancing nucleotide formation, consequently leading to increased uric acid production [4].

PFK is a tetrameric enzyme composed of three isoforms Liver (L), muscle (M) and platelet (P) encoded at 21q, 12q13.3 and 10p, respectively. A six member isoenzyme system for PFK results from the hybridization poof the three distinct subunits: P4, M4, M3L, M2L2, ML3 and L4. Liver contains exclusively the L4 homotetramer, while mature muscle contains exclusively the M4 homotetramer. Erythrocytes contain 50% L type and 50% M4 isoforms, by contrast, leucocyte PFK consists of multiple isoenzymes composed of all three subunits with L4 homotetramer predominating. In Tarui's disease, the genetic defect involves the M4 isoform, resulting in enzymatic absence in skeletal muscle tissue and a 50% reduction in activity in erythrocytes. Because the liver and kidneys only express the L4 isoform, these organs are spared. The heart and brain express predominantly the M4 isoform, although there is only one published report of cardiac and cerebral involvement with Tarui's disease [5].

## Diagnostic Principles

The history of exercise induced fatigue, myalgia and a second wind phenomena suggests a disorder in muscle glycogen metabolism. Myoglobinuruia following vigorous exercise, and early onset gouty arthritis occur. The additional finding of a compensated hemolytic anemia will point towards a diagnosis of PFK deficiency. Biochemical findings include: raised plasma creatine kinase (CK) and uric acid levels, a mild unconjugated hyperbilirubinaemia and reticulocytosis. A forearm ischemic lactate test demonstrates an exaggerated rise in ammonia but no rise in blood lactate. Muscle biopsy demonstrates a variation in fiber type diameter, increased sub-sarcolemmal glycogen and absent phosphofructokinase activity, demonstrated by an enzyme histochemical reaction. Some adult cases have accumulation of acid-Schiff (PAS)-positive polysaccharides, noted as fine granular filamentous material on electron microscopy, similar to that seen in polyglucosan body disease. Erythrocyte PFK activity is reduced by 50%.

## Therapeutic Principles

There is no specific therapy but a gentle aerobic exercise program may be helpful by increasing the muscle aerobic capacity. Vigorous anaerobic exercise is to be avoided. Oral ingestion of fructose has been reported to improve symptoms in one patient and a ketogenic diet was shown to improve symptoms in a severely affected infant. Intravenous glucose and a high carbohydrate diet have been shown to worsen performance due to inhibition of lipolysis. In the future gene mediated enzyme replacement may be developed as a treatment option.

# Taussig-Bing Anomaly

►Double Outlet Right Ventricle

# Tay-Sachs Disease

Thomas Kolter, Ute Schepers, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology and Lipid Biochemistry, University of Bonn, Bonn, Germany

## Synonyms

β-Hexosaminidase α-subunit deficiency; B-variant of the GM2-gangliosidoses

## Definition and Characteristics

Autosomal recessive defect in the α-subunit of the dimeric β-hexosaminidases A (αβ) and also S (αα) leads to accumulation of ganglioside GM2 in the lysosomes especially of neuronal cells [1]. Together with Sandhoff's disease and GM2-activator protein-deficiency, Tay-Sachs disease belongs to the GM2-gangliosidoses (Fig. 1).

## Prevalence

Heterozygote frequency is at 0.006 in the general population and at 0.033 among the Ashkenazi Jewish people in North America and in Israel.

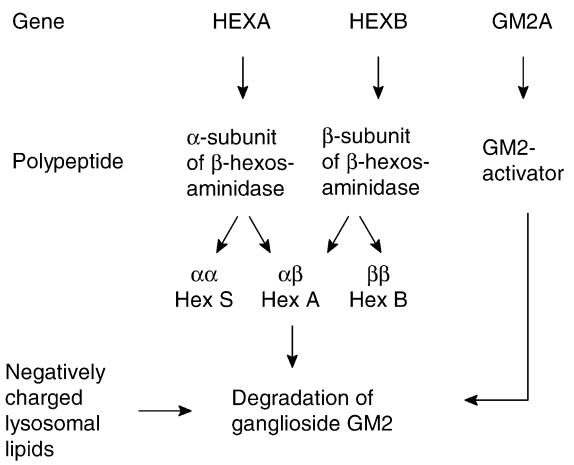
## Genes

HEXA, localized on chromosome 15q23–24. At least 92 mutations reported.

## Molecular and Systemic Pathophysiology

Clinical phenotypes in the GM2 gangliosidoses vary from infantile-onset, rapidly progressive neurodegenerative disease that leads to death before age 4 years to later-onset forms with more slowly progressive neurologic conditions and survival into childhood, adolescence, or with long-term survival. Clinical phenotypes of chronic forms are varying and include progressive dystonia, spinocerebellar degeneration, motor neuron disease, and psychosis.

Presence of swollen neurons with massive accumulation of storage material in lysosomes throughout the nervous system. These form characteristic inclusions, the so-called membranous cytoplasmic bodies (MCBs).



**Tay-Sachs Disease. Figure 1** The β-Hexosaminidase gene system.

## Diagnostic Principles

Enzyme assay in any tissue sample or body fluid, metabolic studies in cultured cells are required to detect defects in the GM2-activator gene [2].

## Therapeutic Principles

Only supportive treatment is available to date.

## Synonyms

ATLL

## Definition and Characteristics

ATLL is etiologically linked to infection with a human retrovirus, known as human T-cell leukemia virus type I (HTLV-I) [1, 2]. ATLL is characterized by an aggressive and fatal monoclonal or oligoclonal expansion of virus infected activated CD4+ T-cells.

## Prevalence

Adult T-cell leukemia/lymphoma has a low prevalence. Current assessment indicates 20–30 million people worldwide are infected with HTLV-I. Endemic areas are for the most part found in Japan, Africa, South America, the Caribbean basin, southern parts of North America and Eastern Europe. The virus induces lifelong infection, but most HTLV-I infected individuals remain asymptomatic carriers with a 1–5% lifelong risk of developing ATLL. All routes of HTLV-I virus transmission require close contact with virus infected T-lymphocytes. HTLV-I virus can be transmitted from mother to child by prolonged breast-feeding in the postnatal period, by sexual intercourse with an infected partner or by the intravenous route, mainly by blood transfusion.

## Molecular and Systemic Pathophysiology

ATLL has a broad clinical spectrum divided into four clinically distinct entities (acute, chronic, smoldering and lymphoma) that differ in their presentation, disease progression and response to treatment [3]. Acute ATLL is characterized by fever, cough, lymphadenopathy, skin lesions, hepatosplenomegaly, marked leukocytosis and hypercalcemia frequently associated with lytic bone lesions and generalized bone resorption. Chronic type ATL is characterized by milder clinical symptoms and signs and a longer clinical course with normal serum calcium levels. The smoldering type is characterized by few leukemia cells circulating in the peripheral blood (<5%) and may present with skin lesions, such as papules, nodules and erythema. Serum calcium levels are normal. The lymphoma type ATLL is predominantly characterized by lymph node enlargement without manifestations of leukemia. Peripheral blood lacks absolute lymphocytosis, but sporadic circulating leukemia cells may be seen (<1%); hypercalcemia is absent. A major complication of ATLL is the immunodeficiency of patients that leads to serious infections with bacteria, fungi, protozoa and viruses. Common infections include pneumocystis carinii, aspergillosis, candidiasis, cytomegalovirus pneumonia and strongyloides stercoralis. Other viral opportunistic malignancies such as Kaposi's sarcoma and Epstein Barr virus (EBV) associated lymphoma have also been reported in patients with ATL.

In contrast to animal retroviruses, HTLV-I does not transduce an oncogene and integrates randomly in the host genome of infected cells. The low incidence and the long latency of HTLV-I associated ATLL suggest that in addition to viral infection, accumulations of genetic mutations are required for cellular transformation in vivo. No specific karyotypic abnormalities have been linked with the development of ATLL, but cytogenetic analyses of leukemic cells often revealed multiple abnormalities such as trisomy 3, 7 and 21, involvement of chromosomes 6 and 14 and loss of chromosome Y. Like the strategies employed by DNA tumor viruses, HTLV-I virus encoded proteins are accountable for undetected proliferation of infected cells to the immune defenses, alterations in DNA repair mechanisms and inhibition of cell cycle checkpoints such as p53, Rb and p16ink leading to cell transformation [4].

## Diagnostic Principles

The diagnosis of ATL is generally made on morphological analysis. Cytological examination may reveal infiltration by "cerebriform" or "flower cells" (activated lymphocytes with convoluted nuclei and basophilic cytoplasm), indicators of acute or lymphoma type ATL. This must be confirmed by demonstrating integration of HTLV-I provirus in the host genome by Southern blotting or polymerase chain reaction. The predominant immunological phenotype of neoplastic cells is helper T-cell, CD3+, CD4+, L-selectin+, CD25+, CD45RA+, HLA-DR+, CD29– and CD45RO– in the peripheral blood or CD3+, CD4+, L-selectin+, CD29+, CD45RO+, HLA-DR+ and CD45RA– in the skin and lymph nodes. Factors suggestive of a poor prognosis include high serum thymidine kinase levels, high serum soluble interleukin-2 receptor levels, high serum β2 microglobulin levels, high expression of the Ki67 antigen and high serum parathyroid hormone related protein levels. The serum neuron specific enolase (NSE) correlated positively with serum thymidine kinase activity and serum soluble interleukin-2 receptor levels and may serve as a marker of disease aggressiveness as well as a prognostic factor for ATL.

## Therapeutic Principles

There is no current satisfactory treatment for acute ATLL. High dose radiotherapy or chemotherapy

regimens, independently or in combination, including those designed for the treatment of aggressive non-Hodgkin's lymphomas or acute lymphoblastic leukemia are ineffective in ATL patients. Although initial treatments frequently result in complete remissions, all patients relapse and die, usually in less than a year. Recent trials include allogeneic bone marrow transplantation (alloBMT), combinations of AZT and α-IFN, arsenic trioxide and α-IFN, all trans-retinoic acid (ATRA) therapy and the use of radio-labeled anti IL-2R (CD25) antibodies [5].

## Synonyms

Mature T-cell and NK-cell neoplasms; Sézary syndrome; Adult T-cell leukemia/lymphoma; Primary cutaneous CD30-positive lymphoproliferative disorders; Lymphomatoid papulosis; Primary cutaneous anaplastic large-cell lymphoma; Subcutaneous panniculitis-like T-cell lymphoma; Peripheral T-cell lymphoma; Unspecified; Primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma; Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma; Cutaneous gamma delta T-cell lymphoma; extranodal NK/T-cell lymphomas

## Definition and Characteristics

Cutaneous T-cell lymphomas (CTCL) other than MF represent a heterogeneous group of neoplastic disorders with a broad spectrum of clinical (papules, nodules, panniculitis-like, bruise-like skin lesions, with or without ulceration), histologic (small to large sized cells, epidermotropic, angiocentric), and immunophenotypic features (e.g., CD56+) [1,2].

Cutaneous T-cell lymphomas other than MF according to the WHO-EORTC classification:

- Mature T-cell and NK-cell neoplasms
  - Sézary syndrome
  - Adult T-cell leukemia/lymphoma
  - Primary cutaneous CD30-positive lymphoproliferative disorders:
    - Lymphomatoid papulosis
    - Primary cutaneous anaplastic large-cell lymphoma
  - Subcutaneous panniculitis-like T-cell lymphoma
  - Peripheral T-cell lymphoma, unspecified:
    - Primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma (provisional)
    - Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma (provisional)
    - Cutaneous gamma delta T-cell lymphoma (provisional)
  - Extranodal NK/T-cell lymphomas

The prognosis varies from a slowly progressive, indolent course (e.g., primary cutaneous small to medium-sized CD4+ pleomorphic T-cell lymphoma) to highly aggressive forms of CTCL (e.g., primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma).

## Prevalence

The prevalence of CTCL other than MF is ~1 cases per 1,000,000 inhabitants per year in Western countries.

## Genes

The most frequent chromosomal alterations in cutaneous T-cell lymphoma other than MF involve chromosomes 1 and 2, 6, 7, 9, 10, 14, 17 [3]. Amplification of 5q and 13q could be identified in subcutaneous panniculitis-like T-cell lymphoma.

## Molecular and Systemic Pathophysiology

Most cases in this group are neoplasms of CD3+ CD4+ CD30- T cells, but neoplasms derived from CD8+ cells and CD3 + CD56+ NK/T-cells have been identified. The etiology of CTCL other than MF is largely unknown.

There is evidence for an etiologic role of human T-cell lymphotropic viruses (HTLV-1 or 2) in adult T-cell leukemia/lymphoma, but not in other CTCL. Epstein Barr virus is found in some cases of NK/T-cell lymphoma, in particular in secondary cutaneous forms. Similar to MF, lymphocytes showing genomic instability ("genotraumatic lymphocytes") are thought to be driven into activation and proliferation by antigenic stimulation. In some cases, CTCL clones need the presence of epidermal cells to survive, and thus depend on the epidermal cytokines network [4]. Epidermal interferon-gamma inducible protein-10 (IP-10) and monokine induced by gamma-interferon (Mig) expression is associated with epidermotropism in cutaneous CD30 negative T-cell lymphomas [5]. In addition, accumulation of genetic alterations occurs during lymphomagenesis leading to proliferation of neoplastic lymphoid cells, independent from microenvironmental factors such as cytokines.

## Diagnostic Principles

Diagnosis is based on the combination of clinical, histological, immunophenotypic and genotypic features.

## Therapeutic Principles

Therapy depends on clinical course of the lymphoma entity. In slowly progressive forms, psoralen-UVA, steroids and retinoids (acitretin, bexarotene), and interferon-alpha are employed. Treatment for rapid progressive forms consists of multiagent chemotherapy and radiotherapy. Extracorporeal photopheresis is effective in Sézary syndrome. Experimental therapeutic strategies include gene transfer mediated by viral vectors or fusion toxins.

# TDP

►Torsades de Pointes

# Telangiectasia, Hemorrhagic Hereditary

URBAN W. GEISTHOFF
Department of Otorhinolaryngology, Hospital of the City of Cologne, HNO Holweide, Cologne, Germany

## Synonyms

Rendu-Osler-Weber syndrome/disease/disorder; HHT; ORW; ROW syndrome/disease/disorder

## Definition and Characteristics

Autosomal dominant inherited multisystemic disorder of the fibrovascular tissue resulting in dilated vessels [1]. (Fig. 1) Telangiectases (TAEs) of mucous membranes and skin tend to bleed, resulting especially in nosebleeds. Larger vascular malformations (VMs) of visceral organs, mainly of lungs (Fig. 2) and brain are often clinically silent but can suddenly become symptomatic by life-threatening events like central nervous symptoms or hemorrhage. Hepatic manifestations can become clinically apparent as high output heart failure, biliary disease or portal hypertension. HHT1 (see below) is associated with a higher prevalence of pulmonary VMs.

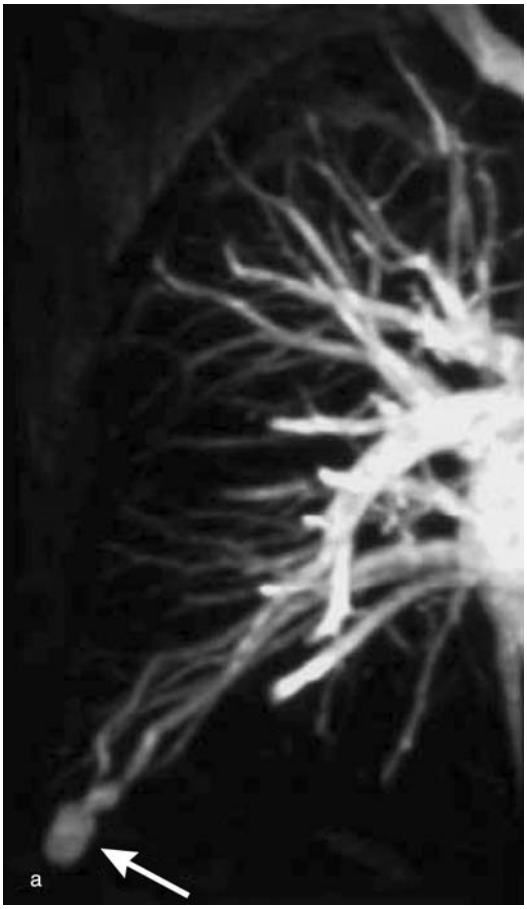
## Prevalence

The prevalence reported varies between 1 in 39,216 for northern England and 1 in 2,351 for the department Ain in France [1].

## Genes

At least two genes are causally related to HHT: Endoglin (ENG; MIM # 131195) on chromosome 9q34.1 mutated in HHT type 1 (HHT1 MIM # 187300) and ALK1 (activin receptor-like kinase-1, ACVRL1; MIM * 601284) on chromosome 12q11–q14, mutated in HHT2 (MIM # 600376). Multiple mutations in different exons have been described for both genes, a genetic database is accessible at www.hht.org. A third and fourth locus have been postulated on chromosomes 5q31.3–5q32 (HHT3; MIM % 601101) and 7q14 (HHT4; MIM % 610655), respectively.

**Telangiectasia, Hemorrhagic Hereditary. Figure 1**
Typical telangiectases of the lips and tongue (from [1]).



**Telangiectasia, Hemorrhagic Hereditary. Figure 2**
Magnetic resonance angiography of a pulmonary arteriovenous malformation (a, arrow) enhanced by contrast material (from [1]).

Additionally a HHT-juvenile polyposis overlap syndrome (mainly HHT2) due to Smad4 mutations exists (MADH4 gene on chromosome 18q21.1).

## Molecular and Systemic Pathophysiology

The mechanisms underlying the pathology of HHT are poorly understood [2,3]. Both endoglin and ALK1 proteins are components of the endothelial transforming growth factor-β (TGF-β) receptor complex. Endoglin is a co-receptor, binding different members of the TGF-β superfamily in the presence of the signaling receptors types I and II (TβR I and II). Two different types of TβRI (ALK1 and 5) have been proposed to alternatively regulate the switch between proliferation and quiescence in angiogenesis and vascular remodeling. Recent findings suggest that interactions with the extracellular and cytoplasmatic domains of endoglin potentiate TGF-β/ALK1 signaling (a bone morphogenetic protein-like ALK1 pathway stimulating Smad1/5/8), while they appear to interfere with TGF-β/ALK-5 signaling (canonical ALK 5 pathway activating Smad2/3) [2]. Complexes of these Smads with Smad4 regulate gene transcription. Contradictory data exists suggesting an alternative model in which endoglin controls cell surface receptor levels and binding characteristics [3]. Endoglin also plays a role in coupling endothelial NO synthase activity and regulating vascular tone in HHT1 [4].

However, dilated vessels at multiple sites can result [1]. Probably trauma and weak protection by the surrounding tissue are the main factors responsible for recurrent bleeding episodes from TAEs, especially of the nose and the gastrointestinal tract causing anemia. Brain VM can lead to stroke by hemorrhage. Pulmonary VM (Fig. 2) seldom bleed, except in pregnancies, probably due to circulatory changes. Right-to-left shunting by the VMs decreases the filter function of the lungs allowing paradoxical sterile or septic embolism. Therefore pulmonary VM most frequently become symptomatic by visceral infarction or abscesses, mainly of the brain. Shunting can also lead to reduced blood oxygenation causing dyspnea, fatigue or polycythemia. Similar symptoms may be present in patients with liver VM (mainly HHT2). All possible shunts between portal vein, hepatic veins and hepatic artery have been described and

might lead to high output heart failure (especially shunts between hepatic artery and hepatic veins) and portal hypertension (caused by shunts from the hepatic artery to the portal vein). Steal effects resulting from shunting of the hepatic artery might lead to hypoperfusion of the peribiliary plexus with subsequent necrosis and stricture of the bile ducts causing biliary disease. In HHT2 additionally primary pulmonary hypertension may occur.

### Diagnostic Principles

The consensus of Curaçao established four criteria: (i) spontaneous recurrent nosebleeds; (ii) multiple telangiectases at typical sites (like lips, oral cavity, fingers and nose); (iii) visceral lesions such as gastrointestinal telangiectasia, pulmonary, hepatic or cerebral arteriovenous malformations; (iv) positive family history with at least one first degree relative with HHT. The diagnosis of HHT is possible or suspected if two criteria are present, it is unlikely with less and definite with more criteria [5].

### Therapeutic Principles

Screening for pulmonary VM has been strongly recommended, no consensus exists regarding cerebral VM [1]. Embolotherapy of pulmonary VM is the method of choice; additionally prophylactic antibiotics should be given during operations with potential bacteremia. Brain VM might be treated by open surgery, embolotherapy or radiation therapy. As a therapy of the first line liver VM should be treated symptomatically, though liver transplantation or embolotherapy might become necessary, the latter one being discussed controversially. A multitude of therapeutical approaches has been described for nosebleeds. Therapeutical aims are to coagulate the TAEs (like laser therapy), improve their protection (e.g. it has been postulated that estrogenes can induce a squamous metaplasia of the nasal mucosa), reduce the traumatization (by nasal ointments or closure of the nasal cavity) or with unknown mechanism (like the use of antifibrinolytics). Some of these approaches have also been applied to treat other TAEs, including the gastrointestinal ones [1].

## Terminal Deletions of 13q

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

### Synonyms

Partial monosomy 13q

## Definition and Characteristics

The majority of cases result from de novo deletions (different breakpoints are involved), the remainder from unbalanced familiar translocations or inversions. About one third of cases with the clinical phenotype of a terminal deletion of 13q are due to ring chromosomes [r(13)], usually occurring de novo. De novo deletions and ring chromosomes arise in 80–90% on the paternally inherited chromosome 13.

## Prevalence

This is a rare disorder.

## Genes

Some of the genes on the long arm of chromosome 13 are clearly implicated in the specific phenotype observed in 13q- individuals: Patients with proximal deletions of 13q often show retinoblastoma, which is correlated with haploinsufficiency of the RB1 locus on 13q14. The ZIC2 and ZIC5 genes on 13q32 have been shown to be the causative genes for holoprosencephaly [1] and haploinsufficiency of the EDNRB gene (endothelin receptor type b) on 13q22 leads to Hirschsprung disease, which is a rare feature of 13q- individuals. For many other genes, it has been proposed that they are involved in formation of the specific 13q- phenotype, such as the DACH gene (dachshund homolog) on 13q22, the SOX21 and SOX1 genes on 13q31 and 13q34, respectively, and the KLF (krueppel-like factor) genes 5 and 12 on 13q22.

## Molecular and Systemic Pathophysiology

The DACH gene has been shown to play a major role in the development of the eye and the limbs in drosophila and to be an important player in mammalian organogenesis [1,2]. However, a causative role in generating microphthalmia or limb defects in humans has not been shown so far. The same is true for the SOX and the Krueppel like genes: The SOX family was shown in mouse models to be important in neurogenesis and the latter in the development of kidney and cardiovascular remodeling, but their role in human development still remains to be defined [3].

Depending on the size of the deletion, clinical manifestations among different patients with monosomy 13q vary a lot. However, deletions of the distal part of the long arm of chromosome 13 [del(13)(q22→qter)] are associated with a characteristic phenotype, including growth and mental retardation, dysmorphisms and major malformations.

*Facial dysmorphisms include*: severe microcephaly, narrow and sloping forehead, small nose, upslanting palpebral fissures with epicanthic folds, small mouth, high palate, large and misshapened ears.

*Extrafacial manifestations include*: genital hypoplasia, small hands with hypoplasia of the midphalanges of little fingers, fusion of the metacarpal bones of the fourth and fifth fingers and hypoplasia or aplasia of the thumbs.

*Major malformations include*: ocular defects (microphthalmia, coloboma, cataract, optic atrophy), brain malformations (holoprosencephaly of varying degree, absence of corpus callosum, encephalocele), heart defects, abnormalities of kidneys, anal atresia or other gastrointestinal malformations (e.g. Hirschsprung disease).

*Correlative phenotypic mapping*: in an attempt to correlate given phenotypes with specific chromosomal regions, patients with interstitial deletions of 13q have been assigned to three groups [4]. *Group 1* includes patients with more proximal deletions (not extending into q32) showing mild or moderate mental retardation, variable minor abnormalities and growth retardation. Depending on deletion of the retinoblastoma locus on 13q14.2, they might present with or without retinoblastoma. *Group 2* includes patients with more distal deletions (including at least part of q32). They usually show severe micro- and trigonocephaly. Major malformations include anomalies of limbs (missing thumbs, hypoplasia of the midphalanges of the fifth fingers, Y-shaped synostosis between metacarpals and/or metatarsal 4/5) and eye (microphthalmia, anophthalmia). Males show characteristic genitalia with a small penis, hypospadia, a bifid scrotum and anal atresia. Usually, severe growth and mental retardation are present. *Group 3* includes patients with the most distal deletions, involving q33–34, with severe mental retardation but without major malformations and growth retardation. From these observations, it has been postulated that the critical region for the severe 13q phenotype is located on 13q 32.

## Diagnostic Principles

Cytogenetic investigations, such as routine chromosomal analysis with fluorescence in situ hybridization (FISH) techniques using specific DNA probes. Array-CGH might be used us an alternative technique.

## Therapeutic Principles

Management is aimed at ameliorating the effects of associated abnormalities.

# Terminal Deletions of 18p

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

## Synonyms

Monosomy 18p

## Definition and Characteristics

Deletions at the short arm (18p) of chromosome 18 are associated with mild to moderate growth retardation, subtle dysmorphisms and About 60–80% of cases are caused by de novo deletions (85% of paternal origin), the remainder result from segregation of translocations between 18p and the long arm of acrocentic chromosomes or from familial rearrangements. The majority of patients carry deletions of almost the entire short arm of chromosome 18 (pter→p11) and recently a breakpoint cluster in the pericentromeric region could be identified [1].

## Prevalence

Monosomy 18p is relatively frequent.

## Genes

So far, a clear correlation between haploinsufficiency for a specific gene and a given phenotype could be established only for a few genes: Examples include the TGIF gene on 18p11.3 (which is implicated in holoprosencephaly) [2] For some genes, a direct phenotypic effect is assumed, as for example for the MC2R gene on 18p11 (might correlate with the autoimmune disorders observed in 18p-).

For a subset of phenotypic features, the candidate region has been mapped to a specific region on chromosome 18, as for example baldness/hypotrichosis to 18p11.

However, the majority of the relatively specific features observed in terminal deletion 18p, as for example decreased levels of IgA (which are observed in 18p- and 18q-!) can not be explained by haploinsufficiency of a specific gene or genes.

## Molecular and Systemic Pathophysiology

The pattern of dysmorphisms may not be striking in the newborn but becomes more evident within the first years of life. Newborns have usually mild to moderate growth retardation. They demonstrate brachycephaly, a broad face with ptosis of the upper lids, strabismus, hypertelorism, epicanthic folds, a broad nose, down turned corners of the mouth, micrognathia with microstomia and large protruding ears. Teeth are often irregularly positioned and prone to caries. The neck is short and broad and many individuals have pectus excavatum, widely spaced nipples and scoliosis. Males have hypoplastic genitalia and females large labia majora. The hands are usually small with short fingers.

Several malformations are relative frequent in monosomy 18p: About 10% of the affected individuals show holoprosencephaly with varying degrees of severity, sometimes in combination with bilateral cleft lip and cleft palate. Heart malformations (septal defects and tetralogy of Fallot) are observed in less than 10% of children. Rare findings include absence of auditory canals, malformations of the eyes (microphthalmia, keratoconus, colobomata) and baldness.

The clinical course is mild: Growth is usually delayed and deficient. Mental retardation varies from moderate to severe with disproportionately delayed speech. There is a tendency towards autoimmune disorders and absence or reduction of serum IgA has been reported repeatedly. Several affected individuals with 18p- have reproduced. Prognosis is poor for patients with holoprosencephaly, patients without this malformation do not have shortened life expectancy.

## Diagnostic Principles

Cytogenetic investigations, such as routine chromosomal analysis with fluorescence in situ hybridization (FISH) techniques using specific DNA probes. Array CGH (comparative genomic hybirdization).

## Therapeutic Principles

Management is aimed at ameliorating the effects of associated abnormalities.

## Synonyms

Monosomy 18q

## Definition and Characteristics

Deletions of the long arm (18q) of chromosome 18 are associated with moderate intrauterine growth retardation, cranio-facial, neurologic, vertebral and genitourinary anomalies, defects of heart and limbs, as well as decreased levels of IgA with frequent infections and eczema.

The breakpoints vary between 18q21 and q23 and the large majority of patients (75%) represent de novo deletions of paternal origin, the remainder resulting from familial rearrangements [1]. The general rule is that smaller deletions cause milder phenotypes, although no clear correlation between the extent of the deletion and the phenotype could be established so far. Patients with ring chromosomes [r(18)] usually show a mild 18q- phenotype and it has been suspected by several authors that the breakpoints of the rings usually lie at 18p11 and 18q23.

## Prevalence

The incidence of terminal deletions of 18q is estimated to be approximately 1 in 40,000 live births.

So far, a clear correlation between haploinsufficiency for a specific gene and a given phenotype could be established only for a few genes such as the GALR1 gene on 18q23, which plays a causative role in growth hormone deficiency [2,3]. A direct phenotypic effect is assumed for the RAX gene on 18q21, which might be implicated in the ocular malformations observed in 18q- [4]. For some of the phenotypic features, such as aural atresia the candidate region has been mapped to a specific region on chromosome 18.

However, the majority of the relatively specific features observed in terminal deletion 18q, as for example decreased levels of IgA (which are observed in 18p- and 18q-) can not be explained by haploinsufficiency of a specific gene or genes.

## Molecular and Systemic Pathophysiology

The major features include moderate intrauterine growth retardation, cranio-facial abnormalities (micro- and brachycephaly, mid face hypoplasia, deeply set eyes, narrow nose with depressed and wide bridge, carp shaped mouth, cleft lip and palate), ear abnormalities (prominent anthelix and antitragus, atresia or stenosis of the external auditory canal), vertebral anomalies, genitourinary malformations (cryptorchidism, hypospadias, hypoplasia of the labia minora in females), heart defects (no single defect predominating), abnormalities of hands and feet (long tapering fingers with protuberant finger tips, proximally placed thumbs, irregularly implanted and overlapping toes) and decreased levels of IgA. Less frequent findings are: ocular anomalies (cataract, coloboma, microopthalmia). Neurologic findings may include hypotonia, choreoathetotic movements, spinal muscular atrophy, and seizures.

Nearly all individuals show growth retardation (which is probably caused in a subset of individuals due to growth hormone insufficiency) and mental retardation (degree varying from mild to severe). Patients are prone to infections and eczema. Live expectancy is normal.

## Diagnostic Principles

Cytogenetic investigations such as routine chromosomal analysis with fluorescence in situ hybridization (FISH) techniques using specific DNA probes. Array CGH might be applied as an alternative technique.

## Therapeutic Principles

Management is aimed at ameliorating the effects of associated abnormalities.

# Testicular Cancer

Stefan R. Bornstein
Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Definition and Characteristics

Testicular cancer is the most frequent solid tumor of young men between 15 and 35 years of age. With respect to therapeutic and prognostic aspects, three groups of testicular germ cell tumors have to be distinguished: seminomas about 40%, non-seminomas (20–30%), and mixed tumors (20%).

## Prevalence

Testicular cancer is a relatively rare form of cancer. It accounts for only 1% of all tumors in men. Testicular germ cell tumors have a low incidence of 6–8/100,000 men and year. Incidence rates vary across the globe, with higher rates in Scandinavia and Germany, and lower rates in Asia and Africa.

## Molecular and Systemic Pathophysiology

The overall incidence of testicular germ cell tumors has been steadily rising throughout the twentieth century, with an increase of 15–20% being seen in successive 5-year periods. This increase might be the result of endogenous or environmental estrogenic compounds that affect the embryonic testis and increase the risk of testicular cancer. Testicular cancer also has a genetic component, but the incidence of a positive family history is low (2%). A mutation in chromosome Xq27 has recently been associated with familial risk. However, a number of other risk factors have been identified as predisposing men to testicular cancer.

The risk factors associated with testicular cancer include white race (fivefold risk), cryptorchidism, testicular atrophy, or dysgenesis.

Up to 10% of testicular tumors are diagnosed in males with a history of an undescended testicle. A male with a history of cryptorchidism has a risk of developing testicular cancer that is 2.5- to 11-fold greater than that of an unaffected male.

Epidemiologic studies have failed to show an association between the incidence of testicular cancer and vasectomy, occupational and environmental exposures, or viral illnesses.

*Clinic:* The classic presentation of testicular cancer is a painless lump in the testis, although a substantial proportion of patients report diffuse pain, swelling, or hardness in the scrotum. The changes are usually found during self-examination, after testicular trauma or by a sexual partner. Signs of metastatic disease include swelling of the lower extremities, back pain, cough, hemoptysis, or dyspnea. These symptoms are commonly associated with testicular cancer but they can also be caused by infections or illnesses.

## Diagnostic Principles

Early diagnosis of testicular cancer is crucial since the doubling time of testis tumors is estimated to be 10–30 days. While survival rates at all stages are very high, an earlier stage at diagnosis carries a better long-term prognosis. Men are often reluctant to report a swelling or lump in the testicle, resulting in a delay in presentation to the physician. It is common for these tumors to be misdiagnosed as epididymitis and treated ineffectively with antibiotics or neglected for months. In several studies, the duration of symptoms before a correct diagnosis ranges from 17 to 87 weeks.

In any patient with a testicular mass, or unexplained scrotal pain or swelling, an ultra-sonogram of the scrotum should be obtained. Scrotal ultrasonography is nearly 100% accurate in distinguishing between intratesticular and extratesticular pathology. All intratesticular masses are considered cancer until proved otherwise.

After an intratesticular neoplasm is identified, a chest radiograph, a computed tomographic (CT) scan of the abdomen, and serum tumor markers (HCG and AFP) are obtained for staging.

Radical orchiectomy, performed for definitive diagnosis, is also the first step in most treatment regimens.

*Staging*: The American Joint Committee on Cancer stages testicular cancer based on a tumor, node, metastases (TNM) staging system.

T = Tumor:
- T – Carcinoma in situ
- T1 – Tumor limited to the testis and epididymis
- T2 – Tumor limited to the testis and epididymis with vascular–lymphatic involvement, or tumor extends to and involves the tunica vaginalis
- T3 – Tumor invades the spermatic cord with or without vascular–lymphatic involvement
- T4 – Tumor invades into the scrotum with or without vascular–lymphatic involvement

N = Nodes:
- N0 – No regional lymph node metastasis
- N+ – Evidence of regional lymph node metastasis. There are three categories of nodal involvement (N1–N3), which depend on the size and number of nodes involved

M = Distant Metastasis:
- M0 – No evidence of distant metastasis
- M1 – Evidence for nonregional nodal or pulmonary metastasis
- M2 – Nonpulmonary visceral metastasis

S = Serum Marker Levels:
- Stage 1 – LDH < 1.5 × normal; HCG < 5,000; AFP < 1,000
- Stage 2 - LDH 1.5–10 × normal; HCG 5,000–50,000; AFP 1,000–10,000
- Stage 3 – LDH > 10 × normal; HCG > 50,000; AFP > 10,000

Stage Groupings:
- Stage 1
  - 1A – T1 N0 M0 S0
  - 1B – T2–T4 N0 M0 S0
  - 1S – Any T N0 M0 S1–3
- Stage 2
  - 2A – Any T N1 S0–1
  - 2B – Any T N2 S0–1
  - 2C – Any T N3 S0–1
- Stage 3
  - 3A – Any T, any N, M1 S0–1
  - 3B – Any T, any N, M0–1 S2
  - 3C – Any T, any N, M0–1 S3, or any T, any N, M2, any S

Serum tumor markers are routinely used for diagnosis, staging, and follow-up. The markers in the serum are the beta subunit of HCG, alpha-fetoprotein (AFP), and lactate dehydrogenase (LDH). Measuring the concentrations of these tumor markers is invaluable in making the diagnosis, determining the prognosis, assessing response to treatment, and in following up of patients.

### Therapeutic Principles

In all cases, patients are treated by orchiectomy. Treatment after orchiectomy depends on the stage and histology of the tumor – pure seminoma versus mixed or nonseminoma. While early stage seminoma is a classical indication for radiotherapy with cure rates of about 99%, non-seminomatous tumors are the domain of surgery and chemotherapy, and rarely an indication for radiotherapy under curative intension. Careful aftercare in intervals of 2–12 months is essential to obtain long-term survival.

Overview of treatment for testicular cancer by stage and type:

*Non-Seminomas and Mixed Tumors*

- Stage I
  - Low risk (no vascular invasion) – Orchiectomy and surveillance.
  - High risk (vascular invasion) – Orchiectomy and adjuvant chemotherapy or surveillance.
- Metastatic
  - Good prognosisOrchiectomy and polychemotherapy
  - Intermediate prognosis – Orchiectomy and polychemotherapy.
  - Poor prognosis – Orchiectomy, polychemotherapy, and referral to specialist oncology center.

*Seminomas*

- Stage I – Orchiectomy and radiotherapy.
- Metastatic
  - Good prognosis
    - Stage II A-B – Orchiectomy and radiotherapy.
    - Stage II C-III – Orchiectomy and polychemotherapy.
  - Intermediate prognosis – Orchiectomy and polychemotherapy.

## Testicular Feminization, 46, XY Sex Reversal

►Androgen Insensitivity Syndrome

## Tetrahydrobiopterin Deficiencies

Nenad Blau
Division of Clinical Chemistry and Biochemistry, University Children's Hospital, Zurich, Switzerland

### Synonyms

Atypical phenylketonuria; Malignant phenylketonuria; BH4 deficiency; GTP cyclohydrolase I (*ar*GTPCH) deficiency; 6-Pyruvoyl-tetrahydropterin synthase (PTPS) deficiency; Pterin-4a-carbinolamine dehydratase (PCD) deficiency; Dihydropteridine reductase (DHPR) deficiency; Autosomal dominant GTP cyclohydrolase I

(*ad*GTPCH) deficiency; Segawa disease; Autosomal recessive sepiapterin reductase (SR) deficiency; PTPS deficiency; PCD deficiency; DHPR deficiency

## Definition and Characteristics

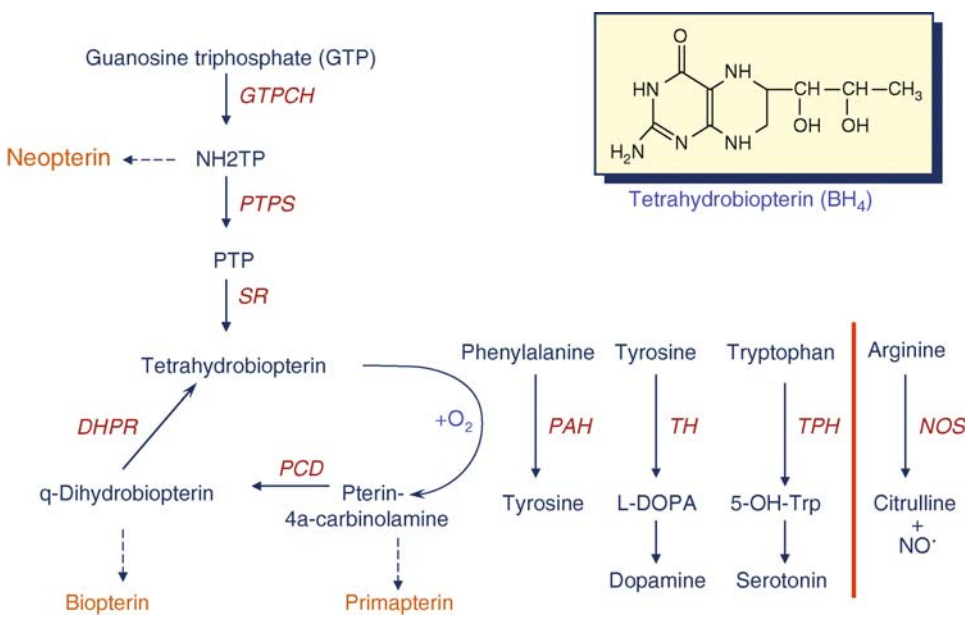
Defects in tetrahydrobiopterin ($BH_4$) metabolism can be divided into two groups: those associated *with* hyperphenylalaninemia (HPA) (GTP cyclohydrolase I (*ar*GTPCH) deficiency, 6-pyruvoyl-tetrahydropterin synthase (PTPS) deficiency, pterin-4a-carbinolamine dehydratase (PCD) deficiency, and dihydropteridine reductase (DHPR) deficiency; all inherited autosomal recessively) and those presenting *without* HPA (autosomal dominant GTP cyclohydrolase I (*ad*GTPCH) deficiency or Segawa disease and autosomal recessive sepiapterin reductase (SR) deficiency) [1]. Symptoms of $BH_4$ deficiency presenting with HPA can manifest during the first weeks of life but usually are noted at about 4 months of age. However, when information about the neonatal period is provided, a careful review indicates that abnormal signs (poor sucking, decreased spontaneous movements, and "floppy baby") may be observed even during the neonatal period. Birth is generally uneventful, except for a higher incidence of prematurity and lower birth weight in severe PTPS deficiency. In *ad*GTPCH deficiency, dystonic posture or movement of one limb (there is a preference for the left side) typically appear between the ages of 1 and 9 years and all limbs are involved within 5 years of onset. The DRD phenotype may be composed of a number of atypical presentations, including Parkinsonism (postural instability, cogwheel rigidity, hypomimia, bradykinesia and/or rest tremor), spastic paraplegia, and a presentation mimicking athetoid cerebral palsy. No axial torsion nor action dystonia or oculogyric crises are noted, as well as an absence of mental retardation. Symptoms are remarkably alleviated following sleep and worsen gradually toward evening. Diurnal fluctuation is present in about 70% of all cases reported and is exacerbated with age. There is a marked and sustained response to low doses of L-DOPA/Carbidopa without side effects [1].

## Prevalence

$BH_4$ deficiency with HPA: 1–2% of all hyperphenylalaninemias (1–2: 1,000,000 newborns). PTPS deficiency most common > DHPR deficiency > PCD deficiency > *ar*GTPCH deficiency.

## Genes

A total of 206 different mutant alleles were described in various form of $BH_4$ deficiency. Patients and mutations data are tabulated in BIOPKU and BIOMDB databases (www.biopku.org and www.biopku.org) [2].



**Tetrahydrobiopterin Deficiencies. Figure 1** Biosynthesis and regeneration of tetrahydrobiopterin ($BH_4$) including its function in the hydroxylation of phenylalanine, tyrosine and tryptophan and as a cofactor of nitric oxide synthase (NOS). GTPCH: GTP cyclohydrolase I; PTPS: 6-pyruvoyl-tetrahydropterin synthase (PTPS); SR: sepiapterin reductase; PCD: pterin-4a-carbinolamine dehydratase; DHPR: dihydropteridine reductase; PAH: phenylalanine-4-hydroxylase; TH: tyrosine-3-hydroxylase; TPH: tryptophan-5-hydroxylase. NH2TP: dihydroneopterin triphosphate; PTP: 6-pyruvoyl-tetrahydropterin; L-DOPA: 3,4-dihydroxyphenylalanine; 5-OH-Trp: 5-hydroxytryptophan; NO: nitric oxide.

## Molecular and Systemic Pathophysiology

The $BH_4$ cofactor is essential for several enzymes, and is involved in a number of functions poorly defined at the cellular level. The de novo biosynthesis pathway of $BH_4$ from GTP involves GTPCH, PTPS, and SR. Three additional enzymes catalyze the last two reduction steps as well; i.e. aldose reductase (AR), carbonyl reductase (CR), and 3α-hydroxysteroid dehydrogenase type 2 (HSDH2). Cofactor regeneration requires PCD and DHPR. The enzymes that depend on $BH_4$ are the phenylalanine, tyrosine, and tryptophan hydroxylases, all NO synthase (NOS) isoforms, and glyceryl-ether monooxygenase (Fig. 1).

Thus, deficiency of the cofactor $BH_4$ results in impaired synthesis of catecholamine, serotonin, and nitric oxide [3].

## Diagnostic Principles

Patients are diagnosed by different analytical and biochemical approaches depending upon the enzyme defect and the mode of inheritance. Patients presenting *with* HPA are usually detected through the neonatal screening programs for PKU (elevated Phe in blood), while those presenting *without* HPA are recognized either by the typical clinical signs and symptoms or by analysis of neurotransmitter metabolites (5-hydroxyindoleacetic acid and homovanillic acid) and pterins (neopterin, and biopterin, and sepiapterin) in cerebrospinal fluid (CSF), by investigations of cultured skin fibroblasts, or by DNA testing. The HPA-patients are differentiated by a series of tests including urinary or dried blood spots analysis of pterins, DHPR activity in dried blood, and by the $BH_4$ loading test [4].

## Therapeutic Principles

Treatment incl1udes substitution with neurotransmitter precursors L-DOPA (+Carbidopa), 5-hydroxytryptophan, monoamine oxidase-A (MAO-A) and COMT inhibitors, and $BH_4$ (Kuvan, Sapropterin). DHPR -deficient patients require additional supplementation with folinic acid. Only very few PTPS-deficient patients (mild peripheral form) can be treated by BH4 alone. Patients with *ad*GTPCH deficiency respond effectively to low dose L-DOPA/Carbidopa while those with SR deficiency need additional 5-hydroxytryptophan substitution [5].

# Tetralogy of Fallot

Elizabeth Goldmuntz
Division of Cardiology, Children's Hospital of Philadelphia, Philadelphia, PA, USA

## Definition and Characteristics

Congenital heart defect involving the conotruncus or outflow tracts of the heart. Though this anomaly was first described by Stensen in 1672, the four classic features were later defined by Dr. Fallot in 1888 and include: ventricular septal defect, subpulmonary and pulmonary stenosis, over-riding aorta and right ventricular hypertrophy. All four features in fact result from the anterior malalignment of the infundibular septum so that some have coined the phrase "monology of Fallot." The pulmonary valve can either be stenotic, atretic or "absent." The branch pulmonary arteries are hypoplastic to varying degrees and may be discontinuous. Aortopulmonary collateral vessels can be found in cases with pulmonary valve atresia. Concurrent aortic arch anomalies are common (25%), as are coronary artery anomalies (5%).

## Prevalence

One of the most common cyanotic heart defects estimated to account for approximately 7% of all types of congenital heart disease.

## Genes

Overall the etiology of tetralogy of Fallot is poorly understood. Thought to result from markedly heterogeneous etiologies including genetic and environmental factors. Tetralogy of Fallot is a characteristic feature of many genetic syndromes and associations for which the specific genetic alteration may or may not be known (see On-Line Mendelian Inheritance of Man). Tetralogy of Fallot is also seen in the context of polysplenia, for which there is likely a genetic etiology. The most common specific associated genetic alterations include: trisomy 21 (7% of all patients with tetralogy of Fallot),

**Tetralogy of Fallot. Table 1** Currently known genetic loci or disease genes for tetralogy of Fallot

| Genetic loci or disease gene | Syndrome |
|---|---|
| Trisomy 21 | Down syndrome |
| 22q11 deletion syndrome | DiGeorge, velocardiofacial, conotruncal anomaly face syndromes |
| *JAG1* | Alagille syndrome |
| *PTPN11* | Noonan syndrome |
| *NKX2.5* | Non-syndromic |
| *ZFPM2* | Non-syndromic |

22q11 chromosomal deletion (15%) [1], and JAG1 mutations (Alagille syndrome) [2]. Other possible disease genes include: NKX2.5 and ZFPM2 [3,4]. Sequence variants of VEGF causing decreased levels of VEGF may increase the risk of conotruncal defects including tetralogy of Fallot [5]. Additional disease-related genes and chromosomal loci are likely to be identified (Table 1).

## Molecular and Systemic Pathophysiology

The molecular and developmental mechanisms leading to tetralogy of Fallot are poorly understood. Possible mechanisms include abnormal neural crest cell function or alterations of the secondary heart field. Several engineered animal models produce cardiac defects resembling the human malformation.

The clinical pathophysiology is characterized by varying degrees of obstruction of blood flow across the right ventricular outflow tract to the pulmonary arterial bed resulting in a fixed right to left shunt across the ventricular septal defect and consequent cyanosis. The obstruction across the right ventricular outflow tract generally increases over time as does the severity of cyanosis. In the most severe cases, there is complete atresia of the pulmonary valve with aortopulmonary collaterals and severely diminutive branch pulmonary arteries. Rarely the pulmonary valve is "absent" with rudimentary valve leaflets and consequent pulmonary insufficiency in conjunction with pulmonary stenosis and markedly dilated branch pulmonary arteries. The latter can be associated with mild to severe respiratory compromise at birth and throughout life. Patients experience hypercyanotic spells (so-called "tet spells") with increasing probability and frequency over time. These episodes are characterized by a sudden increase in cyanosis and irritability with potential loss of consciousness if not death when untreated. The cause of hypercyanotic spells is not known, but they are thought to result from sudden increased pulmonary vascular resistance leading to increased right to left shunting across the ventricular septal defect and severe cyanosis.

## Diagnostic Principles

In the current era, tetralogy of Fallot is generally recognized in the first day or weeks of life, and even prenatally. Newborns and infants present with a pulmonary outflow murmur and/or cyanosis. The diagnosis is made by echocardiography. In some cases further imaging by cardiac catheterization or cardiac MRI may be warranted to detail branch pulmonary artery, aortic arch, collateral or coronary artery anatomy. Given the frequency of associated non-cardiovascular anomalies, thorough examination of the affected infant for additional congenital anomalies and for associated genetic syndromes is warranted. Some advocate testing for a chromosome 22q11 deletion in all newborns, particularly those with aortic arch anomalies [1].

## Therapeutic Principles

All patients with tetralogy of Fallot eventually undergo cardiac surgery. In general, the goal of surgery is to relieve the obstruction to blood flow across the right ventricular outflow tract and close the ventricular septal defect to restore normal circulation. Those with only mild to moderate cyanosis can undergo elective complete repair generally within the first 3–6 months of life. Newborns with severe obstruction or pulmonary valve atresia without aortopulmonary collaterals (ductal dependent lesions) undergo either a palliative modified Blalock-Taussig shunt followed at a later date by complete repair, or complete repair at the first operation. Patients with pulmonary valve atresia with aortopulmonary collaterals and small branch pulmonary arteries can be particularly difficult to treat and may never achieve a complete repair.

Survival to adulthood is excellent for most patients with tetralogy of Fallot. Long term complications include: pulmonary valve insufficiency (following surgery), pulmonary artery stenosis, recurrent obstruction across the right ventricular outflow tract, right ventricular dilation and/or failure, decreased exercise tolerance, aortic insufficiency, arrhythmia and sudden death. Many patients require repeat cardiac catheterization and intervention or surgery. It is important to provide genetic counseling to assess the risk of recurrence in offspring or to assess the risk of complications during pregnancy for the young adult with tetralogy of Fallot contemplating a family.

# Thalassemia Syndromes

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Synonyms

Cooley's anemia (synonymous for β-thalassemia major); Hb Bart's hydrops fetalis (synonymous for alpha 0 thalassemia homozygosity)

### Definition and Characteristics

Recessive hereditary disorders caused by a deficiency in hemoglobin polypeptide chain synthesis. The diseases are characterized by variable degrees of hemolytic anemia with ineffective erythropoiesis and secondary hemochromatosis, splenomegaly, and bony deformations due to extramedullary hematopoiesis. Most patients with thalassemia major die from complications of iron overload [1,2].

### Prevalence

Most common genetic disorder worldwide, with high frequencies in the Mediterranean, the Middle East, South-East Asia, India, Burma and Africa [1].

### Genes

Four α genes (αα/αα; 16ptr-p13.3) encode for α globin chain synthesis and two β genes (11p15.5) encode β globin chain synthesis. Most mutations leading to α thalassemia are gene deletions, whereas in β thalassemia, most mutations affect gene regulation or expression [1].

### Molecular and Systemic Pathophysiology

Normal postnatal hemoglobin consists of two α and two β globin chains ($\alpha_2\beta_2$, or HbA). The underlying cause of thalassemic disease is a reduced or abolished production of globin chain synthesis. α (+) thalassemia refers to deletion of one of two globin genes (α–) or non-deletion mutations resulting decreased α globin gene expression ($\alpha\alpha^T$). A relatively prevalent point mutation is the Hb Constant Spring (CS) variant, giving rise to an elongated α chain, which, when co-inherited with deletion mutations can give rise to symptomatic disease. α (0) mutations (−) result in absence of α globin chains. α thalassemia result in a relative excess of β chains that may form soluble tetramers ($\beta_4$) or HbH. α thalassemia phenotypes include: α+ thalassemia heterozygosity (–α/αα; clinically, often hematologically

normal), and homozygosity (–α/–α, – α/α $\alpha^T$, or alfa 0 thalassemia heterozygosity –/αα; all clinically normal but mild microcytic hypochromic anemia). Hemoglobin H (HbH) disease (–α/–, /–/αα$^T$, /–/$\alpha^{CS}$ $\alpha^T$, or αα$^T$/αα$^T$; can lead to severe hemolytic anemia with ineffective erythropoiesis, splenomegaly and bony changes). α chains are produced from the sixth week of intrauterine life, but in absence of α chains (−/−),γ chains accumulate and Hb Bart's (γ 4) is formed. As Hb Bart's affinity for oxygen is far greater than that of HbA oxygen is not sufficiently released from red cells, leading to severe 'functional' anemia with massive edema. This fourth α thalassemia phenotype, named Hb Bart's hydrops fetalis, is incompatible with extra-uterine life.

Nearly 200 mutations have been described that give rise to β thalassemia syndromes. β (0) mutations result in complete absence of β globin production, whereas β (+) mutations result in decreased β globin gene production. Clinical phenotypes of ββ thalassemic syndromes are β thalassemia silent (β (+)/β), β thalassemia minor (β (+)/β or β (0)/β), β thalassemia intermedia (β (+)/β (+) or β (0)/β) and β thalassemia major, or Cooley's anemia (β (0)/β (0), β (0)/β (+),β (+)/β (+)). With exception of the (−/−) phenotype of α thalassemia, β thalassemia syndromes of comparable genetic severity are more severe as compared to α thalassemia. This is because excess α globin chains do not form tetrameres but precipitate even in young red cell precursors, causing more damage to the red cell. Other thalassemia syndromes occur, such as δβ and γδβ thalassemia, and many combinations occur with structural hemoglobin variants such as with HbS, either ameliorating or worsening such disease states (see ►Sickle cell disease) [1,2].

## Diagnostic Principles

Diagnosis usually suspected based on family history, ethnicity, microcytosis, and depending on the severity, the presence of chronic or hemolytic anemia with relative erythrocytosis. Characteristic hemoglobin patterns are demonstrated with hemoglobin electrophoresis or high performance liquid chromatography in β thalassemia and HbH disease. DNA-based studies are needed to establish the presence of α thalassemia and to characterize specific mutations [1].

## Therapeutic Principles

Therapy is largely supportive. The microcytic hypochromic anemia is not due to iron deficiency and therefore iron supplementation should be stringently avoided. Severely affected patients are blood transfusion dependent and increasing transfusion requirement may warrant splenectomy. Iron chelation therapy should be instituted timely and strict adherace to chelation therapy leads to increased servival [2]. Hematopoietic cell transplantation offers curative therapy in selected individuals and gene therapy is under intense investigation [1–3].

# Thanatophoric Dwarfism

►Thanatophoric Dysplasia

# Thanatophoric Dysplasia

Jacky Bonaventure
Institut Curie, Centre Universitaire Paris Sud, Orsay, France

## Synonyms

Thanatophoric dwarfism

## Definition and Characteristics

Autosomal dominant skeletal disorder characterized by defective growth of long bones, relative macrocephaly, and narrow thorax with respiratory distress leading to perinatal lethality. The disease has been subdivided into two subtypes, TD I and TD II, based on radiological aspects of the femurs (bowed or straight) and presence or absence of cloverleaf skull.

## Prevalence

1/50,000 births. Increased risk linked to elevated paternal age.

## Genes

Fibroblast growth factor receptor 3 (FGFR3) localized on chromosome 4p16.

## Molecular and Systemic Pathophysiology

FGFR3 belongs to a four-member family of tyrosine kinase receptors (FGFR1–4) interacting with variable affinities to 22 fibroblast growth factors (FGFs). Binding of FGF ligand, in the presence of heparan sulfate proteoglycan (HSPG) acting as a co-receptor, leads to receptor dimerization and autophosphorylation [1]. Receptors comprise three functional domains including an extracellular domain with three disulfide bonded immunoglobulin-like (Ig I–III) loops, a hydrophobic transmembrane domain, and an intracellular domain carrying the kinase activity (Fig. 1).

The second half of the third Ig loop originates from alternative splicing of exon 8 or 9 giving rise, respectively, to the IIIc or IIIb isoforms with tissue-specific expressivity. De novo recurrent heterozygous missense mutations affecting the extracellular or intracellular domains have been shown to produce thanatophoric dysplasia types I and II (TD I and TD II). Mutations in the extracellular domain only account for TD I, the most severe form of the disease with bowed femurs [2]. They all create unpaired cysteine residues able to form disulfide bonds between two mutant receptors. TD II, a slightly less severe condition with straight femurs and cloverleaf skull is accounted for by a single recurrent mutation at residue 650 (K650E). Conversion of the same lysine into methionine (K650M) can produce TD I, which has also been ascribed to missense substitutions (X807R/C/G/W/S) eliminating the termination codon, hence resulting in a receptor elongated by 141 amino acids in its carboxy terminal part [3].

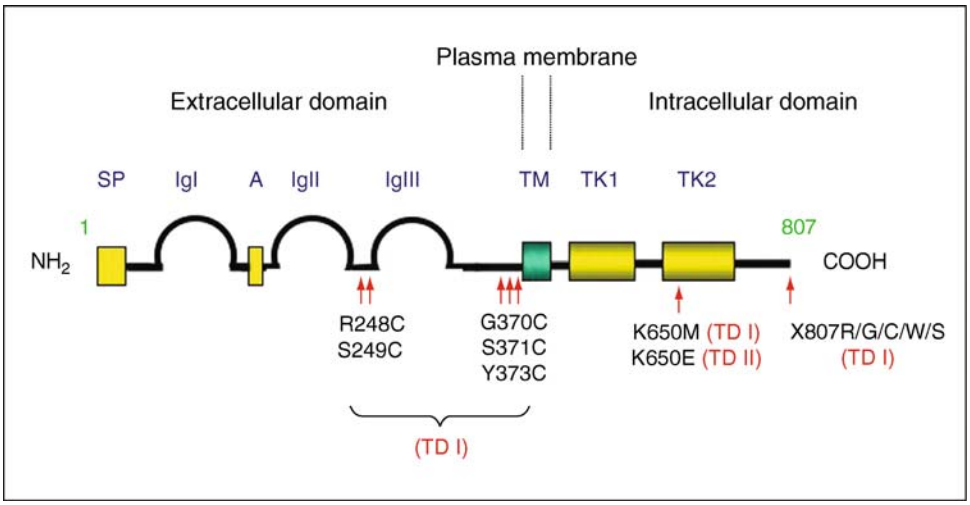
The whole mutations induce constitutive FGFR3 activation resulting in receptor autophosphorylation in the absence of ligand. However, extracellular and intracellular mutations differently affect receptor subcellular localization and could recruit two different sets of target proteins.

During skeletal development, the IIIc isoform of FGFR3 is mostly expressed in proliferative and pre-hypertrophic chondrocytes of control fetal cartilage.

Histological examination of the cartilage growth plate of TD cases reproducibly documented short and disorganized chondrocyte columns with an irregular ossification line. Two FGFR3-related signaling pathways, the MAPK and the STAT pathways, are activated in chondrocytic cells of TD patients at the growth plate level, affecting both proliferation and differentiation. Activation of the cyclin-dependent kinase inhibitor ($p21^{CIP}$) through STAT signaling is likely to induce premature exit of proliferative chondrocytes from the cell cycle and promote their accelerated differentiation into pre-hypertrophic chondrocytes. Activation of the MAPK pathway in pre-hypertrophic cells could hamper their terminal differentiation into hypertrophic chondrocytes and part of these cells may undergo increased apoptosis ultimately resulting in disorganized growth plate and defective long bone elongation [4]. Hence, FGFR3 IIIc clearly appears as a negative regulator of endochondral ossification.

## Diagnostic Principles

Ultrasound detection of short femurs and macrocephaly at 15–20 weeks of gestation is the most reliable technique for precocious diagnosis of TD. Identification of one of the recurrent FGFR3 mutations causing



**Thanatophoric Dysplasia. Figure 1** Diagram illustrating the three functional domains of FGFR3. Positions of mutations causing TD are shown by arrows. The X807R/G/C/W/S mutations give rise to a 947 amino-acid receptor.

T

TD by sequencing analysis further confirms the sonographic diagnosis.

### Therapeutic Principles

Although no treatment for TD is available to date, anti-FGFR3 blocking antibodies and tyrosine kinase inhibitors able to compete with ATP at the ATP binding site adjacent to the catalytic domain have been generated [5]. They are being tested on cultured cells and animal models.

## Thiamine Deficiency

Donatus Nohr
Department of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

### Synonyms

Beriberi (dry, wet, cerebral); $B_1$ avitaminosis

### Definition and Characteristics

Dry beriberi is characterized by peripheral neuropathy, "burning feet syndrome," exaggerated reflexes, diminished sensation, and weakness in all limbs, muscle pain, and problems in rising from squatting position. In severe cases eventually seizures. Wet beriberi is characterized by cardiovascular symptoms, rapid heart rate, enlargement of the heart, edema, problems in breathing, and ultimately congestive heart failure. Cerebral beriberi mostly leads to Wernicke's encephalopathy and to Korsakoff's psychosis, together appearing as ►Wernicke-Korsakoff syndrome [1].

### Prevalence

Mainly in Asia with peeled and polished rice as main food. In affluent countries due to chronic alcohol abuse, malabsorption, disturbance of carbohydrate metabolism (citric acid cycle).

### Molecular and Systemic Pathophysiology

Severe interruption of metabolic pathways in mitochondria; thiamine pyrophosphate (TPP) is a required coenzyme for a number of enzymes (e.g., pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, branched-chain ketoacid dehydrogenase) involved in energy production from food, disturbance of the pentose phosphate pathway. Disinhibition of glycosylation with "advanced glycosylation end products" (AGE) involved in segmental demyelinization. Disturbance of axonal conductivity and the neuromuscular junction (thiamine triphosphate (TTP) alters membrane ion channels). An interaction of thiamine homeostasis with oxidative stress in neurodegeneration is discussed [2].

### Diagnostic Principles

Measurement of TPP in blood by HPLC (normal thiamine level in blood 6–12 µg/100 ml); activation of transketolase (TPP-dependent enzyme) by TPP in red blood cells (>25% high risk; 16–24% medium risk).

### Therapeutic Principles

Severe cases (Wernickes encephalopathy) 50–100 mg i.v. and/or i.m. up to 2 weeks, followed by oral administration. Polyneuropathies or cardiovascular

symptoms 50 mg 2times a day orally, in cases of malabsorption 100 mg/day parenteral for 3 months. May be enhanced to 200 mg/day under hepatic malfunctions. As thiamine is a water-soluble vitamin, excess uptake is regulated by quick excretion. Thiamine ingested has very low toxicity in humans [3]. Side effects (nausea, headache) occurred under supplementation up to 7 g/day given orally, they disappeared after cessation or reduced doses, anaphylactic reactions have been observed under i.v. application, unclear whether thiamine itself was responsible. A daily uptake of 1.4 mg/day and 1 mg/day for males and females, respectively, is recommended. In pregnancy it should be 1.6–1.8 mg/day.

# Thiopurine Methyltransferase Deficiency

Anthony M. Marinaki[1], Monica Arenas[2]
[1]Purine Research Laboratory, St. Thomas' Hospital, London, UK
[2]Purine Research Laboratory, Guy's Hospital, London, UK

## Synonyms

TPMT

## Definition and Characteristics

Autosomal recessive. The natural substrate for thiopurine methyltransferase (TPMT) is unknown and deficiency of the enzyme is not known to be associated with any primary clinical condition. However, TPMT is an important drug metabolising enzyme which catalyses the S-methylation and inactivation of the thiopurine drugs 6-mercaptopurine (6-MP) of which azathioprine (AZA) is the prodrug and 6-thioguanine (6-tG) (Fig. 1). TPMT deficiency is thus of pharmacogenomic importance [1].

## Prevalence

About 1 in 300 Caucasians have zero TPMT activity.

## Genes

Located on chromosome 6p22.3, the TPMT gene consists of nine exons and is about 34 kb in length [2]. More than 20 allelic variants associated with low TPMT activity have been identified [3]. The most common allelic variants associated with deficient TPMT activity in Caucasians are TPMT*3A (460G > A and 719A > G) and TPMT*3C (719A > G), occurring with a combined allelic frequency of approximately 0.06. TPMT*3C (719A > G) is more common in African populations and in Asians, albeit at a lower frequency.

## Molecular and Systemic Pathophysiology

Impaired methylation of thiopurine drugs due to TPMT deficiency leads to enhanced conversion of the thiobase to active thioguanine nucleotides (Fig. 1).

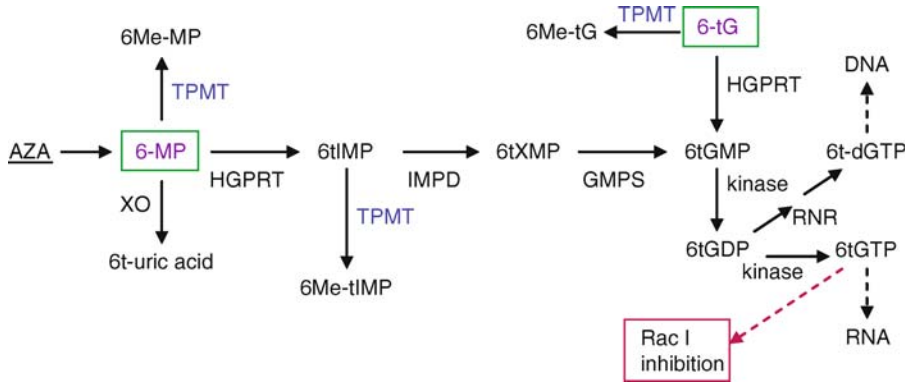
Patients with zero TPMT activity are at risk of life-threatening bone marrow suppression [1]. TPMT carriers are at high risk for mild to moderate neutropenia and other adverse drug reactions requiring therapy withdrawal [1,4]. Conversely, high TPMT activity may be associated with the accumulation of methylated thiopurine metabolites and an increased risk of hepatoxicity [5].

## Diagnostic Principles

Pre-treatment diagnosis of TPMT deficiency is vital to identify patients with zero TPMT activity who are at risk of life threatening bone marrow suppression if treated with thiopurine drugs. TPMT phenotyping by red cell enzyme assay is preferred. Genotyping for common allelic variants only, carries the risk that rare mutations may be missed in some families. Measurement of red cell thio-guanine nucleotides may be useful in predicting response and confirming compliance.

## Therapeutic Principles

Patients with normal TPMT activity can be treated with a standard dose of AZA (typically 2–2.5 mg/kg). TPMT carriers should be treated with half the normal dose due to the possibility of adverse drug reactions. On the whole, patients with zero TPMT activity should not



**Thiopurine Methyltransferase Deficiency. Figure 1** Metabolism of azathioprine (AZA), 6-mercaptopurine (6-MP) and 6-thioguanine (6-tG) On absorption, AZA is rapidly converted to 6MP. 6MP availability is reduced either by methylation to 6-methylmercaptopurine (6Me-MP) catalysed by TPMT or conversion to thiouric acid by xanthine oxidase (XO). Cytotoxic thioinosine or guanine nucleotides are formed via the salvage enzyme hypoxanthine guanine-phosphoribosyltransferase (HGPRT). These include, 6-thioinosine monophosphate (6tIMP), 6-thioxanthosine monophosphate (6tXMP), 6-thioguanine mono-, di- and tri- phosphates (6tGMP, 6tGDP, 6tGTP), 6methylthioguanine (6Me-tG) and 6-deoxythioguaninetriphosphate (6t-dGTP). Other abbreviations IMPDH = Inosine monophosphate dehydrogenase, GMPS = Guanine monophosphate synthase, RNR = ribonucleotide reductase.

receive AZA, although successful treatment with very low dose AZA has been reported [1]. White cell counts should be monitored regularly.

## Thoracic Actinomycosis

►Pulmonary Actinomycosis

## Thoracic Outlet Compression Syndrome

►Thoracic Outlet Syndrome

## Thoracic Outlet Syndrome

Robert F. Groff IV, Jason H. Huang
Department of Neurosurgery, University of Pennsylvania, Philadelphia, PA, USA

### Synonyms

Thoracic outlet compression syndrome; TOS; Cervical band syndrome

### Definition and Characteristics

Thoracic outlet syndrome (TOS) is a compression of the brachial plexus or subclavian vasculature as it projects from the cervical area toward the axilla and proximal arm. Three different subtypes are recognized: *neurogenic* TOS is the compression of axon trunks within the brachial plexus, *vascular* TOS is the compression of the subclavian artery or vein, and *non-specific or disputed* TOS is a poorly defined chronic pain syndrome accompanied by features suggestive of brachial plexus involvement.

### Prevalence

Although the incidence of TOS is a subject of wide dispute clinically, it is estimated to be between 3 and 80 per 1,000 population [1]. True neurogenic TOS is most prevalent in post-pubertal, asthenic females with long necks and drooping shoulders [2].

## Molecular and Systemic Pathophysiology

The vast majority of TOS cases result from compression of neural or vascular elements within the interscalene triangle. The margins of the interscalene triangle are defined by the anterior scalene muscle anteriorly, the middle scalene muscle posteriorly, and the medial surface of the first rib inferiorly. In neurogenic TOS, anomalous ribs and fibrous bands can compress the interscalene triangle causing constriction of brachial plexus trunks. The classic finding is the Gilliatt-Sumner hand on the affected limb exhibiting a characteristic scalloped appearance induced by atrophy of distal musculature (especially abductor pollicis brevis). Sensory loss is typically concentrated within the ulnar aspect of the hand and arm. Pain is not a cardinal feature of true neurogenic TOS although some degree of dull pain may be observed. In vascular TOS, the subclavian artery or vein becomes compressed by fibrous bands or an anomalous cervical rib causing a disruption of circulation to the affected extremity. Pallor, pulselessness, and skin that is cool to the touch result from subclavian artery compression. Alternatively, subclavian vein compression within the interscalene triangle induces cyanosis, edema, and distension of superficial veins on the injured extremity. Non-specific or disputed TOS commonly presents as a chronic pain syndrome without dermatomal confinement or significant radiological features.

## Diagnostic Principles

The presence of the Gilliatt-Sumner hand in combination with abnormal nerve conduction values for the ulnar sensory and the median motor bundles is suggestive of neurogenic TOS. MRI and CT scans may be helpful in the identification of anomalous rib or vertebral structures. A positive Tinel's sign over the supraclavicular fossa has also been observed during physical exam in cases of neurogenic TOS. A diagnosis of vascular TOS is achieved primarily by careful evaluation of arteriography and venography. Color flow duplex ultrasonography, magnetic resonance arteriography, and computed tomographic angiography are particularly illustrative of compression of the subclavian artery or vein. Non-specific or disputed TOS is difficult to diagnose because it lacks the radiological features of neurogenic or vascular TOS and does not present consistently across patients. Pain and paresthesias are incorporated in structures innervated by brachial plexus projections, but structures not commonly associated with the brachial plexus may also be involved.

## Therapeutic Principles

A conservative approach is favored initially for patients suffering from neurogenic or non-specific TOS. Physical therapy is individually tailored and is generally targeted at strengthening the pectoral girdle and correcting postural alignment. Overall, behavioral strategies have been shown to relieve symptoms of TOS by 50–90% [3]. Surgical decompression is typically indicated for patients who do not respond to a more conservative regimen of physical therapy or patients with vascular TOS. Emergency surgery is only indicated in rare cases involving infarction as a result of vascular occlusion or recurrent embolism.

## Synonyms

Carboxypeptidase B2, Plasma; CPB2CARBOXYPEPTIDASE U; CPU; TAFI

## Definition and Characteristics

First purified as a 60-kd plasminogen binding protein from human plasma [1]. Predicted 423-amino acid protein was similar to tissue type carboxypeptidases A and B; Eaton et al designated the gene plasma carboxypeptidase B (pCPB) (different from carboxypeptidase N, now known as CPN [2]. Also known as carboxypeptidase U (CPU), it was observed that the zymogen pro-CPU had affinity for plasminogen and could be converted to the active form by thrombin–thrombomodulin complex and plasmin. By convention, CPU and pCPB are now recognized as TAFI. TAFI is mainly produced by the liver as a single chain protein of 401 amino acids and is a potent inhibitor of fibrinolysis by removing the fibrin C-terminal lysine and arginine residues that bind plasminogen. In the LETS study an increased concentration of TAFI was associated with a twofold increased risk [3].

## Prevalence

Elevated TAFI antigen levels (>90th percentile of controls, i.e., >122 U/dL) have been found in 9% of healthy controls and in 14% of patients with a first deep venous thrombosis [3].

## Genes

Males and females are equally affected. Heterozygous deficiency is associated with an increased risk of venous thrombosis; homozygous deficiency is extremely rare and thought to be incompatible with life [1].
*Gene Map Locus*: 13q14.11

## Molecular and Systemic Pathophysiology

The plasma level appears to be strongly influenced by polymorphisms in the promoter and 3′ untranslated region of the gene [2]. Sequencing of the 5′ regulatory region of the TAFI gene identified seven novel polymorphisms, a number of which was related to TAFI level and combinations of some may be associated with a mildly changed risk of thrombosis. In one study a protective effect of a -438 A/A genotype has been suggested in patients with pulmonary embolism.

TAFI emerges as an important modulator of blood coagulation, through its inhibitory potential of fibrinolysis. Functional levels appear to be correlated with clinical disease, i.e., elevated antigen levels are associated with a mildly elevated risk of venous thrombosis (so far no convincing relation with arterial thrombosis). Lowered plasma levels may be associated with a greater risk of bleeding, as suggested from patients with promyelocytic leukemia and liver cirrhosis [4].

*Clinical Features*: The risk of venous thromboembolism is increased twofold in patients with an antigen level >90th percentile of normal distribution. Effects on arterial thrombosis are uncertain. A high level of TAFI antigen has also been associated with an increased risk of recurrent venous thromboembolism and a high factor IX, XI, or VIII level as compared with a low TAFI concentration and one of these other clotting factors. Particularly the association with a high factor VIII level produces a significant risk elevation (relative risk 6.5, 95% CI 2.9–14.8) [5].

## Diagnostic Principles

Routine measurement of TAFI antigen is not yet included in routine thrombophilia screening, mainly due to a lack of reliable activity assays (now becoming available). The utility for prognosis and risk assessment are so far unknown [4].

## Therapeutic Principles

No specific interventions are clinically available. Several options promise to be of interest. A potato carboxypeptidase inhibitor (PTCI) increased efficiency of thrombolysis in rabbit models of venous and arterial thrombosis [4]. In opposite direction, agents that would increase TAFI activity, such as soluble thrombomodulin or derivatives thereof, may become useful in bleeding conditions such as hemophilia.

# Thrombocythemia Vera

►Thrombocythemia, Essential

# Thrombocythemia, Essential

Ayalew Tefferi
Division of Hematology, Mayo Clinic College of Medicine, Rochester, MN, USA

## Synonyms

Primary thrombocytosis; Idiopathic thrombocytosis; Thrombocythemia vera

## Definition and Characteristics

Essential thrombocythemia (ET) is classified as a BCR-ABL-negative, classic myeloproliferative disorder (MPD), along with polycythemia vera (PV) and primary myelofibrosis (PMF). The World Health Organization (WHO) system for the classification of hematological malignancies sets the platelet count limit, for the diagnosis of ET, at $450 \times 10^9$/L [1]. In addition to ET, other causes of thrombocytosis include reactive thrombocytosis (RT), congenital thrombocytosis, and clonal thrombocytosis associated with other myeloid disorders including PV, PMF, chronic myeloid leukemia (CML), and the myelodysplastic syndrome (MDS) (Table 1).

**Thrombocythemia, Essential. Table 1** Causes of thrombocytosis

| Clonal thrombocytosis | Reactive thrombocytosis |
|---|---|
| Essential thrombocythemia | Infection |
| Polycythemia vera | Tissue damage |
| Myelofibrosis with myeloid metaplasia (overtly fibrotic) | Chronic inflammation |
| Myelofibrosis with myeloid metaplasia (cellular phase) | Malignancy |
| Chronic myeloid leukemia | Rebound thrombocytosis |
| Myelodysplastic syndrome | Renal disorders |
| Atypical myeloproliferative disorder | Hemolytic anemia |
| Acute leukemia | Post-splenectomy |
| | Blood loss |

## Prevalence

ET is the most frequent among the MPDs with an annual incidence that is estimated between 0.2 and 2.5/100,000 [1]. In a cohort of 605 ET patients seen at the Mayo Clinic, median age at diagnosis was 57 years, females represented 66% of the patient population, and approximately 11% were younger than age 30 years and 5% older than age 80 years [2]. ET is rare in children and the possibility of familial thrombocytosis must be considered in the particular context.

## Genes

ET is a stem cell-derived clonal disorder. However, the primary clonogenic event remains poorly defined despite the recent descriptions of two gain-of-function mutations that occur in 50% (JAK2V617F) and 1% (MPLW515L/K) of patients with ET, respectively [3,4]. JAK2V617F represents a guanine-to-thymine transversion at nucleotide 1849, in exon 14 of JAK2, resulting in a valine-to-phenylalanine amino acid substitution at codon 617. MPLW515L mutation represents a G to T transition at nucleotide 1544 resulting in a tryptophan to leucine substitution at codon 515 of the transmembrane region of the thrombopoietin receptor, MPL. Both mutations have been shown to induce a MPD in mice.

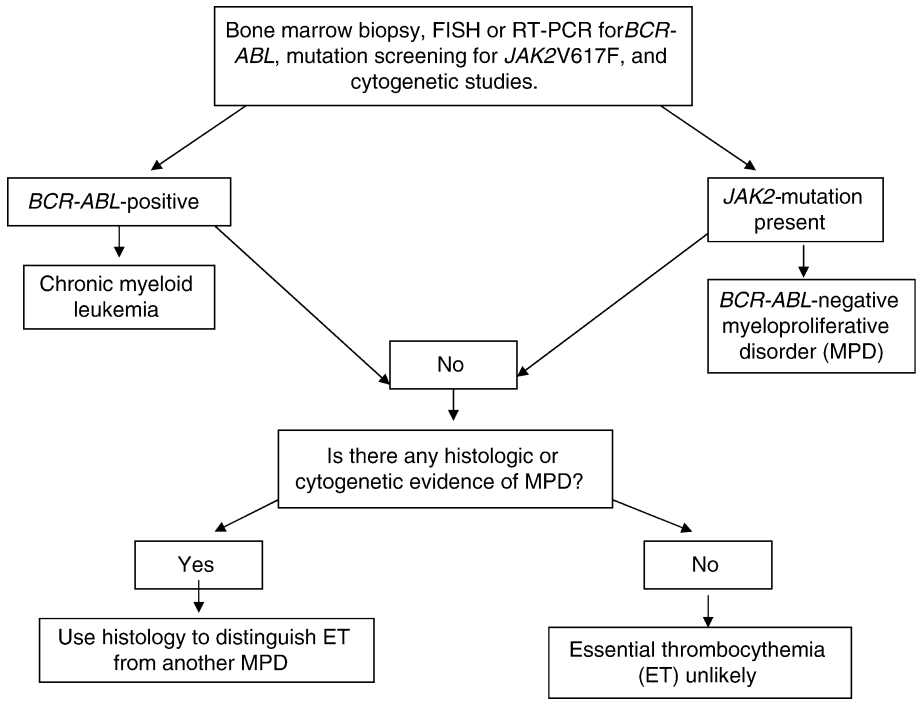
## Molecular and Systemic Pathophysiology

Other biological features in ET include *in vitro* growth factor independence/hypersensitivity of both erythroid and megakaryocyte progenitor cells, altered megakaryocyte/platelet Mpl expression, increased neutrophil PRV-1 expression, and decreased platelet serotonin content. Growth factor-independence of myeloid progenitor cells in ET and related MPDs has now been attributed to mutations involving molecules of the JAK-STAT pathway including the aforementioned JAK2V617F and MPLW515L/K.

## Diagnostic Principles

Before a working diagnosis of ET is made, the possibility of both reactive thrombocytosis (RT) and clonal thrombocytosis other than ET must be considered and ruled out (Fig. 1).

RT can be associated with infectious or inflammatory conditions, iron deficiency anemia, and the post-splenectomy state, among other things. If the clinical scenario is not consistent with RT, a bone marrow examination is recommended in order to confirm the diagnosis of ET, as well as exclude other causes of clonal thrombocytosis. In addition to bone marrow morphological assessment, fluorescent in situ hybridization or RT-PCR for BCR-ABL should be performed in order to exclude the possibility of CML. Mutation screening for JAK2V617F helps in confirming the



**Thrombocythemia, Essential. Figure 1** A diagnostic algorithm for non-reactive thrombocytosis.

presence of an underlying MPD (when the test is positive) but can not distinguish between ET and other causes of clonal thrombocytosis. Furthermore, a negative JAK2V617F test has little diagnostic value because approximately 50% of patients with ET do not display the specific abnormality.

## Therapeutic Principles

ET patients can now be risk-stratified in terms of survival, leukemic transformation, and thrombosis. Current therapy does not affect either survival or disease transformation rates into either acute myeloid leukemia or secondary myelofibrosis. Instead, anti-platelet (e.g. aspirin) and cytoreductive (e.g. hydroxyurea) agents are used in order to either alleviate microvascular symptoms (e.g. headaches, erythromelalgia) or prevent thrombohemorrhagic complications, respectively. However, cytoreductive therapy does not benefit all patients and is indicated only for high-risk for thrombosis patients whereas a conservative approach is preferred for low-risk disease (Table 2).

When indicated, the cytoreductive drug of choice is hydroxyurea. In hydroxyurea-intolerant patients, interferon alpha is a reasonable alternative and is the drug of choice during pregnancy. The two largest studies in ET and PV do not support the concern regarding drug leukemogenicity associated with hydroxyurea [2,5]. In the absence of contraindications, all patients with ET might benefit from aspirin therapy.

**Thrombocythemia, Essential. Table 2** Risk-based treatment algorithm in essential thrombocythemia

| Risk category | Variables | Treatment |
|---|---|---|
| Low-risk | Age below 60 years, *and* No history of thrombosis, *and* Platelet count below 1,000 × $10^9$/L | Aspirin (81 mg/day) |
| Intermediate-risk | Neither low-risk nor high-risk | Controversial |
| High-risk | Age 60 years or older, *or* A positive history of thrombosis | Hydroxyurea*+ Aspirin |

*Substitute interferon-alpha for hydroxyurea in women of child-bearing potential.

## Thrombocytopenia

►Monocytopenia (in Adults)

## Thrombocytopenia and Thrombotic Thrombocytopenic Purpura

Han-Mou Tsai
Division of Hematology, Montefiore Medical Center and Albert Einstein College of Medicine, New York, NY, USA

### Synonyms

Moschcowitz' disease; Schulman-Upshaw syndrome; Upshaw-Schulman syndrome; TTP

### Definition and Characteristics

TTP is a relative uncommon but serious disorder in which widespread platelet thrombi are found in the arterioles and capillaries of multiple organs. The ischemia and injury of the affected organs cause mental changes, focal neurological deficits, fever, seizures, cardiac dysfunction, hematuria, abdominal pain, pancreatitis, and mild renal impairment. Consumption of platelets results in thrombocytopenia, causing subcutaneous and mucosal bleedings, but life-threatening bleeding, e.g., intracranial hemorrhage, is rare. Thrombosis also creates abnormally high levels of shear stress in the microvasculature, causing fragmentation of the red blood cells and hemolysis.

TTP is caused by a profound deficiency of ADAMTS13, a zinc metalloprotease derived primarily from the perisinusoidal stellate cells of the liver. Two forms of ADAMTS13 deficiency are recognized: an acquired form associated with autoimmune inhibitors of ADAMTS13 (Moschkowitz disease) and an inherited form caused by mutations of the ADAMTS13 gene (Schulman-Upshaw syndrome). The acquired form usually affects adolescents or adults and may recur unexpectedly over time. The inherited form of TTP is much rarer and typically appears during the neonatal period or early childhood. In patients with the inherited form of TTP, the symptoms and signs often recur 2–4 weeks after the therapy of plasma infusion.

Until very recently, TTP has been used interchangeably by many investigators with the hemolytic uremic syndrome (HUS), as if both refer to the same disease process. Advances in the past 10 years have demonstrated that approximately 30–50% of the patients with have the HUS defects in the regulation of complement activation, due to heterozygous or homozygous mutations of complement factor H, complement factor I, membrane cofactor protein (CD46), or complement factor B. Thus, TTP and HUS result from distinct molecular defects but may present with overlapping clinical features. It is important to note that some physicians continue to use TTP and HUS interchangeably.

### Prevalence

The precise incidence of TTP is unknown, but has been estimated to be approximately 1.7–10 cases per million adults per year in the United States. The disorder occurs more frequently in women than in men, with a female-to-male ratio of approximately 3:1. Women between 20 and 50 years of age are most commonly affected.

### Genes

Familial occurrence of acquired TTP is distinctly unusual. The inherited form of TTP affects all racial and ethnic groups and is transmitted as an autosomal recessive trait. Carriers of one mutant allele are partially deficient in ADAMTS13 but no phenotypic abnormalities have been identified. More than 65 mutations and 25 polymorphisms of the ADAMTS13 gene have been reported. The mutations include nonsense, missense, frame-shifting insertion or deletion, and intron splicing, which occur throughout the entire span of the ADAMTS13 gene exons or intron–exon boundaries without apparent hot spots. The mutations may decrease ADAMTS13 levels by compromising its synthesis, secretion, or enzymatic activity.

### Molecular and Systemic Pathophysiology

ADAMTS13 cleaves the hemostatic glycoprotein von Willebrand factor in a shear stress-dependent manner. Shear stress causes conformational unfolding of von Willebrand factor from a globular to an elongated form. This conformational change by shear stress increases the platelet aggregating activity of the von Willebrand factor,

but also renders it susceptible to cleavage by ADAMTS13. The response of von Willebrand factor to shear stress is critical for its hemostatic function in the high shear environment of the microvasculature. Nevertheless, if left unchecked, this shear-induced response will lead to the development of platelet–platelet aggregation and thrombosis in the microvasculature. By cleaving only conformationally unfolded von Willebrand factor, ADAMTS13 prevents platelet thrombosis without compromising the hemostatic mechanism in the circulation. It is believed that a deficiency of ADAMTS13 leads to progressive accumulation of evermore active forms of von Willebrand factor, culminating in the development of platelet thrombosis, hemolysis, and organ dysfunctions as encountered in TTP.

Most patients with the acquired form of TTP do not have an obvious aetiology. Paradoxically, TTP with ADAMTS13 inhibitory antibodies may develop in patients taking ticlopidine, an antiplatelet agent used to prevent thrombosis in association with coronary artery or cerebrovascular diseases. Throughout its epidemic, HIV infection was once quite common among patients with TTP, but has become less prevalent in recent years. Although some of the TTP patients have a history of systemic lupus erythematosus or autoimmune thyroiditis, concurrent active autoimmune diseases such as lupus or autoimmune hemolytic anemia has only been noted in a few reports.

## Diagnostic Principles

A suspicion of TTP is usually raised in patients presenting with thrombocytopenia and hemolysis, particularly when fragmented forms of erythrocytes are noted on blood films. Assay of ADAMTS13 activity provides a definitive diagnosis of the disease. Patients with TTP typically have a profound deficiency (<10 or 5%, depending on the assays used) of the protease activity.

An inhibitor or antibody of ADAMTS13 is detected in the acquired form of TTP. In inherited TTP, a partial deficiency of ADAMTS13 is detected in both parents.

Biopsy of the gingiva, skin, bone marrow, or kidney may demonstrate the presence of hyaline thrombi in the arterioles and capillaries. Biopsy is infrequently used because the yield of positive results is low. Since involvement of the kidney is usually not extensive in TTP, a renal biopsy is less likely to reveal the presence of intraglomerular thrombi in patients with TTP than in patients with the HUS.

## Therapeutic Principles

If untreated, TTP is associated with a fatality rate greater than 90%. Plasma exchange is quite effective for TTP, decreasing the risk of death to 10–30%. Infusion of normal plasma without exchange is also effective but its use is limited by the risk of fluid overload. Acetylsalicylic acid, dipyridamole, and corticosteroids are often used, although their roles have not been rigorously investigated. In refractory cases, vincristine, splenectomy, azathioprine, cyclophosphamide, cyclosporin A, or rituximab (a chimeric anti-CD20 monoclonal antibody) are often added to plasma exchange. Recombinant ADAMTS13 or its variants that are resistant to inhibition by autoimmune inhibitors are under development for the treatment of TTP.

For patients with the inherited form of TTP, infusion of a small amount (10–15 mL/kg body weight) of fresh frozen plasma induces remission that lasts for approximately 10–14 days or longer. Recombinant ADAMTS13 or gene therapy should be an effective replacement therapy when it becomes available in the future.

# Thrombocytopenia with Absent Radii Syndrome

Mofid Ibraheim, Amaj Ikomi
Department of Obstetrics and Gynaecology, Basildon University Hospital, Basildon, UK

## Synonyms

TAR syndrome

## Definition and Characteristics

Autosomal recessive disorder characterized by bilateral absence of the radii in the presence of both thumbs and thrombocytopenia (Fig. 1).

Lower limbs, gastrointestinal, cardiovascular, and other systems may also be involved.

**Thrombocytopenia with Absent Radii Syndrome. Figure 1** Showing affected baby with TAR (thrombocytopenia with absent raddi) syndrome. Note the short stature of the forearm, redial deviation of the hand and petechiae and ecchymoses.

## Prevalence

Approximately 1:500,000 to 1 million. The frequency in Spain is 0.42/100,000 live born infants.

An excess of affected females might suggest a sex-linked dominant inheritance with lethality in males.

## Genes

The exact genetic basis of TAR syndrome is uncertain. In one study, chromosomal analysis was carried on 16 cases and two abnormal karyotypes were found. One case had a karyotype 46,XY,dup(8)(p23.1p23.1). Parental chromosome analysis showed that the duplication was maternally inherited. This case had typical TAR syndrome with no unusual features. The second abnormal karyotype was a de novo translocation, 46,X, t ((1;7)(q42;p15). This child also developed a Wilms tumor with a nephrogenic rest in the other kidney. Chromosome breakage studies in 14 cases were normal with no evidence of premature centrometric separation (PCS).

## Molecular and Systemic Pathophysiology

The bone marrow of patients with TAR syndrome shows normal erythroid and myeloid maturation with absent or marked decrease of megakaryocytes. Investigations have focused on thrombopoietin (TPO), the main regulator of thrombopoesis, and its receptors (c-mpl). It was found that serum levels of TPO were raised but expression of the TPO receptors (c-mpl) was similar to that of controls.

Due to an absence of in vitro reactivity to TPO, it is suggested that the defective platelet production is not the result of lack of TPO production, but due to a lack of down stream response in the c-mpl signal transduction pathway. It was also found that the colony-forming unit-megakaryocyte number was reduced in bone marrow and the proportion of megakaryocytes was unable to complete terminal differentiation, suggesting that the defect lies in the early stages of megakaryocytes differentiation. However, many studies have failed to find mutations in the TPO receptors gene.

## Diagnostic Principles

Bilateral absence of the radii in the presence of both thumbs and a thrombocytopenia point to the disease. The presence of the thumbs distinguishes TAR syndrome from other disorders featuring radial aplasia, which are usually associated with absent thumbs. The thrombocytopenia is extremely profound at birth and during the first 4 months of life. The platelet count tends to rise as the child gets older and may approach normal levels in adulthood. The specific prenatal diagnosis is based on cordocentesis revealing thrombocytopenia, normal karyotype without increased chromosomal breakage, and ultrasound scan findings. The position of the fetal hands is the first objective sign of an affected fetus either hypoplastic or proximally placed. It may be accompanied by ulnar or humeral anomalies. The upper limb defects can be divided into three categories according to severity and the most severe cases exhibit phocomelia.

Other systems may be affected: (i) Lower limbs (47%); involvement is variable and includes dislocation of the patella and/or hip, knee and ankle abnormalities. (ii) Cow's milk intolerance (62%) that presents as persistent diarrhea and failure to thrive. An episode of thrombocytopenia may be precipitated by introduction of cow's milk and relieved by its exclusion from the diet. (iii) Cardiac anomalies (22–33%); tetralogy of Fallot, atrial and ventricular septal defects, and patent ductus arteriosus. (iv) Genitourinary (2–23%); duplex ureter, horseshoe kidneys, Wilms tumor with a nephrogenic rest in the contra lateral kidney, and absent uterus. (v) Mental retardation (7%); secondary to intracranial bleeds. (vi) Additional features; central facial capillary hemangioma (24%) and neural tube defects. The presence of additional features may aid understanding of gene expression and be a potential clue for the isolation of the TAR gene

## Therapeutic Principles

Supportive therapy with platelet transfusion remains the only real option for treatment of thrombocytopenia especially in the first 2 years of life. Steroid therapy and splenectomy no longer appear to have a role in treatment. If the patient survives beyond age 2 years, spontaneous resolution of the thrombocytopenia with normal motor tone development (as allowed by the extremity anomalies) and normal life span are the expected course. Splinting of the wrists is the first functional step post delivery. Surgery, if needed, can usually be delayed until later as thrombocytopenic-related bleeding problems are less frequent in older individuals. Adaptive devices seem to be the most functional and the best accepted type of management for the upper extremity. Lower extremity management requires more individualization ranging from no treatment to use of a power wheelchair or motorized cart without any intervening attempts at orthotic or prosthetic management.

# Thrombocytopenic Purpura, Idiopathic

Bob Olsson, Hans Wadenvik
Hematology Section, Department of Internal Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden

## Synonyms

Autoimmune thrombocytopenic purpura; Immune thrombocytopenic purpura; Werlhofs disease; ITP

## Definition and Characteristics

Idiopathic thrombocytopenic purpura (ITP) is an organ-specific autoimmune disease in which platelets are targeted by the immune system and thereby prematurely destroyed. The resulting thrombocytopenia causes mainly subcutaneous and mucosal bleedings, but life-threatening bleedings, e.g. intracranial haemorrhages, can occur. *Acute ITP*, defined as thrombocytopenia lasting less than 6 months and usually resolving spontaneously, most often affects children and young adults. *Chronic ITP*, lasts more than 6 months and usually requires therapy to improve the thrombocytopenia, occurs most commonly in adults [2].

## Prevalence

Although *chronic ITP* can occur at any age and in both sexes, women between 20 and 50 years of age are most commonly affected. The female to male ratio is approximately 3:1.The annual incidence rate is between 2 and 5 per 100, 000 individuals.

## Genes

Familial occurrence of ITP is distinctly unusual, but immunologic abnormalities detected in first-degree relatives of patients with chronic ITP may reflect a hereditary predisposition to develop the disorder. An increased prevalence of HLA-B8, HLA-B12, HLA-DRw2 and HLA-A28 has been observed in selected groups of patients.

## Molecular and Systemic Pathophysiology

Traditionally the decrease in platelet count has been considered to be caused by platelet-specific autoantibodies. However, dysfunctions in the cellular immunity have been reported in ITP and T-cells appear to play a pivotal role in pathophysiology [4]. Thus, the decrease in platelet count is mediated by a multi-dysfunction in the immune system including failure of self-antigen recognition and tolerance, platelet-specific autoantibodies, altered Th1/Th2 cytokine profiles, impaired

megakaryocytopoeisis, and platelet-specific cell-mediated cytotoxicity [3,5].

## Diagnostic Principles

ITP is usually a diagnosis of exclusion based on a demonstration of isolated thrombocytopenia, with a history, physical examination and complete blood count that do not suggest another cause for the thrombocytopenia. ITP causes no characteristic bone marrow changes and bone marrow examination is not routinely performed. Platelet-specific antibodies can be detected in only 50% of ITP patients and their presence is not a requirement for diagnosis.

## Therapeutic Principles

Patients with ITP may have mild thrombocytopenia without bleeding symptoms that can be followed without treatment [1]. Corticosteroids are the conventional first-line therapy for ITP. Intravenous immunoglobulin preparations, other immunosuppressive drugs (azathioprin, cyclophosphamide, cyclosporine, mycophenolate, rituximab), splenectomy and platelet transfusions are sometimes required. Drugs acting by increasing the bone marrow production of platelets in ITP are under development.

# Thrombomodulin

Julian Ilcheff, Hugo Ten Cate
Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

THBD; THRM; CD 141; BDCA-3

## Definition and Characteristics

Thrombomodulin (TM) is a glycosylated type I transmembrane vasoprotective protein, initially found on endothelial cells surface, which acts as a cofactor for thrombin, forming a complex that activates protein C and triggers protein C (PC)/EPCR anticoagulant pathway. It consists of several distinct domains – an N-terminal lectin domain, six EGF (epidermal growth factor)-like domains, an *O*-glycosylated serine-threonine rich region, a transmembrane region, and a short cytoplasmic tail [1].

Thrombomodulin homologues have also been discovered on a variety of other cells like dendritic cells MDC2, astrocytes, keratinocytes, mesothelial cells, neutrophils, monocytes, and platelets. Some of them are still focus of ongoing research.

## Genes

The localization of thrombomodulin structural gene was defined to chromosome 20 in 1987. Later, it was precisely assigned to the 20p11.2 region by the use of radiation hybrid mapping methods [2]. Now, it is appears that there are over 15 genetic polymorphisms in the TM gene which promote pathological phenotype in terms of thrombosis and atherosclerosis [1]. For instance, polymorphisms like 133 C/A, 33 G/A, A 25 T, A 455 V, etc. are associated with an increased incidence of developing myocardial infarction and different forms of thrombosis.

## Molecular and Systemic Pathophysiology

Thrombomodulin plays a key role in the regulation of processes like coagulation, fibrinolysis, inflammation, and cellular proliferation.

Thrombomodulin is the crucial initiator of the protein C/EPCR anticoagulant pathway. It binds a molecule of thrombin, forming a 1:1 TM–T complex which interacts with protein C and converts it into its active form, called activated protein C (APC), all in the presence of $Ca^{2+}$. Consequently, the free form of protein S, which normally circulates in plasma, binds APC and they both, in cooperation, inactivate factors $VIII_a$ and $V_a$, thus blocking thrombin formation and coagulation cascade [3].

The role of thrombomodulin extends beyond its hemostatic properties. It regulates the anti-inflammatory functions of APC. TM is homologous to the CD1/MHC class 1 protein family, which usually take part in inflammation. Studies, using mice with lack of TM activity ($TM^{pro/pro}$ mice) are clear evidence that TM could also influence the inflammatory response to systemic endotoxemia [4]. $LD_{50}$ of LPS administration in $TM^{pro/pro}$ mice causes 100% mortality and decreased levels of TNFα production. This evidently speaks for an altered inflammatory response.

TM–T complex also mediates the activation of the thrombin-activatable fibrinolysis inhibitor (TAFI). The activated $TAFI_a$ removes Lys and Arg residues from fibrinogen and consequently blocks the conversion of

plasminogen to plasmin, thereby also taking part in the regulation fibrinolysis.

Thrombomodulin acts like a potential vasoprotector. It is already well known that increased plasma levels of TM lead to lowering the risk of coronary heart disease development. Several other data, although not completely consistent, show that TM could downregulate cellular proliferation via the MAPK pathway by inhibiting a nuclear MAPK phosphatase (e.g., MKP-1). Further studies with recombinant thrombomodulin soluble agents are ongoing and this could appear an interesting approach for developing novel remedies in terms of prevention and curing cardiovascular diseases in future.

## Diagnostic Principles

From a diagnostic perspective, detection of soluble thrombomodulin has been assessed in patients with, e.g., atherosclerosis [5], but the available commercial assays do not yet have an established place in the diagnostic workup of any specific disorder.

## Therapeutic Principles

Soluble forms of thrombomodulin may have potential as inhibitors of postoperative thrombosis as well as for immune modulating purposes. Initial clinical trials of the antithrombotic potential are promising.

# Thrombophlebitis

Henri Bounameaux, Marc Righini
Angiology and Hemostasis, University Hospitals of Geneva, Geneva, Switzerland

## Synonyms

STP; DVT

## Definition and Characteristics

STP is a usually benign thrombosis [1] of a superficial, varicose or nonvaricose vein characterized by local inflammatory signs (Fig. 1, left). Most of these events are located in the lower (the vast majority) or upper (most of them secondary to injections) extremities. In a minority of cases, STP may extend in the deep venous system and occasionally cause pulmonary embolism (PE).

DVT is a thrombosis occurring in the deep vein system of the lower [2] (the vast majority) or upper (most of them secondary to central venous catheter or pacemaker) extremities. Other locations are exceptional. DVT of the lower extremities (Fig. 1, right) can be complicated by early (PE) or late (postthrombotic syndrome of the lower limbs or chronic pulmonary hypertension) complications.

Proximal DVT is defined as lower limb DVT that includes the popliteal or more proximal veins; it is associated with (mostly asymptomatic) PE in 50% of the cases. More distal or muscle vein thromboses as well as upper extremity thromboses are associated with less complications.

## Prevalence

The precise incidence of STP is unknown. Annual incidence of DVT is about one in 1,000 people in western countries, ranging from 1 in 100,000 people in childhood to 1% in old age.

## Genes

Mutations in the genes encoding for blood coagulation inhibitors (antithrombin, protein C, protein S) or factors (factor V, factor II or prothrombin, and changes in the regulation of gene activity can cause quantitative or qualitative deficiencies or higher concentrations of the proteins (factor VIII, factor IX), which will all result in an increased thrombotic risk. The most frequent genetic abnormalities are the factor V Leiden mutation and the prothrombin mutation. When factor V has a mutation at one of the cleavage sites (at position 506) for activated protein C, it is less sensitive to the protein C–protein S inhibiting pathway, the so-called resistance to activated protein C. A mutation in the prothrombin gene (at position 20210) is associated with an increased plasma concentration of the protein. Antithrombin, protein C and protein S deficiencies are quite rare in the population (0.02–0.4% in caucasians) and are present in only 1–3% of patients with thrombosis. On the other hand, the factor V Leiden and the prothrombin mutations are present in 5 and 2%, respectively, in the general population, and in 20 and 6%, respectively, in the patient population with venous thrombosis. Of note, the prevalence of factor V Leiden in patients with pulmonary embolism seems to be about half of that in patients with DVT, an intriguing "factor V Leiden paradox" [3].

**Thrombophlebitis. Figure 1** Clinical picture of superficial thrombophlebitis (*left*) and of iliofemoral deep vein thrombosis (*right*).

## Molecular and Systemic Pathophysiology

Venous thrombosis occurs in the presence of some combination of environmental and/or genetic risk factors that leads to some form of venous stasis, abnormality of the blood composition, and/or lesion of the vessel wall, the Virchow's triad. Environmental, acquired risk factors include: immobilization, surgery, trauma, obesity, pregnancy, postpartum, malignancy, female hormones (used for contraception or substitution), and the anti-phospholipid syndrome. Thromboses occurring in the context of surgery or trauma are called secondary or provoked while all other events are named idiopathic or unprovoked with or without triggering factors. Secondary events are five times less likely to recur than idiopathic events.

A dynamic age-dependent multicausal model of venous thrombosis [2] allows for various forms of interaction of risk factors: intercurrent factors occurring during one's life (e.g. surgery, infection, or use of oral contraceptives) add to the individual's thrombosis potential, and transiently increase the risk, which, combined with increasing age, may at some time exceed the thrombosis threshold.

## Diagnostic Principles

Several noninvasive diagnostic strategies have been validated [4]. STP is diagnosed clinically or with compression ultrasonography (CUS). In suspected DVT, diagnosis relies on CUS of proximal veins, combined with a clinical prediction rule and/or plasma D-Dimer measurement. In suspected PE, combination of a clinical prediction rule, D-dimer, and multi-row chest computed tomography is probably the most convenient and cost-effective sequential approach [5]. All these strategies are associated with a low (2% or less) 3-month thromboembolic risk, similar to that observed in suspected patients left untreated following a normal venogram or pulmonary angiogram.

## Therapeutic Principles

STP treatment remains controversial, from local or systemic NSAIDs to short periods of anticoagulant therapy (subcutaneous low-molecular weight heparin LMWH for 10 days to 6 weeks at prophylactic or therapeutic dosage). DVT and PE treatment consists of LMWH or fondaparinux at therapeutic dose (at least for 5 days) overlapped and followed by oral anticoagulants (vitamin K antagonists, VKA) for 3 (distal DVT or secondary event) to 6 (first idiopathic event) to 12 (first recurrent event) months and even long-term treatment (recurrent events, special situations), with an intensity corresponding to an INR of 2–3. In thrombosis associated with malignancy, long-term anticoagulant therapy with subcutaneous LMWH may be more efficacious than VKA. Novel, synthetic, orally active anticoagulants directed against thrombin or activated factor X are currently being developed.

Active prophylaxis with LMWH or fondaparinux in all patients at risk (i.e., mainly those hospitalized for surgery or acute medical illness) might reduce substantially the venous thromboembolic burden.

# Thrombosis

Christopher J. Boos, Gregory Y. H. Lip
Hemostasis Thrombosis and Vascular Biology Unit, University Department of Medicine, City Hospital, Birmingham, UK

## Synonyms

Clot

## Definition and Characteristics

The formation, development, or existence of a blood clot/thrombus (with or without downstream embolization) within the arterial or venous vascular system. In the arterial system, this is most commonly due to thrombosis upon an atherosclerotic plaque (atherothrombosis) and in the venous system, it is usually as a result of deep vein thrombosis (DVT) with possible pulmonary embolism (PE) [collectively referred to as "venous thromboembolism" (VTE)]. Atherothrombosis is clinically manifested as coronary artery disease (most commonly), stroke or transient ischemic attack, and peripheral arterial disease.

## Prevalence

Thrombosis is the leading cause of death in the Western World with an incidence that rises with increasing age.

## Molecular and Systemic Pathophysiology

Whilst arterial and venous thrombosis are somewhat different in terms of their pathophysiology, Virchow's triad of thrombogenesis (that is abnormalities of flow (stasis), abnormalities of vessel wall (i.e. vessel injury) and abnormal blood constituents) is still relevant to the two entities and does elucidate the mechanism(s) for their development. However, the relevant contribution of each risk factor is highly variable, depending upon whether it is arterial or venous and the individual. Furthermore, there are important environmental and genetic contributions to both (see Table 1). A full distinction between the two is beyond the scope of this chapter.

Thrombosis is a highly complex process involving simultaneous endothelial activation, the release of proinflammatory cytokines (particularly in the cases of atherothrombosis, e.g. C-reactive protein (CRP)), expression of adhesion molecules (e.g. P-selectin) the initiation and propagation of coagulation with simultaneous platelet activation (with platelet adhesion and aggregation). This ultimately leads to the formation of an endothelium attached platelet/fibrin plug (see Fig. 1).

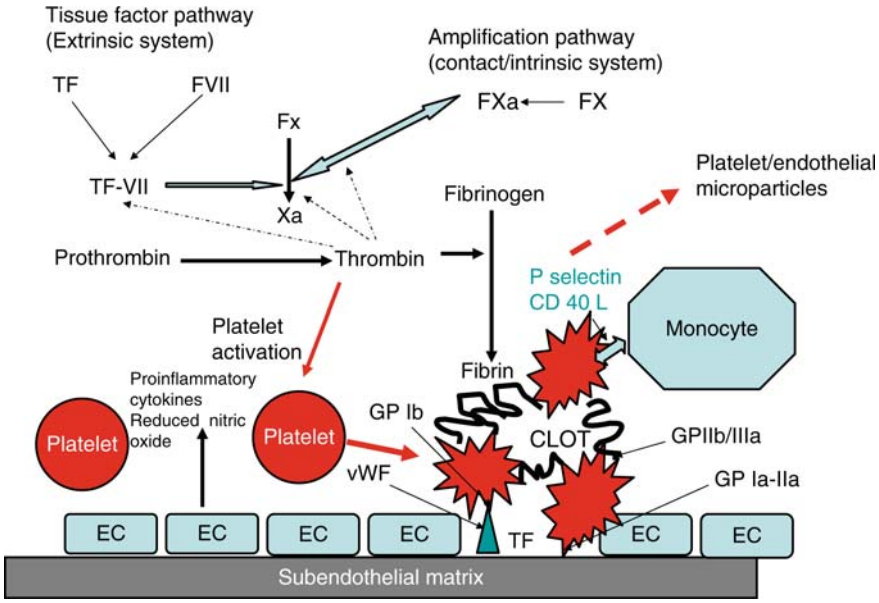
Tissue factor (TF)/factor (F)VII is the key protagonist (extrinsic system) with the intrinsic system, which is activated when FXII [Hageman Factor] comes into contact with negative charges underlying the endothelium, providing an ancillary propagation and amplification role (Fig. 1). In addition to its initiation by trauma, there is also increasing evidence to support a pivotal role of inflammation as a key trigger for the TF pathway. In addition, the TF/FVIIa complex activates a series of clotting factors (FVIII and FIX) leading to the activation of FX to Xa.

TF/FVIIXa – with FVa as a cofactor – and calcium then form the prothrombinase complex, leading to the conversion of prothrombin (FII) to thrombin (FIIa), platelet activation and the subsequent conversion of fibrinogen to fibrin.

**Thrombosis. Table 1** A summary of risk factors that increase the propensity to vascular thrombosis. Some of these are more relevant to the arterial (A) than the venous system

| Hypercoagulability | Direct vessel injury | Blood stasis |
|---|---|---|
| Decreased anticoagulants e.g. | Vasculitis | Increasing age |
| – Protein C | Antiphospholipid syndrome | Obesity |
| – Protein S | Trauma | Pregnancy |
| – Factor V Leiden | Hypercholesterolemia | Sedentarism |
| Hyperhomocysteinuria | Elevated hs-CRP | Increased left atrium |
| Increased procoagulant factors e.g. | Hyperglycemia | Atrial fibrillation |
| – Fibrinogen | Insulin resistance | |
| – TF, FVII, FVIII, FIX, FIX | Hypertension | |
| Platelet hyperreactivity | | |
| Smoking | | |
| Oestrogens e.g. | | |
| OCP/HRT | | |
| Cancer | | |
| Family history | | |

CRP, c-reactive protein; OCP, oral contraceptive pill; HRT, hormone replacement therapy; TF, tissue factor (F).



**Thrombosis. Figure 1** Highly simplified schematic diagram of the process of coagulation and thrombosis. The initiation of blood clot formation occurs following vascular injury and the exposure of tissue factor (TF) to circulating blood. Thrombin exerts a positive feedback loop (*broken arrows*) and additionally activates platelets and other procoagulant proteins. In addition there is variable platelet-leukocyte-endothelial cell (EC) adhesion.

Glycoprotein (Gp) IIb/IIIa plays a major role in the regulation of platelet aggregation during hemostasis. Circulating platelets can adhere either directly to collagen or indirectly via the binding of vWF to the GP1b/FIX complex on the platelet surface Bound fibrinogen/fibrin acts as a bridging molecule facilitating the interaction of adjacent platelets.

This system is simultaneously counterbalanced by a series of activated coagulation inhibitors (tissue factor pathway inhibitor (TFPI), antithrombin (AT) and the Protein C pathway) working in tandem with the competing fibrinolytic pathway, acting to "control" unrestrained coagulation.

Atherosclerosis is a systemic disease involving the intima of large and medium arteries including the aorta, carotid, coronary and peripheral arteries. Endothelial activation/dysfunction/damage, with reduced availability of endogenous nitric oxide, is the key protagonist in this process and may trigger atherosclerosis without the need for physical endothelial injury. There is also exposure of lipid laiden macrophages within the arterial intima to circulating blood and consequent thrombotic vessel occlusion and/or luminal compromise (i.e. atherothrombosis). It is now increasingly recognized that this is a highly active process involving extensive crosstalk between thrombosis, coagulation and inflammation.

The formation DVT of the lower extremity usually begins in the deep veins of the calf with a minority of cases arising primarily in the ileofemoral system. Most calf vein thrombi dissolve completely without therapy, with approximately 20% propagating proximally, prior to potential embolization.

Very crudely arterial thrombi have a higher proportion of platelets and are thus called "white thrombus" whereas thrombi that form in the low pressure systems (such as the venous system and the cardiac atria) are fibrin rich, the so-called "red thrombus."

## Diagnostic Principles

In the case of VTE demonstration of occluded pulmonary arteries (using ventilation perfusion scanning or spiral CT), deep veins (ultrasound or venography) or the quantification endogenous fibrinolysis (e.g. D-dimers). For atherothrombosis: cardiac troponins and creatine kinase (both raised with myonecrosis), quantification of vessel luminal narrowing using arterial, stress echocardiography, nuclear cardiology, MRI, positron emission tomography and/or exercise testing.

## Therapeutic Principles

Antiplatelet therapy for arterial thrombi (e.g. clopidogrel/aspirin), anticoagulation (e.g. vitamin K antagonists, heparins, factor Xa inhibitors, direct thrombin inhibitors) for VTE and in specific cases such as atrial fibrillation, fibrinolysis, percutaneous transluminal coronary angioplasty.

# Thrombosis, Arterial and Fibrinogen

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

A alpha polypeptide; FGA

## Definition and Characteristics

Fibrinogen is a 340 kD glycoprotein of three nonidentical polypeptides linked by disulfide bonds. The promoter regions from these genes contain hepatic nuclear factor 1 and interleukin-6 responsive elements. The latter may be responsible for most of the biological variation during acute phase reactions. Thrombin causes a limited proteolysis of fibrinogen releasing fibrinopeptides A and B from the N terminal regions of the alpha and beta chains respectively. Thrombin also activates factor XIII (fibrin-stabilizing factor), which enables cross linking of fibrin molecules into a polymerized fibrin meshwork.

## Prevalence

Nine and five percent of fibrinogen variability is accountable to beta chain polymorphisms detected by BclI and HaeIII, respectively [1]. The –455 A allele is present in ~20% of the population and these individuals have ~10% higher fibrinogen levels compared to those with the GG genotype [2].

## Genes

Evidence suggests a genetic influence on fibrinogen variations of about 50–65% [1]. In large cardiovascular studies the –455 G/A polymorphism was linked to plasma levels of fibrinogen in smokers (ECTIM study); in the EARS study the –455A allele was associated with elevated levels in males; in the Copenhagen City study the –455 A allele was linked to levels in both genders. A number of other studies have essentially confirmed these associations. In spite of the associations between gene variations and fibrinogen level, and fibrinogen level and arterial vascular disease, there is still uncertainty about the association between polymorphisms and disease. A polymorphism in the coding region of the alpha chain (Thr312Ala), close to the factor XIII cross linking site at 328, is a candidate risk factor because it is associated with more rigid clots. The homozygous Thr312 variant has been linked to thrombosis in selected studies, but the importance remains to be confirmed.

*Gene map locus*: 4q28, three polypeptides, designated alpha (FGA), beta (FGB; 134830), and gamma (FGG; 134850) are encoded by three genes clustered on chromosome 4.

## Molecular and Systemic Pathophysiology

Bcl-1 allele in beta chain, –148CT in Bbeta promoter, 448GA in B beta chain, Thr312Ala variant in alpha chain (the latter not linked with fibrinogen levels).

Although linkage of variations to fibrinogen concentrations would be the most likely explanation for a pathogenetic role of fibrinogen in arterial vascular disease, this association remains inconsistent. As such, fibrinogen concentrations have emerged as a cardiovascular risk factor and those individuals with levels in the highest tertile have approximately twofold increased risk as compared to the lowest tertile [2]. Like with other procoagulant factors, the concentration is probably contributing to the rate of fibrin formation and polymerization. Interestingly, recent studies indicate decreased permeability, with tighter clot structure, upon increased fibrinogen concentrations, depending on factor XIII genotype (34Val as compared to 34 Leu). Similar findings have been reported for Aalpha fibrinogen Thr312Ala variations [3]. Given the influence of acute phase response proteins on fibrinogen level part of the risk of arterial thrombosis may theoretically reside in pro-inflammatory effects on tissue factor expression mediated thrombin production.

*Clinical features:* Elevated fibrinogen levels correspond with an about twofold risk in cardiovascular disease. Specific features of disease include severity of coronary atheroma (ECTIM), myocardial infarction (GISSI-2), carotid atherosclerosis (Austrain Stroke Prevention Study) or cerebrovascular disease [1,4].

## Diagnostic Principles

Fibrinogen levels are usually measured by clotting assay (Claus) or antigen determination. Fibrinogen polymorphisms are not routinely measured in thrombophilia screening.

## Therapeutic Principles

Since fibrinogen levels are susceptible to inflammatory stimuli, the removal, if possible, of such stimuli may partly or completely normalize fibrinogen levels. In cardiovascular disease the anti-inflammatory effects of statins or aspirin may have a beneficial effect, otherwise there is no specific way to modulate fibrinogen levels.

# Thrombosis, Arterial, at Altered Levels of Coagulation Factors

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Increased levels coagulation factors

## Definition and Characteristics

Factor VII is a vitamin-K dependent protein produced by the liver. Upon activation it binds to the cell surface receptor tissue factor forming a catalytic complex. This complex catalyzes the conversion of factors IX and X, stimulating thrombin formation. Factor VIII is produced by endothelial cells in the liver and an essential cofactor in the intrinsic coagulation route, enabling activation of factor X in the tenase complex. Its absence leads to hemophilia A. Current evidence suggests that an increased factor VIII level influences the rate of thrombin formation and may thus be a procoagulant risk factor. The fact that factor VIII binds to and is stabilized by vWF makes it difficult to differentiate vWF from factor VIII in its prothrombotic properties. vWF is produced by vascular endothelial cells and an important protein in primary hemostasis where it promotes platelet adhesion. Its deficiency leads to von Willebrands disease, a hemorrhagic disorder. Its increased presence in plasma may contribute to the risk of arterial thrombosis, but this may (in part) depend on the increased factor VIII concentration.

Factor XIII is a transglutaminase that forms covalent bonds between fibrin monomers leading to crosslinking and stabilization of fibrin clots. It is activated by thrombin cleaving a 37-amino acid bond. Alterations in factor XIII, due to a ValLeu34 mutation may have functional implications for fibrin crosslinking [1]. An interaction with fibrinogen has been observed, i.e. tighter fibrin clots form upon rising fibrinogen concentrations in the presence of factor XIII 34 Val alleles compared to 34Leu alleles [2].

## Prevalence

No reliable population data available.

## Genes

- Factor VII: An Arg353Gln mutation associated with a decreased level of factor VII has been linked to cardiovascular disease; an inverse correlation between family history of myocardial infarction and homozygosity of the Gln353 allele. However, these data have not been confirmed in other studies in broader populations of different age classes [1].
- Factor VIII and von Willebrand factor (vWF): Variations in factor VIII level have not yet been linked to specific gene mutations [3]. The only genetic influence is related to blood group type and in non-type O blood groups the factor VIII level is higher than in type O individuals [1]. Several studies have linked increased levels of factor VIII and vWF with incident cardiovascular disease, both fatal and non-fatal events [1]. Usually, vWF and factor VIII are highly correlated because vWF is the physiologic stabilizing protein of factor VIII.
- Factor XIII: variations in plasma levels of factor XIII are for about 80% genetically determined [4]. A Val34Leu polymorphism of the catalytic subunit has been described and the Leu34 allele corresponds to elevated factor XIII activity levels. In contrast to expectations the Leu34 allele has been linked with a decreased risk of myocardial infarction and ischemic stroke, while the risk of hemorrhagic stroke may be slightly increased. Although the mechanisms are unclear interactions with other coagulation factors or features of metabolic syndromes may contribute to the effect on cardiovascular disease.

*Gene map loci*: Factor VII: 13q34; factor VIII: Xq28; factor XIII: 6p25-p24 (A1 subunit) and 1q31-q32.1 (B subunit); von Willebrand factor: 12p13.3.

## Molecular and Systemic Pathophysiology

The general concept of altered coagulation factor levels is related to its effects on thrombin generation. Thus, even modest increases in most intrinsic factors promote thrombin generation, which may under suitable conditions have a prothrombotic action. Vive versa, reduced concentrations diminish procoagulant mechanisms. Additional, more specific factors may be involved, thus in case of factor XIII specific interactions between the transglutaminase and fibrinogen may have additional consequences as outlined above. With fibrinogen being an acute phase protein, it is likely that the interaction of a specific genotype of factor XIII will become manifest when fibrinogen levels rise above a certain threshold.

*Clinical features*: A general association with cardiovascular disease and increased coagulation factors emerges, but associations with specific pathology remain controversial.

## Diagnostic Principles

Coagulation factor levels are routinely measured by clotting assays using clotting factor deficient plasma. In case of specific mutations PCR based analyses are performed, but for factors VII and XIII such analyses are not part of most routine thrombophilia screening, in contrast to factor VIII levels which are increasingly investigated for this purpose.

## Therapeutic Principles

Factor VIII shows some characteristics of acute phase reactants, but there is no correlation with truly acute phase proteins like fibrinogen and the gene analysis of factor VIII does not provide clues yet as to its regulation. Thus, for instance in chronic inflammatory disease factor VIII may be substantially increased but the mechanism is unclear. Controlled experiments have investigated the potential of beta blocking agents to reduce factor VIII concentrations but the results are highly conflicting. In accordance, the levels of other factors cannot be regulated pharmacologically.

## Definition and Characteristics

Acquired form of thromboembolic disease caused by interaction of drugs with the hemostatic system, causing or promoting thrombosis.

## Prevalence

The prevalence of thrombosis caused by drugs varies for different drugs. This prevalence is higher in people who have other risk factors for thromboembolic events (e.g. hereditary thrombophilia, malignancy and pregnancy). Of note is that the preclinical screening for safety of drugs may not be always effective in prediction of human risk and post-marketing surveillance may reveal thrombogenic properties of the drug (see case of cyclooxygenase-2 inhibitors).

## Molecular and Systemic Pathophysiology

Drugs can induce thrombosis in a variety of ways, by influencing any of the three factors known as the Virchow's triad; namely, abnormalities of blood vessel wall, abnormalities of blood constituents and abnormalities of blood flow.

*Endothelial Damage*: Drugs can influence the endothelial cells either by:

- Direct damage to the cells, causing de-endotheliazation which affects the antithrombogenic properties of the endothelial cells (for example, contrast media infusion or cytotoxic drugs). Drug eluting stents might be connected to thrombotic events by inducing inflammatory reactions in the surrounding endothelial cells.
- Changing the expression of pro- and anti-coagulant properties of endothelial cells. Drugs that induce inflammatory cytokines release (e.g., cisplatin and bleomycin) can induce the formation of endothelial cell procoagulants and down-regulate the production of anticoagulant factors. Inhibitors of cyclooxygenase-2 can induce thrombotic events by blocking the synthesis of prostacyclin, an important product of the endothelial cells, which inhibits platelet aggregation.

*Effect on Platelets*: Drugs can influence the different properties of platelets, thus leading to increased tendency for thrombosis.

This influence can be mediated by:

- An increase in the platelets' adhesiveness to vessel wall (e.g., contrast media and tissue plasminogen activator).
- An increase in the platelets' tendency to aggregate, either by increasing serotonin concentration (e.g., selective serotonin reuptake inhibitors), by inducing sensitization of platelets against endogenous aggregators (e.g., non-ionic contrast media) or by activation of GPIIb/IIIa, the membrane glycoprotein complex that constitutes the fibrinogen receptor and thus mediates platelet aggregation (e.g., nanoparticles).
- Platelet activation and release of their contents into the local environment. A prototypic drug is heparin. Heparin complexes with platelet factor 4 on platelet surface resulting in antibody formation to the complex, thrombocytopenia and platelet activation with clinical thrombosis (HITT, heparin induced thrombocytopenia & thrombosis). These antibodies may activate platelets to promote microparticle release (liberation of ADP, serotonin, histamine, and enzymes) and cell–cell interactions, predisposing to thrombosis.

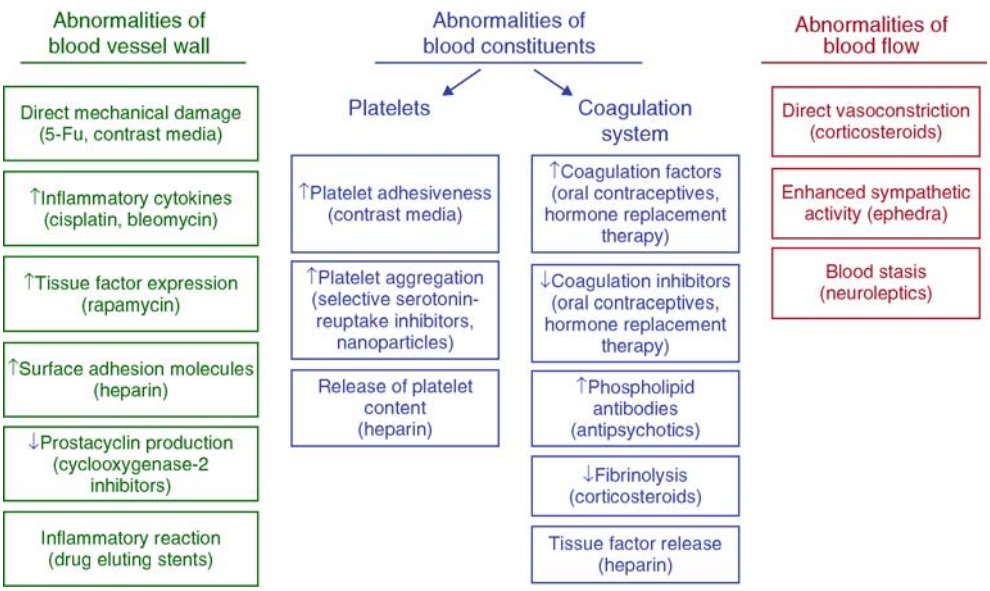
*Effect on Coagulation System*: Drugs can exert a prothrombotic state by:

- Inducing an imbalance between increased coagulation factors and decreased coagulation inhibitors (e.g., hormone replacement therapy and combined oral contraceptives).
- Increase in circulating antiphospholipid antibodies (e.g., certain antipsychotics), which have been associated with an increased risk of thrombosis.
- Inhibition of the fibrinolysis system (e.g., corticosteroids), the ultimate weapon against the consequences of intravascular coagulation.
- Increase in the expression of tissue factor, which is an important initiator of the coagulation pathway (e.g., heparin antibodies).
- Direct activation of the coagulation cascade (e.g., administration of recombinant factor VII or prothrombin complex concentrate) that may result in arterial (as myocardial infarct or stroke) and venous thrombosis (as deep vein thrombosis).
- Direct inhibition of fibrinolysis (e.g., ε-aminocaproic acid and tranexamic acid) has been associated with thrombotic events like myocardial infarction and stroke, especially in patients with DIC, or with concurrent administration of clotting factor concentrates.

*Effect on Blood Flow*: Drugs can cause changes in the blood flow, mediated by:

- Inducing vasoconstriction, either by direct vasoconstrictive effect (e.g., corticosteroids) or by enhancing sympathetic activity (e.g., ephedra).
- Blood stasis induction. Drug-induced arterial hypotony and peripheral vasodilatation may lead to venous stasis in neuroleptic treated patients.

*Unknown*: There are drugs for which the exact mechanism of increased thrombogenicity is still to be elucidated (e.g., thalidomide, cyclosporine, erythropoietin). Further research is required in order to provide



**Thrombosis, Drug-induced. Figure 1** Mechanisms of drug induced thrombosis. Examples of drugs inducing a specific mechanism are given in parentheses.

possible mechanisms to explain the different clinical manifestations.

Summary of the different mechanisms by which drugs can induce thrombosis, including examples of drugs for each mechanism, is given in Fig. 1.

## Diagnostic Principles

Thrombosis may present as either venous or arterial event. The most common presentation is venous thrombosis i.e. deep vein thrombosis and pulmonary embolism (oral contraceptives, thalidomide, cytotoxic drugs as cisplatin). Arterial thrombosis as cerebrovascular event or myocardial infarction (heparin, thalidomide) is less common. Thromboembolism presenting in a patient treated with a known thrombogenic medication should raise the suspicion that the drug predisposed to the event.

## Therapeutic Principles

Treatment mainstay is initiation of antithrombotic therapy and the consideration to discontinue the predisposing drug. Antithrombotic therapy options include heparin (or danaparoid in case of heparin induced thrombosis), low molecular weight heparin and coumarin with or without antiplatelet agents as aspirin. These drugs should be promptly given to prevent thrombus propagation and embolization. The potential predisposing drug should be discontinued permanently (as in heparin induced thrombosis) or resumed after the thrombotic event is controlled (cisplatin, thalidomide).

Prophylaxis with antithrombotic or antiplatelet therapy may be coadministered when a potential thrombogenic drug is essential for patient care (thalidomide).

# Thrombosis, Venous, Elevated Factor VIII Level

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Increased factor VIII; FVIII

## Definition and Characteristics

The gene product is a protein synthesized in the liver. After secretion in plasma it associates with von Willebrandfactor (vWF), which stabilizes its activity as a cofactor in the intrinsic system. FVIII is particularly important for catalyzing the rate of FX activation in the tenase complex. Whereas its absence is associated with a bleeding diathesis (hemophilia A), an increased concentration may increase the rate of thrombin generation and is thrombogenic in an animal model [1].

## Prevalence

Not applicable. In the LETS case-control study the odds ratio for deep venous thrombosis for patients with a factor VIII clotting activity level >150% compared to those with a level <100% was 4.8 (95% CI 2.3–10). [2]. A similarly increased risk ratio was found for recurrent venous thrombosis. In a prospective study in patients after a first episode of venous thromboembolism those with recurrences had on average higher FVIII levels than those without such events; the adjusted relative risk was 6.7 for FVIII levels >90th percentile (95% CI 3.0–14.8) [3].

## Genes

No genetic basis has so far been identified for elevated factor VIII levels. In a study of 12 families with thrombophilia, blood group O was the main determinant of FVIII levels (associated with a lower concentration than non-O blood group) [4]. Genetic studies have so far failed to identify any promoter variations in relation to FVIII concentrations and family studies have remained inconclusive regarding heritability of elevated FVIII levels [5].

*Gene map locus*: Xq28

## Molecular and Systemic Pathophysiology

No specific gene mutations have yet been linked to increased FVIII levels.

FVIII is produced and secreted by the liver but its concentration in plasma is dependent on different influences. In addition, to its complex formation with vWF, FVIII behaves like an acute phase protein and very high concentrations may associate with chronic inflammatory conditions. However, no significant correlations between FVIII and the acute phase protein CRP have been identified and the molecular link with inflammation remains unknown [5].

*Clinical features*: elevated FVIII levels are associated with a fourfold to sevenfold risk of first venous thrombosis and a similar degree for recurrent venous thrombosis. There is evidence for a causal role in arterial thrombosis.

## Diagnostic Principles

The level of FVIII is usually monitored by a functional clotting assay. In some of the clinical studies antigen levels were determined which formed the basis for the risk assessment. Currently, FVIII determinations are being included in thrombophilia screening panels. Of importance is the observation that every 10% increase in FVIII levels raises the risk of a first episode of venous thrombosis or its recurrence respectively with 10 and 24%, allowing for crude estimates of the individual risk of thrombosis as compared to normal.

## Therapeutic Principles

There are no specific interventions that lower elevated factor VIII levels. One controlled study suggested that the use of beta-blockers may lower FVIII, but this result has not been confirmed by others.

# Thrombosis, Venous Elevated Factor IX Level

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Increased factor IX; FIX

## Definition and Characteristics

The gene product is a 415-amino acid serine protease synthesized in the liver and the largest vitamin K dependent protein. Factor IX is involved in secondary hemostasis where it acts as a protein in the intrinsic coagulation system to catalyze the formation of factor Xa. FIX is activated either by the factor VIIa-tissue factor complex, or by factor XIa, to form the tenase complex with factor VIIIa on phospholipids and in the presence of calcium ions.

## Prevalence

Not applicable. In the LETS case-control study the odds ratio for DVT for patients with a factor IX antigen level >90th percentile of the distribution of the controls (129%) was 2.3 (95% CI 1.6–3.5) [1]. High FIX levels may also increase the risk of recurrent venous thrombosis, particularly among patients with an elevated factor VIII level [2].

## Genes

The gene spans 34 kb and contains eight exons. So far, no genetic basis has been identified for elevated factor IX levels, but Kurachi et al. identified two critical age-related regulatory elements that may be involved, AE5′ and AE3′. The effect may be a combination of stabilization of gene transcription and age-dependent increases in mRNA levels [3].

*Gene Map Locus*: Xq27.1–q27.2.

*Molecular Mechanism and Genotyping*: No specific gene mutations have been linked to increased FIX levels yet.

## Molecular and Systemic Pathophysiology

FIX is subject to proteolytic activation by two pathways: the extrinsic route by the FVIIa-tissue factor complex and the intrinsic route, by FXIa. The latter way is dependent on the concentration of thrombin present.

Elevated concentrations of FIXa may increase the rate of thrombin generation, causing a net procoagulant effect under certain conditions.
*Clinical Features*: Elevated FIX levels are associated with a 2.2-fold risk of first venous thrombosis and a similar degree for recurrent venous thrombosis [1,2].

## Diagnostic Principles

The level of FIX is usually monitored by a functional assay. In the LETS study, antigen levels were determined which formed the basis for the risk assessment. Practically, routine screening of FIX levels is not yet included in screening for venous thrombophilia.

## Therapeutic Principles

Being a vitamin K dependent protein FIX levels are lowered by vitamin K antagonists, but there are no other ways of selectively lowering elevated FIX levels.

# Thrombosis, Venous Elevated Factor XI Level

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Increased FXI

## Definition and Characteristics

Factor XI is a homodimer consisting of two polypeptide chains of 607 amino acids. Upon activation by thrombin, or in vitro by factor XIIa, a heavy and a light chain are produced. The heavy chain contains four apple-like domains with distinctive functions. In the coagulation cascade, factor XIa activates factor IX, amplifying the intrinsic cascade.

## Prevalence

Not applicable. In the LETS case-control study the odds ratio for venous thrombosis in patients with a factor XI level >90th percentile of the distribution of the controls (121%) was 2.2 (95% CI 1.5–3.2) [1].

## Genes

The FXI gene contains 23 kb, 15 exons. No genetic basis has so far been identified for elevated factor XI levels in either venous, nor in arterial thrombotic disease [2].
*Gene map locus*: 4q35

## Molecular and Systemic Pathophysiology

Alterations of FXI levels are not explained yet on a genetic basis. Indirect evidence for a prethrombotic role of FXI comes from clinical data showing increased coagulation activity after repletion of purified factor concentrate in congenital FXI deficient individuals [3,4]. Thrombin has been identified as a main activator of FXI, and activated FXIa indeed induces activation of the intrinsic coagulation route in vivo [5]. FXIa significantly contributes to the activation of TAFI (thrombin activatable fibrinolytic inhibitor) and the dual prothrombotic and anti-fibrinolytic effect of FXIa may explain its contribution to the risk of venous thrombosis.

*Clinical features*: Elevated FXI levels are associated with a 2.2-fold risk of venous thrombosis in one study. There is no correlation with arterial thrombosis.

## Diagnostic Principles

The level of FXI is usually monitored by a functional assay. In the LETS study, antigen levels were determined which formed the basis for the risk assessment. Practically, routine screening of FXI levels is not yet included in screening for venous thrombophilia.

## Therapeutic Principles

FXI levels are unaffected by antithrombotic treatment and there is no known therapy for reversing elevated FXI levels.

# Thrombosis, Venous Factor V Leiden, Resistance against Activated Protein C

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Activated protein C, resistance to; APC resistance; APC

## Definition and Characteristics

Factor V is a coagulation protein which is an essential cofactor in the conversion of prothrombin to thrombin (prothrombinase complex). In addition to its procoagulant properties it has a relevant anticoagulant function as a cofactor to APC. The duality of FV has been described as the Jekyll and Hyde property, or the Janus faced protein [1]. The FV Leiden mutation was first identified based on its association with the laboratory phenomenon of APC resistance. In a modified clotting time (APTT), Dahlback et al. observed that the addition of APC did not result in the expected prolongation of the clotting time in a great number of patients with deep venous thrombosis (DVT) [2]. This functional defect is now known as APC resistance. The point mutation was first described in 1994 and has since been known as FV Leiden [3]. Other FV mutations and polymorphisms have been identified since, of which the association with thrombosis has not yet been established. An exception may be the R2 haplotype based on an altered glycosilation in FV, due to a combination of two polymorphisms, which has been linked to venous and perhaps arterial thrombosis [4].

## Prevalence

FV Leiden is highly prevalent in Caucasians with frequencies ranging from 1 to 15% while it is present in patients with a first episode of DVT in 10–15% of cases [5].

## Genes

A gain-of-function mutation in the factor V gene at nucleotide position 1691 leads to an arginine substitution by glutamine at position 506, which is a cleavage site for APC. The functional effect is resistance to the anticoagulant effect of APC [5].
*Gene Map Locus*: 1q23.

## Molecular and Systemic Pathophysiology

The FV Leiden mutation is generally documented by PCR analysis. Alternatively, automated fluorescence, invader assay or multiplex PCR-based assays can be utilized for genotyping. The latter may be optimized for detection of other FV variants such as the rare FV Cambridge.

The main consequence of the FV Leiden mutation is an acquired resistance to the anticoagulant effects of APC. The consequence is persistent coagulation activity which contributes to a risk of venous thrombosis. The extent of this risk is probably less than that linked to deficiencies of any major inhibitor like antithrombin or protein C. In heterozygous carriers the risk of DVT is increased two- to threefold, but the risk may multiply in the presence of additional risk factors such as oral contraceptives. The latter drugs also cause an acquired type of APC resistance, irrespective of the presence of FV Leiden, which is also an independent risk factor for thrombosis. Third generation combined contraceptives are particularly associated with APC resistance, comparable to the effect of the FV Leiden mutation.

Homozygosity for FV Leiden is very rare and increases the risk of thrombosis 50–100- fold.

*Clinical Features*: The presence of the FV Leiden mutation increases the risk of venous thrombosis two- to threefold; the risk association with pulmonary embolism is absent, for unknown reasons. In combination with other risk factors, including the prothrombin G20210A mutation, this risk increases substantially. In combination with oral contraceptives or pregnancy the risk of venous thrombosis increases about 15-fold.

## Diagnostic Principles

The diagnosis of FV Leiden mutation is primarily determined by DNA analysis by PCR based assays. Functionally, the presence of APC resistance can be determined by commercially available clotting test systems. Usually, both tests are carried out to establish that APC resistance when detected is due to a genetic defect or an acquired cause, and to determine the extent to which FV Leiden is accompanied by APC resistance (because other modifying influences may alter APC resistance even when FV Leiden is present between normal and abnormal).

## Therapeutic Principles

FV Leiden associated APC resistance can only be counteracted with anticoagulants including heparin and

low molecular weight heparin (by its anti-factor Xa effect), while specific thrombin inhibitors like hirudin bind and neutralize thrombin. Acquired causes of APC resistance such as oral contraceptives can be corrected by removing the causal factor.

## Synonyms

MNGIE syndrome

*deceased

## Definition and Characteristics

Autosomal recessive. Thymidine phosphorylase (TP) deficiency is associated with the syndrome of ►mitochondrial neuro-gastro-intestinal encephalopathy. Thymidine and deoxyuridine are found in the urine.

## Prevalence

The association between TP deficiency and MNGIE syndrome was published for the first time in 1999 [1]. Since then more than 20 patients have been reported.

## Genes

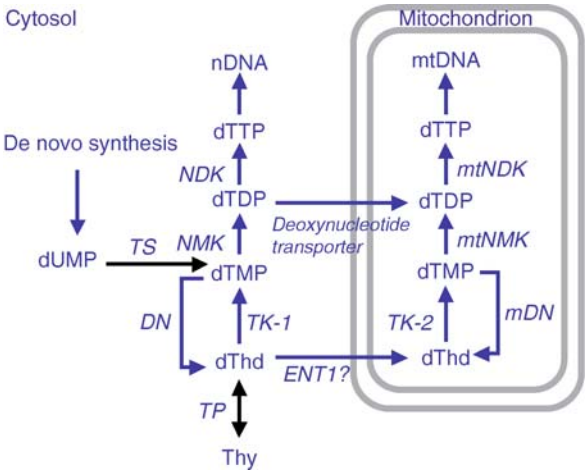
The gene encoding TP has been mapped to chromosome 22q.13.32-qter. It has 10 exons with an open reading frame spanning from exons 2 to 10. The linkage of MNGIE syndrome to chromosome 22q.13.32-qter has been confirmed in seven families with MNGIE syndrome. Homozygous or compound heterozygous mutations were found in the TP gene of all the 21 probands and 12 siblings tested. 16 distinct mutations were identified, eight missense, four splice-site, three microdeletions and one single nucleotide insertion. No genotype/phenotype correlation was found. The mode of inheritance is autosomal recessive [2].

## Molecular and Systemic Pathophysiology

TP plays a role in the homeostasis of the cellular pyrimidine nucleotide pools. Figure 1. Elevated thymidine levels lead to elevated thymidine triphosphate (dTTP) pools, in particular in mitochondria by the activity of thymidine kinase 2 (TK2). The mitochondrial TK2 is expressed constitutively while the cytosolic thymidine kinase 1 (TK1) is only active during cell division. Altered deoxynucleotide pools in the mitochondria may lead to depletion of mtDNA and multiple deletions by stalling of mtDNA replication. The enzyme TP is also called "platelet-derived endothelial cell growth factor (PD-ECGF)" or "endothelial growth factor 1 (ECGF1)," because of its angiogenic properties, or "gliostatin" to denote its inhibitory effects on glial cell proliferation.

## Diagnostic Principles

TP deficiency can easily be identified by the analysis of thymidine and deoxyuridine in body fluids. In patients, thymidine concentrations in plasma and urine are more than 50–100 times the upper limit of normal, respectively. Upper limits of controls (micromoles/L) are 0.03 for plasma ($n$ = 97) and 3 for urine ($n$ = 2). The finding of a low TP activity in leukocytes (patients



**Thymidine Phosphorylase Deficiency. Figure 1** Intracellular metabolism of thymidine. ## Thyroglossal Cyst

►Thyroglossal Duct Cyst

## Thyroglossal Duct Cyst

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Thyroglossal cyst

### Definition and Characteristics

A thyroglossal duct cyst presents as a midline neck mass (Fig. 1) which may move with swallowing and might move upward with protrusion of the tongue [1].

However, its movement may be limited with protrusion of the tongue because of its persistent attachment to the foramen cecum [1]. Approximately 1% of the cysts are located laterally, often on the left side [2]. A thyroglossal duct cyst can occur at any site along the normal pathway of descent from the foramen cecum to the lower neck region [1]. The most common site (61% of cases) is between the thyroid gland and the hyoid bone [2]. Other potential sites include suprahyoidal (24%), suprasternal (13%), or intralingual (2%) locations [2]. Although thyroglossal duct cysts are congenital, these lesions rarely present in the neonatal period. More commonly, the cysts are noted in preschool children, sometimes after an upper respiratory tract infection [1]. At least 50% of the lesions are diagnosed in the second decade of life [3]. Some do not present until adulthood. Thyroglossal duct cysts commonly present as an infected neck mass. Recurrent infections are common if the lesion is not excised. Rarely, a thyroglossal duct cyst might cause extrinsic airway compression or intralaryngeal extension with resultant dyspnea or hoarseness [2]. An intralingual thyroglossal duct cyst might result in dysphagia or speech impairment [2]. A thyroglossal duct cyst has the potential for malignant transformation during childhood, but this is uncommon. Approximately 75–85% of thyroglossal duct malignancies are papillary adenocarcinomas [1].

### Prevalence

The exact incidence is not known. Thyroglossal duct cysts account for approximately 70% of all congenital abnormalities of the neck [4]. The sex ratio is equal. Most cases are sporadic [1]. Thyroglossal duct cysts are occasionally inherited as an autosomal dominant disorder or, rarely, as an autosomal recessive disorder [1].

### Molecular and Systemic Pathophysiology

The thyroid anlage arises from the foregut diverticulum at the site of the future foramen cecum at about the third

**Thyroglossal Duct Cyst. Figure 1** An 8-year-old girl with a thyroglossal cyst, presenting as a midline neck mass.

week of gestation. As the neck develops, the thyroid gland descends along the midline of the neck, between the first and second branchial arteries, and ventral to the hyoid bone and the developing laryngeal cartilage. The thyroid gland remains connected to the foramen cecum by the thyroglossal duct during the descent. A cyst results when the thyroglossal duct fails to involute after the descent of the thyroid gland.

## Diagnostic Principles

The differential diagnosis includes midline dermoid cyst, ectopic thyroid tissue, lymphadenopathy, cystic hygroma, branchial cleft cyst, lipoma, lymphangioma, hemangioma, and sebaceous cyst. Thyroglossal duct cysts are lined by pseudostrafied ciliated columnar epithelium (61% of cases), stratified squamous epithelium, transitional epithelium or cuboidal epithelium [2]. The cysts contain colloid material with cholesterol crystals and phagocytes. Ultrasonography can be used to confirm the cystic nature of the lesion and the presence of a normal-appearing and normally situated thyroid gland. The ultrasonographic appearance of the lesion can be anechoic, homogeneously hypoechoic, or heterogeneous.

## Therapeutic Principles

The Sistrunk procedure is the surgical treatment of choice. The procedure includes excision of the cyst, the thyroglossal tract, and the central portion of the hyoid bone to prevent recurrence.

[2]Department of Medical Affairs, Oncology, U.S. Pharma Ops, Sanofi-Aventis, Bridgewater, NJ, USA

## Synonyms

Thyroid carcinoma; Malignancies of the thyroid gland; Papillary thyroid cancer; Follicular thyroid cancer; Medullary thyroid cancer; Anaplastic thyroid cancer; ThyrCa

## Definition and Characteristics

Thyroid cancer (ThyrCa) is subdivided into: (i) well-differentiated Ca's originating from thyroid follicular cells which account for >80% of all cancer cases, secrete thyroglobulin (Tg), and, in most cases, are able to concentrate iodine: These are subdivided into: a) papillary ThyrCa's (PTC's), and b) follicular ThyrCa's (FTC's); (ii) anaplastic thyroid Ca (ATC) [14% of ThyrCa's], an undifferentiated carcinoma, and (iii) Ca's deriving from elements other than the follicular cell epithelium. The latter group of malignancies primarily includes medullary ThyrCa (MTC) (6% of ThyrCa's).

MTC is derived from calcitonin-producing parafollicular (or C-) cells, which are of neuroectodermal origin, and, hence, not iodine-avid. MTC generally displays a more malignant biological behavior versus that of well-differentiated tumors originating from follicular cells (i.e. papillary and follicular ThyrCa's).

PTC's (65–70% of cases) are usually unencapsulated and often multicentric (multifocal) tumors. Very rarely, PTC may arise as part of a genetic neoplasia syndrome, such as Cowden disease, Peutz-Jeghers syndrome, Carney complex, the very rare familial PTC syndrome, or familial adenomatoid polyposis coli (the latter with unique histologic features). The growth of PTC is partly dependent on TSH stimulation. Notably, microscopic PTC (papillary microcarcinoma) occurs up to 20–25% of the general population, either as an independent focus or with a pattern of microscopic malignant cell clusters within an otherwise benign nodule. The overwhelming majority of these microcarcinomas never become apparent by clinical or imaging modalities.

FTC's (18–20% of cases) are usually encapsulated tumors. Prognosis is excellent if invasion of tumor capsule and/or blood vessels (angioinvasion) is minimal. Overall, FTC is more malignant than PTC, and tends to spread hematogenously to distant sites (mediastinum, lungs, bone, CNS). Metastases from FTC may undergo late de-differentiation and, thus, increase their malignant potential over time. Also, very rarely, FTC may be "hyperfunctioning," and, hence, be able to produce appreciable amounts of thyroid hormones from intracellular processing of the Tg molecule, leading to clinical or biochemical hyperthyroidism.

MTC occurs sporadically as well as in the context of autosomal dominantly (AD)-inherited cancer syndromes. The latter include the following: (i) multiple endocrine neoplasia type 2A (MEN2A), characterized by MTC associated with pheochromocytoma and parathyroid hyperplasia; (ii) MEN2B, characterized by MTC associated with pheochromocytoma, mucocutaneous neuromas, gastrointestinal ganglioneuromatosis, and marfanoid habitus, and (iii) familial MTC (FMTC): characterized by the familial development of MTC only, without clinical evidence of the other MEN2 features. FMTC has been viewed in the past as a separate entity, but belongs genotypically to MEN2A.

## Prevalence

ThyrCa is the most common endocrine malignancy with 33,550 new cases of thyroid cancer annually and a prevalence of 366,466 cases. In the United States (US), there were 25,480 female; 8,070 male new cases (1.1% of all cancers) (2007 estimates by the American Cancer Society [ACS]). Disease-specific mortality is 1,530 deaths per year (yr) (0.27% of all cancer deaths). Most patients with thyroid cancer either achieve long-term status of no evidence of disease (NED), or live with their disease that can remain stable or very slowly progressive over many years.

## Genes

The etiologic factors for the development of non-medullary ThyrCa remain largely unknown, but at least one environmental influence is of cardinal etiologic importance, i.e. exposure of the thyroid gland to ionizing radiation, most importantly during childhood or adolescence. A remarkable increase in ThyrCa incidence occurred in Belarus and Ukraine following the nuclear power plant accident at Chernobyl in 1986, in this case apparently resulting from exposure to various iodine radionuclide species. The latency for the development of clinically evident ThyrCa was about 4 years, a much shorter interval than previously anticipated, and the risk has been shown to continue into later life.

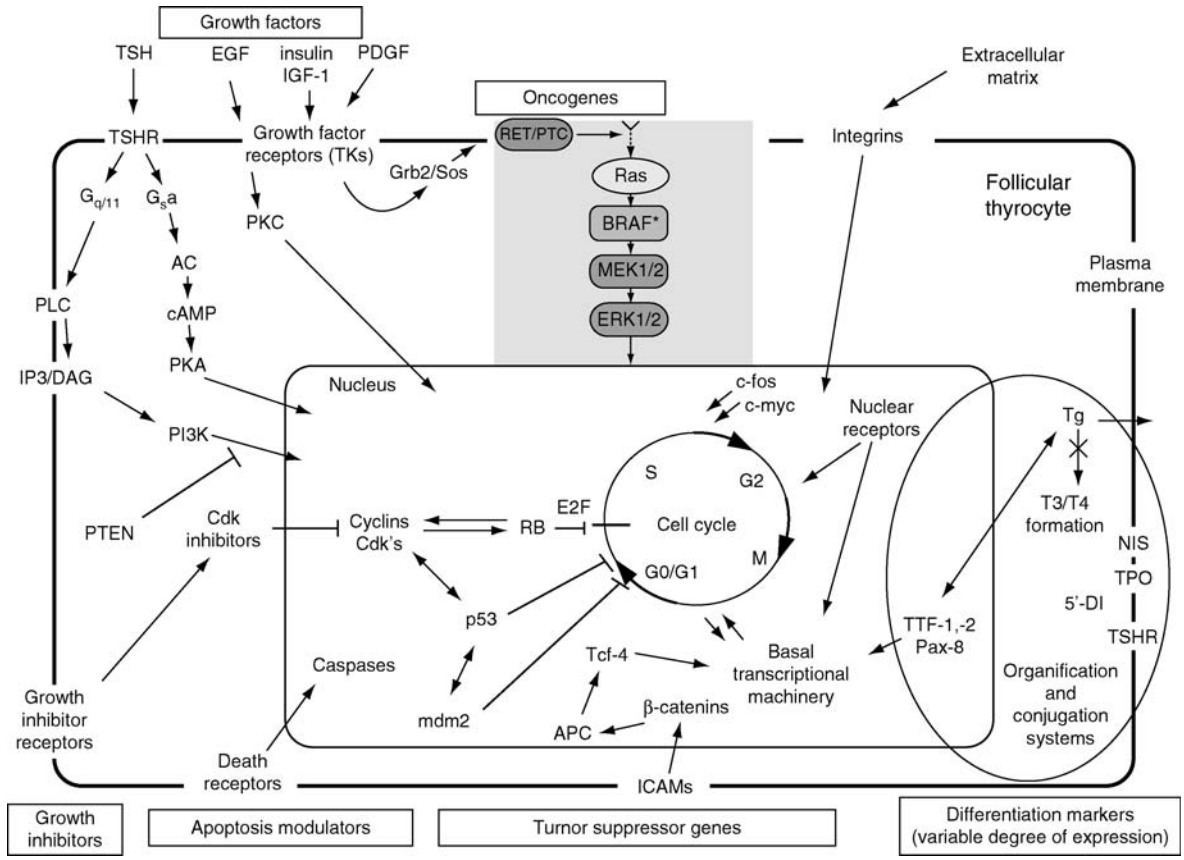
The differential role of oncogenes, cell cycle- and apoptosis-controlling genes, as well as tumor suppressor genes in the molecular pathogenesis of ThyrCa is under intense investigation. The role of mutations in the RET proto-oncogene in the pathogenesis of MEN2/FMTC-associated tumors has become more clear, as it appears that there is an over-expression of mutant RET in the tumor in comparison to normal tissue. Germline mutation testing for RET is commercially available but most laboratories customarily evaluate the 6 so-called "hot spot exons" of RET. Less than 50% of sporadic MTC's harbor somatic RET mutations.

With regard to PTC, a portion of the RET proto-oncogene can merge with other genes, leading to constitutive activation of the novel RET/PTC hybrid gene products (oncoproteins). These molecular events observed in PTC's, occur at the chromosomal level, and are collectively known as RET/PTC rearrangements. Whereas the incidence of RET/PTC activation in spontaneous PTC is less than 40%, it reaches 70% in radiation-induced PTC.

The great majority of ATC's present with mutations and/or over-expression in the p53 oncoprotein; in contrast, p53 abnormalities are rare in most PTC's and FTC's. Specifically for FTC's, loss of expression of the TSH receptor (TSHR) or pro-apoptotic genes, as well as up-regulation of cell cycle-advancing, such as cyclins and cyclin-dependent kinases, and anti-apoptotic genes may underlie a pattern of genomic instability. In fact, these tumors show a wide variety of non-random chromosomal abnormalities. The B-type Raf kinase (BRAF) mutation has recently been found to cause aberrant activation of the MAPK pathway in human cancers including thyroid cancer. An overall scheme of the genes and mechanisms involved in the emergence of malignancies originating from the follicular epithelium (PTC, FTC and ATC) are shown in Fig. 1.

## Molecular and Systemic Pathophysiology

Whether TSH acts as a co-carcinogen, via either the protein kinase A (PKA) or inositol triphosphate ($IP_3$) pathways, remains unclear in humans, despite convincing data for its role in initiating and promoting thyroid oncogenesis in experimental animals. In studies of radiation-exposed patients after partial thyroidectomy, levothyroxine (LT4) treatment reduced the recurrence rate of thyroid nodules, but did not reduce occurrence of malignancies in the subgroup of patients with thyroid nodules. Therefore, thyroid hormone suppression therapy (THST) in patients at high risk for the development of thyroid nodules and Ca after radiation is a logical preventive measure, although the magnitude of its beneficial effect will depend upon the type, dose, and dose rate of the radiation. Further, THST is considered a standard therapy for secondary prevention of recurrence in almost all cases with ThyrCa following initial thyroidectomy.



**Thyroid Cancer. Figure 1** Molecular mechanisms of oncogenesis for non-medullary thyroid cancers. (Abbreviations: AC: adenylyl cyclase, APC: adenomatous polyposis coli gene, cAMP: cyclic AMP, Cdk: cyclin-dependent kinase, DAG: diacylglycerol, 5′-DI: 5′-deiodinase, EGF: epidermal growth factor, ICAM: intercellular adhesion molecules, IGF-1: insulin-like growth factor–1, IP3: inositol triphosphate, MAPK: mitogen-activated protein kinase, MAPKK: MAPK kinase, NIS: sodium/iodide ($Na^+/I^-$) symporter, PDGF: platelet-derived growth factor, PI3K: phosphatidylinositol-3-phospokinase, PKA: protein kinase A, PKC: protein kinase C, PLC: phospholipase C, PTEN: phosphatase-tensin gene product, RB: retinoblastoma-gene protein, T3: triiodothyronine, T4: thyroxine, Tg: thyroglobulin, TSH: thyroid stimulating hormone [thyrotropin], TSHR: TSH receptor, TPO: thyroid peroxidase, TTF: thyroid-specific transcription factor).

## Diagnostic Principles

Thyroid function tests are usually normal in patients with ThyrCa. Tumor markers, other than plasma calcitonin (plus serum carcinoembyonic antigen [CEA] ± serum chromogranin-A [CG-A]) in MTC's, are also of little use, as serum Tg may be markedly elevated in various benign thyroid conditions (such as large multinodular goiters). The effectiveness of current diagnostic modalities, mainly the wide-spread use of fine-needle aspiration biopsy (FNAB) and secondarily the use of neck ultrasonography, is evident from the high incidence of cancer in cases carefully selected for surgery. Depending on the criteria used, this currently is at the range of 40 or 50%.

FNAB is the procedure of choice for the evaluation of patients with a thyroid mass, and has superseded all other diagnostic modalities for the diagnosis of thyroid nodules at initial presentation or for the detection of gross recurrence (after initial therapy) that is evident by physical exam or imaging tests. The interpretation of the FNAB requires the procurement of a satisfactory specimen and its analysis by an experienced cytologist. Results are usually reported as "benign," "malignant," "suspicious," "follicular lesion," "follicular neoplasm," and "indeterminate." The first two diagnoses are correct in >90–95% of cases. Immunostaining for Tg and calcitonin is of help in establishing the histogenetic origin of the tumor. Specifically for MTC, at the time of preoperative staging, the following tests are of essence: Neck ultrasonography, plasma calcitonin (basal and calcium ± pentagastrin-stimulated levels), serum CEA and chromogranin A (CG-A) levels, neck and mediastinal magnetic resonance imaging (MRI), spiral, high-resolution, thin-cut (1 mm) neck, chest, and abdominopelvic computed tomography

(CT) with IV radiographic contrast, RET proto-oncogene mutation screening for MEN2A, MEN2B, and FMTC (this test has been recently suggested for all apparently sporadic MTC cases, as there is a 4–6% rate of "cryptic" heritable disease in these cases).

The diagnosis of recurrent or metastatic disease is based on the carefully selected use of several imaging modalities alone or in combination. These modalities for ThyrCa's in general (including ATC) include neck ultrasonography, positron emission tomography (PET) - often combined with co-registration CT scan -, MRI, and 99m Tc-bone scan. Specifically for PTC/FTC, diagnostic RAI (131-I) whole body scan can be used (under condition of either endogenous-brief iatrogenic hypothyroidism- or exogenous -rhTSH; Thyrogen- TSH stimulation), whereas for MTC 111-In-labeled octreotide (Octreoscan) or RAI-labeled metaiodobenzylguanidine (MIBG) scanning can be used during patient follow-up for the exclusion/detection of recurrent or residual disease.

## Therapeutic Principles

*Pharmacologic Therapy*: For PTC's and FTC's: Thyroid hormone suppression therapy with L-thyroxine (and for short time periods, L-triiodothyronine). In selected cases, chemotherapy (applied alone or in combination) may be of limited benefit. Drugs used include: (i) for incurable PTC's and FTC's, as well as most ATC's: cis-platinum, doxorubicin, bleomycin, taxanes, and gemcitabine; (ii) for MTC's: doxorubicin, streptozocin, 5-fluorouracil, and dacarbazine. Experimental agents under development: inhibitors of HSP90, of histone deacetylase, of angiogenesis including inhibition of multi-targeted kinases, of the ubiquitin-proteasome pathway, and drugs targeting immunomodulation (i.e. dendritic cell vaccination), and DNA methylation.

*Surgery – Primary Operation*: Initial total/near-total thyroidectomy upon diagnosis.

*Surgery – Secondary Operations*: Resection of metastases is used in cases of residual/recurrent disease in PTC and FTC where RAI does not prove to be clinically effective or in MTC (neck and mediastinal dissections for locoregional disease and metastasectomies for distant metastatic deposits).

*Radioactive Iodine (RAI; $^{131}I$)*: Administered shortly after initial surgery, aiming at the ablation of the normal thyroidal remnant (as well as any co-existing metastases) in most cases of PTC and FTC. In patients with PTC and FTC, if residual/recurrent disease is detected during follow-up after the initial therapy, then more RAI ($^{131}I$) is given for treatment.

*External Beam Radiotherapy (EBRT)*: Used whenever surgery is not a treatment option for RAI-"resistant" metastatic deposits from PTC and FTC or MTC/ATC metastases. Also used as a primary treatment for ATC at its initial presentation for control of the primary thyroid tumor.

# Thyroid Carcinoma

►Thyroid Cancer

# Thyroid Hormone-dependent Hearing Loss

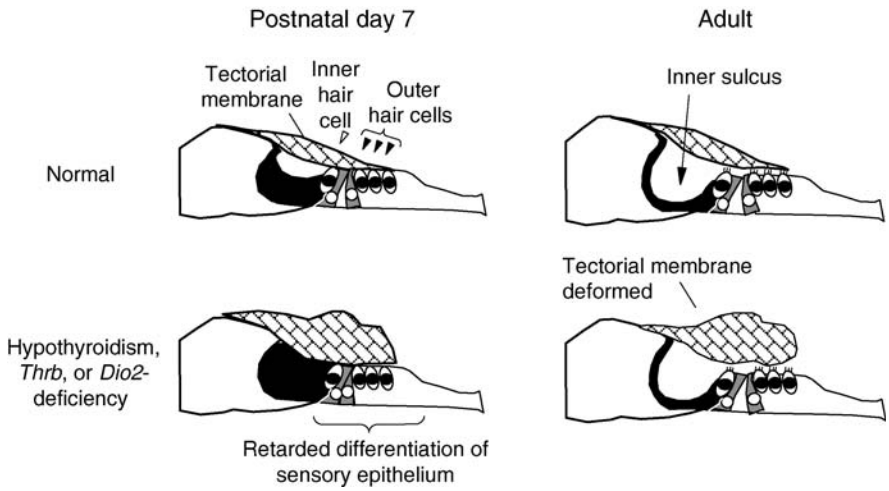
Douglas Forrest[1], Peter Kopp[2]
[1]NIDDK, National Institutes of Health, Bethesda, MD, USA
[2]Northwestern University, Chicago, IL, USA

## Definition and Characteristics

Developmental defects in thyroid hormone (TH) production or receptor mediated tissue responses can cause sensorineural deafness. Causative factors include (i) lack of dietary iodine, an essential component of TH, (ii) congenital defects in thyroid gland formation or TH biosynthesis and (iii) rare defects in TH receptor β (TRβ) in the syndrome of resistance to thyroid hormone (RTH). The most serious risk is associated with impairment in utero, resulting from combined maternal–fetal hypothyroidism.

## Prevalence

A high incidence of deaf mutism has been reported in regions with severe iodine deficiency. Although eradicated in many countries, iodine deficiency is still a



**Thyroid Hormone-dependent Hearing Loss. Figure 1** Some defects in the mouse cochlea caused by hypothyroidism or deletion of the *Thrb* or *Dio2* genes.

major health problem affecting almost a third of the world population and as a result, about twenty million people are believed to be significantly handicapped. In iodine sufficient countries, sporadic congenital hypothyroidism arises in 1 in ~3,500 newborns. Only a subset of these children presents with hearing impairment. Hearing loss has been reported in 21% of cases of RTH [1].

## Genes

Genetic causes of hypothyroidism include mutations in genes for thyroid gland formation or TH biosynthesis [2,3]. Mutations in THRB, encoding TRβ on chromosome 3p24, cause RTH. Deletion of Dio2, encoding type 2 deiodinase, causes deafness in mice [4]. Human DIO2 mutations have not been reported to date. Iodine deficiency is a dietary not a genetic condition.

## Molecular and Systemic Pathophysiology

The auditory system requires TH during fetal and neonatal development. The TH receptors TRβ and TRα1 are ligand regulated transcription factors and are expressed in the organ of Corti in the cochlea. Hypothyroidism in rodents retards the late differentiation of the inner sulcus and sensory epithelium and deforms the tectorial membrane [5] (Fig. 1).

Deletion of TRβ produces a subset of these phenotypes. TRα1 is dispensable but deletion of both TRβ and TRα1 exacerbates the defects, indicating that both receptors mediate a complex control in the cochlea [6]. The Dio2 gene, encoding a thyroid hormone activating deiodinase enzyme, is induced during cochlear maturation. Dio2-/- and Thrb-/- mice show similar auditory phenotypes, suggesting that this deiodinase is necessary to amplify levels of TH ligand at a critical stage in cochlear maturation. The spiral ganglion, brainstem and central brain regions may also be target tissues. Besides sensorineural defects, some deafness in thyroid disorders is conductive and may result from middle ear infections.

## Diagnostic Principles

The diagnosis of hypothyroidism is confirmed by measurement of TH. Thyrotropin (TSH) levels are high in primary hypothyroidism but are low or normal in central hypothyroidism. RTH is characterized by high TH levels and non-suppressed TSH. The vast majority of RTH cases involve autosomal dominant mutations in the THRB gene. A single kindred with recessive RTH had a homozygous deletion of THRB and a few familial cases of RTH without linkage to THRB indicate the existence of non-allelic heterogeneity.

## Therapeutic Principles

Following a neonatal diagnosis of hypothyroidism, thyroxine replacement is essential for normal development and growth. Earlier impairment in utero, as caused by iodine deficiency, may be irreversible after birth. Prevention of iodine deficiency is achieved by the iodization of salt or, in endemic regions, by injection of iodized oils in women of childbearing age.

# Thyroid Nodules, Cold

Seda Sancak[1,2], Markus Eszlinger[2], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III. Medical Department, University of Leipzig, Leipzig, Germany

## Definition and Characteristics

The term cold nodule indicates that this thyroid lesion shows reduced technetium uptake compared with normal thyroid tissue on scintiscan [1] (Fig. 1).

## Prevalence

Approximately 85% of all thyroid nodules are cold thyroid nodules (CTNs) [1]. The large majority of them are benign and ~5% of all nodules are malignant [2]. The prevalence may vary geographically with iodine supply.

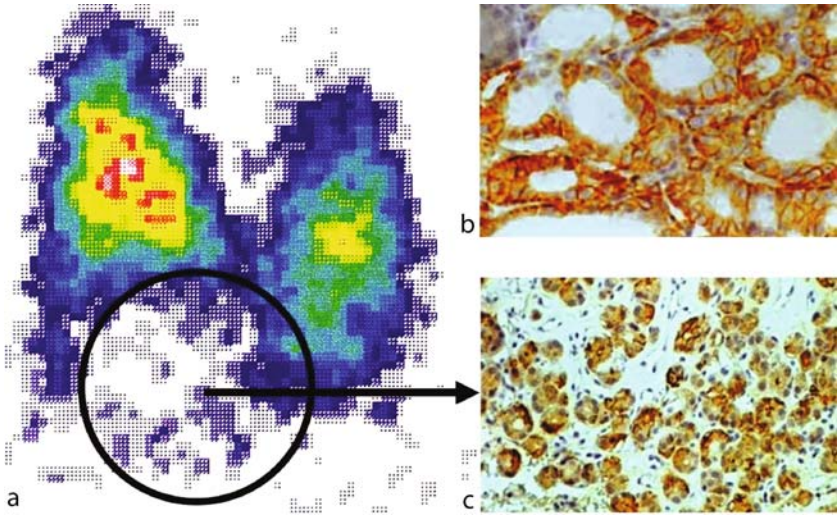
## Genes

In agreement with the decreased scintigraphic uptake, a defective cell membrane targeting of NIS has been reported for CTNs [3]. Moreover, a markedly increased proliferation, increased expression of histone mRNAs and cell cycle-associated genes like cyclin D1, cyclin H/cyclin dependent kinase 7, and cyclin B and loss of heterozygosity at the thyroid peroxidase (TPO) locus, and rarely a Pax-8/peroxisome proliferator-activated receptor γ gene rearrangement or ras mutations have been identified in CTNs [1].

## Molecular and Systemic Pathophysiology

NIS mediates the active iodide uptake into thyroid cells, which represents the first step in the thyroid hormone synthesis [3]. Failure in the iodide transport system or failure of the organic binding of iodide has been detected as a functional aberration of CTNs [1]. A decreased expression of the NIS mRNA is often, the result of hypermethylation of CpG islands in the NIS promoter [3]. Furthermore, this failure of the iodide transport system can be caused by constitutive activation of RET or RAS genes [1].

However, the reduced NIS mRNA expression does not necessarily lead to a reduced NIS protein expression, and, does not seem to be the major cause of the defective iodide uptake in CTNs [1,3]. Rather



**Thyroid Nodules, Cold. Figure 1** The lack of scintigraphic Technetium uptake in CTNs correlates with a lack of NIS cell membrane insertion, (a) Scintigraphy, (b) NIS localized in the cell membrane of hot nodule, (c) NIS localized intracellularly in cold nodule.

posttranslational events such as the cell membrane targeting of the NIS protein to the plasma membrane are distributed in CTNs [1,3].

Further, molecular events that lead to activation of other cascades, which exert synergy with MAPK signaling (e.g., cAMP signaling) or inactivation of independent cascades that restrict proliferation (e.g., TGF-β signaling) could contribute to the pathophysiology of CTNs [1].

The increased expression of histone mRNAs and of cell cycle-associated genes like cyclin D1, cyclin H/cyclin dependent kinase 7, and cyclin B most likely reflect the increased proliferation in CTNs [1].

Most CTNs are monoclonal thus implying a somatic mutation. However, the respective somatic mutation has not yet been identified.

## Diagnostic Principles

The diagnosis of CTNs is based on the technetium scintiscan of the thyroid nodule showing diminished iodide uptake compared with normal thyroid tissue [2, 3].

High-resolution US is the most sensitive test available to detect thyroid lesions to measure their dimensions accurately, to identify their structure and evaluate diffuse changes in the thyroid gland [4]. Thyroid carcinoma should always be taken into consideration in the differential diagnosis of CTNs. In a study of palpable CTNs, thyroid carcinoma was reported in 4.6% [5].

Several US features have been reported to be associated with an increased risk of thyroid cancer including the presence of calcifications, hypoechogenicity, irregular margins, absence of a halo, predominantly solid composition, and intranodule vascularity. However, all the sonographic criteria show a low sensitivity and specificity [4].

Factors predicting malignancy include a history of head and neck irradiation, family history of thyroid carcinoma in a first-degree relative (MTC or MEN 2), male sex, cervical adenopathy, fixed nodule on examination, and rapid growth [4].

With the discovery of a thyroid nodule, measurement of the serum thyrotropin (TSH, thyroid-stimulating hormone) level should be obtained. If TSH levels are outside the normal range, the measurement of serum free thyroid hormones and thyroid peroxidase antibody (TPO Ab, if TSH is increased) levels should be obtained [4].

Any cold nodule (≥1 cm) should be submitted to fine needle aspiration cytology guided by ultrasonography (US-FNAC) [4].

## Therapeutic Principles

Indications for surgery include local symptoms related to the growth of the nodule and suspicious or malignant FNAC results [4].

Treatment of thyroid nodules is controversial. Most clinical trials investigated the efficacy of levothyroxine (LT4) to suppress TSH and to arrest further growth or reduce the size of thyroid nodules, reduce the symptoms associated with the pressure that has emerged because of the growing nodule [1].

However, a clinically significant (>50%) decrease of the nodule volume with LT4 therapy can only be obtained in 20% of the patients with palpable thyroid nodules [4]. Cross-sectional studies provide no evidence that the stimulation of thyroid growth or thyroid function through serum TSH is responsible for thyroid nodule growth [1].

Currently, routine LT4 treatment in patients with nodular thyroid disease is not recommended [4]. Furthermore, TSH suppression may lead to symptoms of hyperthyroidism, reduced bone density, and atrial fibrillation, especially in elderly patients and postmenopausal women. Nodule regrowth is usually observed after cessation of LT4 therapy [4].

Because thyroid nodules were more often detected in iodine-deficient areas than in iodine-sufficient areas [1], iodine supplementation is the first choice in thyroid nodule prevention [1]. Iodine supplementation is the first choice for nodular goiter [1].

# Thyroiditis, De Quervain's

►De Quervain's Thyroiditis

# Thyroiditis, Subacute

Seda Sancak[1,2], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III Medical Department, University of Leipzig, Leipzig, Germany

## Synonyms

De Quervain's thyroiditis; Giant-cell thyroiditis; Pseudogranulomatous thyroiditis; Subacute painful thyroiditis; Subacute granulomatous thyroiditis [1]

## Definition and Characteristics

Sudden onset of thyroid pain radiating to the jaw or ear with symptoms of hyperthyroidism transiently suppressed levels of TSH, low radioiodine uptake, elevated erythrocyte sedimentation rate, fever, malaise, which last several weeks to months [2–4]. It frequently follows an upper respiratory tract infection, and its incidence is highest in summer [2,3].

## Prevalence

Subacute thyroiditis is the most common cause of thyroid pain and occurs in up to 5% of patients with clinical thyroid disease [3]. The disease is more prevalent in females than males [2,4], in a ratio of 3–6:1 [4].

## Genes

There is an apparent genetic predisposition to subacute thyroiditis with human leukocyte antigen (HLA)–Bw35 association in many ethnic groups [5].

## Molecular and Systemic Pathophysiology

The subacute thyroiditis is characterized by infiltration with lymphocytes and giant cells and parenchymal destruction [1,5].

Clinically, the disease has several characteristics that are typical for viral infections including a viral prodrome with myalgias, malaise and fatigue, and absence of leukocytosis. Many cases have been reported in association with adenovirus, Coxsackie, Epstein-Barr, mumps, and influenza viruses [4]. A higher prevalence of the disease has been reported during enterovirus infections [3,4]. Therefore, a viral etiology has often been discussed for subacute thyroiditis, but with rare exceptions, specific viruses have not been cultured from the thyroid [1].

Several reports have suggested the development of an autoimmune response in subacute thyroiditis [4]. Thyroid autoantibodies [antithyroglobulin (anti-Tg) and antithyroid peroxidase antibodies (anti-TPO)], thyrotropin (TSH) receptor, and sensitization of T cells against thyroid antigens may be present during the acute phase of the disease. In most of the patients, the antibody titer gradually decreased and remained low or disappeared as the disease faded [4]. Therefore, these autoimmune phenomena represent a nonspecific, and transient, response to the inflammatory release of thyroid antigens rather than a primary event [4].

Only in rare cases do Hashimoto's thyroiditis and Grave's disease develop after typical subacute thyroiditis [2,4].

## Diagnostic Principles

The clinical course of subacute thyroiditis is self-limited, comprising four phases: The acute phase, consisting of thyroidal pain and thyrotoxicosis, usually lasts 3–6 weeks. Then follows a transient asymptomatic euthyroid period. Transient hypothyroidism occurs after several further weeks in 30–50% of patients and may last for several months. During the final recovery phase the thyroid function returns to normal after 4–6 months [1,2].

Permanent hypothyroidism has been reported in 5% of cases. Painful subacute thyroiditis recurs in only about 2% of patients [2].

The erythrocyte sedimentation rate (ESR) is elevated during the active phase. This is the hallmark of painful subacute thyroiditis. If the ESR is normal, the diagnosis of thyroiditis can be ruled out [1,3].

Thyroid hormone concentrations are elevated during the acute phase. The serum thyroxin (T4) concentration is disproportionately elevated relative to the serum triiodothyronine T3 concentration with ratios T4 to T3 of more than 20, and serum concentrations of thyrotropin are low or undetectable [3]. The radioactive iodine uptake (RAIU) is low. A normal RAIU like a normal ESR rules out subacute thyroiditis [1].

Consistent with follicular destruction, serum Tg concentrations are elevated and anti-TPO and anti-Tg are usually normal [1,3].

## Therapeutic Principles

Salicylates and other nonsteroidal anti-inflammatory drugs (NSAIDs) are often adequate to decrease thyroidal pain in mild to moderate forms of the disease [2,3]. In severe forms of thyroid pain, high doses of glucocorticoids provide relief of symptoms in most cases within 24–48 h [2,3]. Prednisone therapy may be initiated in dosages of 40 mg daily, with a gradual reduction over a period of 4–6 weeks [2,3]. If clinical thyrotoxicosis is present, beta-blockade helps to control the symptoms [2,3].

Therapy with levothyroxin sodium is rarely required, because the hypothyroid phase is generally mild and

transient. If the patients are symptomatic, the levothyroxin sodium therapy is indicated [2,3].

Thyroidectomy should be considered for a minority of patients who have repeated relapses despite appropriate treatment [2].

## Synonyms

Chondropathia tuberosa; Costal chondritis; Parasternal chondrodynia; Costochondral syndrome; Thoracochondralgia [1]

## Definition and Characteristics

Tietze's syndrome can be defined as a benign, painful, non-suppurative localized swelling of the costosternal, the costochondral (most often involves the second or the third rib), or the sternoclavicular joints (Tietze's area) in the absence of other evident causes which could be responsible for this condition [2].

## Prevalence

The exact occurrence of this pathology is not well known, because it often goes undiagnosed. It predominantly strikes subjects between 20 and 50 years of age. However, cases in children or in the elderly have been documented.

## Molecular and Systemic Pathophysiology

The etiology is unknown. Among the hypotheses that have been put forward, the most likely is that of a microtrauma and contracture of the costal cartilage connecting the rib to the sternum, with a successive rotation or ventral angulation of the costal cartilage.

*Clinical Features*: Patient report pain, sometimes severe, with swelling of the affected area. It is a self-limiting condition, but the pain can continue for several years. The non specific indexes of inflammation (Erythrocyte Sedimentation Rate, C Reactive Protein) are within the standard limits [1].

## Diagnostic Principles

Different diagnostic procedures have been used to document Tietze's syndrome, and only a few recent studies have analyzed the value of radiography [3], CT [4] and ultrasonography (US) [5].

Standard radiography is often suboptimal because of underlying thoracic and mediastinal structures. In many cases, conventional radiological methods (standard X-ray, conventional tomography) help to exclude lesions of the bone (sclerosis, erosions, calcification of the

**Tietze's Syndrome. Figure 1** Clinical involvement of right clavicula in SAPHO syndrome.

**Tietze's Syndrome. Figure 2** CT appearance of Tietze's syndrome: (a) focal cartilage enlargement of right sternoclavicular joint compared to opposite side; (b) hypodensity of the affected cartilage.

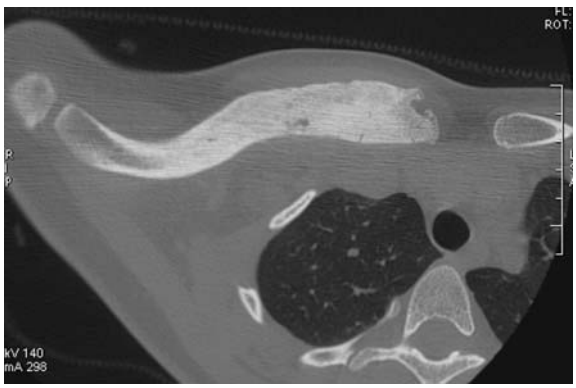
ligament and cartilage tissue). They are unable, however, to show other cartilaginous lesions because they don't permit a direct visualization of this anatomical structure most affected by early Tietze's syndrome. In Tietze's syndrome, US showed a dishomogeneous increase in echogenicity in pathological cartilage and an increased thickness (2–4 mm) compared to the opposite normal side [5]. However, this technique does not allow for an immediate comparison between the two sides, as its use depends strongly on the operator, and it is not suitable for clearly demonstrating the complex anatomy of the sternoclavicular joints and condrosternal joints.

MR imaging and CT, especially after the introduction of the multidetector technology, have the advantage of improved delineation of the complex anatomy of the sternoclavicular joints and condrosternal joints. The spectrum of CT findings in idiopathic Tietze's syndrome includes focal cartilage enlargement, ventral angulation and hypodensity of the affected cartilage (Fig. 2).

CT has the ability to help to exclude a mass if it has been clinically suggested, or to recognize pathologies that can enter into differential diagnosis (Fig. 3).

MR was able to reveal the changes in cartilage abnormalities and bone marrow edema that could not be revealed by CT or by US. The greatest advantages of MR compared with other techniques are its capability to detect inflammation in the form of edema of the cartilaginous components, and in the subcondral bone, before subsequent morphological alterations occur at that level. The spectrum of MR findings of Tietze's syndrome includes focal cartilage enlargement, edema of cartilaginous tissue and subcondral adjacent bone, and vivid and rapid contrast enhancement of cartilage and articular components adjacent to the joint involved (Fig. 4).

These MR findings confirm the histological observations of hypervascularization and degenerative phenomena of the cartilage [1]. While in the differential diagnosis



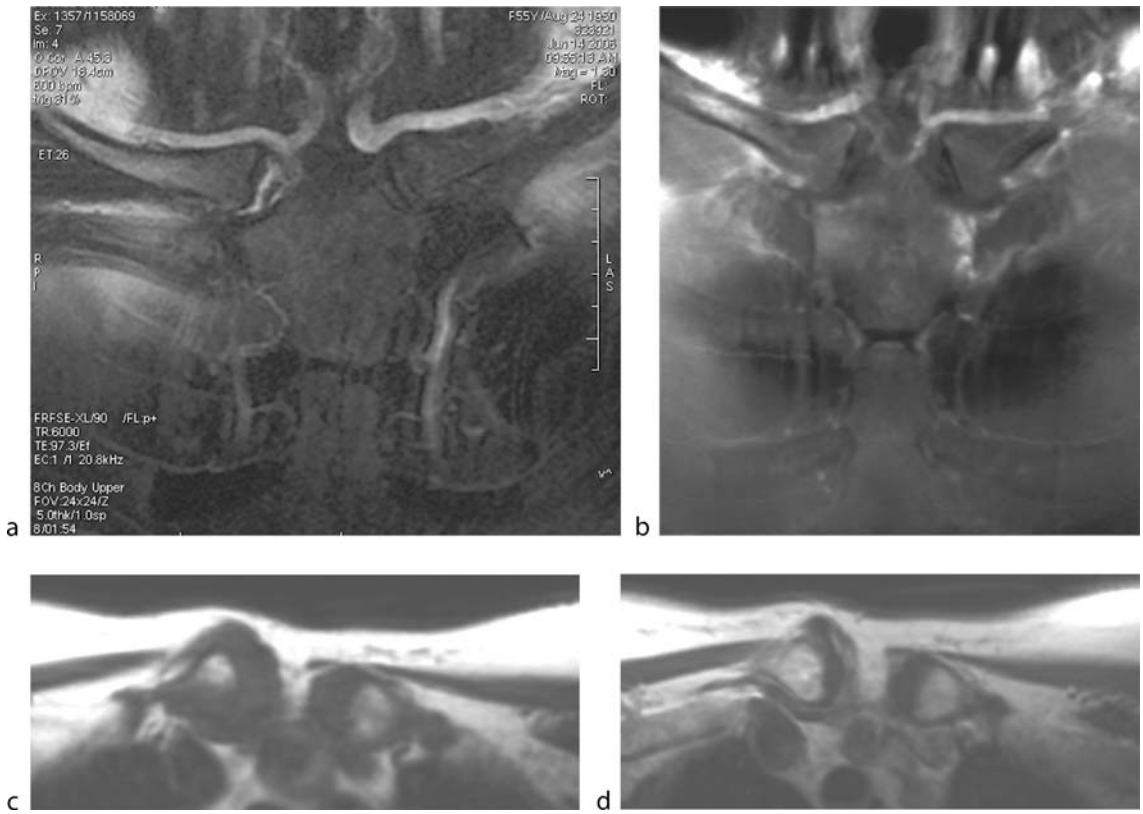
**Tietze's Syndrome. Figure 3** CT appearance of SAPHO syndrome localized to right clavicula.

of the majority of the pathologies involving the anterior chest wall, the CT, and only occasionally the US, (septic arthritis) are sufficient, the MR represents the only diagnostic technique that can provide a differential diagnosis between Tietze's syndrome and the rheumatic diseases that involved Tietze's area.

*Differential Diagnostics*: Different pathologies can account for the pain with or without the swelling of the Tietze' area, and can therefore present problems of diagnosis. The differential diagnosis includes various rheumatological and non rheumatological diseases, among which, in particular, we will note the following causes:

- Seronegative spondyloarthropathies
- Rheumatoid arthritis
- Gout
- Septic arthritis (Pyogenic, mycotic, brucellosis, tuberculosis)
- Costochondritis
- Fibromyalgia

T



**Tietze's Syndrome. Figure 4** MR findings of Tietze's syndrome: edema of the cartilagineous tissue in Tietze' syndrome of the right sternoclavicular joint (a) and edema of subcondral adjacent bone in Tietze' syndrome of first left condrosternal joint (b), on T2 fat sat weighted images; focal cartilage enlargement (c) and vivid contrast enhancement of cartilage and articular components (d) in Tietze' syndrome of right sternoclavicular joint on T1 weighted images.

- Lymphomas
- Benign tumors (e.g. Chondroma, lipoma)
- Malignant tumors (e.g. Chondrosarcoma, metastasis)
- Fractures or cough
- Thoracic pain due to cardiac or pulmonary diseases

*Seronegative spondyloarthropathies* are a group of inflammatory joint diseases, which include Ankylosing Spondylitis (AS), Psoriatic Arthritis (PA), Reactive Arthritis (ReA), Enteropatic Arthritis, and Undifferentiated Spondyloarthropathies. All of these share common clinical, laboratory and imaging findings, with characteristic involvement of the sacroiliac joints, spine, and in various degrees, the peripheral joints. In most cases they are associated with Histocompatibility Antigen, HLA B-27. Radiological involvement of the sternoclavicular joint were found in 17% of patients with AS, in 6–9% of patients with ReA and PA; the manubriosternal joint was involved in 51–57% of patients with AS as well as in 18–24% of patients with ReA and PA [3].

Another characteristic expression of spondyloarthropathies is represented by the SAPHO syndrome (synovitis-acne-pustolosis-hyperostosis-Osteitis). This syndrome combines skin and osteoarticular manifestations. The skin lesions typically consist of severe acne and/or palmoplantar pustolosis. The preferred targets of osteoarticular involvement are the anterior chest wall, spine and pelvis, although the long bones and peripheral joints are sometimes affected. Often patients complain of pain in the upper-anterior wall of the chest, which can be associated with the swelling of one or both of the sternoclavicular joints (Fig.1).

*Rheumatoid arthritis* (RA) is a chronic inflammatory disease characterized by progressive damage of synovial-lined joints and variable extra-articular manifestations. RA can affect any joint, but it is usually found in metacarpophalangeal, proximal interphalangeal and metatarsophalangeal joints, as well as in the wrists and in the knees. The costochondral localization is rare in RA, while sternoclavicular and manubriosternal localizations occur much more frequently.

*Acute gout* may involve the chest wall by affecting the sternoclavicular or the costochondral joints. The medical history of the patient is important for the diagnosis, as is analysis, whenever possible, of urate crystals in the synovial fluid.

*Septic arthritis* rarely affects Tietze's area; it occurs more frequently following surgeries, especially after total joint replacement or articular infiltration, in heroin addicts, and in subjects in any way immunodepressed. A detailed medical record, analysis of symptoms and characteristic signs of the infective process, and visual imaging techniques [Scintigraphy, Computed Tomography (CT), and Magnetic Resonance (MR)] can aid in a correct diagnosis, even if an etiological diagnosis can only be provided by means of a bioptic sample. Tubercular arthritis can also occur with a localization at the level of the anterior chest wall; in particular we note the possible involvement of the costochondral joints. Yet Tietze's syndrome rarely extends below the third costochondral joint, while tubercular arthritis can involve the lower costochondrals as well.

*Hodgkin lymphoma* frequently strikes the sternum in its initial phases, perhaps because of its proximity to the thoracal lymphatic ducts, or possibly because of the mediastinal localizations of lymphoma, which can compress and invade the structures of the thoracic cage. Costal or clavicular localizations are, however, rare. The possibility that lymphoma may mimic Tietze's syndrome require accurate clinical investigations and imaging techniques.

### Therapeutic Principles

The patient should be reassured regarding the benign and self-limiting nature of the pathology. Non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics should be prescribed for the pain. Eventually localized corticosteroid injections alongside the local anesthetics should be administered.

►Dermatomycosis

## Tinea Versicolor

►Pityriasis Versicolor

## Tinnitus

Hans-Peter Zenner, Ilse Maria Zalaman
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

### Definition and Characteristics

A sensation of ringing, buzzing, or other sounds in the head or ears when no corresponding outside sounds are present, signalling a malfunction of the auditory pathway to the auditory cortex, whereby the symptoms do not necessarily reveal the actual steps that led to the tinnitus.

### Prevalence

In Germany and the United Kingdom, the ratio prevalence of individuals who have tinnitus at a particular time or during a particular period to the population at risk of having tinnitus is reported to be 3.9%.

### Molecular and Systemic Pathophysiology

Pathophysiologically tinnitus can be classified as objective or subjective. Reasons for an objective tinnitus could be a glomus tumor, vascular stenoses, or a protruding bulbus venae jugularis. Subjective tinnitus can be divided into a peripherally or centrally originating tinnitus. A peripheral tinnitus can be the result of malfunctions in sound conduction or sensorineural malfunctions. The extremely rare sound conduction tinnitus is usually produced by middle ear malfunctions such as incorrect ventilation of the Eustachian tubes or muscle cloni of the middle ear. According to Zenner, the much

more frequently occurring sensorineural tinnitus can be divided into four types. Centralized tinnitus can be classified as primary or secondary, whereas the former occurs infrequently and may be caused, for example, by brain tumors or multiple sclerosis. The secondary centralized tinnitus, however, occurs frequently and is considered to be induced by chronic peripheral sensorineural tinnitus. Secondary centralization can almost always be traced back to the pathological neurophysiological centralized reinforcement of an existing tinnitus perception, which can turn into phantom auditory perception without auditory stimuli. Centrally caused pathological tinnitus reinforcement often incurs decompensated tinnitus, which should receive professional care. Tinnitus decompensation is the pathophysiological response to tinnitus cognitions. For this reason, one can consider this type of centralization a secondary process since tinnitus decompensation is the result of and not the cause of tinnitus.

### Diagnostic Principles

The patient's medical history is recorded with a detailed structured tinnitus questionnaire. One single objective assessment tool for routine tinnitus examinations is not available at this time. Most tinnitus patients also have hearing disorders that can be used for etiological and pathogenetical purposes. Tinnitus-specific procedures are psycho-acoustic tinnitus assessments, tinnitus suppression measures, as well as tinnitus-specific questionnaires.

### Therapeutic Principles

Acute idiopathic tinnitus should receive the same medical treatment as sudden hearing loss. Chronic tinnitus – frequently accompanied by secondary centralized symptoms – should be treated with the tinnitus desensibilization therapy, which is based on cognitive behavioral principles. Moreover, psychosomatic therapies should be available to patients suffering from comorbidities such as sleep disorders, anxiety disorders, or psychosocial withdrawal behaviors.

# Tonsillitis

Ulrike Schumacher, Ingo B. Autenrieth
Institute for Medical Microbiology and Hygiene, University of Tuebingen, Tuebingen, Germany

## Synonyms

Angina; Sore throat

## Definition and Characteristics

Acute infection of tonsils with group A beta-hemolytic streptococci (GAS; streptococcus pyogenes) causing 30% of the cases, group C beta-hemolytic streptococci causing 10%. Rarely, tonsillitis occurs as a mixed anaerobic infection (Vincent's angina). In association with common cold, rhinoviruses cause about 20% of cases, Epstein-Barr-virus and cocksackievirus A (herpangina) are less common viral pathogens.

## Prevalence

Most cases of tonsillitis are transmitted from human to human by the inhalation of aerosols from colonized or infected patients. Despite the fact that highest incidence occurs in early childhood, under crowded conditions all age groups may be affected, with a peak during fall and winter seasons worldwide.

## Molecular and Systemic Pathophysiology

GAS are characterized by a variety of extracellular gene products (proteins, adhesins, capsules, toxins, and enzymes) which are associated with pathogenicity. GAS can be divided into more than 80 distinct serotypes, based on the serological reactivity of the M protein. The M protein forms fibrils which are anchored in the cell membrane via the carboxy-terminal region, transverse, and extend from the cell wall. The amino terminus of the M protein contains hypervariable regions conferring serotype specificity. There is accumulating epidemiological and experimental evidence that class I M protein serotypes are associated with acute rheumatic fever due to cross-reaction of class I epitope specific antibodies with human proteins. M proteins play a key role in bacteria-host cell interaction and mediate adhesion to host cells in addition to several other adhesins, e.g., lipoteichoic acid and several fibronectin-binding proteins. M proteins and fibronectin-binding proteins (protein F, SfbI) have also been demonstrated to participate in internalization of the bacteria by epithelial cells. In conjunction with hyaluronic acid capsule, M proteins are major virulence determinants by conferring antiphagocytic properties. Binding of factor H to M protein blocks complement activation as well as binding of fibrinogen via blocking the alternative pathway of complement activation. Inhibition of host defense mechanisms are also achieved by a protease cleaving C5a affecting chemotaxis and the streptococcal inhibitor of complement-mediated lysis directed against the complement membrane attack complex. GAS express plasminogen-binding proteins as cell surface associated proteins (enolase, glyceraldehyde-3-phosphate dehydrogenase) as well as secreted proteins (streptokinase). Streptokinase has been found to be associated with the pathogenesis of acute glomerulonephritis, probably due to the binding of streptokinase to renal glomeruli via its V1 region. GAS produce numerous pyrogenic exotoxins, including the erythrogenic toxins SpeA-SpeD, the mitogenic factor, the streptococcal superantigen and the streptococcal mitogenic exotoxin Z. Besides their pyrogenicity, these exotoxins function as superantigens, activating large numbers of T cells without being processed by antigen-presenting cells and leading to the release of excessive amounts of inflammatory cytokines.

Suppurative complications of tonsillitis by GAS are peritonsillar cellulitis, peritonsillar and retropharyngeal abscess formation, bacteremia and metastatic foci (e.g., arthritis or endocarditis). Lemierre's disease, a postanginal septicemia, usually caused by fusobacterium necrophorum, is now an uncommon complication as a consequence of early and widespread use of antibiotics in pharyngeal infections. Scarlet fever is a tonsillitis caused by erythrogenic toxin-producing GAS strains, characterized by a typical rash. The most important nonsuppurative complications of GAS infections of the pharynx are acute rheumatic fever (ARF) or acute glomerulonephritis (AGN). M proteins of rheumatogenic GAS strains share common epitopes with human cardiac myosin and sarcolemmal membrane proteins. Cross reacting autoantibodies and cell mediated cytotoxic reactions lead to heart valve damage. In contrast, AGN, synovitis and Sydenham's chorea are produced by nondestructive immuncomplexes.

## Diagnostic Principles

Diagnosis of GAS tonsillitis is based on rapid antigen detection tests (RADT) as well as on throat swab cultures. RADTs detecting the group A carbohydrate moiety mostly have a high specificity but a lower sensitivity as throat cultures. Detection of antibodies to streptococcal products (streptolysin O, streptodornase, and hyaluronidase) is of value in the diagnosis of ARF.

## Therapeutic Principles

Current guidelines recommend a 10-day course of oral penicillin V for every symptomatic culture and/or RADT based diagnosed GAS tonsillitis. This therapeutic regimen is mainly directed toward the prevention of ARF.

# Torsades de Pointes

Nitin Wadhani, Hari Red, Shah Azmoon, Harpreet Singh, Bramah N. Singh
Division of Cardiology, Veterans Affairs Greater Los Angeles Healthcare System, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

## Synonyms

TdP

## Definition and Characteristics

Torsades de pointes ( TdP) has come to be recognized as a distinctive arrhythmia complex that occurs in the setting of non-homogeneous and variable prolongation of the QT interval usually with a well-characterized mode of onset (see Fig. 1) and with a life-threatening potential. It usually manifests with dizziness or syncope. Most cases are associated with drugs that prolong ventricular repolarization. The first antiarrhythmic drug, quinidine, introduced in 1918 was known to induce syncope from very early years of clinical usage. However, the nature of the arrhythmia and its association with the prolonged QT interval was not clearly defined until Francois Dessertenne in 1966 in France coined the term torsades de pointes which translates to "twisting of points" [1]. The QRS complexes in torsades appear to be "twisted" around the isoelectric line hence the name.

## Prevalence

Some 1% of the general population may be at risk to experience torsade de points.

## Genes

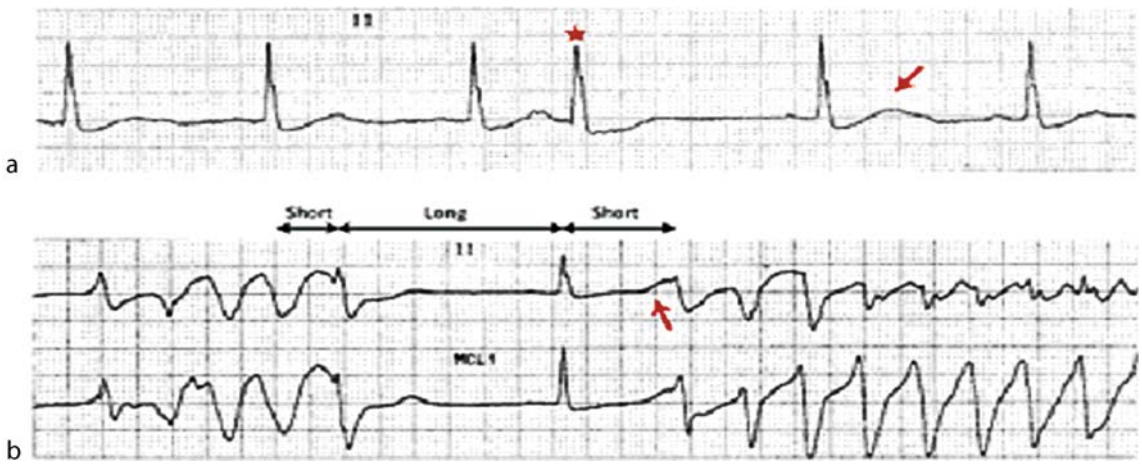
►Long QT Syndrome (LQTS), as described above, can be acquired or inherited. The inherited form is typically caused by a mutation or polymorphism in one of the seven LQTS genes (Table 1). It usually takes on the form of two clinical phenotypes that vary with the type of inheritance and presence or absence of sensineural hearing loss. Romano-Ward syndrome is transmitted as an autosomal dominant trait and characterized by LQTS without deafness, while Jervell and Lange-Nielsen syndrome is transmitted as an autosomal recessive trait that is characterized by LQTS and sensineural hearing loss [3]. There is, however, a subgroup of individuals expressing a mutation or polymorphism in one of the LQTS genes that is clinically unapparent until the patient is exposed to a particular drug or to a predisposing factor [2].

## Molecular and Systemic Pathophysiology

Torsades has classically been found to be associated with conditions that increase the baseline QT interval including certain gene mutations, cardiac and non-cardiac drugs, electrolyte disturbances (hypokalemia and hypomagnesemia), and bradycardia especially in patients with complete heart block. The arrhythmia occurs more commonly in females. Other factors including increased QT dispersion, structural heart disease, and hypertension have been shown to play a role in the genesis of torsades.

Medications that predispose to the development of torsades (Table 2) are usually associated with chronic use, or with concomitant use of other QT-prolonging drugs. This is especially the case in the simultaneous use of erythromycin, ketoconazole, or other known inhibitors of CYP3AY [1], the enzyme responsible for the biotransformation of these drugs to non-cardioactive metabolites. Of particular interest is the fact that quinidine can cause torsades with a single dose even at sub-therapeutic levels. In sustained atrial fibrillation torsades is uncommon except during the process of acute conversion of the arrhythmia to sinus rhythm especially in the setting of the QT-prolonging drugs. However, it should be emphasized that not all chemical agents that induce prolongation of repolarization lead to the development of torsades de pointes.

The mechanism of torsades may be understood most readily relative to the nature of ventricular repolarization. During repolarization, which occurs during phases II and



**Torsades de Pointes. Figure 1** Mode of onset of torsades de pointes. Rhythm recordings are from a 76-year-old woman with renal dysfunction who was treated with sotalol for atrial fibrillation. Panel A was recorded after spontaneous conversion to sinus rhythm. There is a premature atrial beat (*star*) followed by a pause, and the subsequent sinus beat shows marked QT prolongation and deformity (*arrow*). Panel B was recorded several minutes later and shows a typical episode of torsades de pointes: there is a four-beat run of polymorphic ventricular tachycardia, a pause, and a sinus beat with a long and deformed (reproduced with permission from DM Roden [2] and New England Journal of Medicine).

**Torsades de Pointes. Table 1** Genes that can cause LQTS and predispose to torsades de pointes [17]

| | |
|---|---|
| **KVLQT1 (LQT1)** | Mutations in this gene which account for 40–55% of congenital LQTS and suppress the slowly acting component of the outward rectifying potassium current (IKs) and as a result prolong the action potential duration and increase the QT interval [3,4]. Homozygous mutations have been reported to cause the Jervell-Lange-Nielsen syndrome [5]. |
| **HERG (LQT2)** | Mutations in this gene which accounts for 35–45% of congenital LQTS cause suppression of the rapidly-acting component of the outward rectifying potassium current (IKr), likewise, increasing the QT duration [3,4]. |
| **SCN5A (LQT3)** | This mutation affects the sodium channel causing a slow leakage of sodium into the cell which keeps the membrane in a slight depolarized state [5]. This can prolong repolarization and predispose to early after depolarization. Mutations in this gene have also been seen to be associated with Brugada syndrome [6]. |
| **Ankyrin-B (LQT4)** | Ankyrin-B is a plasma membrane protein that links the lipid bilayer to the membrane skeleton. It is the first protein associated with LQTS that is not an ion channel or channel subunit [7]. |
| **KCNE1 (LQT5)** | Mutations in this gene as in LQT1 cause suppression of the slowly acting component of the outward rectifying potassium current (IKs). Homozygous mutations have been reported to cause the Jervell-Lange-Nielsen syndrome [8,9]. |
| **MiRP1 (LQT6)** | Mutations in this gene cause suppression of the rapidly acting component of the outward rectifying potassium current [10]. |
| **KCNJ2 (LQT7)** | This is a mutation that encodes Kir 2.1, the inward rectifier potassium channel expressed in cardiac and skeletal muscle. It can prolong the terminal phase of the myocardial action potential [11]. |

III of the cardiac cycle, there is an efflux of $K^+$ ions out through two $K^+$ channels known as the slow activating ($I_{Ks}$) and rapid activating ($I_{Kr}$) rectifier channels. This outflow is counteracted by the influx of $Na^+$ ions through the $Na^+$-$Ca^{++}$ exchange pump. The net flow through these channels determines the length of repolarization. Any reduction in the conductance of the outward $K^+$ flow or any increase in conductance of the inward $Na^+$ flow can prolong the duration of the action potential. Such an increase in the action potential duration has the capacity to recruit the influx of transient $Ca^{++}$ ion channels which can decrease the threshold for depolarization [12]. These early after depolarizations (EADs) which occur when the time course of repolarization is markedly lengthened (the QT) are now believed to be the basis for the development of torsades de pointes. While many antiarrythmic agents have shown the propensity for increasing the action potential duration and the QT interval on the electrocardiogram, these per se may not be the crucial factors for the genesis of torsades. For

example, amiodarone which is known to increase the QT interval (to levels of 600–700 ms) does not induce torsades. There is evidence now that this "protection" occurs on the basis of the electrophysiological properties of this compound. Amiodarone is a multi-faceted agent in terms of the ionic channels it blocks unlike other class III such as dofetilide and sotalol which act largely by blocking the rapid component of the delayed rectifier current in the epicardium, endocardium, and the M cells as well as in Purkinje fibers.

Amiodarone blocks the delayed rectifier current in the epicardium and endocardium without or little effect on the mid-myocardial (M) cells in which some actual shortening can occur. Since the action potential duration in the M cell is substantially longer than those in the epicardium and endocardium, the net effect is a greater myocardial homogeneity under the action of amiodarone. Such an effect is created largely by a shortening effect of drugs like amiodarone (dronedarone, ranolazine, and sodium pentothal) in the M cells and Purkinje cells. These cells have a lower density of $I_{Ks}$ channels and a greater density of $I_{Na}$ channels in relation to the epicardium or endocardium [13]. Here, the use of amiodarone has shown to decrease the transmural dispersion of repolarization [14]. Thus, its effects on the Na and Ca channels counteract the slow repolarization

properties of the M cells and Purkinje fibers which may be the origin of the EADs. In comparison to other class III as well as class I antiarrhythmic, there is a homogeneous rate of repolarization. On surface EKG, this is reflected by a decrease in QT dispersion which likely reflects the low rates of torsades with use of this drug. Recent trials have even shown that amiodarone decreases the torsadogenic potential of other QT-prolonging drugs such as intravenous ibutilide.

While amiodarone decreases QT dispersion, most drugs listed above tend to increase dispersion and hence increase the potential for torsades. This has also been shown in patients with the congenital form of the long QT syndrome where mutations in the outward K and inward Na channels cause a heterogeneous rate of repolarization predisposing the development of EADs and ultimately torsades. The observed effects of amiodarone when considered in light of the experimental electrophysiological data on dronedarone, ranolazine, and sodium pentothal raise the issue of developing selective anti-torsadogenic compounds for the prevention of proarrhythmic reactions of class III compounds [15].

## Diagnostic Principles

Torsades de pointes are diagnosed by ECG.

## Therapeutic Principles

Acute management of torsades includes the withdrawal of the offending drug, repletion of serum potassium to the high normal range, and the intravenous administration of 1–2 g of magnesium sulfate initially in 30–60 s, repeated in 5–15 min if needed. If the arrhythmia persists, isoproterenol can be administered to increase heart rate and shorten QT interval but caution is warranted in patients with ischemic heart disease. Alternatively, temporary transvenous pacing has been shown to be effective in terminating this rhythm. Chronic management which only applies to congenital long QT syndrome includes beta-adrenergic antagonists or permanent pacing in those who are symptomatic despite adequate beta blockade [16].

# TOS

►Thoracic Outlet Syndrome

# Total Colorblindness

►Achromatopsia

# Totally Anomalous Pulmonary Venous Connection

David W. Brown, Tal Geva
Department of Cardiology, Children's Hospital, Boston, MA, USA

## Synonyms

Totally anomalous pulmonary venous return; TAPVC

## Definition and Characteristics

Totally anomalous pulmonary venous connection (TAPVC) is a cyanotic congenital cardiac defect characterized by anomalous drainage of all of the pulmonary veins to the systemic venous circulation, resulting in mixing of the pulmonary and systemic venous blood.

## Prevalence

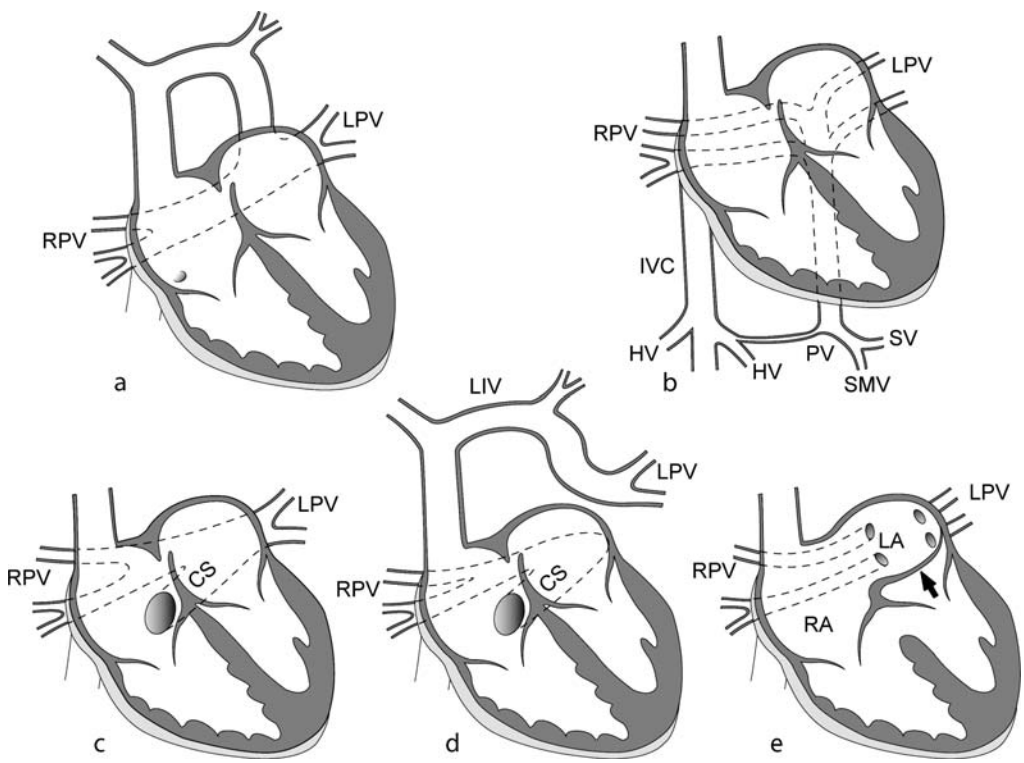
TAPVC is a rare disorder with a reported prevalence in the Baltimore-Washington Infant Study of 6.8/100,000 (~1.5% of all cardiovascular malformations observed) [1]. Male to female ratio was 0.8; non-cardiac malformations were present in 22%. Hoffman and Kaplan reported an incidence of 9.4/100,000 [2].

## Genes

Typically sporadic, isolated cases with low recurrence risk; no known genes yet identified. Known syndromic associations include cat-eye syndrome (dup 22pter–q11.2), Holt-Oram syndrome (defect at 12q24.1, TBX5 mutation), and asplenia syndrome. Numerous case reports of non-syndromic familial cases suggest heritable genetic cause, with heterogenous genetic loci reported. A large Utah-Idaho kindred with TAPVC inherited as an autosomal dominant trait with reduced penetrance was mapped by linkage analysis to 4p13–q12 [3].

## Molecular and Systemic Pathophysiology

Early in embryologic development, the pulmonary veins are in communication with the precursors of the systemic veins, as both arise from a common vascular splanchnic plexus. At 32–33 days of gestation, the pulmonary veins establish a communication with the common pulmonary



**Totally Anomalous Pulmonary Venous Connection. Figure 1** (a) Supracardiac TAPVC to the left innominate vein; (b) Infradiaphragmatic TAPVC to the portal vein; (c) TAPVC to the coronary sinus (CS); (d) Mixed-type TAPVC. In the example shown, the left pulmonary veins (LPV) connect to the left innominate vein (LIV), and the right pulmonary veins (RPV) connect with the CS; (e) Totally anomalous pulmonary venous drainage due to malposition of septum primum. The pulmonary veins connect normally to the back wall of the atria, but pulmonary venous drainage is to the right of the malattached septum primum (*arrow*).

vein, which becomes incorporated into the posterior aspect of the developing left atrium. As this communication is established, the connections of the pulmonary and systemic veins involute. TAPVC results from failure to establish a normal connection between the pulmonary venous plexus and the common pulmonary vein before the connections with the splanchnic venous system have regressed [4]. The anatomic classification of TAPVC is based on the site of connection(s) between the pulmonary and systemic veins (Fig. 1).

As oxygenated pulmonary venous blood mixes with deoxygenated systemic blood, TAPVC is a cyanotic heart lesion. Return of both systemic and pulmonary venous blood to the right side of the heart lead to enlargement of the right heart chambers. Systemic blood flow depends on an adequate inter-atrial communication (patent foramen ovale or atrial septal defect). Obstruction to pulmonary venous drainage, seen in most patients with the infradiaphragmatic type and is less common with other types, leads to pulmonary venous hypertension, pulmonary edema, pulmonary hypertension, reduced pulmonary blood flow, and progressive systemic hypoxemia. Without intervention, metabolic acidosis, organ failure, and death in the early neonatal period often ensue. Restrictive interatrial communication is uncommon but when encountered can lead to similar albeit less severe pathophysiology.

### Diagnostic Principles

Cyanosis is invariably present, but may be clinically inconspicuous. Infants born with obstructed TAPVC exhibit marked cyanosis, respiratory distress, and pulmonary hypertension, with chest x-ray findings of normal heart size but increased pulmonary vascular markings, perihilar congestion, and pulmonary edema. Infants with restrictive interatrial communication are typically asymptomatic initially, and develop congestive symptoms (tachypnea, feeding difficulties, failure to thrive) at 1–2 months of age; those with nonrestrictive interatrial communication may have mild dyspnea and failure to thrive that develops over the first 1–2 years of life. Other cardiac anomalies may be present. In cases with the asplenia syndrome, single ventricle cardiac anatomy is found in ~30% of cases [5]. Echocardiography is the primary modality for establishing the diagnosis.

### Therapeutic Principles

Corrective surgery of TAPVC should be performed as soon as possible. Newborns with obstructed TAPVC may require an emergent operation. Mortality for repair of isolated TAPVC is less than 10%, with significantly less favorable prognosis for those with complex associated cardiac malformations [5]. The major long term complication is recurrent pulmonary venous obstruction, seen in up to ~10% of patients; reoperation and/or catheter based techniques (balloon dilation, stenting) can be helpful for alleviating obstruction, but the prognosis for these patients remains poor.

## Touraine-Solente-Golé Syndrome

Claudio Guarneri, Francesco Borgia, Mario Vaccaro
Institute of Dermatology, Policlinico Universitario, Messina, Italy

### Synonyms

Hyperostosis of the entire skeleton; Pachydermoperiostosis; Primary hypertrophic osteoarthropathy; Hereditary hypertrophic osteoarthropathy

### Definition and Characteristics

A rare genodermatosis, mainly affecting both the skin and bones, characterized by digital clubbing,

subperiosteal new bone formation, polyarthritis, cutis verticis gyrata, seborrhea, hyperhydrosis.

Three clinical subtypes have been proposed: (i)"complete" form characterized by the full expression of skin and bone abnormalities, (ii)"incomplete," defined by the absence of "cutis verticis gyrata," and (iii)"fruste" form exhibiting one or more cutaneous findings but no, or minimal, osseous changes.

## Prevalence

A single study performed in a selected population report a prevalence of 0.16%; the precise incidence of the disease is still unknown. It occurs predominantly in men, with a ratio 9:1, who are usually affected more severely than women.

## Genes

The molecular basis remains unexplained and the hypothesized genetic heterogeneity awaits confirmation. Genetic transmission is commonly attributed to a dominant autosomal gene with variable expression and penetrance. An autosomal recessive mutation has also been claimed in some instances of parental consanguinity. Responsible genes may be involved in the bone morphogenetic proteins pathway, which has a major role in skin and bone development and interacts also with other growth factor families.

The X-linked inheritance has been considered, but no consistent data support this hypothesis. Previously reported associated chromosomal abnormalities have been excluded in successive studies. HLA-B12 antigen has been found in 8 of 18 patients (44%).

## Molecular and Systemic Pathophysiology

An increased proliferation rate of fibroblasts, endothelial cells, and osteoblasts, with skin and bone tissue progressive overgrowth, seems to be the underlying mechanism of this syndrome. Demonstration of abnormal plasma levels of several substances in affected subjects, including osteocalcin, endothelin-1, β-thromboglobulin, platelet-derived growth factor, von Willebrandt factor, and vascular endothelial growth factor, suggested the possible role of one of these mediators as responsible agent in disease progression. Successive evidence of high concentrations of nuclear steroid receptors, with low concentrations of epidermal growth factor (EGF) receptors, could justify an increased tissue sensitivity to circulating sex hormones, potentially inducing an enhanced tissue EGF and transforming growth factor-α production and utilization. This hypothesis theoretically supports also marked male prevalence, by testosterone promoting proliferation. The role of alcohol consumption, reported in some cases, has to be considered only as a revealing or aggravating factor.

## Diagnostic Principles

The diagnosis is mainly clinical. Disease onset is typically during adolescence, increasing in severity for 5–20 years and then remaining stable throughout life.

Frequent dermatological aspects are represented by: (i) pachydermia, varying from light to severe, more common on face and extremities, (ii) substantial thickening and furrowing of the scalp and the forehead, resulting in marked, hard-elastic symmetrical or asymmetrical convolutions resembling the cerebral gyri (cutis verticis gyrata), often involving the underlying eyelids or provoking ptosis, (iii) "watch glass" appearance of nails, (iv) sebaceous hyperplasia, wide sebaceous pores filled with plugs of sebum, oily skin and sporadic folliculitis and acneiform rashes, (v) palmo-plantar hyperhidrosis, sometimes involving the big folds.

Extracutaneous manifestations include digital clubbing, with characteristic terminal broadening of fingers and toes in a "paw-like" appearance, enlargement of hands and feet, cylindrical shape of legs and forearms and painful, swollen joints.

Radiological examination reveals swelling of periarticular tissue, irregular periosteal new bone formation with cortical thickening (periostosis) not only in long bones, but also in short and flat ones, ossification of ligaments or interosseus membranes and rare erosions of the joints.

Periodontal abnormalities, gynecomastia, sparse facial and pubic hair may be present.

Associations with myelofibrosis, gastrointestinal disease (mainly peptic ulcer and Chrohn's disease), mental retardation are reported in literature; other associations have to be considered anecdotic.

## Therapeutic Principles

Plastic surgery may be employed for functional or aesthetic reasons. Anti-inflammatory agents may improve the joint symptoms.

# Tourette Syndrome

Norbert Müller
Hospital for Psychiatry and Psychotherapy,
Ludwig-Maximilians-University, Munich, Germany

## Synonyms

Gilles-de-la-Tourette syndrome

## Definition and Characteristics

Though it is a disorder with a probable major genetic component, affected genes have not been identified up to now. Male:female ratio ~4:1. Tourette's syndrome (TS) is clinically characterized by simple and/or complex motor tics and simple or complex vocal tics, (see Table 1) which cause marked distress or significant impairment in social or other important functions [1]. There is a great variability of symptoms, which show a waxing and waning course with exacerbations in periods of emotional stress; however, periods without such obvious symptoms are also typical. The onset of TS is before the age of 18. Other symptoms than tics such as echolalia and echopraxia, palilalia, coprolalia, mutilations, and disturbed impulse control characteristically often occur, although they are not obligatory for the diagnosis of TS. An increased comorbidity of TS and obsessive-compulsive disorder, mood disorders and anxiety, as well as phobias and attention deficit/hyperactivity disorder (ADHD) has been reported [2].

## Prevalence

TS prevalence is estimated at about 4 to 5 per 10,000 [1]. Other findings suggest that especially in males the age-dependent prevalence is up to 1% of the population.

**Tourette Syndrome. Table 1** Examples for complextics

| Complex motor tics | Complex vocal tics |
|---|---|
| Touching | Imitation of sounds |
| To lie down flatly | Repetition of senseless items |
| Deep knee bends | Coprolalia |
| Pushups | Echolalia |
| Steps backwards | Palilalia |
| Certain order of steps during walking | Echokinesia |
| Turning around | |

## Molecular and Systemic Pathophysiology

TS is probably based on different pathophysiological mechanisms. The overactivity of the dopaminergic system of the basal ganglia is a key feature but cortical structures are also involved. A disinhibition within the cortical-striatal-thalamic motor loop including the limbic system has been shown. Caudate volumes in children with TS predict the severity of tics and obsessive-compulsive symptoms in early adulthood. There is compelling evidence that morphologic disturbances of the caudate nucleus within cortico-striatal-thalamo-cortical circuits are central to the persistence of both tics and obsessive-compulsive symptoms into adulthood.

Although the pathological mechanisms of TS are unclear, contribution from an inflammatory process is suggested. Increased antibody production, including anti-phospholipid and anti-neural antibodies directed against structures in the basal ganglia, has been described. Since tics manifest themselves or exacerbate during acute infections such as Lyme disease, infection with *M. pneumoniae*, acute streptococcal infection, and a common cold, and since improvement or remission of the tics is associated with antibiotic therapy, infectious agents may contribute to the pathogenesis of tics and TS [3]. In childhood TS, there is a broad overlap with PANDAS (**P**ediatric **A**utoimmune **N**europsychiatric **D**isorders **A**ssociated with **S**treptococcal infection). Increased antistreptococcal antibody titers and other features of PANDAS, however, have also been described in adult TS patients. Different types of infectious agents and different stages of infection seem to be associated with TS.

## Diagnostic Principles

The diagnosis is based on the clinical picture according to the criteria of the ICD 10 or DSM IV. Other movement disorders and the high rate of co-morbidity have to be considered.

## Therapeutic Principles

Dopamin-D2 receptor blocking agents such as haloperidol or pimozide are effective in TS, according to evidence-based medicine, but they also have a broad spectrum of side effects. All other drugs are not well tested [4]. A typical antipsychotics such as risperidone, olanzapine, and aripiprazole, a dopaminergic modulator, are reported to be effective in case-series or small studies. In many European countries, tiapride is the drug of first choice, particularly for children. Clonidine, a central α2-adrenoceptor agonist reducing noradrenergic activity in the CNS, was also reported to be effective in TS, although less pronounced as compared to antipsychotics. When an infectious agent can be

identified, antibiotics are the first treatment of choice. In PANDAS and cases of TS, immunomodulatory treatment strategies with iv immunoglobulines or plasmapheresis were observed to be effective [5]). Further experimental therapeutic approaches currently under investigation are repetitive transcranial magnetic stimulation and, in therapy resistant cases, electro-convulsive therapy and deep brain stimulation.

# Townes-Brocks Syndrome

Jürgen Kohlhase
Center for Human Genetics, Freiburg, Germany

## Synonyms

Renal-ear-anal-radial syndrome; TBS

## Definition and Characteristics

Townes-Brocks syndrome (TBS) is characterized by the triad of imperforate anus, dysplastic ears (frequently associated with sensorineural and/or conductive hearing impairment), and thumb malformations (triphalangeal thumbs, duplication of the thumb (preaxial polydactyly), and rarely hypoplasia of the thumbs). Renal impairment, including end stage renal disease (ESRD), may occur with or without structural abnormalities (mild malrotation, ectopia, horseshoe kidney, renal hypoplasia, polycystic kidneys, vesico-utereral reflux). Congenital heart disease occurs in 25%. Foot malformations (flat feet, overlapping toes) are common. Mental retardation has been reported in less than 10% of cases. Rare features include iris coloboma, Duane anomaly, Arnold–Chiari malformation type 1, growth retardation, uterine malformations, and hypospadias.

## Prevalence

Townes-Brocks syndrome (TBS) is inherited in an autosomal dominant fashion. About half of cases represent de novo mutations. TBS occurs with an estimated frequency of 1 in 200.000 births. There is no increased incidence related to paternal or maternal age, although most mutations are of paternal origin.

## Genes

TBS is caused by mutations in the gene SALL1 on chromosome 16q12.1 [1]. The SALL1 protein is a member of the SAL-like family of zinc finger transcription factors sharing similarity with the Drosophila melanogaster protein SAL (Spalt). About 66% of patients with typical TBS carry point mutations in SALL1, and 3–5% have larger deletions not detectable by sequencing [2]. Of patients with pathogenic SALL1 mutations (not including the most common mutation p.R276X, c.826C>T), 81% have anal anomalies, 87% hand anomalies, and 87% ear anomalies. Sixty-six per cent have the characteristic triad. The most common mutation c.826C>T, p.R276X, occurs in about 50% of sporadic cases and is associated with a higher rate of heart defects (50%) (Fig. 1).

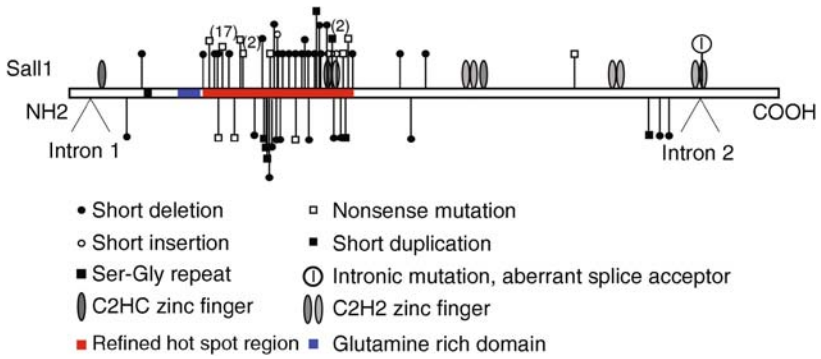
Rarely, TBS can be caused by mutations of the similar gene SALL4. However, about 30% of cases are unexplained, suggesting the existence of another, yet unidentified gene.

## Molecular and Systemic Pathophysiology

All SALL1 mutations (except for the larger deletions) detected in TBS patients to date lead to premature stop codons [3]. Transcripts carrying a premature stop codon are in most instances rapidly degraded, and therefore these mutations are a priori likely to cause TBS via SALL1 haploinsufficiency. The concept of haploinsufficiency was finally confirmed by the detection of larger heterozygous deletions including also the complete SALL1 gene in patients with TBS.

In the mouse, a complete knock-out of Sall1 does not result in defects affecting tissues other than the kidneys. Only if a typical TBS mutation is inserted in the mouse Sall1 gene a TBS-like phenotype is observed [4]. In these mutants, truncated Sall1 proteins were detected, suggesting a role of those proteins in the pathogenesis of TBS. In the zebrafish, sall1a knock-down leads to limb malformations, which can be aggravated by concomitant knock-down of sall4.

Although both point mutations and larger deletions of SALL1 can cause TBS, the phenotype associated with deletions is milder than that resulting from truncating mutations, especially from that associated with p.R276X. The current hypothesis therefore suggests that mutated SALL1 transcripts with premature stop codons escape the NMD pathway and lead to truncated proteins



**Townes-Brocks Syndrome. Figure 1** Schematic representation of the *SALL1* protein (1,324 amino acids) and localization of the mutations identified to date. Zinc fingers are indicated as ovals. (17) indicates that the c.826C>T (p.R276X) mutation has been found in 15 sporadic and two familial cases. At position c.1115, two different nonsense mutations have been detected (2), and the mutation c.1403_1404insG was found in two unrelated families (2). All other mutations have been found only once. The red horizontal bar marks the refined "hot spot region," the blue bar assigns the glutamine rich domain. Positions of the introns are indicated. (From: [3], Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.).

similar to those detected in the mice with a TBS mutation. However, truncated SALL1 proteins have not yet been observed in TBS patients.

In different functional studies, it was observed that different Csal (chicken) proteins can interact with each other via mediation of an N-terminal glutamine-rich domain conserved in all known Sal proteins, and this was also seen with Sall proteins in the mouse. Expression of truncated Sall1/csal1 proteins is detected throughout the cell and not confined to the nucleus as full-length Sall1. Truncated Sall1 can interact with full-length Sall proteins and cause their displacement from the nucleus [5].

SALL1 mutations in the 5′ region of exon 2 would lead to truncated proteins with strong repressor activity but without the central repression and heterochromatin localization domain. These proteins will probably not localize to the physiological site of action, but bind other SAL proteins and move them from the nucleus to the cytoplasm. Mutations located more 3′ in the SALL1 gene are likely resulting in milder phenotypes than the 5′ mutations. Truncated proteins made from such alleles could include both repression domains and the heterochromatin localization domain, and therefore these proteins could still localize to their place of action and have some residual function, resulting in a milder phenotype.

The correct dosage of functional SALL1 protein at the heterochromatic foci seems the critical point in the pathogenesis. Heterozygous deletions result in a 50% reduction of this dosage. Most 5′ truncating mutations could lead to truncated proteins, which do not reach their site of action and in addition probably even remove some full length protein of the normal allele from the nucleus. Therefore, the typically more severe phenotype associated with 5′ truncating mutations might result from a reduction of the functional protein at the site of action by more than 50%.

The additive phenotype of the combined sall4 and sall1a knock-down in zebrafish and the additive phenotype of Sall1 and Sall4 knock-out in mice suggest that both genes have partly overlapping functions and are able to compensate to some extent for each other. In view of the additive effects of sall1a and sall4 knock-down or Sall1 and Sall4 knock-out it seems likely that the TBS phenotype in humans is not only caused by loss of SALL1 function. At least some of the observed malformations may either be aggravated or even caused by an effect of the hypothetical truncated SALL1 proteins on the function of other SALL proteins.

As the interaction between truncated SALL1 and functional SALL1 or other SALL proteins and the relocalization of the functional proteins requires the presence of the evolutionary conserved glutamine-rich region in the aminoterminal part of the truncated protein, the effect of the TBS-causing SALL1 mutations c.419delC and c.313delA, which would result in truncated proteins lacking the interaction domain, still needs to be explained, since the phenotypes associated with these mutations did not appear milder than that resulting from other mutations.

Interestingly, 47 out of 57 (82.5%) smaller mutations cluster within the 802 bp-large refined "hot spot region" between the coding sequence for the glutamine-rich domain and around the coding sequence for the first double zinc finger, whereas only two mutations were found within the remaining 763 bp upstream in the coding region and only six within the 2.4 kb coding region to the 3′ end. Therefore, the existence of

truncated proteins in cells of TBS patients would not be surprising. If it holds true that SALL1 point mutations lead to truncated SALL1 proteins with dominant-negative action, one could expect that all truncated proteins have at least slightly different characteristics. This might explain the considerable phenotypic variability observed in TBS.

### Diagnostic Principles

Townes-Brocks syndrome is diagnosed clinically based on the presence of imperforate anus, dysplastic ears (overfolded superior helices, microtia) and typical thumb malformations (preaxial polydactyly, triphalangeal thumbs, hypoplastic thumbs) without shortening of the radius. Since only 67% of mutation carriers have the characteristic triad, diagnosis can sometimes by challenging. In persons who show only two typical malformations, presence of additional anomalies commonly seen in TBS (for example renal malformations, hearing loss or heart defects) can lead to the diagnosis. The diagnosis is confirmed by detection of a SALL1 mutation by direct sequencing or deletion testing, but failure to detect a mutation does not rule out the clinical diagnosis, since a considerable fraction of typical patients do not have a SALL1 mutation. The differential diagnosis should consider Goldenhar syndrome, Branchio-Oto-Renal syndrome, Okihiro syndrome or VACTERL association.

### Therapeutic Principles

At present, there is no specific gene therapy available for TBS. Therapeutic strategies focus on surgical correction of the observed malformations of thumbs, anus and heart. If the diagnosis is suspected, early evaluations of the heart, the kidneys and renal function, and hearing tests are required. Renal function impairment requires continuous monitoring, hemodialysis and possibly kidney transplantation. Patients with significant hearing impairment should receive early treatment, mostly with hearing aids. Renal function should be regularly monitored in all individuals with and without renal anomalies, even if no impairment of renal function is detected on initial examination.

# Toxic Hepatitis, Acute

Andreas Erhardt
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany

## Definition and Characteristics

Acute toxic hepatitis relates to the acute dysfunction or destruction of liver cells due to dose-dependent (intrinsic) toxicity, immunoallergic (idiosyncratic) or autoimmune-mediated toxicity of drugs, natural toxicants, or industrial chemicals [1].

Intrinsic liver necrosis is characterized by dose dependency, reproducibility in animals, or other persons exposed to a certain dose and uniform latency period. Typical representatives are, e.g., paracetamol, isoniazid, chemotherapeutic agents like methotrexate, cocaine, carbon tetrachloride ($CCl_4$), or α-amanitin (mushroom poisoning). In idiosyncratic toxicity dose dependency is not apparent, latency period is variable, and incidence rate is low among exposed persons. Immunoallergic toxicity may be accompanied by hypersensitivity reactions such as fever, chills, exanthema, eosinophilia, immunoallergic thrombopenia. Prototypes are halothane, chlorpromazine, nitrofurantoine, macrolides, NSAID, efavirenz, troglitazone [2].

## Prevalence

It is estimated that drug-induced hepatotoxicity accounts for up to 50% of acute and fulminant hepatitis cases in Western countries [3]. Crude incidence rates of 14 per 100,000 inhabitants per year have been reported.

## Genes

Pharmacogenetics of the cytochrome P-450 (CYP) enzymes plays a key role in acute liver toxicity. Genetic polymorphisms leading to deficiency in CYP2D6 or CYP2C19 (perhexiline), induction of CYP2E1 (paracetamol), deficiency in the *N*-acetyltransferase (sulfonamides, dihydralazine), glutathione synthetase (paracetamol), or glutathione S-transferase have been identified [4]. An association between several HLA haplotypes and drug toxicity has been observed for tricyclic antidepressants, amoxicillin-clavulanate, or clometacine. Interleukin-10 promoter and TNF-α polymorphisms are implicated in diclofenac and paracetamol toxicity. Polymorphisms of bile canalicular transporters of the ATP-binding cassette (ABC) superfamily (e.g., the multidrug resistance protein) are important candidates for toxic susceptibility.

## Molecular and Systemic Pathophysiology

A number of factors increase the risk for drug-induced hepatotoxicity among those age above 60 years, female gender, obesity, pregnancy, chronic alcohol abuse through induction of CYP2E1, drug interactions (rifampicin, phenobarbital), or extrahepatic diseases (e.g., HIV). The primary mechanisms of liver toxicity include lipid peroxidation (e.g., $CCl_4$), formation of reactive oxygen species, e.g., by glutathione depletion (paracetamol), inhibition of protein synthesis (amanitin), direct mitochondrial toxicity (amiodarone, valproic acid, fialuridine), interference with bile secretion (chlorpromazine), haem synthesis (hexachlorbenzene, dioxine), or sinusoidal cell injury (cyclophosphamide) [5].

## Diagnostic Principles

Assessment of drug history and exclusion of other liver diseases is important. Onset of liver injury usually occurs between 1 week and 3 months after administration of the toxic agent in idiosyncratic reaction, earlier in case of reexposure, or intrinsic toxicity. Differentiation of acute hepatocellular hepatitis (ALT to AP ratio of ≥5) from acute cholestatic hepatitis (ALT to AP ratio ≤2) has prognostic implications. Detection of specific serum antibodies (anti M6, anti LKM2, anti CYPIA2, anti CYP2E1) and determination of serum levels of paracetamol can be helpful. Liver biopsy is optional.

## Therapeutic Principles

Withdrawal of the toxicant is the major therapeutic and an important diagnostic measure. In most cases there is no specific treatment for acute toxic liver injury. In paracetamol overdose initiation of *N*-acetylcysteine administration within the first 24 h at a dose of 150 mg/kg within 15 min, 50 mg/kg over 4 h, 100 mg/kg over 16 h has a protective effect. Liver transplantation has to be considered for fulminant cases.

### Synonyms

Tracheobronchopathia osteochondroplastica; Tracheopathia chondroosteoplastica; Tracheobronchopathia osteoplastica

### Definition and Characteristics

Tracheopathia osteoplastica (TO) is a rare benign cartilaginous and osseous metaplasia of the laryngotracheobronchial tree commonly diagnosed in adults over 50 years of age [1].

### Prevalence

The prevalence is unknown. The disease has been found in 3/1,000 autopsies and 1/3,720 bronchoscopies. In more than 90% of cases, TO had been postmortem findings [1]. It equally affects both genders.

### Molecular and Systemic Pathophysiology

The pathogenesis is unknown. TO is occasionally associated with chronic inflammation or with trauma. Until now, there is no demonstration of the theories of ecchondrosis and exostosis arising from the cartilaginous tracheal rings, or metaplasia of the submucosal elastic and connective tissue. The bone morphogenetic protein-2 has been suggested to play an important role in nodule formation [2]. Histologically, there may be inflammatory cells in the submucosa [1] with metaplastic cartilage and bone often in continuity with the inner surface of the tracheal cartilage [3]. The overlying mucosa is intact and may appear to be normal, hyperplastic [1], or metaplastic [3]. Multiple nodules of varying size are invading principally the anterior and the lateral wall of the trachea and the main stem bronchi [1], sparing the posterior wall, where the cartilage is deficient. The development of the nodules could induce impairment of ciliary clearance [4], sometimes resulting in recurrent lower respiratory tract infection. Progressive narrowing of the upper respiratory tract could occur, rarely leading to significant airway compromise [1,3,5]. No malignant degeneration has been described.

### Diagnostic Principles

In most cases, the pathology remains asymptomatic. However, for some patients, dyspnoea, cough, expectoration, hoarseness, and pulmonary infection point to the diagnosis. Rapidly progressing tracheal stenosis, unexpected difficult endotracheal intubation, and bleeding [1] are further rare complications. Computed tomography may show thickening of the wall with multiple submucosal calcified protrusions inside the major airway, arising from the anterior and lateral walls. The bronchoscopy with biopsy confirms the diagnosis [1,5].

### Therapeutic Principles

Currently, no etiopathogenic treatment is available. Simple follow-up is advised in mild localized disease and in asymptomatic patients. Depending on the symptoms and the magnitude of the airway involvement and narrowing, conservative treatment, bronchoscopic dilation, laser therapy, tracheal stenting [5], or surgical correction may be applied.

## TRALI

►Transfusion Reactions

## Transfusion Associated Circulatory Overload

►Transfusion Reactions

## Transfusion Reactions

Karina Yazdanbakhsh, Millicent Sutton
Laboratory of Complement Biology, New York Blood Center, New York, NY, USA

### Synonyms

Acute hemolytic transfusion reactions; Delayed transfusion reactions; Febrile non-hemolytic transfusion reactions; Transfusion associated circulatory overload; TACO; Transfusion related acute lung injury; TRALI

### Definition and Characteristics

A transfusion reaction is an adverse event which occurs during or after the transfusion of a blood product [1,2]. In hemolytic transfusion reactions (HTRs), transfused donor red blood cells (RBCs) are destroyed by the host's immune system and they can be acute (immediate) or delayed, and severe or mild. In severe acute hemolytic transfusion reactions (AHTRs), RBCs are destroyed intravascularly as seen with ABO-incompatible transfusion reactions and disseminated intravascular coagulation (DIC) and renal failure can also occur. In delayed transfusion reactions (DHTRs), RBCs are destroyed extravascularly, rarely causing hemoglobinemia and hemoglobinuria. Febrile non-hemolytic transfusion reactions (FNHTRs) are caused by antibodies in the transfusion recipient to white cells present in the donor blood or component. Transfusion associated circulatory overload (TACO) results from a rapid or massive transfusion of blood. Transfusion related acute lung injury (TRALI) is characterized by acute respiratory distress resulting from transfusion of blood components. Another possible type of transfusion reaction is an allergic reaction to the transfused plasma products.

### Prevalence

AHTRs and DHTRs occur as frequently as one per 1,500 units transfused. The mortality rate is estimated at one per 100,000 units transfused which is mostly due to transfusion of ABO incompatible blood, the major cause of which is due to clerical errors in issuing the wrong unit [3]. TRALI is the most common cause of fatal transfusion reactions with a mortality rate of one in 5,000 transfusions.

### Genes

No genes are known to affect transfusion reactions.

### Molecular and Systemic Pathophysiology

Factors influencing the severity of a HTR include: the class and the subclass of the antibody causing the reaction, the specifically, titer and avidity and its ability

to activate the complement system; the number and density of the target RBC antigen that the antibody reacts with and the amount of incompatible red cells transfused [4]. If complement activation goes to completion, direct cell lysis can occur as seen in intravascular hemolysis, releasing complement split products C3a, responsible for the hypotension and tachycardia and C5a which can induce the activation of granulocytes and neutrophils. Intravascular hemolysis with excessive production of plasma free hemoglobin production competes with nitric oxide, a potent vasodilator resulting in renal ischemia and renal failure. In DHTR, RBCs are sensitized by antibodies and possibly complement factor C3 and are subsequently removed by macrophages in spleen and liver by phagocytosis. Release of endogenous pyrogens induced by antibodies to donor leukocytes or platelets occur in non hemolytic reactions, while immune mediated proinflammatory cytokine responses produced by activated macrophages are responsible for fevers associated with HTRs. Passive transfer of donor antibodies directed against recipient human leukocyte (HLA) antigens has been implicated in TRALI.

### Diagnostic Principles

Laboratory tests to determine presence of hemolysis include: reticulocyte count, serum haptoglobin, LDH and bilirubin levels and examination of the peripheral smear. A direct antiglobulin test, DAT, should be performed to detect donor RBC sensitization. A newly positive DAT in the absence of hemoglobinemia and hemoglobinuria is consistent with DHTRs occurring typically 10–14 days after a transfusion. Elution off the RBCs can elucidate the identification and specificity of the antibodies. Acute intravascular hemolysis is generally evident within minutes. Fever involving increase in body temperature of $>1^{o}C$ with chills are the most common features of AHTR and DHTR. Allergic reactions to plasma products are usually mild but can be severe manifesting as hives, wheezing, hypotension or shock. Shortness of breath, dyspnea, pulmonary edema and increased systolic blood pressure are symptoms of TACO which can result in deterioration of cardiovascular status in some recipients who are already compromised. TRALI is defined as acute onset pulmonary edema, in the absence of cardiogenic components, occurring within 1–6 h of transfusion and in many cases symptoms resolves within 24–48 h. Testing of the donor for HLA or granulocyte antibodies and demonstration of the specificity against recipient antigen may be helpful in the diagnosis.

### Therapeutic Principles

Careful monitoring of the recipient's renal and coagulation status and rigorous diuresis to maintain adequate urinary output is the mainstay of therapy of intravascular hemolysis. DIC and shock should be treated if present. FNHTRs are typically mild and are managed with antipyretics administered prior to transfusion and can be prevented with the use of leuko-reduced products. Antihistamines are administered for mild non-systemic allergic reactions to plasma proteins however corticosteroids may be required for more severe reactions. If bacterial contamination is suspected, the recipient should be cultured and prompt administration of broad spectrum antibiotic should be initiated. All components from that donor should be cultured and quarantined to prevent the possibility of subsequent recipients being affected. Management of TACO is supportive. Symptoms generally resolve when the transfusion is stopped. Phlebotomy is rarely used however diuretics may be warranted in particular situations. There is no specific therapy for TRALI. Care is supportive and diuresis may not be beneficial.

# Transplant Arteriosclerosis

Jan-Luuk Hillebrands[1], Roel de Weger[2], Jan Rozing[1]
[1]Department of Cell Biology, Immunology Section, University Medical Center Groningen, Groningen, The Netherlands
[2]Department of Pathology, Molecular and Immuno-Pathology, University Medical Center Utrecht, Utrecht, The Netherlands

## Synonyms

Cardiac allograft vasculopathy; Chronic cardiac rejection; Graft coronary artery disease; Transplant coronary artery disease

## Definition and Characteristics

Transplant arteriosclerosis (TA) in cardiac allografts is a concentric proliferation of the intima. It involves infiltration and proliferation of smooth muscle cells (SMC) and fibroblast proliferation forming a neointima composed of two layers: a luminal layer composed of fibroblasts and infiltrating mononuclear cells, and a SMC layer adjacent to the media. This vascular remodeling process results in the formation of an occlusive neointima in the coronary arteries (Fig. 1) [1].

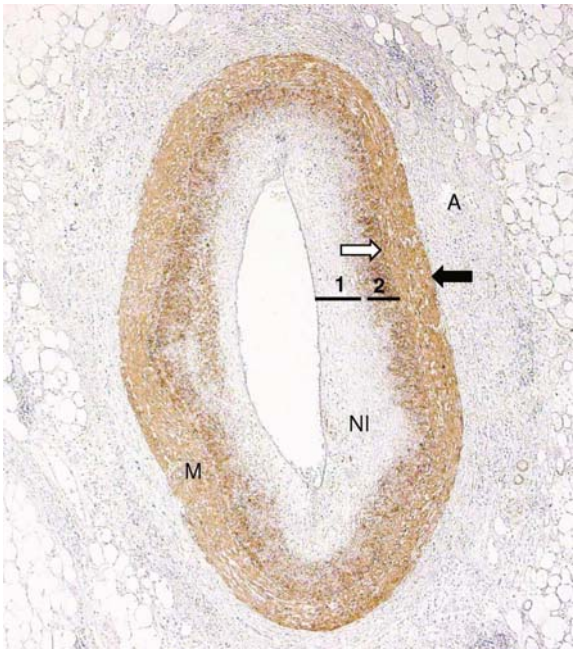
In contrast to conventional atherosclerosis with its lipid core and focal distribution in major coronary arteries, TA is a diffuse process affecting the entire vascular tree including the intramyocardial vessels [2]. Although TA is most frequently observed in cardiac allografts and associated with functional deterioration, TA can also be observed in renal allografts with Chronic Allograft Nephropathy.

## Prevalence

Development of TA after cardiac transplantation is the second leading cause of death >1 year after engraftment, second only to malignancy. In the registry of the International Society for Heart and Lung Transplantation (ISHLT), TA is reported in 7%, 32% and 46% after respectively 1, 5 and 8 years after cardiac transplantation [3].

## Genes

No genetic defects have been associated with the development of TA after cardiac transplantation. However, polymorphisms in genes (or promotor regions) encoding cytokines (especially transforming growth factor-β), mediators of the renin-angiotensin system or growth factors have been associated with increased risk to develop TA.



**Transplant Arteriosclerosis. Figure 1** Overview of a coronary artery with transplant arteriosclerosis (72 months after transplantation) after staining for α-smooth muscle actin. The filled arrow indicate the elastica externa (transition adventitia/media) and the open arrow indicate the elastica interna (transition media/neointima). The neointima is composed of two layers: (1) a luminal layer composed of α-smooth muscle actin negative fibroblasts and infiltrating mononuclear cells, and (2) an α-smooth muscle actin positive SMC layer adjacent to the media (Abbreviations: *A* adventitia; *M* media; *NI* neointima).

## Molecular and Systemic Pathophysiology

The development of TA is a complex process in which both immunologic events (alloreactive T cells and alloantibody formation) and non-immunologic factors (e.g. donor age, ischemia/reperfusion injury, hyperlipidemia and infections) are involved. Especially events during the first year after transplantation appear to be important in the development of TA. The response-to-injury paradigm has been accepted widely for the development of TA [4], holding that graft endothelial cells become damaged by immunologic and non-immunologic events. Consequently, a remodeling process is initiated which is coordinated by cytokines (e.g. interleukin (IL)-2, IL-1β, IL-6, tumor necrosis factor-α, interferon-γ), chemokines [1] and growth factors (e.g. platelet-derived growth factor, fibroblast growth factor and transforming growth factor-β) produced by endothelial cells, parenchymal cells and infiltrating leukocytes. From an immunological point of view T-helper 1 cells (by producing interferon-γ) are

considered to be the most important effector cells which may activate macrophages that start to produce transforming growth factor-β [1]. Eventually, this cascade results in fibroblast proliferation and extracellular matrix (ECM) formation, next to medial SMC migration and proliferation during which they change their phenotype from "contractile" to "synthetic". According to this concept the SMC in TA originate from the graft vascular wall and are therefore donor-derived. However, data from predominantly experimental animal studies indicate that also host-derived mesenchymal cells can participate in the process leading to TA development [4]. Host-derived mesenchymal cells may be recruited from a host stem cell niche upon exposure to pro-inflammatory and pro-fibrotic mediators that are released after damage of the intragraft vascular tree.

### Diagnostic Principles

Cardiac transplant recipients with TA do not often present with classical symptoms of angina but rather tend to present with heart failure. Routinely performed coronary angiography (i.e. lumenogram) is the standard diagnostic tool for detection of TA. In addition to coronary angiography, intravascular ultrasound (IVUS) is being used to diagnose TA. IVUS has the advantage of visualizing the entire arterial wall and is more sensitive and specific than coronary angiography, but lacks the ability to assess the entire coronary tree.

### Therapeutic Principles

Modification of the traditional risk factors for cardiovascular disease (diabetes, hypertension, dyslipidemia and smoking) is key in prevention of endothelial dysfunction and may thereby attenuate the development of TA. Since TA development is related to inflammation (rejection), also immunosuppression is likely to attenuate TA. However, calcineurin inhibitors (cyclosporine and tacrolimus), the mainstay of current immunosuppressive therapy, have never been shown to reduce TA after clinical heart transplantation. Also steroids and purine synthesis inhibitors (mycophenolate mofetil and azathioprine), the other two members of the triple-drug therapy, have not been clinically proven to reduce the incidence of TA [5]. So far, only the mTOR (mammalian target of rapamycin) inhibitors sirolimus and everolimus (mainly inhibitors of ECM formation) have been shown to slow down the development of TA in clinical heart transplants [2]. Established TA can be treated by coronary stenting, coronary angioplasty and coronary bypass surgery although these treatments offer only symptom relief and palliative care. To date, the only definitive therapy for TA after cardiac transplantation is retransplantation after which survival rates are generally inferior to that after primary transplantation [5].

## Transplant Coronary Artery Disease

►Transplant Arteriosclerosis

## Transposition of the Great Arteries

Linda Leatherbury[1], Cecilia Lo[2]
[1]Children's National Medical Center, CGMR, Washington, DC, USA
[2]Laboratory of Developmental Biology, National Heart Lung Blood Institute, National Institutes of Health, Bethesda, MD, USA

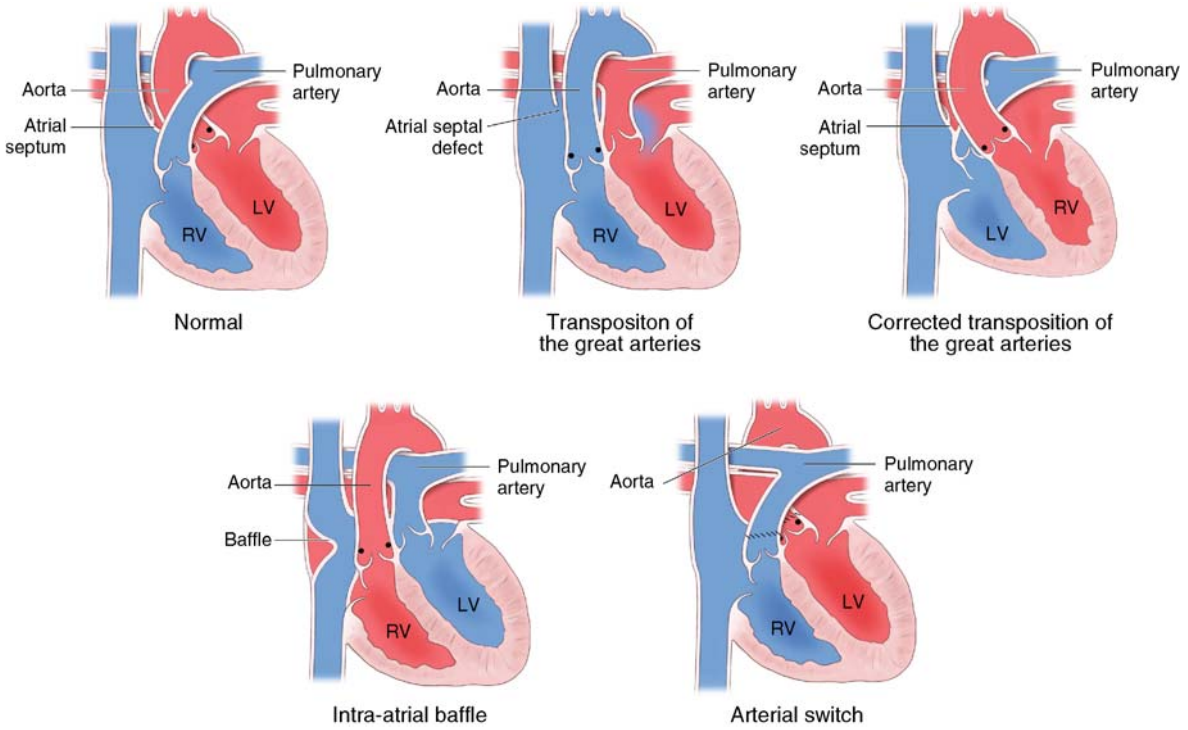
### Synonyms

Transposition of great arteries; TGA; d-TGA; {S,D,D} congenital heart defect; Ventriculo-arterial discordance

### Definition and Characteristic

Transposition of the great arteries (TGA) is a congenital malformation of the cardiovascular system involving the abnormal positioning of the great arteries (Fig. 1).

TGA in the "simple" form corresponds to when the aorta arises entirely from the right ventricle and the pulmonary artery from the left ventricle, with the venous return from the body recirculating via the right-sided ventricle to the aorta and then to the body, and the venous return from the lungs recirculates via the left-sided ventricle to the pulmonary artery and then to the lungs (Fig. 1). These two circuits, systemic and pulmonary, are therefore connected in parallel and not in series. As a result the systemic blood to the body is severely deoxygenated, causing severe cyanosis. This congenital cardiovascular malformation also may



**Transposition of the Great Arteries. Figure 1** Transposition of the great arteries.

present in "complex" forms that are associated with laterality (situs) and ventricular chamber abnormalities. There are other complex forms of transposition with associated malformations comprising of septal defects, hypoplasia of the ventricles, systemic or pulmonary artery obstructions, or abnormal venous connections. Different terminologies have been adopted for categorizing transposition, with the focus on defining and categorizing simple vs. complex transpositions. Many cardiologists and pathologists in the U.S. refer to simple TGA as D-TGA, meaning the aorta is to the right and anterior of the pulmonary artery. Van Praagh has refined this terminology with a segmental approach for categorizing the different anatomic types of TGA [1]. It is based on three distinct criteria: (i) whether body/atrial situs is solitus or inverted (S or I), (ii) whether the ventricles are L or D looped (L or D), and (iii) whether the transposition is to the right or left (D or L). For example, a complex TGA with inverted ventricles, referred to by some as corrected transposition, would be named {S,L,L} in the Van Praagh segmental terminology (Situs *S*olitus, *L*-Looped Ventricle, and *L*eft Sided Transposition). The L-looped or inverted ventricle has switched placement of the anatomical right vs. left ventricles such that the morphological right ventricle is found on the left side of the body, while the morphological left ventricle is found on the right. This complex transposition has the systemic venous blood return to the right atrium, then through the right-sided morphologic left ventricle and into a posterior-right sided pulmonary artery. The oxygenated blood from the lungs goes through the left-sided morphological right ventricle and into the left sided-anteriorly positioned aorta and back into the body. This defect is called a corrected transposition, because a person with this defect is not cyanotic (Fig. 1). In contrast to the Van Praagh system, the European terminology focuses on the connections being normal or concordant versus abnormal or discordant between the atria, ventricles and great arteries. In this terminology, "simple" TGA is referred to as a malformation with concordant connections between the atria and ventricles and discordant connections between the ventricles and great arteries [1].

## Prevalence

The prevalence of D-TGA is 2–3 per 10,000 live births and accounts for 5–7% of all congenital heart malformations. There is male predominance (2–3:1) and interestingly, D-TGA is not associated with other syndromes, nor does it tend to cluster in families, whereas the complex forms are the opposite. However, some examples of precurrence of TGA in affected families suggest TGA could have a monogenic or oligogenic origin in some families [2].

## Genes

Recent studies have identified mutations in PROSIT 240 or CFC1 in patients with transposition of the great arteries

[3,4]. As CFC1 mutations are also found in patients with heterotaxy syndrome, this would suggest TGA without other laterality defects could share a common genetic etiology with heterotaxy syndrome. Other genes potentially playing a role in TGA include perlecan, pitx2, sox4 or activin receptor IIB, as studies of knockout mouse models have shown deficiencies in these genes can cause cardiac malformations that include TGA. In addition, an ENU induced mouse mutation was recently recovered that causes TGA without any abdominal situs anomalies. Together these findings suggest multiple genes and genetic pathways may contribute to TGA with or without situs anomalies.

## Molecular and Systemic Pathophysiology

Several gene defects may underly TGA (see above). Beyond that retinoic acid has been shown to exert teratogenic effects that include TGA and other cardiac malformations. This suggests possible environmental contribution that may include other chemicals or pesticides, which together with the genetic make up of the individual, may ultimately determine each person's susceptibility to transposition of the great arteries or other congenital cardiac malformations.

TGA is a severe cyanotic heart defect that has deoxygenated systemic venous blood returning from the body being pumped back out to the body, while the oxygenated pulmonary venous return is pumped back to the lungs without circulating to the body. Thus the systemic and pulmonary circulation are in parallel and do not mix. To sustain life, the two circulatory pathways need to be connected in series to allow oxygenated blood from the pulmonary circulation to flow to the rest of the body via the systemic circulation. Patients with TGA will require medical intervention soon after birth for survival.

## Diagnostic Principles

Diagnoses of TGA are made by perinatal echocardiography. Cardiac catheterization is performed for diagnosis in complex cases and selectively for an interventional atrial septostomy to improve mixing of blood through creation of a large atrial communication. The hallmark pathophysiology of D-TGA arises from the systemic and pulmonary circulations being arranged in parallel rather than in series. Hence, postnatal survival is dependent on communication at the atrial, ventricular, or arterial levels to allow oxygenated blood to reach the body.

## Therapeutic Principles

Newborns can be sustained with administration of prostaglandin E1 to maintain patency of the ductus arteriosus (PDA), a prenatal vessel that connects the great arteries and is normally closed when pulmonary circulation is established after birth. The mixing or shunting of oxygenated/deoxygenated blood between the systemic/pulmonary circulation via a patent ductus allows time until further neonatal therapy or corrective surgeries may be performed. Historically atrial switching surgical operations were performed for D-TGA [1] (Fig. 1). However, life threatening arrhythmias occurring years after the operation have led to their replacement by the Jatene arterial switch procedure [1] (Fig. 1). Atrial switch operations, as well as other complicated surgical procedures, are usually reserved for complex transpositions.

# Treacher Collins Syndrome

Jutta Engel
Institute of Physiology Department II and Tuebingen Hearing Research Centre, University Tuebingen, Germany

## Synonyms

Autosomal dominant mandibulofacial dysostosis

## Definition and Characteristics

Disorder of craniofacial development including conductive hearing loss and cleft palate.

## Prevalence

1: 50,000 live births.

## Genes

TCOF1 coding for treacle, localized on chromosome 5q32-q33.1 [1,2].

## Molecular and Systemic Pathophysiology

TCOF1 encodes a protein of 1,411 amino acids (treacle) localized in the nucleolus [3] with a structure similar to nucleolar trafficking proteins suggesting that it plays a role in nucleolar-cytoplasmic transport. A mouse model exists demonstrating that treacle is a novel spatiotemporal regulator of ribosome biogenesis required for neural crest cell generation and proliferation [4]. Mutation analysis of the gene has resulted in identification of over 70 mutations, the vast majority of which introduce a premature stop codon [5]. Treacher Collins syndrome therefore seems to result from haploinsufficiency of the protein. Only 40% of the cases have a previous family history, whereas 60% appear to arise as a result of a de-novo mutation.

## Diagnostic Principles

Abnormalities of the external ear, atresia of the external ear canals, malformation of the middle ear ossicles, often resulting in conductive hearing loss; lateral downward sloping of palpebral fissures, frequently with coloboma of the lower eyelids and paucity of lid lashes medial to the defect; hypoplasia of the mandible and zygomatic complex, cleft palate. Clinical features are bilaterally symmetric. There is large variation in the penetrance of the gene; some individuals are affected so mildly that it is difficult to reach a clinical diagnosis.

## Therapeutic Principles

Neither gene therapy, pharmacological therapy nor dietary therapy are available.

Other treatments include cleft palate repair, reconstructive surgery of the external ear canal and the middle ear or bone-anchored hearing aid.

►Hearing Impairment, Syndromal

# Tremor, Essential

Elan D. Louis
Academic Affairs and Faculty Development, College of Physicians and Surgeons and Mailman School of Public Health, Columbia University, New York, NY, USA

## Synonyms

Benign essential tremor; Familial tremor; Senile tremor

## Definition and Characteristics

A progressive neurological disease characterized by a 4–12 Hz kinetic tremor of the arms [1]. A head tremor is also present in approximately 35–50% of patients. The tremor severity can range from mild and subclinical to severe and disabling. Patients also may have signs of widespread cerebellar involvement (e.g. intention tremor and ataxia), abnormalities referable to basal ganglia involvement (e.g. rest tremor and subclinical signs of bradykinesia), olfactory dysfunction and cognitive deficits (ranging from mild executive dysfunction to dementia).

## Prevalence

The prevalence, which ranges from 1 to 6% in the general population, increases with age [2].

## Genes

Specific genes for essential tremor (ET) have not yet been identified. Given the high prevalence of this disorder, the expectation is that multiple genetic loci will contribute to the etiology of this disease on a population level. In fact, linkage has been reported in different families to three different chromosomes (3q13, 2p22 and 6p23) [3] suggesting that ET is genetically heterogeneous. Families have been reported with a familial form of the disease in whom there is no linkage to these chromosomes.

## Molecular and Systemic Pathophysiology

Both genetic and environmental (toxic) factors probably contribute to the disease etiology on a population level [3,4]. First-degree relatives of ET cases are nearly five times more likely to have ET than are first-degree relatives of control subjects [3]. The cause of sporadic disease is unclear, although several toxins, including beta-carboline alkaloids (harmane, harmine) and lead have been implicated [4]. The pathophysiology of this disease is poorly understood, although it is clinically progressive, with an increase in tremor amplitude over time, a spread of tremor over time to involve body regions besides the hands (e.g. head tremor) and the development of signs of basal ganglia involvement in

severe cases with longstanding disease. This suggests that the disease is neurodegenerative. Electrophysiological studies suggest that the tremor is generated in the central rather than peripheral nervous system. Pathological data are few, but in recent studies, two patterns are emerging, suggesting that ET may represent a family of diseases rather than a single disorder. One subgroup of patients has cerebellar degenerative changes, including cell loss and torpedo formation. The other subgroup has a distinctive pattern of Lewy body deposition, with primary involvement of the locus ceruleus rather than other pigmented brainstem nuclei [5]. Either type of lesion could result in diminished cerebellar inhibitory gamma amino butyric acid (GABA)-ergic output. Indeed, ethanol, which binds to the GABA(A) receptor, temporarily reduces the amplitude of tremor.

### Diagnostic Principles

The presence of a progressive, bilateral kinetic tremor of the arms is diagnostic. Head tremor may also be present in 35–50% of cases, particularly in women. ET must be distinguished from enhanced physiological tremor. Quantitative computerized tremor analysis using accelerometry may be used for this purpose; when inertial weights are placed over the dorsum of the hands while maintaining the arms extended, the predominant tremor frequency should be invariant, consistent with a tremor generated in the central nervous system rather than enhanced physiological tremor, which is generated in the peripheral nervous system. The absence of sustained muscle contractions distinguishes ET from the dystonias and the absence of rigidity or bradykinesia distinguishes it from Parkinson's disease.

### Therapeutic Principles

The two front-line medications are primidone, which may act by enhancing GABA-ergic neurotransmission in the central nervous system and propranolol, which blocks beta receptors in the peripheral nervous system, thereby peripherally modulating the amplitude of this centrally-generated tremor [1]. These medications reduce the severity of the tremor but do not modulate disease progression. In severe cases, deep brain stimulation, with implantation of an electrode in the Vim nucleus of the thalamus, is effective in reducing tremor amplitude as well. The mechanism of action may be the disruption of abnormal cerebellar outflow into the thalamus or modulation of cerebellar-thalamic outflow to the motor cortex.

## Trichopoliodystrophy

►Menkes Disease

## Trichorhinophalangeal Syndrome

Fabrizio Guarneri, Mario Vaccaro
Institute of Dermatology, Policlinico Universitario, Messina, Italy

### Synonyms

Trichorhinophalangeal syndrome type I (no synonyms); Trichorhinophalangeal syndrome type II; Langer-Giedion syndrome; Trichorhinophalangeal syndrome type III; Sugio-Kajii syndrome; TRPS

### Definition and Characteristics

Trichorhinophalangeal syndrome (TRPS) is the collective name of three rare congenital conditions characterized by craniofacial and skeletal abnormalities: TRPS type I (MIM #190350), II (MIM #150230) and III (MIM #190351). All TRPS types share some clinical and radiological features: sparse and slowly growing scalp hair, laterally sparse eyebrows, bulbous tip of the nose, protruding ears, long and flat philtrum, thin upper vermilion border, cone-shaped epiphyses and hip malformations (coxa plana, coxa magna, coxa vara).

Short stature is usual in TRPS type I. Winged scapulae, multiple cartilaginous exostoses, redundant skin, and mental retardation are distinctive characteristics of TRPS type II, while severe brachydactyly, due to short metacarpals, and severe short stature are typical of TRPS type III.

### Prevalence

Trichorhinophalangeal syndrome is a rare condition.

### Genes

TRPS type I and III are inherited as autosomal dominant, TRPS type II is mainly sporadic.

TRPS type I and III are caused by mutations of the TRPS1 gene. The TRPS1 gene is positioned at locus 8q24.12, and contains seven exons. Trichorhinophalangeal syndrome type III is correlated with a specific class of mutations occurring in exon 6 and causing severe malfunctions of the protein encoded by the TRPS1 gene, while other mutations (documented, to date, in exons 4, 5 and 7) cause haploinsufficiency, which is the basis of trichorhinophalangeal syndrome type I. The degree of alteration of protein functions matches the severity of the above forms of trichorhinophalangeal syndrome: indeed, TRPS type III is clinically similar to TRPS type I, but particularly severe.

TRPS type II is a contiguous gene syndrome, due to deletion of the segment 8q24.11–8q24.13 and, consequently, to loss of functional copies of at least two genes which are located in that segment, namely TRPS1 and EXT1.

The EXT1 gene contains 11 exons. Mutations of this gene have been shown as the cause of the genetic disorder known as "multiple hereditary exostoses". Interestingly, the multiple exostoses found in TRPS type II are indistinguishable, in radiographic features and natural history, from those of multiple hereditary exostoses.

## Molecular and Systemic Pathophysiology

TRPS1 gene encodes a zinc finger transcription factor of 1,281 amino acids, which contains a nuclear localization signal (the RRRTRKR motif, amino acids 946–952) and an unusual combination of different zinc finger motifs, including IKAROS-like and GATA-binding sequences. Two regions of the TRPS1 protein (region A, amino acids 635–723, and region B, amino acids 1182–1281) can interact with the dynein light chain protein DNCL1. Region A spans three potential C2H2 zinc finger structures, while region B covers the 100 most C-terminal amino acids of the protein, containing the IKAROS-like motif. Interaction with DNCL1 lowers the binding of TRPS1 to the GATA consensus sequence, and consequently could suppress the transcriptional repression activity of TRPS1.

Mutations in exon 6 of the TRPS1 gene have the most negative consequences on the funcion of transcription factor TRPS1, because they can alter the structure of the GATA DNA-binding zinc finger domain, and make the binding to DNA impossible. These mutations are, indeed, associated with trichorhinophalangeal syndrome type III, which is at the severe end of the TRPS spectrum.

Other alterations (mutations, insertions, deletions) have been documented in different exons, and are linked with less severe forms (trichorhinophalangeal syndrome type I).

The EXT1 gene, which is deleted together with TRPS1 in trichorhinophalangeal syndrome type II, encodes exostosin 1, an endoplasmic reticulum-resident type II transmembrane glycoprotein of 746 amino acids, with a molecular mass of 86.3 kD, whose expression in cells results in the alteration of the synthesis and display of cell surface heparan sulfate glycosaminoglycans. Although the exostosin 1 is ubiquitously expressed in many tissues, multiple exostoses appear to be the only known effect of mutation/inactivation of EXT1.

Exostosin 1 forms in vivo a Golgi-localized hetero-oligomeric complex with exostosin 2: this complex possesses substantially higher glycosyltransferase activity than exostosin 1 or exostosin 2 alone, and thus probably represents the biologically relevant form of the enzyme(s). These findings provide a rationale for the causation of hereditary multiple exostoses by loss of activity in either of the two EXT genes.

## Diagnostic Principles

The diagnosis of the different types of TRPS is based on clinical and radiological findings, ventually integrated by genetic analysis (particularly useful in some cases with non-classical clinical presentation).

## Therapeutic Principles

No etiologic therapy is currently available.

# Trichothiodystrophy

Mark Berneburg[1], Thomas Schwarz[2]
[1]Department of Dermatology, Eberhard-Karls-University, Tuebingen, Germany
[2]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany

## Synonyms

(P)IBIDS; Tay syndrome; TTD

## Definition and Characteristics

Autosomal recessive disorder with wide clinical variability. The name derives from the reduced sulfur content of the hair [1]. Clinical characteristics are recurring alopecia and ichthyosis starting from birth as well as growth and mental retardation. There are forms with or without varying degrees of photosensitivity. The risk to develop skin cancer is not increased. The hair is difficult to comb, breaks easily and episodes of effluvium can occur after infectious diseases. The synonym PIBIDS stands for photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility and short stature [2].

## Prevalence

In Western European populations the incidence is 1.1 per 1 million livebirths [3].

## Molecular and Systemic Pathophysiology

Mutations in the XP-B (2q21) and XP-D gene (19q13.2–q13.3) are causative for TTD. These genes are subunits of the TFIIH complex, a DNA repair factor that is also required for basal transcription of genes. Both the XP-B and XP-D genes are helicases acting in nucleotide excision repair (NER) and basal transcription [4]. A thermal instability of TFIIH has been proposed as the cause for a third form of TTD (TTD-A). The exact pathophysiology is unclear. Although repair defects exist which are responsible for the photosensitivity, it is currently believed that TTD is caused by a subtle defect in basal transcription explaining the developmental and neurological symptoms of TTD. Recent evidence supports a defect in the transcription of proteins such as ß-hemoglobin [5].

## Diagnostic Principles

Ichthyosis either present at birth or developing later in life, recurring episodes of alopecia, slow mental development and failure to thrive point to the diagnosis. Polarized light microscopy shows intermittent normal and reduced hair pigmentation giving the hair a "tiger-tail" like appearance. The diagnosis is confirmed by the detection of a reduced content of cysteine in the hair. Due to reduced ß-hemoglobin the values for median corpuscular hemoglobin (MCH) and median corpuscular volume (MCV) of erythrocytes may be decreased.

## Therapeutic Principles

For mild cases of ichthyosis topical and for severe cases systemic retinoids are recommended together with supportive treatment of neuroectodermal symptoms. If photosensitivity exists, photoprotection in the same way as for ►Xeroderma pigmentosum (see there) is advisable.

# Trichterbrust

►Pectus Excavatum

# Tricuspid Incompetence

►Tricuspid Regurgitation

# Tricuspid Insufficiency

►Tricuspid Regurgitation

# Tricuspid Regurgitation

Gabriele A. Krombach
Department of Diagnostic Radiology, University Hospital, Aachen, Germany

## Synonyms

Tricuspid insufficiency; Tricuspid incompetence

## Definition and Characteristics

Tricuspid regurgitation is the abnormal leaking of blood (backward flow) through the tricuspid valve from the right ventricle into the right atrium during systole. It is due to improper closure of the valve, either owing to dilatation of the annulus fibrosus or direct damage of the valve itself.

## Prevalence

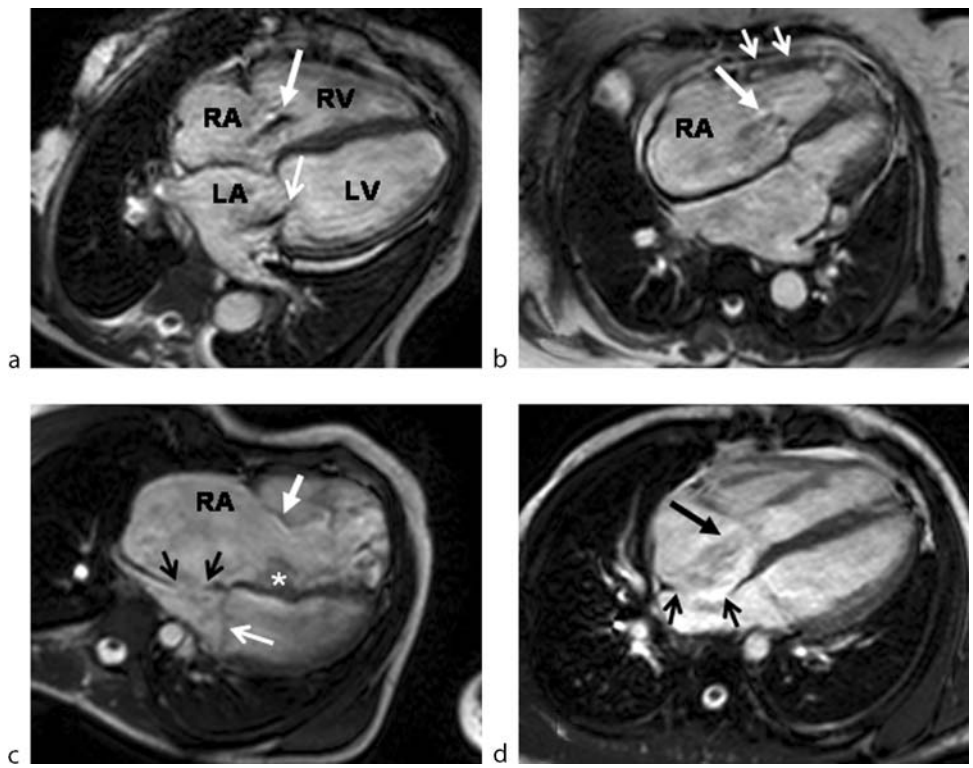
Approximately four out of 100,000 people have tricuspid regurgitation.

## Molecular and Systemic Pathophysiology

Usually, tricuspidal regurgitation is caused by dilatation of the right ventricle following pulmonal hypertension or myocardial insufficiency, due to myocardial infarction [1]. Congenital tricuspidal regurgitation can be associated with Ebstein's anomaly [2]. Rheumatic or infectious endocarditis can cause tricuspid regurgitation by damage of the valve itself. Endomyocardial fibrosis is a rare cause of tricuspidal regurgitation.

## Diagnostic Principles

Signs on plain chest radiography are cardiomegaly and right atrial enlargement, normal or reduced prominence of the pulmonary vascularity and, occasionally, enlargement of the superior and inferior vena cava. Stetoscopy reveals a holosystolic murmur parasternal on the left side. Clinical findings in patients with tricuspid regurgitation are due to systemic venous congestion and reduction of cardiac output. Neck vein congestion, hepatomegaly, ascites and pleural effusion are signs, which should bring tricuspid regurgitation to mind. Color Doppler confirms the diagnosis. Valve dysfunction is associated with a flow jet, which can be delineated as a signal void on Cine MR images [3]. MR imaging also has the potential to delineate associated findings (Fig. 1).



**Tricuspid Regurgitation. Figure 1** Cine MR images in the 4-chamber view of four different patients with tricuspid regurgitation. (a) Dilated cardiomyopathy. The heart is globally enlarged. There is a jet from the tricuspid valve into the right atrium (*closed arrow*) and from the mitral valve into the left atrium (*open arrow*) during systole. (*RA* right atrium; *LA* left atrium; *RV* right ventricle; *LV* left ventricle). (b) Pulmonary hypertension. The right atrium (RA) is enlarged. Hypertrophy of the wall of the right ventricle is delineated (*open arrows*). There is a jet from the tricuspid valve into the right atrium during systole. (c) Ebstein's anomaly. The tricuspid valve orifice is placed towards the apex (*closed arrow, asterisk*). The tricuspid valve remains open, while the tricuspid valve is already closed (*open arrow*). An atrial septal defect is present (*open black arrows*). The right atrium is enlarged. (d) Large atrial septal defect with left right shunt. Enlargement of the right atrium (RA) and right ventricle are delineated. There is a jet flow into the right atrium (*arrow*) during systole.

## Therapeutic Principles

Therapy of the underlying disease usually causes improvement of tricuspid regurgitation. Isolated tricuspid regurgitation (following endocarditis) usually does not require therapy. Surgical valve replacement is required, if severe symptoms are present.

# Tricuspid Stenosis

►Tricuspidal Stenosis

# Tricuspid Valve Stenosis

►Tricuspidal Stenosis

# Tricuspidal Stenosis

Alfonso Baldi
Department of Biochemistry, Section of Pathology, Second University of Naples, Naples, Italy

## Synonyms

Tricuspid stenosis; Tricuspid valve stenosis

## Definition and Characteristics

Tricuspidal stenosis is a narrowing of the tricuspid valve opening that increases resistance to blood flow from the right atrium to the right ventricle. It is usually caused by rheumatic heart disease and is generally accompanied by mitral stenosis [1]. Rarely, the cause is a tumor in the right atrium, a connective tissue disorder, or, even more rarely, a birth defect of the heart [2].

## Prevalence

Tricuspidal stenosis is found in ~3% of the international population and is more frequent in females than in males. It is more prevalent in areas with a high incidence of rheumatic fever. The congenital form of the disease is rare and true incidence is not available.

## Molecular and Systemic Pathophysiology

The tricuspid valve is one of four valves that control the flow and direction of blood in and out of the heart. If the valve is narrowed (stenosed), it becomes difficult for a sufficient amount of blood to move through the right heart chambers with each beat. Over many years, the right atrium enlarges because blood flow through the narrowed valve opening is partially blocked, increasing the volume of blood in the atrium. In turn, this increased volume causes an increase in pressure in the veins bringing blood back to the heart from the body, with the exception of the lungs. The obstructed venous return results in hepatic enlargement, decreased pulmonary blood flow, and peripheral edema

## Diagnostic Principles

Signs of tricuspid valve disease can be individuated at physical examination and include the following: (i) slight presystolic pulsation in the jugular vein in the neck at inspection, (ii) a presystolic thrill over the right ventricle at palpation, (iii) dullness extending to the right of the sternum, due to the enlarged auricle at percussion, and (iv) a presystolic murmur at auscultation. A chest X-ray, an electrocardiogram (EKG) with a characteristic P pulmonale, and an echocardiogram (ultrasound study of the heart muscle and valves) may be helpful in reaching the diagnosis.

## Therapeutic Principles

Treatment varies depending on the severity of the stenosis [3]. If the condition is mild, attempts are made to prevent possible complications, such as endocarditis, by giving antibiotics. Digitalis (digoxin) and anticoagulants may be given for atrial fibrillation. In case of heart failure, diuretics and vasodilators may be used. In the case of severe tricuspid stenosis or regurgitation, surgery to repair or replace the defective valve is recommended [4].

# Trilogy of Fallot

Koichiro Niwa
Department of Pediatrics, Chiba Cardiovascular Center, Chiba, Japan

## Synonyms

Pulmonary stenosis with patent foramen ovale; Pulmonary stenosis with interatrial communication; Combination of pulmonary stenosis with reversed interatrial shunt

## Definition and Characteristics

In the paper published 1950, the combination of pulmonary stenosis with reversed right-to-left interatrial shunt without ventricular septal defect was called as "the triologie de Fallot" [1].

The physiologic consequences of pulmonary stenosis with an interatrial communication depend on the degree of obstruction to the outflow of the right ventricle or pulmonary artery and the size of the interatrial communication. Also the end-diastolic pressure difference between right ventricle and left ventricle has an influence on that [2]. Cyanosis and/or right ventricular dysfunction or failure may result.

This entity can date from birth, or can begin in childhood, adolescent, or young adulthood. Infants come to attention because of a heart murmur or cyanosis. Symptoms can be appreciable when cyanosis is mild. Because RV pressure can exceed systemic before the right to left interatrial shunt becomes manifest. Giddiness, lightheadedness, shortness of breath or syncope may be experienced on exertion. Chest pain occasionally resembles angina pectoris attributed to ischemia in the high pressure hypertrophied right ventricle [3]. Death is due to right ventricular failure, or less commonly to hypoxia, cerebral abscess, infective endocarditis, or ventricular arrhythmias from right ventricular origin

In case with severe pulmonary stenosis and hypoplastic right ventricle, severe cyanosis occurs in the neonate. The pulmonary blood flow is not dependent on the right ventricle but mostly on the patent ductus arteriosus. This entity belongs to the so called hypoplastic right heart syndrome (similar hemodynamics as pulmonary atresia with intact ventricular septum) and is believed to be a different entity from "triology of Fallot."

## Prevalence

Incidence of pulmonary stenosis is around 3% of congenital heart disease (congenital heart disease is around 1–2% of live birth) and severe pulmonary stenosis is 20% of total pulmonary stenosis. Not all patients with severe pulmonary stenosis and persistent foramen ovale reveal reversed interatrial shunt therefore the true incidence of this entity is unknown.

## Genes

Responsible genes for pulmonary artery stenosis are not identified.

## Molecular and Systemic Pathophysiology

Morphogenesis of pulmonary stenosis is not well established. Low blood flow through right ventricular outflow tract due to unknown causes during fetus is responsible for limiting pulmonary valve opening and result in pulmonary stenosis. Right ventricular outflow obstruction is usually represented by mobile dome pulmonary valve stenosis, or much less commonly by stenosis of the pulmonary artery and its branches. Infundibular obstruction takes the form of secondary hypertrophic subpulmonary stenosis. Subinfundibular stenosis in infants was assigned to right ventricular fibromas. When severe pulmonary valve stenosis coexists with a right to left shunt, the shunt is almost always across a patent foramen ovale rather than an atrial septal defect. Severe pulmonary stenosis increases right atrial contraction that distends the right ventricle in presystole so it can achieve greater contractile force. The large right atrium and A wave are responsible for a presystolic right to left interatrial shunt. The high pressure right atrium dilates, stretching the margins of the foramen ovale and increasing its patency. When right atrial blood escapes through the interatrial communication, pulmonary flow reciprocally falls.

## Diagnostic Principles

Physical underdevelopment coincides with right ventricular failure. Large A waves appear in the jugular venous pulse and is in contrast to the systemic arterial

pulse. The right ventricular impulse is strong and sustained and is accompanied by presystolic distension. There is a systolic thrill in the second left intercostal space. A pulmonary ejection sound precedes the pulmonary stenotic murmur, which is loud and long, extending up to or beyond the aortic component of the second heart sound. The pulmonary component of the second heart sound is delayed, soft, or inaudible. Right atrial P waves can be strikingly tall, and right axis deviation is common and sometimes extreme. Right precordial leads show R waves of great amplitude followed by upward convexity of the ST segments and deep inversion of the T waves, while left precordial leads exhibit deep S waves and upright T waves. The pulmonary trunk is dilated, the ascending aorta is inconspicuous and the cardiac silhouette reflects enlargement of the right atrium and right ventricle. Real-time echocardiogram identifies the mobile stenotic pulmonary valve. Doppler echocardiography determines the gradient, and color flow mapping detects the right to left shunt across a patent foramen ovale.

### Therapeutic Principles

Catheter balloon angioplasty or surgical intervention is available treatment for this entity in patients with moderate to severe pulmonary artery stenosis combined with/without patent foramen ovale or atrial septal defect device closure. Catheter intervention is feasible nowadays in most cases [4].

## Trisomy 8

Sefik Guran
Department of Medical Biology, Gulhane Medical Academy, Ankara, Turkey

### Synonyms

+8 cytogenetic abnormality

### Definition and Characteristics

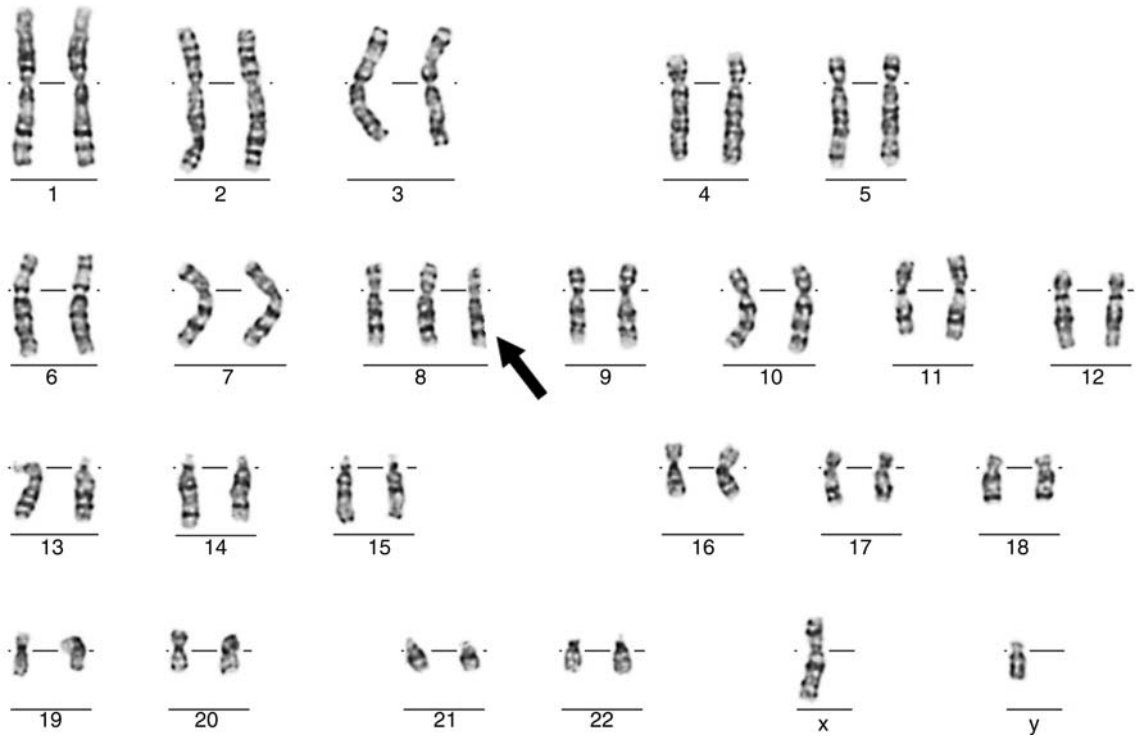
Trisomy 8 is an extra chromosome, which is relatively specific for myeloid disorders. It is frequently seen in acute myeloid leukemia (AML), myelodysplastic syndromes (MDS), and chronic myeloid leukemia (CML) in blast transformation. Trisomy 8 occurs as both a primary and a secondary cytogenetic abnormality in AML. It is not restricted to any particular FAB groups; it is particularly common in M2, M4 and M5 subtypes of AML. Trisomy 8 represents the most common chromosomal gain in MDS. MDS cases with trisomy 8 may transform through a myelodysplastic preleukemic phase before developing full-blown AML. On the contrary, it is rare in the malignancies of lymphatic series [1–3].

### Prevalence

It is the most common numerical cytogenetic aberration in AML, MDS, CML in blast transformation and other types of chronic myeloproliferative disorders (polycthemia vera, idiopathic myelofibrosis, essential thrombocthemia). Trisomy 8 was reported after imatinib mesylate therapy with Philadelphia negative chromosomal finding in few CML cases [4]. The prevalence of trisomy 8 in ALL is only about 1–2% in both T and B cell lineage. Also trisomy 8 was reported as the sole cytogenetic abnormality in some rare malignancies such as extraskeletal mesenchymal condrosarkoma [2,3].

### Molecular and Systemic Pathophysiology

Boveri and Hansemann proposed over 100 years ago that abnormal chromosome numbers were cause of cancer. Carcinogenesis is initiated by random aneuploidies, which are induced by carcinogens or spontaneously. Aneuploidy unbalances thousands of genes, it corrupts



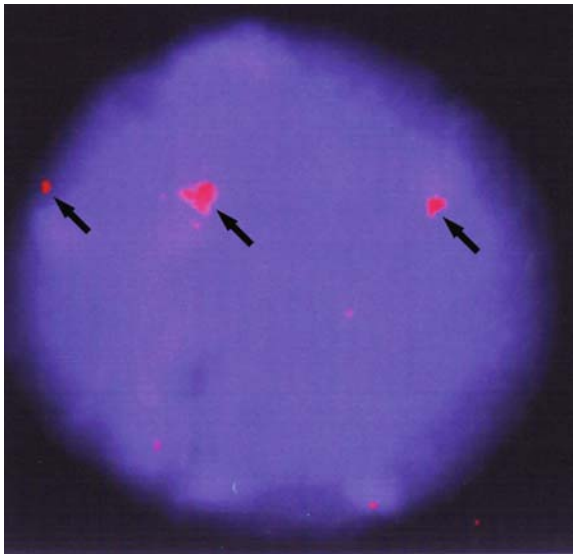
**Trisomy 8. Figure 1** Trisomy 8 cytogenetic abnormality observed in an AML case.

the proteins that segregate, synthesize and repair the chromosomes. Aneuploidy is therefore a steady source of malignant progression of cancer cells. Also the chromosomes of cancer cells are extremely unstable compared to normal cells. As a result cancer is caused by chromosomal disorganization which increases karyotypic entropy [5]. The obvious molecular consequence of trisomy 8 is the presence of an additional copy of all of the genetic material on chromosome 8. Nevertheless, the relationship between trisomy 8 and malignant transformation has remained unclear. The affected mechanisms and genes are not known in this cytogenetic abnormality in malignancies [2,3].

## Diagnostic Principles

The diagnosis is possible with cytogenetic analyses and fluorescence in situ hybridization (FISH) analyses of bone marrow, peripheral blood and tumor tissue samples (Figs. 1 and 2).

The cytogenetic and FISH analyses are recommended in initial diagnosis phase and during the follow up period for the diagnosis and prognosis. FISH with probes hybridizing with the centromeric regions of specific chromosomes allows the detection of numerical chromosomal abnormalities in interphase cells. FISH can be performed on blood smears as well as on bone marrow samples prepared for cytogenetic examination [1–3].



**Trisomy 8. Figure 2** An interphase nucleus demonstrated trisomy 8 with a specific centromeric FISH probe in a tumor material.

## Therapeutic Principles

This very common cytogenetic abnormality is correlated with poor prognosis in diseases affecting the myeloid series including AML, MDS and CML. Tetrasomy 8 was also reported in few AML cases with poor

prognosis. Aggressive treatment protocols are recommended in malignancies with trisomy and tetrasomy 8 cytogenetic abnormality in remission induction and remission maintenance therapy. Careful clinical follow up is recommended in AML, MDS, CML and chronic myeloproliferative disorders with trisomy 8 [1–3].

# Trisomy 9

Trevor J. Pugh, Marco A. Marra
Genome Sciences Centre, BC Cancer Agency, Vancouver, BC, Canada

## Synonyms

Chromosome 9 trisomy mosaic; Trisomy 9 mosaic; Trisomy 9 mosaicism; Trisomy 9 mosaicism syndrome; Complete trisomy 9 syndrome

## Definition and Characteristics

Trisomy 9 is a rare genetic disorder in which three copies of chromosome 9 are present in the cells of the human body. This disorder involves the complete duplication of chromosome 9. Other abnormal permutations of this chromosome include partial trisomy 9p (only the chromosomal p-arm is duplicated) and partial trisomy 9q (only the chromosomal q-arm is duplicated) [1] as well as a spectrum of deletions, duplications, and triplications of smaller chromosomal regions [2]. As complete trisomy 9 is often lethal to the fetus [3], individuals affected by this disorder commonly display mosaicism, harboring a mixture of cells in which some cells contain the normal two copies of chromosome 9, while other cells contain a third copy of chromosome 9. Trisomy mosaicism may either be of somatic origin due to mitotic non-disjunction of a normal fertilized egg leading to a cell line with an additional chromosome or of meiotic origin due to the loss of a chromosome from an abnormal trisomic fertilized egg leading to a cell line with a normal pair of chromosomes. Nearly all forms of trisomy 9 result in mental retardation and cranio-facial abnormalities which can include sloping forehead with narrow temples, deep-set eyes with narrow eyelids, broad bulbous nose, small jaw with a prominent upper lip overhanging a receding lower lip and malformed, low-set ears [2,3]. A wide range of other anomalies can include growth retardation, congenital heart defects, intra-uterine growth restriction, brain malformations and urogenital abnormalities [2,3]. In the case of mosaicism, clinical features generally become more distinct with a higher proportion of aneuploid cells [2].

## Prevalence

Trisomy 9 is detected only rarely and prevalence is difficult to determine as most data take the form of single patient case reports. It has been estimated that trisomy 9 comprises 2.7% of trisomic spontaneous abortions [3]. A large Japanese study identified two cases of partial trisomy 9 mosaicism in 27,472 infants born consecutively at a single institution [1].

## Genes

Chromosome 9 contains over 1,100 genes of which 95 are associated with human disease. No single gene has been definitively linked with the trisomy 9 phenotype, possibly indicating that the characteristic phenotypes arise as the result of complex abnormal molecular interactions driven by the extra copy of chromosome 9.

## Molecular and Systemic Pathophysiology

Studies of trisomy 21 have suggested that trisomic phenotypes are primarily due to elevated transcript levels from the duplicated chromosome and are moderated by phenotype-genotype interactions throughout development [4]. The effects of duplicated dosage-dependent genes may be direct or indirect and manifested through a host of molecular mechanisms involving disomic and triosomic genes [4].

## Diagnostic Principles

Trisomy 9 is often diagnosed by amniocentesis, cordocentesis, or chorionic villus sampling following an abnormal ultrasound or blood test during pregnancy. These techniques collect fetal cells from the amniotic fluid, umbilical cord blood, or placental tissues. The cells are subject to cytogenetic analysis to identify chromosomal abnormalities. Routine analysis involves treatment of metaphase chromosomes with trypsin followed by staining, most commonly with Giemsa stain, to create unique chromosomal banding patterns which are analyzed by microscopy and often presented

as a standardized arrangement of chromosomes called a karyotype [2]. Due to the high frequency of genetic mosaicism associated with this disease, examination of cells from several tissue sites should be used to detect trisomy 9. Advances in genome technology, such as fluorescent in situ hybridization and genomic microarrays, have lead to more sensitive, higher resolution analyses of genetic abnormalities. For example, in a recent microarray-based whole genome analysis of 100 children with idiopathic mental retardation, a case of mosaic trisomy 9 was identified that had not been detected using traditional cytogenetic methods [5].

### Therapeutic Principles

Treatment of trisomy 9 is directed towards treatment of the symptoms of each individual. Often, a coordinated team of specialists is needed to address the spectrum of physical abnormalities and mental challenges associated with this syndrome.

## Trisomy 13

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

### Synonyms

Patau syndrome

### Definition and Characteristics

About 80% of all cases are free trisomies, and the majority arise from nondisjunction failure in maternal meiosis I. The remainder is associated with rearrangements, either isochromosomes or translocations. Of the latter, Robertsonian 13;14 translocations predominate, the majority occurring de novo [1,2]. Trisomy 13 frequently leads to intrauterine or early postnatal death. Few survivors suffer from multiple malformations, profound retardation, blindness, deafness, and epilepsy.

### Prevalence

Trisomy 13 is the third commonest autosomal trisomy, the incidence is 1 in 12,000–30,000 live births.

### Genes

Four-hundred sixty-three genes have been mapped to the long arm of chromosome 13, and many of them are implicated in human diseases. Examples include the GJB2 and GJB6 genes (connexin 26 and 30) on 13q11-q12, which play a role in nonsyndromic deafness, the BRCA2 gene on 13q12.3, which is implicated in susceptibility to develop breast and ovarian cancer, the RB1 gene (retinoblastoma gene) on 13q14.2, a cluster of genes on 13q14, which play a causative role in chronic lymphatic leukemia, the ATP7B gene on 13q14 causing Wilson disease, the SCA8 gene on 13q21 involved in spinocerebellar ataxia type 8, and the CLN5 gene on 13q21.1 causing the late infantile type of ceroid lipofuscinosis, to mention just a few. However, only for a few genes a direct implication in the specific phenotype of trisomy 13 could be established. These are, for example, the ZIC2 and ZIC5 genes on 13q32, which have been shown to cause holoprosencephaly and probably the DACH gene (dachshund homolog) on 13q22, which is a candidate for the severe ocular defects and the skeletal malformations observed in trisomy 13. Many of the genes on chromosome 13 code for transcription factors that have been shown to play an important role during development in experimental models, but their specific role in human development has not been elucidated so far.

## Molecular and Systemic Pathophysiology

Trisomy 13 is a common cause among spontaneous abortions during first trimester, but fetuses might die at various stages of pregnancy. It has been proposed that the loss of the additional chromosome in a subpopulation of placental cells determines intrauterine survival [3]. Postnatal median survival is less than a week, and more than 80% of affected infants die during the first month. However, 3% are alive at 6 months [4].

Mean birth weight at term is reduced (2.6 kg), and the placenta might be abnormal. Feeding difficulties and postnatal growth retardation are common findings.

*Craniofacial Features*: Bilateral cleft lip and cleft palate, scalp ulcerations, metopic ridge, ocular hypotelorism and associated features, capillary hemangioma at the glabellar region, malformed ears. Ocular findings: microphthalmia, colobomata, retinal dysplasia, cyclopia.

*Central Nervous System*: Moderate microcephaly, any degree of holoprosencephaly (often associated with seizures and apneic episodes), deafness.

*Cardiovascular System*: Patent ductus arteriosus, septal defects (ASD and VSD) and more complex heart malformations.

*Urogenital System*: Cystic dysplasia of kidneys, hydronephrosis, hypoplastic male genitalia with cryptorchidism and hypospadias, bicornuate uterus, small labia majora.

*Limb Anomalies*: Postaxial hexadactyly of fingers or toes (uni- or bilateral), fingers are often flexed. New chapters: Other findings Anomalies of the ribs, the vertebrae and the pelvis, neoplasia (leukemia).

*Long Time Survivors*: Show profound physical and mental retardation, and the development is usually arrested at the level of 6 months or less. Individuals are often blind and deaf and suffer from epilepsy.

## Diagnostic Principles

In prenatal diagnosis, 80% of fetuses with trisomy 18 can be identified within the first trimester by a screening method based on a combination of maternal age and fetal nuchal translucency [5]. Ultrasound examination at that stage reveals growth retardation, omphalocele, and/or hydrops in the majority of cases. In the second trimester, visualization of major brain (holoprosencephaly), facial (orofacial clefts, anophthalmia), heart, renal, and limb (postaxial polydactyly) malformations should be possible in all cases with trisomy 13.

## Therapeutic Principles

Management after birth is aimed at ameliorating the effects of associated abnormalities.

# Trisomy 16 Mosaicism, Confined Placental Mosaicism and UPD16mat

John Wolstenholme
Institute of Human Genetics, University of Newcastle, Newcastle upon Tyne, UK

## Synonyms

CPM16; Maternal uniparental disomy for chromosome 16; Upd(16)mat

## Definition and Characteristics

The presence of a trisomy 16 cell line alongside a normal cell line in any combination or distribution within the entire feto-placental unit is referred to as trisomy 16 mosaicism. An important sub-group of this, confined placental mosaicism (CPM), is a feto-placental karyotype discordance where a chromosomally normal fetus has a placenta and other extra-embryonic tissues that are usually, mostly or wholly trisomy 16. About one third of all mosaic trisomy 16 cases, including those with CPM16, also have an additional, superimposed maternal uniparental disomy for chromosome 16, where both copies of chromosome 16 in the normal cell line are maternally inherited. Intrauterine growth restriction (IUGR) is common in all these conditions, as are late pregnancy losses. IUGR can be severe. A minority of cases have associated congenital abnormalities. Information regarding postnatal development of CPM cases is poor. Intellectual development may be relatively normal; limited catch-up growth has been reported in some cases.

## Prevalence

Trisomy 16 and trisomy 16 mosaicism are detected during prenatal diagnosis using Chorion Villus

Sampling (CVS) at a combined frequency of 1 in 3,000–3,500 tested pregnancies. The majority appear to be CPM, but a small proportion will have overt low-level mosaicism in fetal tissues, which is often difficult to detect. One in three of these CVS cases have upd(16)mat, an incidence of 1 in 10,000 in this group. The population incidences will be lower than these, as women undergoing CVS include a surplus of older mothers and there is a positive correlation between maternal age and trisomy 16 mosaicism. UPD16 can also occur in karyotypically normal individuals without evidence of a trisomic line having been present in any extra-embryonic tissues. This condition is likely to be much rarer than the mosaic trisomy 16 form; its prevalence is essentially unknown.

## Genes

IUGR and late pregnancy losses are thought to be due to the placental trisomy. The presence of any trisomic cells in fetal tissues will have direct effects on development. Undetected fetal mosaic trisomy is also likely to be important, particularly for those apparent CPM cases with congenital abnormality. It is unclear if UPD16mat cases have additional clinical features that can be directly attributed to the effects of maternally imprinted genes. No genes on chromosome 16 have, as yet, been demonstrated to be imprinted. Yong et al. [1] list several candidate genes that may be imprinted based on mouse homology studies.

## Molecular and Systemic Pathophysiology

Trisomy 16 mosaicism leads to a complex spectrum of interlinked clinical scenarios. The mosaicism itself is primarily the consequence of correction of a maternally derived trisomy 16 conception of meiosis I origin. Correction is clonal and occurs in the first few cell divisions post-fertilization, to produce a normal cell line alongside the trisomic cell line. The mechanism of trisomy 16 correction is unknown; similar corrections have been recorded for other trisomies. The fate of these "mosaic" trisomy 16 pregnancies largely depends on where the normal cells become distributed in the blastocyst. Significant levels of trisomy 16 in the fetal cell lineages are presumed to be lethal. The inevitable consequence of a chromosomally normal fetus is that the placenta is mostly or totally comprised of the trisomic cells. Which chromosome 16 is lost appears to be random, with one in three cases having loss of the paternal chromosome, resulting additionally in UPD16mat; the remaining cases will have normal biparental inheritance. IUGR and late fetal losses are seen in both the UPD16mat and biparental inheritance CPM cases, indicating that placental trisomy is the major causative factor. The placenta is often small and thickened. The presence of large placental vesicles has been reported on ultrasound in some cases. Significantly raised, mid second trimester levels of maternal serum AFP and hCG have also been reported. UPD16mat has been associated with congenital abnormality in some cases, notably cardiac abnormalities, imperforate anus and hypospadias. However, as abnormalities are also seen in cases with biparental inheritance, and cardiac abnormalities are a known feature of demonstrable low-level fetal trisomy 16 mosaicism, much of this may be attributable to undetected low-level and/or tissue specific trisomy 16 in the fetus. Poor relative growth/survival of trisomy 16 cells at the embryonic stage may result in "hypoplastic" malformations early in pregnancy, whilst actually compounding the problem of detecting low-level fetal trisomy mosaicism. The potential for co-existence of placental trisomy, low-level fetal mosaic trisomy, UPD16mat and isodisomic chromosome segments leading to unmasking of unknown recessive genes, makes analysis of their individual contributions to the overall pathology somewhat problematical.

## Diagnostic Principles

Analysis of polymorphic DNA markers positioned along chromosome 16 will usually detect both maternal alleles and one paternal allele at one or more loci in the trisomic cell line. Absence of the paternal allele in the disomic cell line indicates UPD16mat; absence of one of the maternal alleles indicates biparental inheritance. Pericentromeric markers are usually the most informative as maternal non-disjunction of chromosome 16 is associated with reduction of numbers of chiasmata, particularly in the proximal regions of both chromosome arms.

## Therapeutic Principles

If detected prenatally, both biparental inheritance and UPD16mat cases should be regarded as high-risk pregnancies. Detailed anomaly scans should be undertaken. Early induction should be considered if severe IUGR becomes apparent. No specific treatment is available.

# Trisomy 18

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

## Synonyms

Edwards syndrome

## Definition and Characteristics

Trisomy 18 frequently leads to intraterine or early postnatal death. The few survivors suffer from multiple malformations and profound physical and mental retardation. It is almost always caused by an extra free chromosome 18, very few cases are associated with translocations or other structural abnormalities. The occurrence of trisomy 18 is related to maternal age and the vast majority of cases are caused by maternal meiotic non-disjunction, errors in meiosis II predominating [1].

## Prevalence

The incidence of trisomy 18 is about one in 6,000 livebirths.

## Genes

*Correlative Phenotypic Mapping*: Duplication of 18p produces a very mild phenotype (unspecific dysmorphisms, normal to slightly decreased intelligence), which leads to the conclusion that the genetic information on the long arm of chromosome 18 is the critical determinant for trisomy 18. However, duplications of the entire 18q12-qter region produce variable phenotypes and there is consensus in the literature that there is no distinct region on 18q sufficient to produce the full trisomy 18 phenotype, as it is observed for example with trisomy 21. It seems rather that the classical phenotype in trisomy 18 is caused by interaction of proximal and distal regions (18q12.1-21.2 and 18q22.3-qter) [2,3].

*Role of Specific Genes in Trisomy 18*: Little is known about the role of specific segments or individual genes on the phenotypic expression in trisomy 18. So far, 368 genes have been mapped to chromosome 18, 113 to the short arm, 255 to the long arm. Many of them are transcription factors which have been shown to be implicated in basic developmental processes such as cell adhesion and growth control. Examples include the MAD genes on 18q21.1 (which play a role in the signaling pathways of the transforming growth factor-beta receptor family), the cluster of the SERPIN genes on 18q21 (implicated in growth control and fibrinolysis) and several members of the CDH (cadherin) genes which are located at different loci on 18q. The specific role of the majority of these genes on human development still remains obscure. However, a small number of genes are linked to specific phenotypes, such as the RAX gene on 18q21.32 (which plays an important role in eye development), the TGIF gene on 18p11.3 (which is implicated in holoprosencephaly), the NPC1 gene on 18q11.2 (implicated in Niemann-Pick disease), the DTN4 (dystrobrevin alpha) gene on 18q12 (limb girdle muscular dystrophy), the MBP gene on 18q32 (neurodegeneration) and the FLJ90130 gene on 18q21.1 (Dyggve-Melchior-Clausen syndrome). It remains to be determined, which features of the trisomy 18 phenotype are due to a more general cumulative result of genetic imbalance, and which are caused by altered dosage of single genes.

## Molecular and Systemic Pathophysiology

*Survival*: Intrauterine mortality is high: It has been estimated that only 2.5% of trisomy 18 conceptions survive to birth and 70% of the fetuses diagnosed at midtrimester amniocentesis will not survive to term. About 4/5 of liveborn are female, which is not the case for prenatally diagnosed fetuses with trisomy 18. Not only prenatal but also postnatal mortality is high: The median survival time is less than one week and 90% of infants with trisomy 18 die during the 6 first months. There are, however, reports of children surviving into the second decade [4].

*Phenotype*: At birth, the affected neonates show reduced weight and the placenta is small. The typical features include: small, narrow head with a prominent occiput, small mouth, micrognathia, low-set and malformed ears, short sternum, a wide spectrum of cardiovascular anomalies, overlapped flexed digits of the hand (such that the index finger overlaps the third finger and the fifth the forth), prominent calcaneus, short and dorsiflexed great toes. Long time survivors suffer from profound physical and mental retardation and the overall development does not progress beyond that of a 6 month-old infant. Variable degrees of holoprosencephaly and many other structural abnormalities of the central nervous system (neuronal heterotopias, paucity of myelinisation, absence of corpus callosum or geniculate body, etc.) have been observed. Most of the children suffer from severe functional visual impairment which can be associated with different malformations of the eyes (corneal opacities, microphthalmia, iris coloboma, optic nerve hypoplasia) and the adnexa (narrow palpebral fissures, ptosis, blepharophimosis).

Malformations of the ear might include atresia of external auditory canals and deformities of the organ of Corti, etc. The vast majority also show cardiovascular anomalies (VSD, PDA, ASD, anomalies of the valves). Malformations of the limbs (radial or thumb aplasia, postaxial hexadactyly, clubfoot) or the urogenital system (renal anomalies, cryptorchidisms, prominent clitoris) are often observed. Children are prone to infections (probably due to a multifactorial defect of the immune system) and various malignant tumors have been reported in long term survivors with trisomy 18.

## Diagnostic Principles

Trisomy 18 is readily diagnosed by prenatal ultrasound due to the classical combination of major malformations with growth retardation and oligo- or polyhydramnios. Specific signs detectable by ultrasound scanning include omphalocele bilateral choroid plexus cysts (or other central nervous system malformations), abnormal nuchal skin fold, ventricular septal defect, abnormalities of the outflow tract and right- to left disproportion of the heart chambers [5]. In practice, any combination of major malformations (heart defects, omphalocele, myelomeningocele, obstruction of the urogenital tract, esophageal atresia, clenched fists, radial limb defects) with or without an abnormal maternal serum biochemical screening result should lead to the suggestion of trisomy 18. The diagnosis is confirmed by cytogenetic analysis.

## Therapeutic Principles

Management after birth is aimed at ameliorating the effects of associated abnormalities.

# Trisomy 21

Alexander K. C. Leung, Hardally R. Hegde
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Down syndrome; Mongolism

## Definition and Characteristics

Trisomy 21 is characterized by hypotonia that improves with age, short stature, obesity during adolescence, hypermobility of the joints with laxity of the ligaments, cheerfulness, gentleness, mental retardation, brachycephaly with relatively flat occiput, microcephaly, up-slanting palpebral fissures, inner epicanthal folds, midfacial hypoplasia, a flat nasal bridge (Fig. 1), speckled iris (Brushfield spots), refractive errors, strabismus, nystagmus, cataract, small ear lobes with overfolding of an angulated upper helix, sensorineural hearing loss, macroglossia, furrowed tongue, delayed eruption of teeth, microdontia, hypoplastic and hypocalcified teeth, short neck with loose overlying skin, cutis marmorata, xerosis, hyperkeratosis, short and broad hands, hypoplasia of the midphalanx and clinodactyly of the fifth finger, single transverse palmar or simian crease, distal palmar axial

**Trisomy 21. Figure 1** A 6-year-old boy with trisomy 21. Note the dysmorphic facial features and the short, broad hands.

triradius, ulnar loops on fingertips, wide space between the first two toes, hypoplasia of the pelvis with outward lateral flaring of the iliac wings, micropenis, and decreased testicular volume [1]. Congenital heart disease and gastrointestinal anomalies occur in ~50 and 12% of patients, respectively [1].

## Prevalence

The overall incidence is ~1 in 700 live births [2]. The incidence rises from 1 in 1449 live births at a maternal age of 20 years to 1 in 26 live births at a maternal age of 45 years [2].

## Genes

Down syndrome is caused by the presence of extra genetic material from chromosome 21. The Down syndrome (DS)-specific region has been mapped to 21q22.2-22.3 [3]. In ~95% of cases, the condition is the result of non-familial trisomy 21 or non-disjunction of chromosome 21 during the meiotic formation of the oocyte or spermatocyte [3]. DNA testing has shown that the oocyte is the location of the non-disjunction in about 92% of cases [4]. In ~3–4% of cases, the extra genetic material is the result of an unbalanced translocation between chromosome 21 and another acrocentric chromosome (Robertsonian translocation) [3]. Approximately 75% of translocations arise de novo; 25% are inherited from a translocation carrier parent [3].

## Molecular and Systemic Pathophysiology

The chromosome 21 contains 225 genes, some of which are located at the Down Syndrome Critical Region [5]. The region D21S58–D21S42 is associated with dysmorphic facial features and mental retardation. The D21S55 locus accounts for many of the phenotypic features of the syndrome.

## Diagnostic Principles

The diagnosis is usually based on the presence of the typical dysmorphic features. The diagnosis should be confirmed with cytogenetic studies, which also help determine the risk of recurrence. Karyotyping of the parents should be performed when a translocation is identified. A low maternal serum level of α-fetoprotein and unconjugated estriol, and an elevated maternal serum level of β-human chorionic gonadotropin are biochemical markers for trisomy 21 [1]. Prenatal ultrasonography may show nuchal translucency, caused by subcutaneous edema at the base of the skull. Amniocentesis or chorionic villus sampling to examine the fetal chromosomes should be offered to women who will be 35 years or older on their delivery due date and to those with abnormal serum screening results or prenatal ultrasonography.

## Therapeutic Principles

All children with trisomy 21 should have a thorough physical examination, an echocardiogram, and an auditory brainstem response in the neonatal period. Thyroid function tests need to be repeated when the child is 6 months old and yearly thereafter. Each annual assessment should include an age-appropriate developmental and physical examination, complete blood count, audiologic evaluation, and ophthalmologic assessment. Radiographs to investigate for atlantoaxial instability should be obtained when the child is 3–5 years old. Education and rehabilitation need to be provided to maximize the child's potential. Adolescents require sex education.

# Trisomy X

►X Polysomies, in Females

# Tropical Sprue and Postinfective Malabsorption

Joachim Richter
Tropical Medicine Unit, Clinics for Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

PIM; Postinfective malabsorption

## Definition and Characteristics

Postinfective malabsorption (PIM) is defined by chronic diarrhea and malabsorption of 3 months and

more duration. It usually follows an acute parasitic or bacterial intestinal infection. PIM includes all types of malabsorption, whereas tropical sprue should be reserved to important malabsorption of nutrients more than water and electrolytes. Many infectious agents especially prevalent in tropical and subtropical regions may cause malabsorption. The definition of PIM and/or tropical sprue applies to those cases where malabsorption persists although the initial infective agent has been eradicated.

## Prevalence

The highest prevalence in tropical regions is observed in the Indian subcontinent, followed by Southeast Asia and the northern part of South America and the Caribbean. It is unusual in Africa. PIM is much less common in the Middle East and the Mediterranean basin.

## Molecular and Systemic Pathophysiology

The pathogenesis of PIM is understood as a vicious cycle triggered by an acute intestinal infection: mucosal injury leads to intestinal hypomotility favoring bacterial overgrowth, which then itself maintains mucosal injury [1,2]. PIM results from the interaction of an infectious agent with immunological host factors related to a particular genetic background: on one hand, PIM is particularly common in regions where enteric infections abound, on the other hand, there are regions with a high incidence of enteric infections where PIM is uncommon. An association between PIM and HLA-Aw31 and HLA-B28 has been observed, whereas PIM is significantly less frequent in individuals with HLA-A1, A28, and Bw35. The response of PIM to folic acid is not well understood. Folates may aid mucosal recovery, whereas malabsorption leads to folate deficiency. The responsiveness of PIM to tetracycline is related to its effect in reducing enteric bacterial overgrowth.

## Diagnostic Principles

After having excluded persisting infectious causes of malabsorption investigations include urinary D-xylose excretion, 72 h fecal fat estimation, a Schilling test, and jejunal biopsy. Biopsy samples are ridged and submucosa is invaded by lymphocytes and plasma cells. Vitamin B12 and folic acid serum concentrations have to be determined. Serum albumin and globuline concentrations are frequently decreased. Further investigations include anti-transglutaminase, anti-gliadin, and endomysium auto-antibodies to rule out coeliac disease as well as a lactose absorption test. The detection of the causative agent of Whipple's disease of tropheryma whippeli per se does not preclude the diagnosis of tropical sprue [3].

Differential diagnosis must take into account persisting infectious causes of malabsorption in tropical areas, in particular parasitic infections, tuberculosis, and AIDS-related wasting. The most common cause of infectious malabsorption is undoubtedly giadia lamblia, followed by strongyloides stercoralis. Both agents may be difficult to detect when parasite load is low. Giardia parasites may remain undetected in up to 15% even if multiple stool examinations are performed. Examination of duodenal fluid and duodenal biopsies may contribute to diagnosis but are no more sensitive than stool examinations [4]. PCR techniques have been developed for both parasites in specialized laboratories and are more sensitive than parasitological examinations. In HTLV-associated strongyloides hyperinfection worm larvae usually abound in stool samples. Other parasites to be excluded before a final diagnosis of tropical sprue is made include cyclospora cayetanensis, cryptosporidia, microsporidia, isospora belli, schistosoma spp., and yersinia enterocolitica. Intestinal tuberculosis must also be considered, especially when abdominal masses and confluent intra-abdominal lymph nodes are present. Extrapulmonary tuberculosis occurs frequently in tropical countries. This condition is neither excluded by a negative chest X-ray nor by a negative intradermal tuberculine test. Enteroviral infections, e.g., by rotavirus and herpes simplex viruses have also been reported to cause malabsorption in children. Mediterranean enteropathy-associated α-chain-lymphoma sporadically occurs in many parts of the tropics.

## Therapeutic Principles

Symptoms usually respond dramatically to folic acid and antibiotics. Folic acid (5 mg/t.i.d.) is given for 1 week followed by a maintenance dosage of 1 mg/t.i.d. for other 3 weeks. Tetracycline (preferable to doxycycline) 3 × 250 mg – 3 × 500 mg/day therapy for 2–4 weeks. When tetracycline is contraindicated, ampicillin 500 mg/day four times daily is an alternative.

# TRPS

►Trichorhinophalangeal Syndrome

# Truncus Arteriosus

Hiroyuki Yamagishi[1], Keiichi Fukuda[2]
[1]Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan
[2]Department of Regenerative Medicine and Advanced Cardiac Therapeutics, Keio University School of Medicine, Tokyo, Japan

## Synonyms

Persistent truncus arteriosus; PTA; Truncus arteriosus communis; TAC

## Definition and Characteristics

A conotruncal (cardiac outflow tract) defect characterized by a single arterial trunk arising from the heart, instead of separate pulmonary artery and aorta, which supplies the systemic, pulmonary, and coronary circulations (Fig. 1). A large ventricular septal defect (VSD) is also present.

## Prevalence

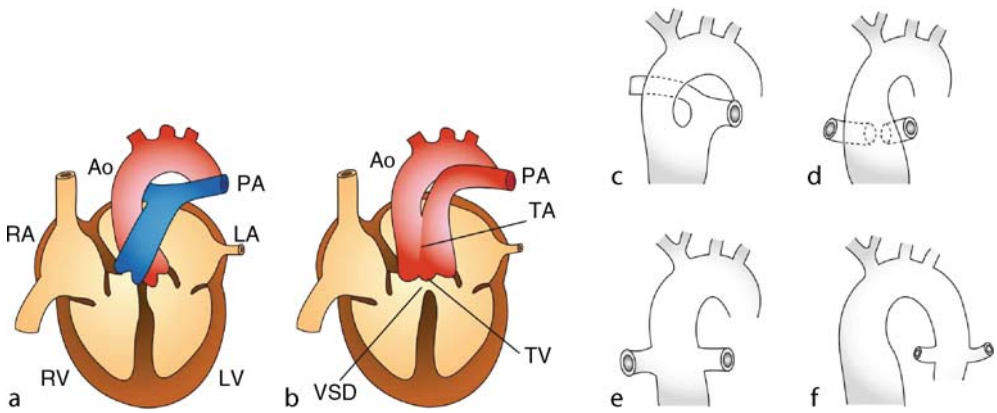
The reported prevalence ranges from 0.04 to 0.1 cases per 1,000 live births and accounts for 1.1–2.5% of all types of congenital cardiovascular diseases (CCVD). It also accounts for ~10% of CCVD associated with DiGeorge/22q11.2 deletion syndrome.

## Genes

Truncus arteriosus (TA) is genetically heterogenous and multifactorial in nature. Several transcription factors (e.g., Pax3, Cited2, AP2a, Pitx2) and signaling proteins (e.g., Sema3C, BmprII, Alk2, Dvl2, Etar) highlight the importance of the cardiac neural crest cells (cNCC: see later) while other transcription factors (e.g., Isl1, Tbx1, Foxh1, Nkx2.5, Mef2c) and signaling proteins (e.g., Fgf8, Fgf10) highlight the importance of the secondary heart field (SHF: see later). Mice deficient for genes encoding these proteins result in the TA. Inactivation of Hira or Ufd1l in chick embryo results in defects of truncal septation. Heterozygous deletion of chromosome 22q11.2 locus, encompassing TBX1, HIRA, UFD1L, and other ~30 genes, results in the most common human deletion syndrome known as DiGeorge syndrome, and has been noted in approximately 30% of patients with TA. The DiGeorge/22q11.2 deletion syndrome has served as an entry to understanding the basis for associated CCVD and craniofacial anomalies, among many other defects. TBX1 has been proposed as a critical gene for CCVD. Although mutations in human patients have been difficult to identify, there is a report of TBX1 mutations in three unrelated CCVD patients without the 22q11 deletion. In addition, a few cases with TA without 22q11.2 deletion resulting from mutation of NKX2.5 or NKX2.6 have been reported.

## Molecular and Systemic Pathophysiology

During the fifth week of human development, the embryonic truncus arteriosus, or the outflow tract of



**Truncus Arteriosus. Figure 1** Anatomic illustration of the normal heart (a) and the truncus arteriosus (b). The truncus arteriosus is subdivided into three types depending on the basis of the anatomic origin of the PA: (c) type I (most common), (d) type II, and (e) type III. (f) shows the anatomy of "pseudotruncus arteriosus (or type IV)," which represents a form of pulmonary atresia with VSD. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; RA, right atrium; RV, right ventricle; TA, truncus arteriosus; TV, truncal valve; VSD, ventricular septal defect.

the embryonic heart, is divided into two channels: the proximal ascending aorta and the pulmonary trunk. Partitioning of the truncus arteriosus begins, when mesenchymal cell proliferation forms endocardial ridges (the truncal ridges distally and the bulbar ridges proximally). cNCC migrate from the hindbrain region to these ridges through the third, fourth, and sixth pharyngeal arches. The truncal and bulbar ridges then grow and twist around each other in a spiral fashion and eventually fuse to form the aorticopulmonary septum that produces the normal relationship of the great arteries with the left and right ventricles. Recent studies in chick and mouse embryos have identified a previously unrecognized SHF, located in the ventral midline splanchnic mesoderm, which provides the myocardium with the embryonic truncus arteriosus resulting in the elongation and appropriate alignment of the outflow tract.

When the process described above is deficient, various conotruncal defects may occur such as TA, which results from complete failure of the aorticopulmonary septum formation. Ablation of the cNCC in chick leads to failure of partitioning the embryonic truncus arteriosus and disrupts conotruncal development by interfering with addition of the myocardium derived from the SHF, resulting in conotruncal defects, most commonly the TA.

### Diagnostic Principles

The majority of patients have minimal cyanosis upon presentation. Signs of congestive heart failure (CHF) develop within several weeks of life as a result of increased pulmonary blood flow (PBF). Auscultation is characterized by a normal S1, a loud and single S2, and typically a holosystolic murmur at the left lower sternal border. Diastolic murmurs occur secondary to truncal valve insufficiency. Continuous murmurs are noted if there is ostial stenosis of pulmonary artery (PA), and these patients may present with cyanosis due to reduced PBF. Echocardiography demonstrates a large VSD directly under the truncal valve and a large single great truncal artery arising from the heart with the posterior branching of the PA from the truncus. An echocardiogram provides complete diagnosis, including the type of truncus, degree of PBF, truncal valve function, and associated anomalies.

### Therapeutic Principles

Treatment includes medical management of CHF with diuretics and digitalis, and early corrective surgery. The surgical repair of TA involves closure of the VSD, separating the PA from the truncus, and creating a connection from the right ventricle to the PA using a valved conduit. Truncal valve repair is required in case of severe truncal regurgitation.

### Synonyms

Intestinal tryptophan malabsorption; Hartnup disorder

## Definition and Characteristics

Abnormal tryptophan availability can be seen in subjects with fructose malabsorption [1] and in patients with Hartnup disorder (OMIM 234500). While subjects with fructose malabsorption have a reduced intestinal absorption of tryptophan due to chemical affinity between tryptophan and high intestinal fructose concentrations, patients with autosomal recessive Hartnup disorder do have a disturbed neutral amino acid transporter. The proposed transporter is named SLC6A19 which is a sodium-dependent and chloride-independent transporter expressed predominately in kidney and intestine, with properties of system B(0).

## Prevalence

Fructose malabsorption nowadays affects about 30% of the population in Western Europe, data from other countries are not yet available. Hartnup disease has an incidence of approximately 1 in 33,000, but epidemiologic data are only scarce. Population frequencies for the most common mutated SLC6A19 alleles are 0.007 for 517G → A and 0.001 for 718C → T [2].

## Genes

Fructose absorption is mediated by the facilitative fructose transporter GLUT-5. So far there were no genetic mutations described for this clinical entity.

A gene causing Hartnup disorder has been localized to chromosome 5p15.33 and a new gene, (SLC6A19) was cloned in this region. Seow et al. identified six mutations in SLC6A19 associated with the disease in a recessive manner, with most affected individuals being compound heterozygous [2].

## Molecular and Systemic Pathophysiology

Fructose malabsorption is characterized by a defect of the GLUT-5 transporter leading to high fructose concentrations in the intestine. Then fructose can attract tryptophan and form a fructose–tryptophan complex which cannot be absorbed by the neutral amino acid transport system leading to lower serum tryptophan concentrations.

Hartnups disease-causing mutations lead to a reduced neutral amino acid transport function in the intestine and in the kidney. Its constant feature is a specific hyeraminoaciduria that is caused by a diminished capacity for renal reabsorption of neutral amino acids. In most affected individuals there is also a reduced intestinal absorption of at least some of the neutral amino acids and of the amino acid tryptophan.

## Diagnostic Principles

Malabsorbed fructose reaches the large intestine and is metabolized to $CO_2$, short chain fatty acids and molecular hydrogen ($H_2$), which can be measured in the expired breath. The $H_2$-breath test is the gold standard in the diagnosis of fructose malabsorption and is most widely applied in clinical practice. Genotyping for GLUT-5-transport-defects is not readily available.

The diagnosis of Hartnups disease is based on biochemical rather than clinical abnormalities. A characteristic pattern of neutral aminoaciduria is the only constant feature on which diagnosis is based on. Molecular diagnosis of SLC6A19 polymorphism is not available for routine clinical diagnosis.

## Therapeutic Principles

Therapy of fructose malabsorption is based on the avoidance of fructose and/or sorbitol containing products such as fruits, honey and industrial products that are enriched with fructose. Daily uptake of fructose should be less than 5 g/day.

Hartnups disease is treated with nicotinic acid or, better nicotinamide in patients who have clinical signs suggesting a deficiency of this vitamin. This treatment has been used with dosages from 50 to 300 mg/day. In addition to nicotinamide, a high-protein diet or protein supplementation might be beneficial in some instances, particularly in patients with low plasma amino acid levels. Intravenous nutrition has been beneficial in correcting an eczematous rash in one patient [3].

### Synonyms

Tubercule bacillus (TB); Consumption; White plague; Phthisis; Scrofula; King's evil; Pott's disease (spine); Tabes misenterica (abdominal TB); Lupus vulgaris (skin TB); Prosector's wart

### Definition and Characteristics

Tuberculosis is an infectious disease caused by the bacterium Mycobacterium tuberculosis (Mtb) that primarily infects lungs. The symptoms of active disease are progressive and prolonged cough along with hemoptysis, occasional chest pain, chill, night sweat, fatigue, and weight and appetite loss. Extra-pulmonary infection occurs in skin, central nervous system, lymphatic system, genitourinary system, bones, etc. Co-existence of pulmonary and extra-pulmonary TB is also not uncommon. Mtb is a Gram-positive, acid-fast, facultative intracellular pathogen with a slow generation time of 15–20 h in macrophages and ~23 h in different culture media.

### Prevalence

Nearly 75% infected individuals develop pulmonary TB. It is more prevalent in developing countries irrespective of the age group than in developed countries. Extra-pulmonary TB is common in the HIV-infected population. WHO estimate showed that that every year ~2 million people die, ~8 million new cases appear where ~0.5 million are multi-drug resistant. Mtb is transmitted through air-borne droplet nuclei generated by sneezes/coughs of an individual with active disease. Upon inhalation of droplets, bacilli reach the alveoli of the lung, multiply, and spread through lymphatic fluid to the lymph nodes, and through blood to other sites.

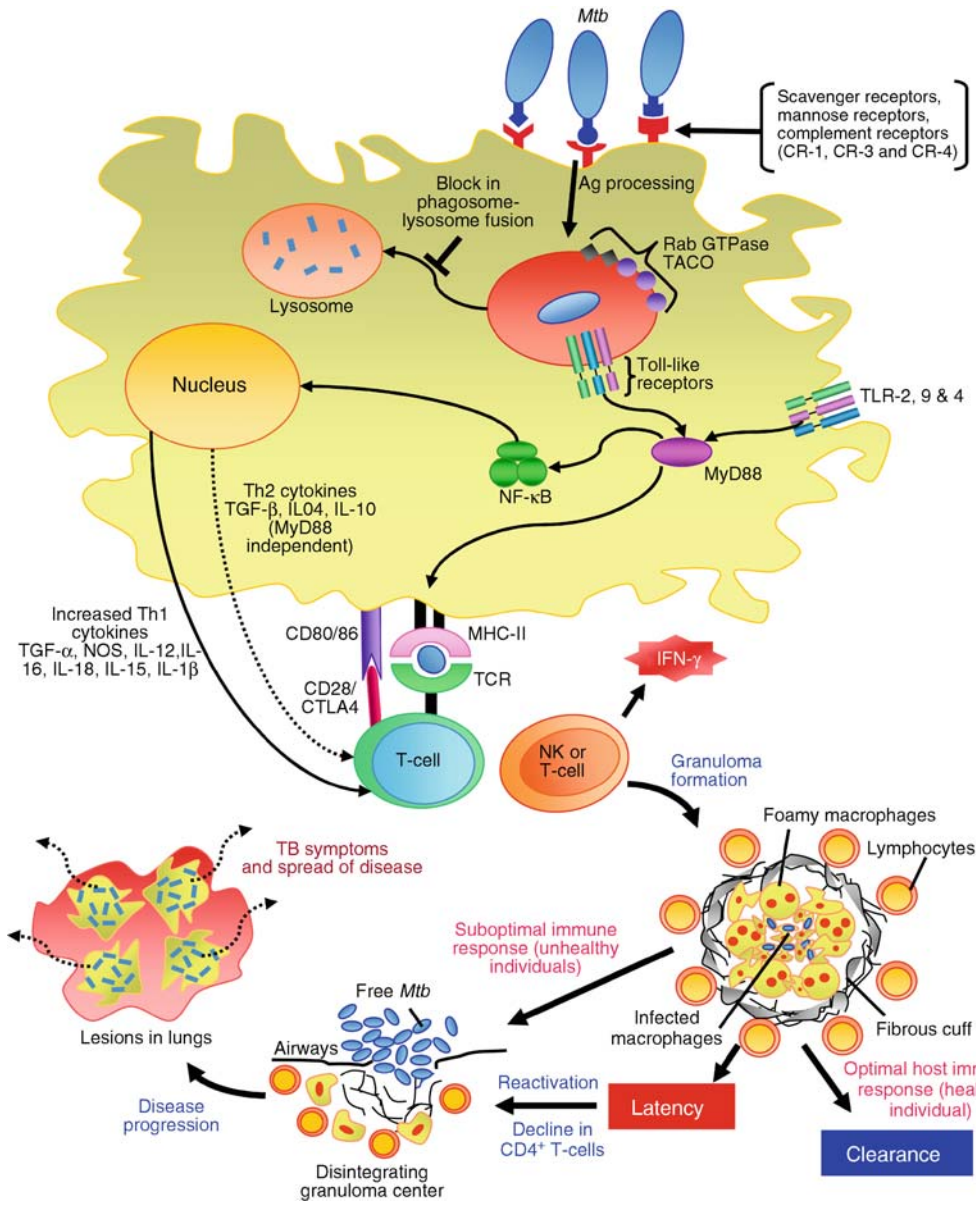
### Genes

The genome of Mtb is highly G+C rich and comprises of 4,411,529 bp. It contains ~4000 genes, where 15.3% codes for proteins of unknown function and 22.9% are of conserved hypothetical functions [1]. Some of the major class of genes involved in virulence and pathogenesis are: secretion and envelope functions e.g. esat6, cfp10, glnA1 etc., enzymes of fatty and mycolic acid metabolism, metal uptake genes e.g. mgtC, mbtB, ideR etc., anaerobic respiration and oxidative stress e.g. narG, katG, ahpC, sodA/C etc., transcriptional regulators e.g. sigF/H, hspR etc., genes involved in cellular signaling e.g. protein kinases etc.

### Molecular and Systemic Pathophysiology

Mtb is an intracellular pathogen and resides in alveolar macrophages. The infection is through phagocytosis, which is assisted by both bacterial and host receptors. Within macrophages, Mtb arrests the phagosomal maturation thus escaping destruction by lysosomal enzymes. The process enables Mtb to form a niche, where it survives and replicates. The phagosome–lysosome fusion is prevented by altered protein content of the vacuole, e.g., Rab GTPase composition, exclusion of the vacuolar proton ATPase, and retention of TACO. Uptake of Mtb by macrophages and subsequent retention of TACO in the mycobacterial phagosome has been shown to depend upon the accumulation of host-derived cholesterol in the plasma membrane at the point of pathogen entry [2]. Recently, an eukaryotic-like Ser/Thr protein kinase G and many lipid components of Mtb cell wall have also been shown to participate in the inhibition of mycobacterial phagosome maturation [3]. Innate immune system of the host generally responds to TLR (Toll-like receptor) agonists, e.g., LPS for TLR4,

†Equal contributions



**Tuberculosis. Figure 1** Molecular events in Mycobacterium tuberculosis infection, host immune response, and disease development Mtb adheres to macrophages with the help of several receptors, and after internalization resides in phagosomes. Following phagocytosis, Mtb alters the vacuolar protein content to prevent phagosome and lysosome fusion. However, in the majority of the cases, macrophages process and present the Mtb antigens via MHC-II to T cells. The co-stimulatory signals result in the activation of T cell-mediated immune response. Simultaneously, the TLR-dependent innate immune response is stimulated by the interaction of TLRs with pathogen-associated TLR agonists on the cell surface as well as in the phagosome; subsequently TLR-MyD88 signaling mounts a rapid response to produce pro-inflammatory Th1 cytokines like TNF-α, INOS, IL-12, IL-16, IL-18, etc. by the activation of NF-κB. Inflammatory cytokines also help in the activation and maturation of T cells. The T and NK cells produce IFN-γ, which regulates the production of Th1 cytokines from activated macrophages. Under optimal immune response, Mtb infection is limited and bacilli remain confined to a special structure called "granuloma." The granuloma consists of a central mass of infected macrophages surrounded by foamy macrophages, other mononuclear phagocytes, and is enveloped by lymphocytes along with a fibrous cuff of collagen and other extracellular matrix that forms the boundary of the structure. The granuloma facilitates destruction or containment (latency) of bacilli depending upon the immune status of the host. The containment fails when the host mounts a suboptimal immune response mainly due to impaired function of $CD4^+$ T cells, resulting in active disease or reactivation of latent bacilli through disintegration of granuloma. Finally, viable and infectious bacilli are spread into the airways leading to transmission and clinical manifestation of the disease.

lipoteichoic acid, peptidoglycans, and muramyl-dipeptide for TLR2 and heat shock proteins for TLR2 and TLR4. Mannans and β-glucans receptors also play an important role in the immune recognition. The interaction of these receptors, particularly the TLRs with myeloid differentiation factor 88 (MyD88) or other cellular factors, e.g., TRIF, SYK, etc., lead to the translocation of nuclear factor-κB (NF-κB) from cytoplasm to nucleus; where NF-κB activates the transcription of pro-inflammatory cytokines, e.g., TNF-α, INOS, IL-12, IL-16, IL-18, IL-15, IL-1β, etc. [4,5]. Production of TNF-α and inflammatory chemokines orchestrates the adaptive response, which results into the recruitment of series of neutrophils, natural killer T cells, $CD4^+$, and $CD8^+$ T cells. The recruited cells produce specific cytokines that amplify cellular recruitment and containment of the infection. The inflammatory cascade thus generated is regulated through a specific cellular immune response that is mediated by the production of IFN-γ. These sequences of events result in the formation of granuloma that contain Mtb (Fig. 1) [6]. Depending upon the host immune response, granuloma either facilitates clearance of bacilli or restricts it in the latent state. Reactivation of the disease occurs due to the altered immune status that is mainly associated with the impaired function of $CD4^+$ T cells as a manifestation of age, malnutrition, or co-infection with HIV. At this stage, a resuscitation promoting factor (rpf) is activated in Mtb, which helps in the reactivation of the virulence properties of the bacilli. Following such changes, granuloma decays into a structureless mass and ruptures. In the process, large number of infectious bacilli are transmitted into the airways, resulting into disease symptoms and transmission of infectious bacilli through aerosol.

### Diagnostic Principles

The preliminary diagnosis of TB is based on antibody test, where the purified protein derivative (PPD) of Mtb is injected to the skin of an individual (Mantoux test) and hypersensitivity reaction is monitored. In case of an infected individual the area around the injection turns hard, swollen, and red within 1–3 days. To confirm the PPD test result and clinical manifestation of the disease, chest X-ray is carried out, where advanced stage of infection is shown as enlarged lymph nodes and numerous white irregular areas against a dark background. Culturing Mtb followed by acid fast staining is another useful tool to diagnose TB bacilli. The molecular techniques such as PCR and nucleic acid probes are often used to detect mycobacterial DNA in patient specimens. The genetic-based susceptibility testing is used for the identification of drug-resistant strains of Mtb.

### Therapeutic Principles

The antibacterial drugs, isoniazid, streptomycin, pyrazinamide, ethambutol, rifampin, etc. are used in different combinations. Cycloserine has been recommended as a second line drug. However, proper supportive treatment in the form of all essential nutritional supplements like proteins, vitamins have to be administered. A new drug gatifloxacin is in the third phase of clinical trial. BCG vaccine is routinely used but the efficacy varies with the population and age. However, novel DNA vaccines are under trial.

## Tuberous Sclerosis

►Tuberous Sclerosis Complex

## Tuberous Sclerosis Complex

Ralf Wienecke
Department of Dermatology, Tuberous Sclerosis Center, Ludwig-Maximilian-University, Munich, Germany

### Synonyms

Tuberous sclerosis; Bourneville-Pringle's disease

### Definition and Characteristics

Autosomal dominant tumor-associated syndrome leading to the formation of numerous hamartomas in

multiple organs. The clinical appearance is highly variable. Hamartomas of the brain, which may take the form of giant cell astrocytomas, may lead to epilepsy and mental retardation; hamartomas of the kidneys can cause renal insuffiency, and hamartomas of the heart may cause arrhythmia and cardiac insufficiency. About 25% of the patients are not mentally affected and do not suffer from epilepsy. A clinical hallmark are numerous angiofibromas of the face.

## Prevalence

The estimated prevalence is 1:5,000 to 1:10,000. Half of the cases are familiar, the other half sporadic.

## Genes

Tuberous sclerosis is caused by a heterozygous mutation of the tuberous sclerosis complex gene-1 or -2 (TSC1 or TSC2) on Chromosome 9q34 (TSC1) and 16p13.3 (TSC2). TSC1 and TSC2 are tumor suppressor genes. In most hamartomas, a loss of the healthy TSC1 or TSC2 allele could be shown.

## Molecular and Systemic Pathophysiology

TSC1 encodes for hamartin and TSC2 encodes for tuberin. Hamartin and tuberin stabilize each other and are believed to form a functional complex that requires both proteins. The absence of either of the proteins is sufficient to cause the biological effects such as increased cell size. Therefore the phenotype of TSC1- and TSC2-mutations is almost identical, although it may be more severe in patients with a TSC2-mutation. Hamartin and tuberin have been shown to be part of the PI3kinase/akt pathway. Tuberin is inactivated by akt. Tuberin inactivates the target of rapamycin (TOR) or its downstream targets. A lack of tuberin leads to a constitutive activation of the TOR pathway. Therefore the function of tuberin can be substituted at least partly by rapamycin. TSC1/2 have been shown to suppress cell proliferation, differentiation and growth as well as angiogenesis.

## Diagnostic Principles

*Major diagnostic criteria*: Facial angiofibromas or connective tissue nevi of the forehead, non-traumatic (peri)ungual angiofibromas, three or more hypomelanotic macules, sacral connective tissue nevus, multiple hamartomas of the retina, cortical dysplasia, subependymal giant cell astrocytomas, cardiac rhabdomyomas, pulmonal lymphangiomyomatosis, renal angiomyolipomas.

*Minor diagnostic criteria*: Multiple enamel defects, harmartous rectal polyps, bone cysts, radial stripes of the white brain matter, gingival hyperplasia, non-renal hamartomas, retinal achromatic macule, confetti-type depigmentation, multiple renal cysts.

*Definitive tuberous sclerosis*: Two major criteria or one major criterion and two minor criteria. Probable tuberous sclerosis: One major and one minor criterion. Possible tuberous sclerosis: One major or two minor criteria.

## Therapeutic Principles

Symptomatic anti-epileptic treatment including brain surgery, if seizures cannot be controlled by anticonsulsive medication. Regular examinations of the brain and the kidneys. If necessary, surgical treatment of cerebral, renal, cardiac, pulmonal and dermal hamartomas. Clinical trials using rapamycin as a possible drug for tuberous sclerosis have been initiated. Rapamycin has been shown to substitute tuberin at least partially in tissue culture systems. Renal tumors of rats with tuberous sclerosis can be cured with rapamycin.

# Tubular Acidosis

Giovambattista Capasso
Department of Medicine, Second University of Naples, Naples, Italy

## Synonyms

Proximal renal tubular acidosis; Distal renal tubular acidosis; Hyperkalemic renal tubular acidosis

## Definition and Characteristics

The term renal tubular acidosis (RTA) is reserved for those forms of hyperchloraemic acidosis with normal anion gap that occur in the absence of renal failure and diarrhea [1]. Four main types are discriminated, named in the order that they were first recognized. Type I RTA is a disorder of the distal nephron (dRTA); it is associated with clinically significant hypokalemia, medullary nephrocalcinosis, recurrent stone disease. Type II RTA is a disorder of the proximal nephron

(pRTA), typically manifests as part of a generalised defect of proximal tubule function, namely the renal Fanconi syndrome. Isolated pRTA occurs rarely and usually presents as growth retardation in childhood. Type IV RTA is associated with deficient ammonia production and hyperkalemia. It is the most common form of RTA seen in clinical practice and it is caused by various renal disorders. Type III RTA has a mixed phenotype of proximal and distal RTA and it has been associated with a defect in carbonic anhydrase.

## Prevalence

It is highly variable. In northeast of Thailand a recent survey suggested that 2.8 percent of the general population might be affected.

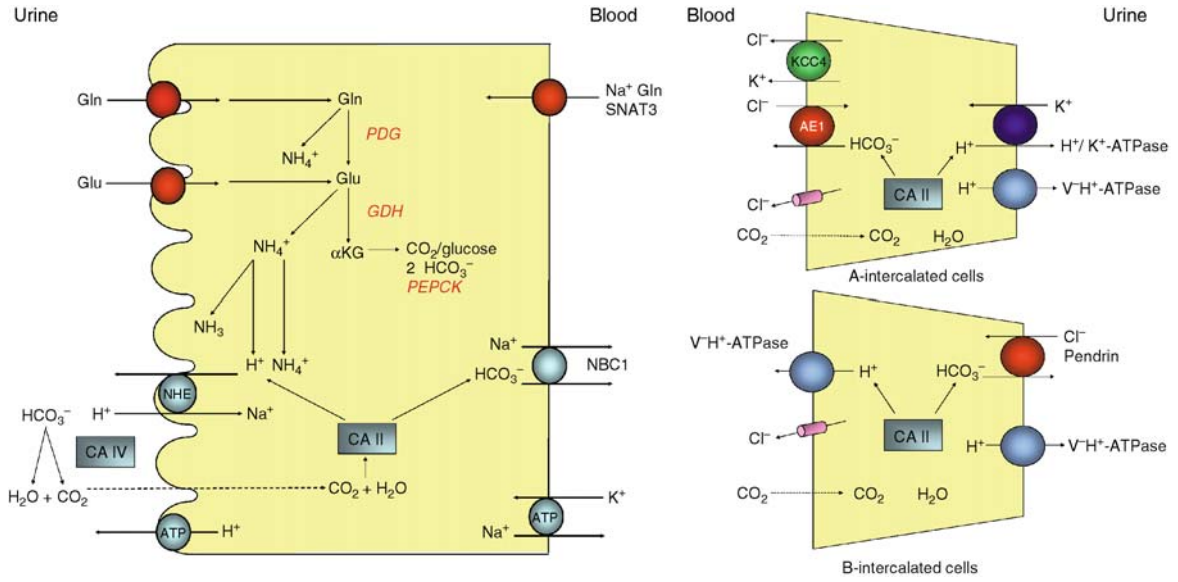
## Molecular and Systemic Pathophysiology

In dRTA, the process of distal nephron net acid secretion is impaired thus leading to a high urine pH. Urinary acidification, along this segment, is dependent from two transport proteins, the vacuolar $H^+$-ATPase and the $Cl^-$-$HCO_3^-$ exchanger (AE1), both localized in the intercalated cells (IC) of the connecting and collecting tubules (Fig. 1) [2].

Mutations in two different subunits of the vacuolar $H^+$-ATPase, the A4 and the B1 subunit, encoded respectively by the ATP6V0A4 and ATP6V1B1 genes, cause the recessive forms of inherited dRTA (Table 1).

Sensorineural hearing loss accompanies the renal acidification defect in most affected kindreds with mutations of the B1 subunit, most likely because of loss of function of the protein in the cochlea and endolymphatic sac, which results in alteration of the normally acidic endolymphatic pH. The hearing loss is milder in patients affected by the A4 subunit defect.

Mutation of AE1, encoded by the gene SLC4A1, causes a dominant form of dRTA. The $Cl^-$-$HCO_3^-$ exchanger is expressed both in red blood cells (RBC) and in acid-secretory type A-IC. Due to this expression pattern, mutations in the AE1 gene cause spherocytosis, Southeast Asian ovalocytosis and dRTA. However, with rare exceptions, only either RBC or the kidney are affected. This may be partially explained by the fact that



**Tubular Acidosis. Figure 1** Scheme of the proximal tubular cell and type A and B intercalated cells. T

missorting of AE1 would obviously not affect AE1 function in the non-polarized RBC, but reverse the physiological direction of transport in the polarized renal epithelial cells. Recently, also a recessive form of dRTA has been described, which is linked to AE1 mutation in subjects from Northeastern Thailand affected by haemolytic anaemia [3]. Acquired dRTA is often secondary to autoimmune diseases, such as Sjogren's syndrome.

In the complete forms of both dominant and recessive dRTA, bone disease is common as well as nephrocalcinosis complicated by renal stone. The occurrence of renal stones is attributed to the combination of hypercalciuria, low urinary citrate excretion (due to the systemic and intracellular acidosis) and high urine pH, all favoring calcium phosphate stone formation. Hypokalaemia is present though its cause is still unclear.

With respect to pRTA, they are usually associated with the Fanconi syndrome. The inherited forms are due to the accumulation of metabolites in the proximal tubule cells that eventually interfere with the proximal tubule function. The most commonly inherited defect is cystinosis. Other causes include tyrosinemia and some forms of glycogen storage diseases.

The isolated forms of pRTA are due to defects in genes encoding for proteins involved in proximal tubular bicarbonate reabsorption. The renal $Na^+/HCO_3^-$ co-transporter, NBC1, expressed in the basolateral membrane of the proximal tubule, is responsible for most of the$HCO_3^-$ transport across this membrane. It is also expressed, at a low level, in the cornea and duodenum. Mutations in the gene SLC4A4, encoding NBC1, cause an autosomal recessive form of proximal RTA characterized by bicarbonate wasting and ocular abnormalities. Affected patients have cataracts, glaucoma, and band keratopathy, likely reflecting increased bicarbonate in the cornea predisposing to pathologic calcium carbonate precipitation. Patients with pRTA frequently show hypokalemia due to the osmotic diuretic effect of the higher luminal $HCO_3^-$. Nephrocalcinosis and renal stones are less common than in dRTA, perhaps due relatively normal citrate excretion [4].

Mutations in the gene CA2, encoding carbonic anhydrase II, result in autosomal recessive RTA with a mixed phenotype of proximal and distal RTA, because the enzyme is present in the cytosol of both, proximal and distal, cells. This RTA resembles type 3 RTA and it is characterized by cerebral calcification and osteopetrosis due to the disruption in the normally balanced processes of bone formation and bone reabsorption.

## Diagnostic Principles

In dRTA, distal nephron net acid secretion is impaired. This leads to a high urine pH, even in the presence of systemic acidosis. The defect in renal acid excretion must be demonstrated by a failure to lower urine pH below 5.5 following an $NH_4Cl$ load or a modified furosemide test.

In pRTA, reabsorption of bicarbonate is reduced, leading to urinary bicarbonate wasting and a high urine pH. The consequent decrease in plasma $HCO_3^-$ levels lowers the amount of filtered $HCO_3^-$ and urine pH eventually becomes more acid. The loss of $HCO_3^-$ can be evaluated by intravenous loading with $NaHCO_3$; a fractional excretion of $HCO_3^-$ higher than >15% is indicative of pRTA [5].

## Therapeutic Principles

In the dRTA correction of metabolic acidosis may be achieved by administration of alkali, preferentially in the form of potassium citrate especially for those patients with persistent hypokalemia or with calcium stone disease. The treatment of pRTA is quite difficult due to the rapid urinary excretion of bicarbonate, even when it is administered in large amounts. The use of thiazide diuretics, inducing volume depletion, may enhance the effectiveness of alkali therapy. Thiazide diuretics may be useful also in the treatment of hyperkalemic RTA by their specific action to increase distal $Na^+$ delivery and consequently stimulate $K^+$ and $H^+$ secretion.

# Tuftsin Deficiency

Mauro Bernardi, Franco Trevisani
Dipartimento di Medicina Interna, Cardioangiologia, Epatologia, Alma Mater Studiorum Università di Bologna, Bologna, Italy

## Definition and Characteristics

Tuftsin is a biologically active tetrapeptide (Thr-Lys-Pro-Arg) that stimulates the functions of macrophages and polymorphonuclear granulocytes, such as motility,

phagocytosis, immunogenicity, hexose monophosphate shunt activation and bactericidal and tumoricidal activities [1]. Tuftsin deficiency can be both congenital and acquired.

The congenital form derives from a mutation in tuftsin tetrapeptide. The clinical manifestations are related to widespread infections, which are particularly severe in early childhood, while adults only present with mild symptoms or can even be asymptomatic. The most common infections involve the respiratory tract (pharingytis, tonsilitis, bronchitis, pneumonia) and skin and can be complicated by septicemia. Streptococcus pneumoniae, Staphylococcus aureus and Candida albicans are the most frequent causative agents [2].

Acquired tuftsin deficiency has been documented in different conditions sharing a reduced splenic function, such as splenectomy, myelocytic leukemia or myelofibrosis, idiopathic thrombocytopenic purpura, sickle cell disease, acquired immunodeficiency syndrome and acquired immunodeficiency syndrome related complex, short bowel syndrome, coeliac disease and liver cirrhosis [2–4]. All these conditions are characterized by increased susceptibility to bacterial infections and it is likely that tuftsin deficiency contributes to this abnormality.

## Prevalence

Congenital tuftsin deficiency is rare and its current prevalence is unknown. Five affected families in the United States (four) and Japan have been described to date. The prevalence of the acquired deficiency varies with the clinical condition of the underlying disease. Mild to severe tuftsin deficiency ranges from 40% in liver cirrhosis patients belonging to Child-Pugh class A to 100% in class C. Up to 90% of patients with AIDS have reduced tuftsin activity, which is also found in 80% of patients with short bowel syndrome and 65% of those with untreated celiac disease with splenic hypofunction.

## Genes

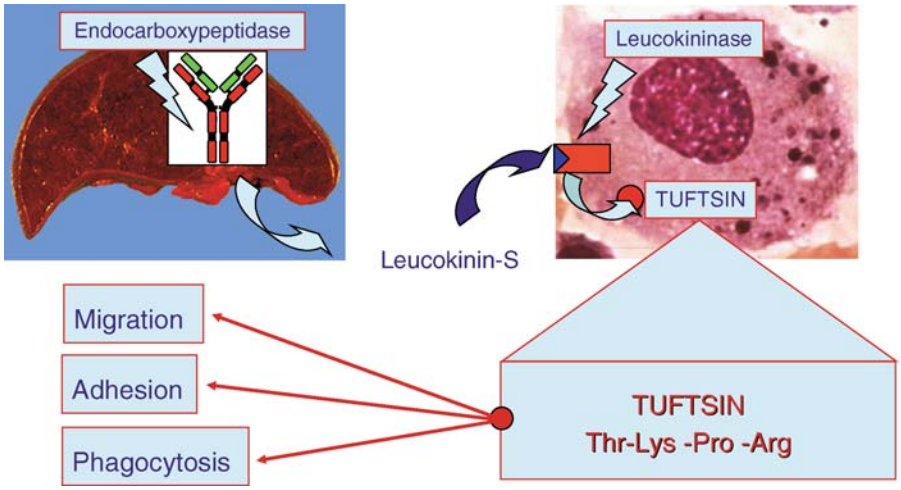
A tuftsin tetrapeptide mutation consisting in the replacement of the second residue lysine by a glutamic acid residue was identified in one case of congenital tuftsin deficiency [1].

## Molecular and Systemic Pathophysiology

Tuftsin is a part of the Fc region of the heavy chain (residues 289–292) of leucokinin, a leucophilic gammaglobulin of $\gamma G_1$ class. Tuftsin activation is triggered by two enzymes, one located in the spleen, the second on the surface of target cells, leading to tuftsin release (Fig. 1). Tuftsin then stimulates cell functions by binding with specific cell receptors.

Tuftsin deficiency may derive from anomalies such as (i) alteration of molecular structure, (ii) inactive or absent leucokininase, (iii) inactive or absent endocarboxypeptidase, (iv) anatomical or functional asplenia or (v) defective binding with the membrane receptor in target cells.

Only type (i) deficiency has been documented in the congenital form. Interestingly, minor structural changes



**Tuftsin Deficiency. Figure 1** Scheme of the tuftsin pathway. Tuftsin, located in the Fc region of the heavy chain of leucokinin, undergoes cleavage at its carboxyl terminus from the adjacent part of the molecule by a specific enzyme (tuftsin endocarboxypeptidase) during circulation in the spleen. Tuftsin is then transported as an integral part of the leucophilic IgG to target cells, where the leucokinin molecule binds to the membrane Fc receptor. There, tuftsin is cleaved at the $NH_2$-terminus from the Fc portion by the specific protease leucokininase. Once released, it binds to a specific membrane receptor resulting in stimulation of target cell functions.

in the tuftsin molecule not only impair or abolish activity, but can also have an inhibitory function.

Acquired deficiency is linked to surgical splenectomy, atrophy (as in coeliac disease), extensive parenchymal damage (i.e., infarction or neoplastic infiltration) or hypofunction (as in intestinal failure on long term intravenous nutrition). Interestingly, functional hyposplenism can also occur in patients with cirrhosis, despite splenomegaly and hematological hypersplenism [4]. The actual mechanisms underlying this abnormality are not fully defined, but liver transplantation, presumably by resolving portal hypertension, restores tuftsin activity. It is worth noting that splenectomy after accidental rupture of the spleen usually leads to a moderate reduction in tuftsin activity, probably due to scattering of splenic pulp into the peritoneum, while severe deficiency can be seen after elective splenectomy [3]. The clinical counterpart is that overwhelming infections do not occur after post-traumatic splenectomy, whereas they are an ominous complication of elective splenectomy.

### Diagnostic Principles

Congenital tuftsin deficiency can be suspected in children undergoing overwhelming infections without an apparent predisposing condition. The acquired form is present in the diseases associated with splenic atrophy or hypofunction and is certain in splenectomized individuals, especially after elective splenectomy. Tuftsin assay is generally performed by phagocytosis assay. A far more accurate radioimmunoassay has been devised, but is only available in the research setting. An indirect way to suspect tuftsin deficiency consists in assessing splenic function by counting erythrocytes with indentations (pitted cells), which are normally removed by the spleen.

### Therapeutic Principles

Tuftsin tetrapeptide is not available for use in humans and its administration has been limited to experimental studies in animals. Repeated doses (4–6 weeks apart) of pooled γ-globulin have been successfully employed as a substitute in patients with mutated tuftsin molecule, but this treatment is likely to be ineffective in acquired deficiency, due to the absent or reduced activity of splenic endocarboxipeptidase.

Interestingly, tuftsin has been grafted on the surface of liposomes used as antibiotic carriers, which are known to accumulate in the mononuclear phagocyte system [5]. With this technique, the natural killer activity of these cells has been enhanced and proved to be highly effective in experimental settings against infectious agents such as Lehismania donovani, fungi (Aspergillus fumigatus, Candida albicans, Criptococcus neoformans), Mycobacterium tuberculosis and Plasmodium malariae.

## Tyrosinemia Type I

Kimitoshi Nakamura, Shiro Matsumoto, Hiroshi Mitsubuchi, Fumio Endo
Department of Pediatrics, Kumamoto University Graduate School of Medical Science, Kumamoto, Japan

### Synonyms

Hereditary tyrosinemia type I; Fumarylacetoacetate hydrolase deficiency; FAH deficiency; Fumarylacetoacetase deficiency; Hepatorenal tyrosenemia

### Definition and Characteristics

Tyrosinemia type I is an autosomal recessive disorder that causes liver and kidney dysfunction by defect of fumarylacetoacetate hydrase. The disease is characterized by abnormal gene expression, inhibition of enzyme activity, apoptosis, chromosomal instability, and cancerous changes in the liver.

### Prevalence

Tyrosinemia type I affects ~1 in 100,000–120,000 births. Relatively high incidence is observed in French-Canadian population, in Norway, and in Finland.

### Genes

The disease is caused by a defect of the fumarylacetoacetate hydrase gene, located in chromosomal locus of 15q23-q25. The gene extends more than 35 kb with 14 exons and codes for a protein predicted to have 419 amino acids. Expression of the gene is detected abundantly in the liver and renal tubules but is slightly observed in most tissues.

### Molecular and Systemic Pathophysiology

The accumulation of intracellular fumarylacetoacetate leads to the dysfunction of various organs especially in the liver and kidney. Analyses of clinical cases and model mice have revealed details of the pathogenesis of this disease. The disease is characterized by abnormal gene expression, inhibition of enzyme activity, apoptosis, chromosomal instability, and cancerous changes in the liver. These pathological manifestations occur because of the strong toxicity of the accumulating fumarylacetoacetate caused by the intracellular enzymatic defect. It is very likely that the decreased expression of various genes leads to hypoglycemia, amino acid metabolism disorders, and a reduction of coagulation factors. In addition, a high frequency of juvenile liver cancer is associated with chromosomal instability. Cell death by apoptosis finally advances to hepatic failure. Cell damage and dysfunction in proximal tubular cells lead to the development of the symptoms of Fanconi syndrome, such as aminoaciduria, diabetes, and metabolic acidosis. As a result of Fanconi syndrome, hypophosphatemic rickets becomes a clinical problem.

Cell damage is essentially limited to hepatocytes and proximal tubular cells in the kidney. Progressive liver and renal tubular disorders are characteristic clinical features of tyrosinemia type I. The type I is classified into acute, subacute, and chronic forms. The acute form exhibits hepatomegalia, growth retardation, diarrhea, vomiting, and icterus starting from a few weeks after birth. Severe cases in the acute form progress to hepatic failure and either die at 2 or 3 months of age or require liver transplantation. Hepatic tumor appears in a considerable number of cases. Multiple tumors in the liver are found in some cases. Hepatic disorder is evident by several months to one year of age in the subacute form. Slowly progressive hepatomegaly and functional liver impairment characterizes the chronic form. The liver progresses to cirrhosis and hepatic failure with advancing disease. Renal tubular dysfunction such as Fanconi syndrome appears in the acute to chronic forms. The renal disorders are accompanied by low phosphorus rickets, or vitamin D-resistant rickets. In addition, acute intermittent porphyria-like symptoms such as abdominal pain and polyneuropathy appear as a result of inhibition of aminolevulinate dehydratase by succinylacetones. The severity of clinical symptoms is associated with a defect in enzymatic activity caused by a genetic mutation.

### Diagnostic Principles

It is important to identify the presence of any hepatic disorder on a diagnosis of tyrosinemia type I. In the laboratory examination, it is characteristic to find liver functional impairment such as an elevation of aminotransferases, coagulopathy with reduced coagulation factors, and renal tubular dysfunction such as hypophosphatemia, glucosuria, and proteinuria. In addition, an elevation of serum alphafetoprotein is characteristic. Plasma amino acid analysis reveals an increased level of tyrosine, methionine, serine, and threonine as a result of the impairment of various amino acid metabolic pathways. The blood tyrosine level of the patients is

more than 166 μM (3.0 mg/dl), values overlapping with those in transient tyrosinemia. The urinary excretion of many amino acids increases, including tyrosine. Organic acid analysis in the urine reveals a remarkable elevation of 4-hydroxyphenylpyruvic acid, 4-hydroxy phenyllactic acid, and 4-hydroxyphenylpyruvic acetic acid. Excretion of δ-aminolevulic acid in urine increases as a result of a porphyrin metabolic disorder. Hepatomegalia, liver cirrhosis, and fatty liver are characteristic features revealed by imaging analysis. Irregular liver architecture, various shapes of hepatocytes, and fatty liver changes are found on liver biopsy. However, tyrosinemia type I is not diagnosed by these findings alone. It is a highly useful diagnostic test to detect increases of succinylacetone in addition to metabolites of tyrosine by urine organic acid analysis. An enzymatic diagnosis requires measurement of fumarylacetoacetic acid hydrase activities. Liver and cultured skin fibroblasts are suitable for the measurement of such activities. It is important to rule out other hepatic disorders when making a diagnosis of tyrosinemia type I.

## Therapeutic Principles

It is important to prevent the progression of the hepatic disorder in the early stages of disease. NTBC: 2-(2-nitro-4-trifluoromethyl-benzoyl)-1,3-cyclo-hexanedione), which is an inhibitor of 4-hydroxyphenylpyruvic acid oxidase, is commonly used for the treatment of tyrosinemia type I. Together with NTBC, dietary therapy using low phenylalanine and low tyrosine foods, is required. Liver transplantation is frequently avoidable when NTBC treatment is started in the early stages of the disease. The serum alphafetoprotein level and liver function determined by laboratory examination are useful to evaluate the therapeutic effect. A normal range of serum alphafetoprotein achieved with NTBC treatment can lead to an expectation of a relatively favorable prognosis because the serum level of alphafetoprotein reflects the clinical pathology. Hepatic failure is unavoidable if NTBC is not taken, and liver transplantation may be performed in such cases. In addition, liver transplantation may be required in cases with evident liver cancer even if NTBC is used for treatment. Liver cancer and low phosphorus rachitis are not rare complications during NTBC treatment. Liver cancer may occur in the case of applications of NTBC treatment even starting from early stages of the disease. Therefore, screening for liver cancer has to be performed during any course of treatment.

# Tyrosinemia Type II

Kimitoshi Nakamura, Shiro Matsumoto, Hiroshi Mitsubuchi, Fumio Endo
Department of Pediatrics, Kumamoto University Graduate School of Medical Science, Kumamoto, Japan

## Synonyms

Hereditary tyrosinemia type II; Oculocutaneous tyrosinemia; Richner-Hanhart syndrome; TAT deficiency; Tyrosine aminotransferase deficiency; Tyrosine transaminase deficiency

## Definition and Characteristics

Tyrosinemia type II is an autosomal recessive disorder caused by a defect in tyrosine aminotransferase located in the cytoplasm. The disease affects the skin, the ocular cornea, and the central nervous system.

## Prevalence

More than 50 cases have been described in patients of many ethnic and geographic origins.

## Genes

The disease is caused by a defect of the tyrosine aminotransferase gene, located in chromosomal locus 16q22.1-q22.3. The gene extends more than 10.9 kb with 12 exons and codes for a protein predicted to have 454 amino acids. Expression of the gene is strictly limited to the cytoplasm of hepatocytes.

## Molecular and Systemic Pathophysiology

The tyrosine level in body fluids becomes elevated, which in turn causes the clinical manifestations of the disease. A portion of the features of this disease is associated with the low solubility of tyrosine. A relatively lower temperature in the skin and the cornea leads to crystal precipitations in these tissues and causes cellular damage. Mental retardation is observed in many patients. This form of the pathology is related to elevation of blood tyrosine, but the mechanistic details. Metabolites of the tyrosine aminotransferase reaction are paradoxically excreted into urine. The phenomenon is caused by another enzyme, mitochondrial tyrosine aminotransferase (mTAT), located in the mitochondria of the kidney, which is encoded by a different gene.

It is characteristic that the blood tyrosine level is higher in tyrosinemia type II in comparison with type I and III. The liver and renal impairment, which is found in type I is not found in type II. Skin lesions, such as excessive keratinization and erosion often develop in the palm and plantar regions because tyrosine crystals appear in these tissues. In addition, tyrosine crystallization precipitated in the cornea leads to erosion and ulceration. A corneal change is detectable starting from several months of age. The lesion sometimes becomes clear during or after adolescence in some cases. A similar symptom appears in the cornea of rats loaded with a large quantity of tyrosine. Generally, skin symptoms develop later than eye manifestations. Keratinization with pain and erosion are characteristic in skin lesions, which are restricted to the palm and plantar regions. Mental retardation is associated with the blood tyrosine level in some cases. In the case of tyrosinemia type II with a lower tyrosine level, mental retardation is not reported.

## Diagnostic Principles

There are many cases which are diagnosed with findings of skin or ocular lesions. In terms of the ocular symptom, a diagnosis of herpes simplex keratitis sometimes becomes an issue for differential diagnosis. Blood tyrosine is detected at extremely high levels, which mostly exceed 1,100 μM (20.0 mg/dL) in blood amino acid analysis. In addition, a large amount of 4-hydroxyphenylpyruvic acid, 4-hydroxyphenyllactic acid, and 4-hydroxyphenylpyruvic acetic acid is found in the urine by organic acid analysis with GC/MC. The measurement of the level of enzymatic activity requires a liver biopsy. There are two isozymes of tyrosine aminotransferase, sTAT, which is present in the soluble fraction of the cytoplasm, and mTAT, located in mitochondria. sTAT, not mTAT, is defective in this disorder. Therefore, it is necessary to distinguish these isozymes when an enzymatic diagnosis is performed. Differential diagnosis between transient hypertyrosinemia and tyrosinemia type II is important in a diagnosis of the newborn. Neonatal patient of type II should be followed-up in the absence of organ damage.

## Therapeutic Principles

Skin and ocular lesions improve dramatically when the blood tyrosine level is decreased. Therefore, it is effective to restrict dietary intake of phenylalanine and tyrosine. The therapeutic aim of restricted dietary intake is to maintain a blood tyrosine level of less than 10 mg/dL. The blood tyrosine level is used for evaluation of the therapeutic effect. The prognosis for tyrosinemia type II is relatively good compared to type I.

# Tyrosinemia Type III and Hawkinsinuria

Kimitoshi Nakamura, Shiro Matsumoto, Hiroshi Mitsubuchi, Fumio Endo
Department of Pediatrics, Kumamoto University Graduate School of Medical Science, Kumamoto, Japan

## Synonyms

4-Hydroxyphenylpyruvic acid oxidase deficiency; 4-Hydroxyphenylpyruvate dioxygenase deficiency; HPD deficiency

## Definition and Characteristics

Tyrosinemia type III is an autosomal recessive disorder caused by a defect in 4-hydroxyphenylpyruvate dioxygenase [1]. It is characterized by elevated levels of blood tyrosine and massive excretion of its derivatives into urine. Heterozygous mutation of the gene can cause hawkinsinuria.

## Prevalence

More than ten cases have been described. There must be more affected patient without diagnosis because most of the patients are asymptomatic.

## Genes

The disease is caused by defect of 4-hydroxyphenylpyruvate dioxygenase gene, located in chromosomal locus of 12q24-qter [2]. The gene extends more than 21 kb with 14 exons and codes for a protein predicted to have 392 amino acids. Expression of the gene is detected in the cytoplasm of hepatocytes and renal tubular cells.

## Molecular and Systemic Pathophysiology

Tyrosine and its α-keto acid, 4-hydroxyphenylpyruvic acid, are increased. Excretion of 4-hydroxyphenylpyruvic acid into urine is increased remarkably. A mouse model of this disease (III mice) shows a similar level of blood tyrosine compared to the type III patient. The symptoms of tyrosinemia type III are milder than the other forms of tyrosinemia, type I and type II. The clinical manifestations reported include ataxia, convulsions, and mental retardation. However, there is generally a patient of type III without any clinical manifestations. These symptoms are different from type I or II, and an increased level of 4-hydroxyphenylpyruvic acid in body fluid is associated with these symptoms. There is no impairment of the liver, kidney, skin, or eyes.

Hawkinsinuria is an autosomal dominant disorder caused by a heterozygous defect in 4-hydroxyphenylpyruvate dioxygenase. Homozygous mutation of the gene can cause hereditary hypertyrosinemia type III [3]. The disease exhibits transient developmental disturbances and excessive hawkinsin in urine.

## Diagnostic Principles

There is no overt characteristic feature reported for tyrosinemia type III. Increased tyrosine levels range from 355 to 640 μM (6.4–11.6 mg/dl) in blood and excessive excretion of 4-hydroxyphenylpyruvic acid to urine are detected in the type III patient. Enzymatic activity of 4-hydroxyphenylpyruvate dioxygenase in the liver is measured for a definitive diagnosis. Differential diagnosis between transient hypertyrosinemia and tyrosinemia type III is important in the diagnosis of the newborn. Neonatal type III patients should be followed-up if there is no evident organ damage.

## Therapeutic Principles

It is reasonable to restrict dietary phenylalanine and tyrosine. Ascorbate supplementation is also recommended to try. The prognosis for tyrosinemia type III is relatively good.

## Acknowledgments

This work was supported in part by a Grant-in-Aid for Research for the Future Program from the Japan Society for the Promotion of Science; a Grant-in-Aid for Scientific Research and a Grant-in-Aid for 21st Century COE Research (Cell Fate Regulation, Research and Education Unit) from the Ministry of Education, Science, Technology, Sports and Culture; a Grant-in-Aid for Pediatric Research from the Ministry of Health, Labor and Welfare; a Grant-in-Aid for the Ministry of Education, Culture, Sports, Science and Technology; National Agriculture and Bio-oriented Research Organization, Japan.

## Ullrich-Turner Syndrome

GUDRUN RAPPOLD
Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany

### Synonyms

Turner syndrome

### Definition and Characteristics

X chromosomal syndrome with key symptoms of short stature and ovarian failure. High embryonic lethality.

### Prevalence

Ullrich-Turner syndrome is a common chromosomal disorder affecting approximately 1:2,000 live-born females [1,2].

### Genes

X-Y homologoes genes that escape X-inactivation have been predicted as Turner candidate genes. Yet to date only haploinsufficiency of a homeobox gene, SHOX, has been demonstrated unequivocally to lead to short stature and skeletal features in Turner syndrome [3]. The genetic basis for the other somatic stigmates of Turner syndrome remains unknown.

### Molecular and Systemic Pathophysiology

Ullrich-Turner syndrome can be regarded as a "contiguous gene syndrome" with several X-Y homologous genes on the short arm of the X chromosome contributing to the disorder. The wide range of somatic features in Ullrich-Turner syndrome suggests that a number of different genes may be responsible for the complete phenotype. Other than short stature, Ullrich-Turner phenotypes have not been clearly associated with deletions of specific regions of the X chromosome. Several

gene candidates for Ullrich-Turner syndrome, such as ZFX, RPS4X and USP9X, have been brought forward in the past, but none of those was verified. A pseudoautosomal gene, SHOX, has been shown to have a causal role for the short stature and skeletal features seen in Turner syndrome [3, 4]. SHOX represents a homeobox gene and is expressed in the first and second pharyngeal arches and in the forearms and the lower legs of the developing human embryo. The gene is composed of seven exons resulting in at least two isoforms. The SHOX protein levels are regulated by transcriptional and translational control mechanisms. SHOX represents a transcription factor regulating target genes. The lack of one SHOX copy leads to haploinsufficiency. Intragenic mutations within the SHOX gene can cause Léri-Weill Syndrome with a subset of Turner-specific clinical features but are also found in upto 5% of patients with idiopathic short stature.

## Diagnostic Principles

Growth failure, pubertal delay and gonadal dysgenesis are the cardinal clinical features of the syndrome, although many other organ systems and tissues may also be affected to a lesser or greater extent. These include renal and cardiovascular anomalies (coarctation of the aorta, hypoplastic left heart), abnormalities of the skeleton (cubitus valgus, brachymetacarpie, scoliosis) and the eyes (ptosis etc.), ears (sensorineural hearing loss), high-arched palate and micrognathia. Although most common during infancy, lymphedema are frequently seen at any age with webbed neck, low posterior hairline and nail dysplasia further considered as lymphatic defects. Ullrich-Turner syndrome is also associated with a high degree of embryonic lethality with only about 1% of 45,X fetuses surviving to term. Patients with SHOX deletions are usually classified as having Ullrich-Turner syndrome if the deletion extends proximal to Xp22.2. Prenatal and postnatal diagnosis is usually carried out by karyotyping. The presence of centromere-adjacent Y chromosomal material may cause the development of gonadoblastoma. Although the most common forms of mosaicism (45,X/46,XX) may modify the phenotype toward normal, the degree of mosaicism detected in blood is generally not predictive of the severity of the Turner phenotype.

## Therapeutic Principles

Due to the different clinical problems, a multidisciplinary approach to treatment is necessary [5]. Management of short stature is usually by growth hormone treatment and management of puberty by estrogen replacement therapy.

[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Synonyms

Congenital Heinz body hemolytic anemia; UDH

### Definition and Characteristics

Hereditary hemolytic anemia due to unstable hemoglobin, leading to intracellular hemoglobin precipitates detectable as Heinz bodies. Minimal and compensated hemolysis with potential hemolytic crises in response to exogenous factors, as well as life-long significant hemolytic anemia, can be the clinical manifestations of the disease, with pigmenturia (presence of dipyrrole methenes in urine, which are also present in Heinz bodies) often present [1,2].

### Prevalence

Unstable hemoglobin disease (UHD) is rare with unknown prevalence and even though more than 200 unstable variants have been reported, less than half gives rise to symptomatic disease. The most common variant is Hb Köln (<b >98 Val→Met), which has a worldwide distribution [1,2].

### Genes

Mutations (usually single amino acid replacements) reported in genes coding for < a > (16pter-p13.3), < b > (11p15.5), < g > (11p15.5) and rarely < d > (11p15.5) hemoglobin chains [1,2].

### Molecular and Systemic Pathophysiology

Inheritance follows autosomal dominant pattern. Mutations responsible for UHD result in major conformational changes in the hemoglobin molecule. Mutations can either weaken or change the heme–globin interaction, or interfere with the secondary, tertiary, or quaternary hemoglobin structure (excellently reviewed and illustrated in [1]). Upon febrile illness or exposure to drugs with oxidant potential, or spontaneously, unstable hemoglobins oxidize and form methemoglobin. Even though "normal methemoglobin (see Methemoglobinemia)" is a stable structure, in UHD, hemichromes are formed (characterized by interactions between heme ligand binding site and a nitrogen atom on the globin chain). Precipitation of hemichromes leads to characteristic (but not specific) Heinz bodies. Attachment of Heinz bodies to the cytosolic membrane limits cellular deformability and is accompanied by an increment in membrane permeability. Heinz bodies are selectively removed by the spleen leaving damaged erythrocytes, thereby contributing to the hemolytic process. Other potential factors that contribute to red cell destruction are antibody recognition of Heinz body containing red cells and damage to red cell constituents due to formation of radicals. Most variants are characterized by a change in oxygen affinity. It is usually increased, leading to clinical symptoms of anemia despite normal hemoglobin levels. Therefore, symptomatology does not always correlate to hemoglobin concentration. UHD can be classified according to the severity of symptoms and expected response to splenectomy (reviewed in [2]).

### Diagnostic Principles

Heinz bodies are not diagnostic of UHD, occurring in various other congenital and acquired forms of hemolytic anemia. Both the heat stability test and the isopropanol test (in both, stress is induced upon the hemoglobin molecules) are simple screening tools based upon detection of intraerythrocytic precipitates. Hemoglobin electrophoresis may be helpful in characterization of unstable hemoglobins, but is not sensitive. Precise identification of the variants employing DNA analysis may be required when considering splenectomy in a specific patient [1,2].

### Therapeutic Principles

These are supportive (folic acid supplementation, transfusion) and preventive. Splenectomy is considered in severely affected patients [1,2].

## Synonyms

Progressive myoclonus epilepsy (PME) of Unverricht-Lundborg type; PME type 1 (EPM1); Baltic myoclonic epilepsy

## Definition and Characteristics

The progressive myoclonus epilepsies (PMEs) are a heterogeneous group of rare inherited disorders defined by the combination of myoclonus, epilepsy and progressive neurological deterioration. Unverricht-Lundborg disease (EPM1) is a form of progressive myoclonus epilepsy with onset at 6–15 years of age. Myoclonic jerks are usually the first symptoms observed and are most prominent in the morning upon awakening. They are typically sensitive to passive joint movements, voluntary movements and auditory or light stimuli. The myoclonus aggravates during stress and shows a generalized irregular asynchronous pattern. With progression over the years, the myoclonic jerks interfere with all parts of daily living activities. In almost half of the individuals the presenting symptom is a generalized tonic-clonic seizure. Epileptic seizures are infrequent at the early phases of the disease, more frequent some years after the onset and may later cease entirely. On neurological examination, ataxia, intention tremor and dysarthria can be found in later stages of the disease. However, ataxia is generally difficult to differentiate from the effects of the myoclonic jerks. Major cognitive decline has not been observed. With improved prognosis and improved diagnostic precision it has become evident that the EPM1 phenotype is more heterogeneous than previously believed. Anecdotal evidence exists of rare forms of EPM1 without the full symptomatology, e.g. of patients with late-onset myoclonias without epileptic seizures or of patients with so-called progressive myoclonic ataxia without epileptic seizures. The relative intensity of the symptoms and the speed of disease progression may also vary between patients, even within one family. The life expectancy has gradually increased and is most probably nowadays normal. Inheritance is autosomal recessive [1].

## Prevalence

EPM1 is the most common single cause of PME. Initially it was called Baltic myoclonic epilepsy because of a high incidence in the countries flanking the Baltic Sea. In Finland an incidence rate of 1:20.000 has been reported [1]. EPM1 is also relatively common in the Western Mediterranean region. It has been reported worldwide, but exact incidence or prevalence rates outside Finland have not been published.

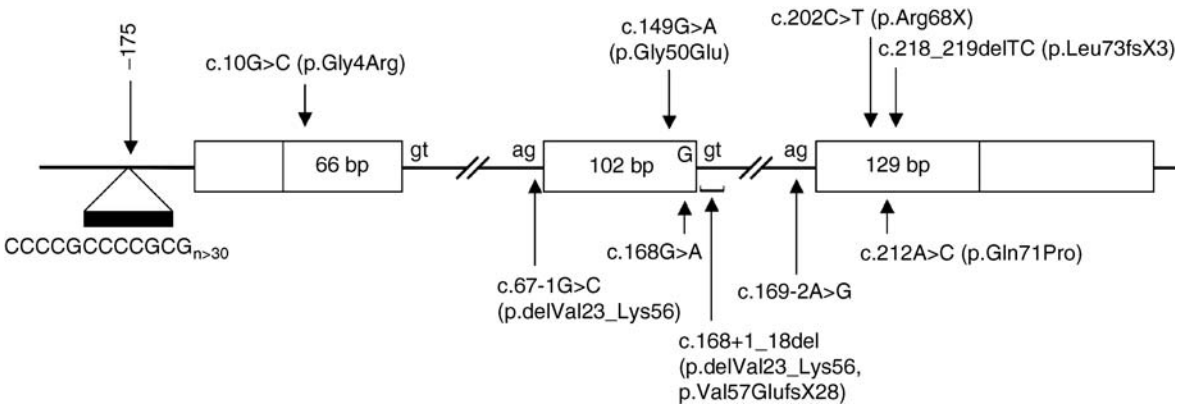
## Genes

Mutations in the gene encoding cystatin B (CSTB), identified by positional cloning, underlie EPM1 [2]. Up to now ten underlying CSTB gene mutations have been described (Fig. 1).

A second locus, denoted EPM1B, has been identified on chromosome 12.

## Molecular and Systemic Pathophysiology

The 98–amino acid CSTB protein is an inhibitor of several cysteine proteases of the papain family. The unstable expansion of the dodecamer repeat 5′-ccccgccccgcg-3′ located upstream of the first exon in the putative promotor region of CSTB is the most common EPM1-associated mutation. In the normal population 2–3 copies of the repeat are found [3]. In EPM1 patients, alleles from 30 to approximately 125 copies have been detected. No correlation was found between the repeat size and the age of onset or the severity of the clinical picture. Four mutations affect splicing, two predict truncated proteins and three are single amino acid substitutions. Most mutations result in reduction of CSTB mRNA expression and CSTB inhibitory activity resulting in increased cysteine protease activity in patients' cells. Mice deficient for CSTB develop a phenotype that resembles the human phenotype with progressive ataxia and myoclonic seizures [4]. The mice show striking cerebellar granule cell loss due to apoptosis as well as neuronal atrophy, apoptosis and gliosis in the cerebrum. Findings in mice double deficient for CSTB and the cysteine protease cathepsin B imply that cathepsin B is a contributor to the disease pathogenesis. CSTB is expressed ubiquitously. Cytosolic, lysosomal and nuclear localization of CSTB in cells has been reported. The physiological function of CSTB is still unknown. It has been suggested that the protein might be important in preventing inappropriate intracellular



**Unverricht-Lundborg Disease. Figure 1** EPM1-associated mutations in *CSTB* reported to date (arrows). The positions, the nucleotide level changes and the predicted consequences on the protein product are shown. For the splice-site mutations c.168G > A and c.169–2A > G no experimental data on mRNA level exist and therefore the consequence for the protein structure cannot be predicted. The size of the coding sequence of the three exons (boxes) and the position of the dodecamer expansion in the promoter of *CSTB* are shown.

degradation by proteases but it may have other functions as well.

## Diagnostic Principles

The first diagnostic step is the exact identification of the clinical picture in the patient. The combination of progressive involuntary, action-activated myoclonic jerks with or without generalized tonic-clonic seizures and the typical changes in the electroencephalogram (EEG) define the disease in its initial phases. The EEG is always pathological at the beginning of the disease. It shows a slow background activity beside generalized 3–5 Hz spike-wave or polyspike-wave discharges. Photosensitivity is common. Routine blood tests are normal. Somatosensory evoked potentials show high amplitudes. Later other neurological symptoms, such as ataxia, may be present. Brain MRI may show loss of bulk of the basis pons, medulla and cerebellar hemispheres [5]. The detection of a mutation in the CSTB gene confirms the diagnosis.

## Therapeutic Principles

Valproate and clonazepam have been used to treat myoclonic seizures based on clinical experience. Piracetam is effective as an add-on therapy for myoclonus. Anecdotal evidence exists of the efficacy of lamotrigine, levetiracetam, topiramate and zonisamide in the treatment of PMEs. N-acetylcysteine may decrease myoclonus and prevent neurological deterioration. Phenytoin, carbamazepine, tiagabin, pregabalin, gabapentin, oxcarbazepine and vigabatrin may worsen seizures in Unverricht-Lundborg disease and should not be used. In addition, speech and physical therapy are useful and attention should be paid to the psychosocial circumstances and rehabilitation of the patients.

# UPD(7)mat

►Silver-Russell Syndrome

# UPD14mat

Alessandra Baumer
Institute of Medical Genetics, University of Zurich, Scherzenbach, Switzerland

## Synonyms

Maternal uniparental disomy for chromosome 14,UPD (14)mat

## Definition and Characteristics

Only few patients with UPD14mat have been described to date [1–3]. This could be due to the very mild phenotypes encountered in some patients. Typical clinical features include pre- and postnatal growth retardation and early puberty.

## Prevalence

UPD14mat is a very rare sporadic disorder. Only a dozen or so cases have been reported to date.

## Genes

No genes responsible for the phenotypes are known to date.

## Molecular and Systemic Pathophysiology

The maternal UPD14 and paternal UPD14 are associated with clearly different clinical features [4–6]. It is assumed that the abnormal phenotypes encountered in patients with UPD14 are due to disruption of imprinted genes rather than a possible phenotype due to confined placenta mosaicism.

## Diagnostic Principles

The main criteria for the clinical diagnosis of UPD14mat are pre- and postnatal growth retardation and precocious puberty. The molecular investigations are to date limited to the detection of a possible UPD14mat since no causative genes are known to date. Such analyses are performed by microsatellite analysis using markers mapping to chromosome 14 and DNA derived from the patients and their parents.

## Therapeutic Principles

No therapy is available.

## Synonyms

β-UP

## Definition and Characteristics

Autosomal recessive disease leading to N-carbamyl-β-aminoaciduria.

## Prevalence

Unknown but population screening of healthy Japanese individuals identified one individual with a β-ureidopropionase deficiency (1:20,000).

## Genes

The human β-ureidopropionase gene (UPB1) is present as a single copy gene on chromosome 22q11.2 and consists of 11 exons (Fig. 1). A physical map indicates that UPB1 spans approximately 20 kb with an open reading frame of 1,152 bp [1]. To date, two different splice acceptor site mutations and one missense mutation have been identified in UPB1 in four patients [2].

*deceased

## Molecular and Systemic Pathophysiology

To date, only five individuals suffering from a complete β-ureidopropionase deficiency have been reported which, to some extent, may be due to the lack of specific and efficient methods in most laboratories to detect the N-carbamyl-β-aminoacids. The first patient described with a putative primary β-ureidopropionase deficiency was a 17-month-old girl presenting with muscular hypotonia, dystonic movements, scoliosis, microcephaly and severe developmental delay. The other three patients presented with various neurological problems including seizures. The fifth patient was asymptomatic. It has been suggested that an altered homeostasis of β-aminoisobutyric acid and/or increased oxidative stress might contribute to some of the clinical abnormalities encountered in these patients.

## Diagnostic Principles

Patients present with increased levels of N-carbamyl-β-alanine and N-carbamyl-β-aminoisobutyric acid in urine, plasma and cerebrospinal fluid; no activity of β-ureidopropionase can be detected in liver [3]. The N-carbamyl-β-amino acids can be detected via amino acid analysis or with HPLC/tandem MS [3,4]. Analysis of UPB1 allows the identification of the underlying mutations of this disease.

## Therapeutic Principles

No specific therapies have been reported for patients with a β-ureidopropionase deficiency. Treatment with β-alanine and β-aminoisobutyric acid might be a possibility.

## Uridine Monophosphate Hydrolase-1 Deficiency

David C. Rees
King's College Hospital, London, UK

### Synonyms

Pyrimidine 5′ nucleotidase deficiency; Pyrimidine 5′ nucleotidase-1 deficiency; UMPH-1

### Definition and Characteristics

UMPH-1 deficiency is an autosomal recessive condition, characterized by moderate hemolytic anemia with mean hemoglobin of 9 g/dl (range 7–12 g/dl) and a reticulocytosis of 5–10%. The red cells show mild anisopoikilocytosis and florid basophilic stippling. The spleen is usually enlarged. There is an association with learning difficulties in about 10% of published cases, although its significance is not clear [1].

### Prevalence

It is rare but possibly the third commonest enzymopathy causing hemolytic anemia. The exact prevalence is not known, but it has been identified in all major ethnic groups.

### Genes

The gene for UMPH-1 is found on chromosome 7p15–p14. It has ten exons, spans about 50 kb and produces a cDNA of about 1300 bp. Two alternatively spliced forms of mRNA are produced in reticulocytes, one containing all ten exons and one without exon 2 [2]. The alternatively spliced mRNAs are predicted to produce two proteins consisting of 286 and 297 amino acids. The UMPH-1 protein is not homologous to any other known nucleotidase, but is highly homologous to p36 protein [3].

### Molecular and Systemic Pathophysiology

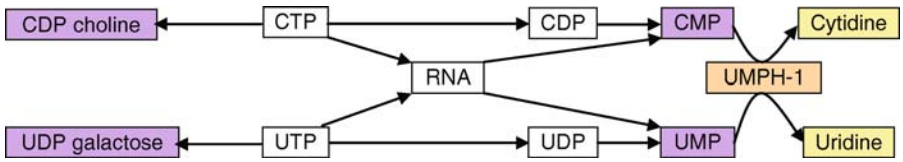
UMPH-1 catalyses the dephosphorylation of pyrimidine nucleoside monophosphates. UMPH-1 is thought to allow the red cell to lose unwanted pyrimidine nucleotides, whilst its selective action preserves the valuable pool of purine nucleotides.

Fourteen different mutations have so far been identified. All are predicted to abolish or severely reduce enzyme activity. UMPH-1 deficiency causes the massive accumulation of pyrimidine nucleotides within the red cell, consisting of cytidine and uridine nucleotides, CDP-ethanolamine and CDP-choline (Fig. 1).

Hemolysis is thought to relate to the excess of pyrimidine nucleotides, which may alter membrane composition, increase intracellular acidity, chelate magnesium ions and compete for ATP/ADP binding sites. Acquired UMPH-1 deficiency is caused by lead poisoning and the beta thalassemia trait.

### Diagnostic Principles

Hematological studies show a non-immune hemolytic anemia and basophilic stippling. The diagnosis is confirmed by demonstrating low UMPH-1 activity in red cells. The concentration of pyrimidine nucleotides in the red cells can also be measured either spectrophotometrically or by HPLC [4]. Heterozygotes have reduced levels of UMPH-1 activity but no accumulation



**Uridine Monophosphate Hydrolase-1 Deficiency. Figure 1** UMPH-1 in pyrimidine catabolism in the reticulocyte. In UMPH-1 deficiency uridine and cytidine are not produced and pyrimidine nucleotides and derivatives are retained within the cell (purple).

of pyrimidine nucleotides. They cannot be reliably diagnosed at the phenotypic level.

## Therapeutic Principles

There is no specific treatment. Regular blood transfusions are rarely necessary. Splenectomy has been performed in a small number of cases and has not been associated with benefit. Folate supplementation may be appropriate.

# Uridine Monophosphate Synthase Deficiency

Lynette D. Fairbanks, H. Anne Simmonds
Purine Research Laboratory, Department of Chemical Pathology, Guy's Hospital, London, UK

## Synonyms

Hereditary orotic aciduria

## Definition and Characteristics

Autosomal recessive defect resulting from a loss of activity of the bifunctional protein which catalyses the last two steps of the pyrimidine de novo synthetic pathway, orotic acid phosphoribosyltransferase (OPRT) and orotidine monophosphate decarboxylase (ODC) Fig. 1. The clinical presentation in the majority (type 1) is characterized by intractable megaloblastic anemia, failure to thrive, orotic aciduria and problems associated with the orotic acid crystalluria, such as renal tract obstruction [1].

Three cases have been described with orotidinuria as well orotic aciduria and neurological problems, two of them without anemia (type 2) [2–4].

## Prevalence

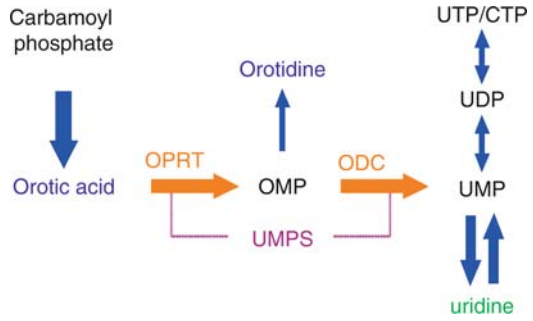
Rare. About 17 cases identified worldwide. Wide racial distribution, thus not confined to any single ethnic group.

## Genes

The activities of OPRT and ODC reside within separate domains of a single polypeptide coded for by a single gene localised to chromosome 3 (3 q13.1). The majority of the patients have point mutations in the OPRT domain (Fig. 1). A point mutation in a highly conserved region of the ODC domain has been identified in a patient with the type 2 defect [3]. Alternatively spliced mRNAs are predicted to produce two proteins consisting of 286 and 297 amino acids.

## Molecular and Systemic Pathophysiology

UMPS catalyses the final two steps of the six-step pyrimidine de novo pathway and provides the total body requirement for pyrimidine nucleotides. Patients with complete UMPS deficiency have a macrocytic hypochromic megaloblastic anemia, sometimes leucopenia and immunodeficiency [2]. Other symptoms include failure to thrive, developmental retardation, cardiac malformations, bilateral strabismus, sparse hair and inability to sit unaided [1]. Orotidinuria as well as orotic aciduria has been reported in patients with the type 2 defect [3]. Symptoms in type 2 patients include developmental delay, visual problems and congenital motor ocular dyspraxia, but without megaloblastic anemia [3]. The onset of symptoms in either type 1 or type 2 UMPS deficiency is usually within the first weeks or months of life. UMPS is of particular importance to the human erythrocyte, which picks up excess orotic acid, principally in the liver and delivers it as uridine to tissues such



**Uridine Monophosphate Synthase Deficiency.**
**Figure 1** Role of UMPS in pyrimidine nucleotide synthesis. The build up of orotic acid when UMPS is defective is illustrated.

as brain. Healthy nucleated cells do not take up orotic acid, but by contrast malignant cells do. Defective DNA synthesis and cell cycle arrest in bone marrow have been implicated in the megaloblastic anemia. Likewise pyrimidine nucleotide starvation may underlie the immunodeficiency in some patients. Although pyrimidine nucleotides are also intermediates in the formation of essential cofactors, such as UDP-sugars, CDP-choline (in galactose and glycogen metabolism) and CDP-ethanolamine (in phospholipid metabolism), defective synthesis of these cofactors has not been associated with the disease [2].

## Diagnostic Principles

Homozygotes for type 1 may be detected clinically by the gross crystalluria (including crystals on the diaper) and chemically from the high levels of orotic acid in urine (up to 10 mmol/24 h) or plasma (up to 40 µmol/l) by GCMS, HPLC or tandem MS. Colorimetric methods may give false positive results.

The most usual clinical presentation for the type 1 defect is severe macrocytic hypochromic megaloblastic anemia, which does not respond to normal therapy (iron, folic acid, B12).

Orotic aciduria plus orotidinuria are diagnostic of type 2.

Confirmation by erythrocyte enzyme assay (providing there has been no prior blood transfusion) is essential to confirm the defect.

Purine metabolism is normal, but uric acid excretion/clearance is high because of the uricosuric effect of orotic acid. The enzyme defect has also been confirmed in liver, fibroblasts, lymphoblasts and leucocytes from affected individuals.

Orotic aciduria/orotidinuria secondary to analogue therapy with inhibitors of UMPS (azaorotic acid, pyrazofuran, allopurinol etc.) must be excluded. Orotic aciduria of similar magnitude to that in UMPS deficiency can occur also secondary to genetic defects in four of the six urea cycle enzymes [2].

## Therapeutic Principles

Uridine therapy, but not uracil, has proved beneficial in treating the deficiency [1]. 13 patients have been maintained successfully on oral uridine (dose increasing with age) for up to 40 years [2]. The lack of any effect with oral uracil, but reversal of symptoms on uridine therapy long-term, confirms that, in contrast to purines, pyrimidines are salvaged at the nucleoside not the base level, confirming that humans lack a functional phosphoribosyltransferase for pyrimidines.

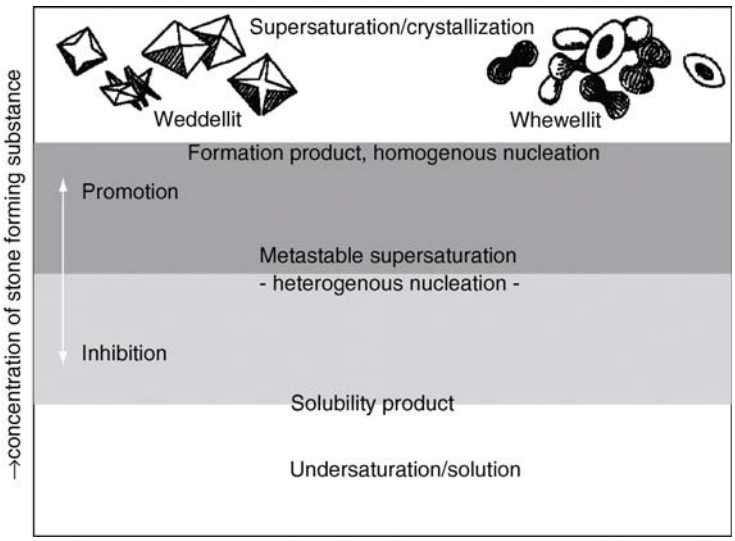
# Urinary Stones

Albrecht Hesse
Department of Urology, University of Bonn, Bonn, Germany

## Definition and Characteristics

Urinary stones are pathological biomineralizates. Biomineralization resulting in a urinary stone is of multifactorial origin, in which socioeconomic, genetic, and constitutional factors, together with diet, pharmacological treatment, and metabolic abnormalities, may act in concert.

Supersaturation of urine with the stone-forming salt(s) is of fundamental importance and a prerequisite for the necessary precipitation. The solubility of the different stone components depends on the urinary pH and the excretion of other urine constituents. Accordingly, saturation of urine above the solubility product (SP) and the associated risk of crystallization are determined



**Urinary Stones. Figure 1** Diagram showing the saturation of urine with stone-forming substances, and crystal and/or stone formation.

by the urinary concentration (mmol/l) of the solutes involved in the crystal formation and by the pH. When the SP has been exceeded, supersaturation is metastable (Fig. 1).

At this level of supersaturation, crystals can grow and aggregate (agglomerate), but no new crystal formation is possible. Regarding initiation of new crystallization, increased concentrations are of no diagnostic significance but might simply reflect the concentration capacity of the kidney. Normal values of urine constituents are usually expressed as total excretion during a 24-h period or a fraction of a 24-h period.

## Prevalence

Epidemiological data on the occurrence of urolithiasis ranges between 2 and 20% [1,2], depending on geographical location, race, age and sex, climate, nutrition, and other environmental factors. In a representative study from 2000, prevalence (proportion of people in a population found to be suffering from the disease at a given point in time) was 4.7% and incidence (number of new cases of the disease per population measured over a given time interval) was 1.47% [3]. About 27–35% of initial cases of the disease occurred between age 25 and 50, the age of highest activity. Twenty-four percent of the stone patients had already three or more stones.

## Genes

There is no genetic predisposition to urinary stones in general. However, genetic defects can promote crystal formation and stone formation in the urinary tract. Characteristic examples of this are cystinuria, xanthinuria, 2,8-dihydroxyadeninuria, and primary hyperoxaluria, which are described in separate chapters.

## Molecular and Systemic Pathophysiology

The pathophysiology of urinary stone formation differs specifically according to the nature of each individual stone. In terms of stone formation, we distinguish between stones resulting from genetic defects, (e.g., cystinuria), infection of the urinary tract with urea-splitting (urease-forming) bacteria (e.g., struvite), acquired defects such as primary hyperparathyreoidism (e.g., carbon apatite, brushite), and from faulty diet (i.e., uric acid, calcium oxalate).

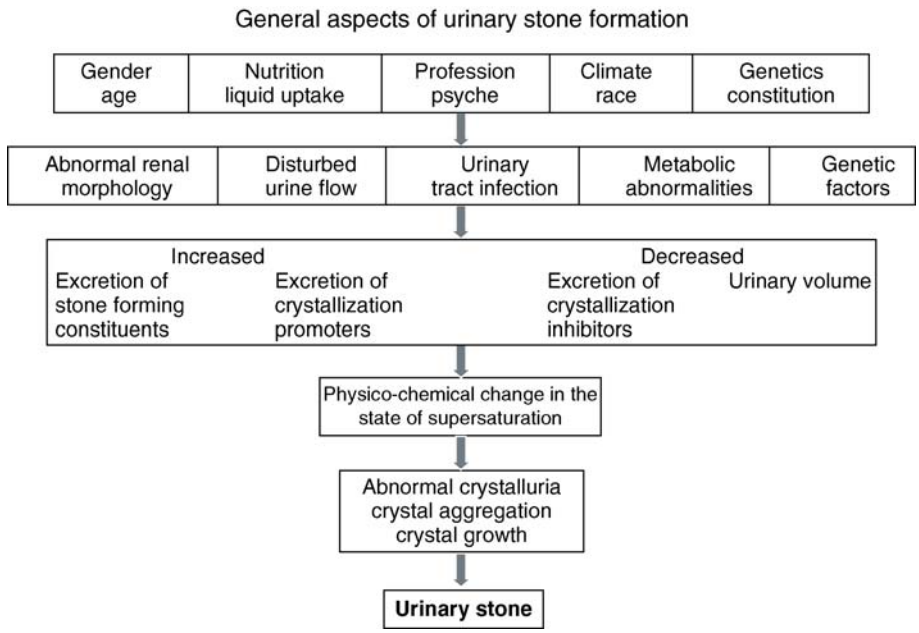
Figure 2 shows a general scheme of urinary stone formation.

## Diagnostic Principles

After clinical diagnosis and therapy by removal of the stone(s), the most important laboratory diagnostic measure is correct urinary stone analysis. Generally, accepted standard methods of stone analysis are infrared spectroscopy and X-ray diffraction. Because of its high error rate, chemical stone analysis is no longer used [4]. The most important urinary stone components are summarized in Table 1.

Two-thirds of all stones comprise two and more components. Once the nature of the stone is known, a specific diagnostic procedure for each separate type of stone will follow [5].

The basic evaluation program comprises a minimum of laboratory investigations (blood – creatinine, calcium, uric acid; urine – dipstick tests, urinary sediment,



**Urinary Stones. Figure 2** General aspects of urinary stone formation [5].

**Urinary Stones. Table 1** Composition of the most important stone constituents [5]

| Stone constituents | Chemical name | Mineral name | Frequency (%) |
|---|---|---|---|
| Oxalate | Calcium oxalate monohydrate | Whewellite | 50–60 |
| | Calcium oxalate dehydrate | Weddellite | 15–20 |
| Phosphate | Carbonate apatite | Dahllite | 5–6 |
| | Calcium hydrogen phosphate dihydrate | Brushite | 1–2 |

| | Xanthine | – | Rare |
| | 2,8-Dihydroxyadenine | – | Rare |

crystalluria) to detect severe disorders related to stone formation (renal insufficiency, hyperparathyreoidism, hyperuricemia; infection).

## Therapeutic Principles

With known types of stone, very specific metaphylactic procedures are adopted [5]. Where the nature of a stone has not yet been determined, the recommendations of Table 2 should be adopted.

### Definition and Characteristics

Primary hyperoxaluria is a rare, autosomal recessive inherited disease of the glyoxylate metabolism resulting in an excessive endogenous oxalate synthesis. Two forms of primary hyperoxaluria (PH) are currently defined. All genetic defects subsumed under primary hyperoxaluria result in calcium oxalate urolithiasis and/or nephrocalcinosis, which leads to kidney damage, eventually to renal failure with systemic calcium oxalate deposition (=systemic oxalosis).

While a single cause for calcium oxalate stone formation exists in patients with primary hyperoxaluria, the origin of calcium oxalate urolithiasis is, however, multifactorial in the large majority of non-PH patients. Calcium oxalate crystals are always formed in urine when the limit of supersaturation is exceeded. Causes are, therefore, either a high concentration of promoters (calcium, uric acid and oxalate) or insufficient concentration of stone inhibitory substances such as citrate, magnesium and certain high molecular weight compounds like glycosaminoglycans, Tamm-Horsfall protein and others. Calcium oxalate crystalluria occurs regularly even in healthy individuals, e.g., after a high oxalate meal. Only if crystals or crystal aggregates are not eliminated by the urine flow, formation of a urinary stone sets in. A urinary stone obstructing the renal collecting system results in an emergency situation, either by an episode of renal colic or by infection of the obstructed urinary tract.

### Prevalence

Five percent of the adult population in Germany are affected by urolithiasis, 70–75% suffer from calcium oxalate containing stones [1]. In other parts of the world, the prevalence is three to five times higher (USA, Arab peninsula). The prevalence of primary hyperoxaluria is approximately two per million head

of population. However, as diagnosis is all too often missed or only made at end stage renal failure, the true prevalence may even be higher [2].

## Genes

To date, well over 60 mutations have been described in patients with primary hyperoxaluria types I and II [2]. In some of the idiopathic calcium oxalate stone patients, family history indicates genetic causes. Of the polygenetic causes, none have been identified unequivocally.

## Molecular and Systemic Pathophysiology

Calcium oxalate urolithiasis is a multifactorial disease. Figure 1 summarizes the most important exogenous and endogenous risk factors. In 86% of patients, more than one cause for calcium oxalate stone formation is diagnosed (Fig. 1).

## Diagnostic Principles

Serum analysis: creatinine, calcium, sodium, potassium, chloride, uric acid, parathyroid hormone (in case of increased calcium levels), and if applicable, oxalate determination.

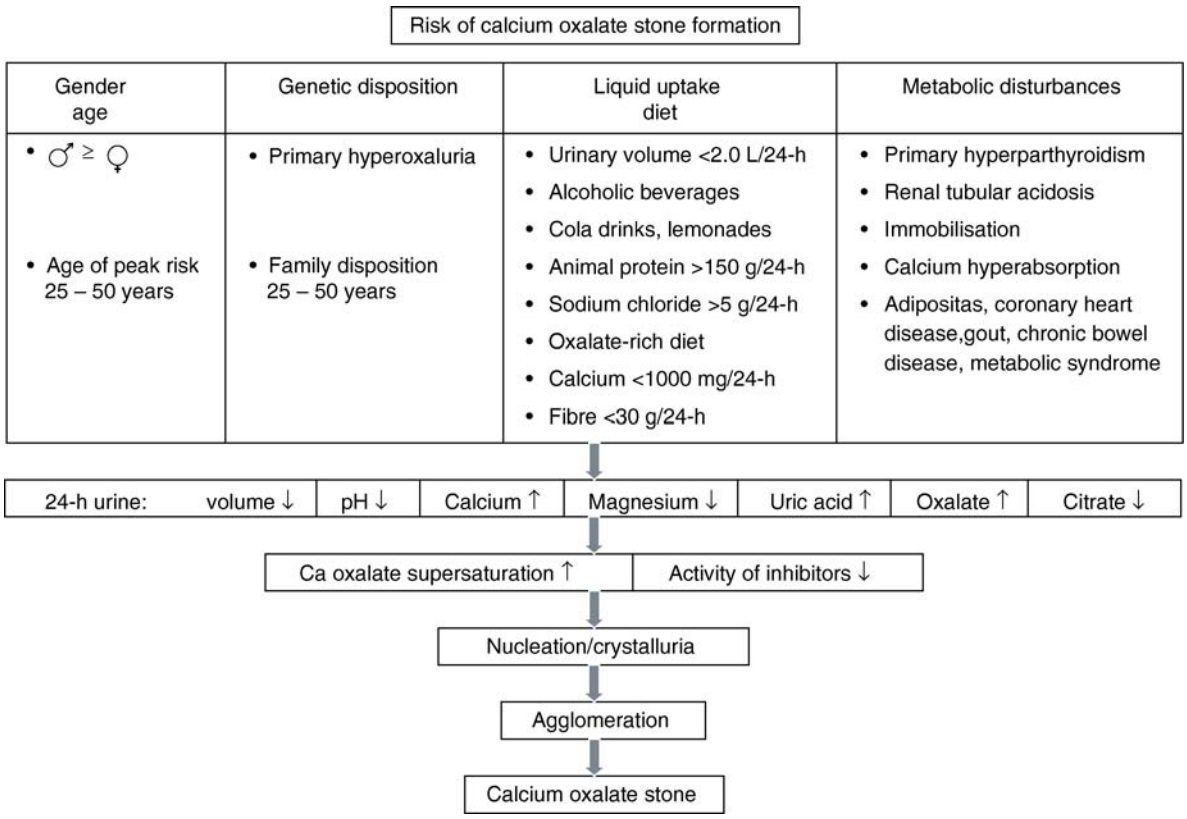
Urine analysis: pH profile (minimum pH determination: four times a day), two 24-h urine samples – volume, specific gravity, calcium, magnesium, oxalate, uric acid, citrate [3].

The causes of calcium oxalate stone formation can be further differentiated with specific tests. These tests also allow evaluation of efficacy of therapy. BONN-Risk-Index: Determination of the calcium oxalate crystallization risks in undiluted urine. Calcium loading test: Differentiation of the causes of a hypercalciuria (absorptive, renal or resorptive) [3]. Ammonium chloride loading test: Differentiation between complete and incomplete renal tubular acidosis (RTA) [3]. [$^{13}C_2$] Oxalate absorption test: Determination of the intestinal oxalate absorption in patients with hyperoxaluria [4].

## Therapeutic Principles

Gene therapy is not available and difficult for the primary hyperoxalurias with the current vector technology, as 100% of cells have to be transfected. Pharmacological therapy, dosage for adults [3] or specific dosage for children summarize Table 1:

Dietary therapy – fluid intake 2.5–3.0 l/24-h (diuresis 2.0–2.5 l/24-h) in adults, or >1.5 l/m$^2$ body surface area in children.



**Urolithiasis, Calcium Oxalate. Figure 1** Risk of calcium oxalate stone formation.

**Urolithiasis, Calcium Oxalate. Table 1** Risk factors in urine, border line excretion for start of therapy and treatment options

| Risk factor in urine | Border lines, excretion in 24 h urine | Treatment options |
|---|---|---|
| 1. Hypercalciuria | 5–8 mmol/day | Alkaline citrate (9–12 g/day) |
| | | Sodium bicarbonate (3 × 1.5 g/day) |
| | >8 mmol/day | Alkaline citrate (9–12 g/day) |
| | | Hydrochlorothiazide (initially 25 mg/day, up to 50 mg/day) |
| | >4 mg/kg body weight in children | HCT 0.5–1 mg/kg body weight |
| | | Alkaline citrate 1–1.5 mEq/kg body weight |
| 2. Hypocitraturia | <2.5 mmol/day | Alkaline citrate (9–12 g/day) |
| | <1.9 (male) or <1.6 (female) in children | Alkaline citrate 1–1.5 mEq/kg body weight |
| 3. Sec. hyperoxaluria | >0.5 mmol/day | Calcium supplement (≥500 mg/day) (attn: hypercalciuria) |
| 4. Primary hyperoxaluria | | Pyridoxine in PH type I (5–20 mg/kg body weight) |
| | | Magnesium (200–400 mg/day) (attn: renal insufficiency) |
| Future treatment options | | Oxalate degrading bacteria |
| | | Chaperones |
| 5. Hyperuricosuria | >4.0 mmol/day | Alkaline citrate (9–12 g/day) |
| | | Allopurinol (100–300 mg/day) |
| | >0.12 mmol/kg body weight in children | Alkaline citrate 1–1.5 mEq/kg body weight |
| 6. Hypomagnesuria | <3.0 mmol/day | Magnesium (200–400 mg/day) (attn: renal insufficiency) |

Balanced diet, rich in vegetables and fiber, calcium content 1,000 mg/24-h, sodium chloride intake 3–5 g/24-h, limited animal protein 0.8 g/kg body weight and day, low in oxalate content [5].

Other treatments – weight normalization, physical activity.

# Urolithiasis, Calcium Phosphate

Roswitha Siener, Albrecht Hesse
Department of Urology, University of Bonn, Bonn, Germany

## Definition and Characteristics

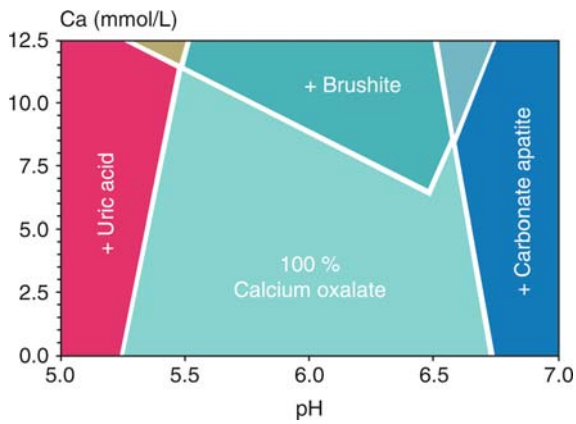
Various types of calcium phosphates are constituents of urinary stones (Table 1).

The most important calcium phosphates involved in urinary stone disease are carbonate apatite and brushite. Although both minerals contain calcium and phosphate, carbonate apatite and brushite are two completely different kinds of stones.

Brushite stones show a high and rapid tendency toward recurrence. Hypercalciuria is a major pathogenetic factor of brushite stone formation. Renal loss of calcium (renal leak) is the most common cause of hypercalciuria. Brushite crystallizes in weakly acidic urine (pH optimum 6.5–6.8) at high concentrations of calcium and phosphate. Most commonly brushite has a monomineral structure. Transformation to carbonate apatite is possible at pH 6.9 and above, whereby crystallography shows dissolution and a new arrangement [1]. Fig. 1 shows the relationship between hypercalciuria and urinary pH in stone formation according to *in vitro*

**Urolithiasis, Calcium Phosphate. Table 1** Calcium phosphate urinary stones

| Chemical nomenclature | Mineral names | Chemical formula |
|---|---|---|
| Tricalcium phosphate | Whitlockite | $Ca_3(PO_4)_2$ |
| Calcium hydroxyl phosphate | Hydroxyapatite | $Ca_5(PO_3)_3(OH)$ |
| Carbonate apatite | Dahllite | $Ca_{10}(PO_4)(CO_3OH)_6(OH)_2$ |
| Octacalcium phosphate | – | $Ca_8H_2(PO_4)_6 \cdot 5H_2O$ |
| Calcium hydrogen phosphate dihydrate | Brushite | $CaHPO_4 \cdot 2H_2O$ |



**Urolithiasis, Calcium Phosphate. Figure 1** Diagram of the formation of calcium oxalate mixed stones and the transformation to carbonate apatite [2].

experiments with artificial urine [2]. At high calcium concentrations, brushite occurs mixed with calcium oxalate even at low pH. Even slight hypercalciuria is sufficient for brushite crystallization if the urinary pH is elevated to levels above 6.5. Above pH 6.8, mixtures of brushite and carbonate apatite are formed. Urinary tract infections are not involved in brushite stone formation, which indicates that they form in sterile urine. Stones composed of brushite are characterized by particular hardness, resulting in physical resistance to ESWL.

Carbonate apatite stones develop at pH levels >6.8 with high calcium and low citrate concentrations. They are basically not associated with an infection. Pure carbonate apatite stones occur at urinary pH values persistently >7.0 and high phosphate concentrations. Carbonate apatite commonly forms mixed calculi with calcium oxalate if circadian urinary pH is increased several times a day. In case of urinary tract infection with urease producing bacteria, struvite is another component of the precipitate. Thereby urinary pH usually increases to levels above 7.0 [3].

## Prevalence

Calcium phosphate stones (percentage main component) account for 5–20% of all stones [2].

## Genes

Genetic influence on calcium phosphate stone formation has not been identified.

## Molecular and Systemic Pathophysiology

The most common causes of calcium phosphate stone formation are disturbances in the calcium phosphate metabolism, distal renal tubular acidosis (dRTA) and urinary tract infection. In all these conditions, urinary pH is a major determinant that triggers crystallization. The pathogenic factors for brushite stone formation have not yet been clearly established.

## Diagnostic Principles

- For an efficient treatment of calcium phosphate stone disease, knowledge of other stone constituents is highly important. All stones that are removed or passed spontaneously should be analyzed by infrared spectroscopy or X-ray diffraction [2]. A change in the type of stone can occur during metaphylactic treatment. Alkaline citrate, an effective treatment for calcium oxalate stones with hypocitraturia, may promote the formation of calcium phosphate stones via high urinary pH.
- Blood analysis: calcium, parathyroid hormone (in case of increased calcium levels), sodium, potassium, chloride and blood gas analysis.
- Urine analysis: pH profile (minimum pH determination: four times a day), two 24 h urine samples – volume, specific weight, calcium, phosphate, citrate [4].
- Ammonium chloride loading test (differentiation between complete and incomplete dRTA) [4].

## Therapeutic Principles

*Pharmacological Therapy*:

- Acidification of urine to pH 5.8–6.2 with L-methionine (dosage for adults: 200–500 mg three times daily) (contraindication: complete dRTA) [4].
- Hydrochlorothiazide in patients with excessive urinary calcium excretion above 8 mmol/day (dosage: initially 25 mg/day up to 50 mg/day in adults, 0.5–1.0 mg/kg in children) [3,4].
- Eradication of urinary tract infection with appropriate antibiotic therapy in case of infection associated calcium phosphate stones.

*Dietary Therapy*:

- Fluid intake 2.5–3.0 L/day (urine dilution at least 2.5 L/day) [3].
- Neutral and acidifying beverages (mineral water with a low content of calcium and bicarbonate; cranberry juice) [3].
- Balanced mixed diet, calcium content 1,000 mg/day, limited dietary protein intake of 0.8 g/kg body weight per day, low in phosphate content, rich in dietary fiber, no vegetarian diet.

*Other Treatments*:

- Percutaneous chemolytic dissolution of residual fragments composed of carbonate apatite and brushite can be attained by irrigation of the renal collecting system with hemiacidrin and Suby G solutions [2].
- Treatment of primary hyperparathyroidism by parathyroidectomy followed by autologue transplantation of parathyroid tissue into the arm musculature [4].
- Reduction of overweight [5].

# Urolithiasis, Uric Acid

Naim M. Maalouf, MaryAnn Cameron, Khashayar Sakhaee
Center for Mineral Metabolism and Clinical Research, University of Texas Southwestern Medical Center, Dallas, TX, USA

## Synonyms

Uric acid nephrolithiasis; Gouty diathesis; Uric acid stones

## Definition and Characteristics

A condition characterized by the formation of uric acid calculi in the urinary tract, due to an increased urinary concentration of sparingly soluble undissociated uric acid.

## Prevalence

Uric acid stone formers represent about 8–12% of the population of nephrolithiasis patients. This proportion is higher in certain ethnic groups (e.g. Hmongs) and geographic areas (e.g. Middle East), or in patients with some metabolic disorders such as gout, obesity and/or type 2 diabetes mellitus.

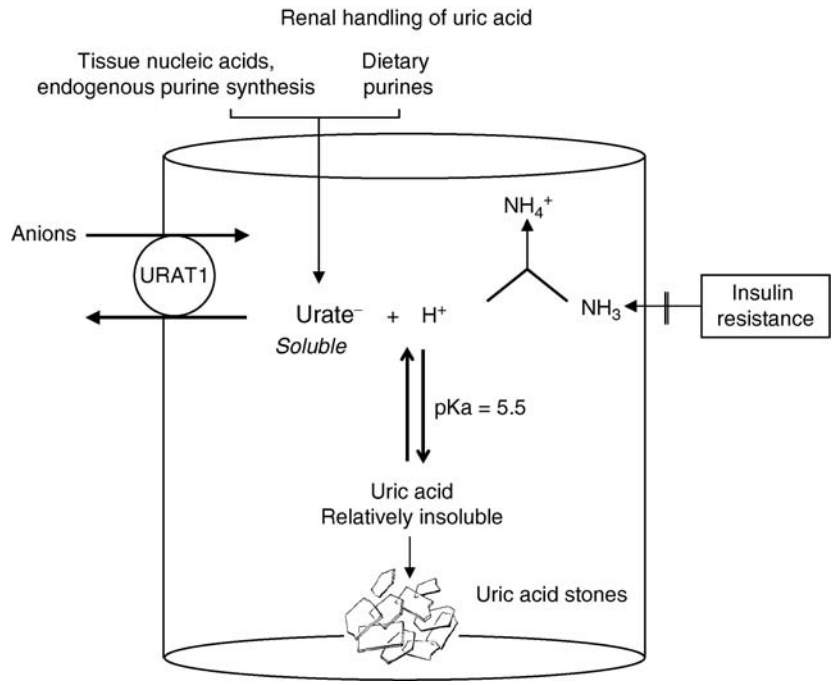
## Genes

Uric acid urolithiasis is a multifactorial disorder, and is unlikely to be caused by a single genetic defect. However, a putative genetic locus linked to uric acid urolithiasis has been described in a homogeneous population from Sardinia with a high incidence of uric acid stones but a variable urinary profile. This locus on chromosome10q21–22 was identified using multi-step linkage and allele-sharing analysis. Subsequent investigation further identified a candidate gene, which was designated as Zinc Finger protein 365 (ZNF365). Although the function of the protein product is still unknown, mutation analysis of the gene has shown that a Ala62Thr coding variant in exon 12 of the ZNF365D isoform is associated with uric acid urolithiasis in this Sardinian population [1].

Mutations in the gene on chromosome 11q13 encoding URAT1, a urate transporter located in the apical membrane of proximal tubule cells [2], have been shown to cause hyperuricosuria and hypouricemia and are associated with uric acid urolithiasis in rare cases.

## Molecular and Systemic Pathophysiology

The major factors implicated in uric acid urolithiasis are a low urine volume, hyperuricosuria and an acidic urine pH (≤5.5, the pKa of uric acid) [3]. Of these three, the most prevalent feature is low urine pH. At a urinary pH below 5.5, the relatively soluble urate salt is converted into insoluble uric acid (Fig. 1). Uric acid will then precipitate and lead to the formation of either pure uric acid stones, or mixed uric acid/calcium oxalate stones. The unduly acidic urine is caused by a low urinary ammonia concentration, which leaves the free $H^+$ ion relatively unbuffered (Fig. 1). Patients with uric acid stones have impaired urinary ammonium excretion after an oral acid load (ammonium chloride) [4]. The mechanism underlying the low urinary pH and ammonium has been linked to renal insulin resistance, as low peripheral insulin sensitivity



**Urolithiasis, Uric Acid. Figure 1** Schematic representation of renal handling of uric acid and uric acid stone formation. Urinary concentration of uric acid is determined by urinary urate and urinary pH. Urinary urate content is in part dependent on the amount filtered and reabsorbed in the proximal tubule by URAT1. Urinary pH is affected by the availability of ammonia, the major urinary buffer. Renal insulin resistance leads to a lower urinary pH, likely by decreasing urinary ammonia (shown by ‖).

has been correlated with a low urinary pH [5]. Renal insulin resistance plays a key role in both defective ammoniagenesis and impaired ammonia transport via sodium–hydrogen exchanger-3 (NHE3) in the proximal renal tubular cell.

## Diagnostic Principles

The diagnosis is usually suggested from typical symptoms of kidney stones such as hematuria, flank pain and/or obstructive symptoms. Pure uric acid stones are radiolucent and thus not seen on a plain X-ray film. However, they are readily detected by Computed Tomography (CT) scanning. Confirmation of the diagnosis is made by analysis of a stone that has been passed. The most common biochemical finding on 24-h urine collection is a urine pH $\leq$ 5.5.

## Therapeutic Principles

No gene therapy is currently available for the treatment of uric acid nephrolithiasis.

The main treatment modalities are alkalinization of the urine to a urine pH between 6.0 and 6.5 and maintenance of the urine output above 2 L/day to reduce the urinary concentration of uric acid. Potassium alkali (potassium citrate) is preferred over sodium alkali due to the lower urinary calcium excretion and to inhibition of sodium urate-induced calcium oxalate crystallization. Allopurinol use should be reserved for patients who have significant hyperuricosuria (24-h urine uric acid > 750 mg/day).

Dietary therapy includes reducing the intake of animal proteins that provide a dietary acid load that lowers urinary pH, and are a source of purines that are metabolized to uric acid.

## Urticaria

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, Alberta, Canada

### Synonyms

Hives; Nettle rash

### Definition and Characteristics

Urticaria is characterized by pruritic, erythematous, oedematous wheals of the superficial layers of the skin. The hallmark of urticaria is that individual lesions wax and wane rapidly, usually lasting less than 4 h and rarely persist longer than 24 h. The lesions blanch on pressure, vary in size from a few millimeters to a few centimeters in diameter, and can be localized or generalized. The lesions are usually well circumscribed with central clearing. Peripheral extension and coalescence of individual lesions result in a clinical picture of oval, annular, or bizarre serpiginous configurations (Fig. 1) [1].

**Urticaria. Figure 1** A 10-year-old girl with urticaria.

Although somewhat arbitrary, urticaria of less than 6 weeks' duration is considered acute whereas urticaria greater than 6 weeks' duration is considered chronic [1].

### Prevalence

Between 15 and 20% of the population is estimated to experience at least one episode of urticaria at some time in their life time [2]. Urticaria has a bimodal age distribution with peaks in the first and third decades of life. The female to male ratio is approximately 2:1 for chronic urticaria.

### Molecular and Systemic Pathophysiology

Urticaria lesions are caused by dilation of blood vessels in the superficial dermis giving rise to the erythema or flare and by increased vascular permeability with leakage of fluid into the surrounding connective tissue giving rise to the wheal [2]. The majority of acute urticarias are caused by type-I, anaphylactic, IgE-mediated or immediate hypersensitivity reactions to allergens such as food (notably peanuts, eggs, chocolate) or drugs (notably beta-lactam). Mast cell is the major effector cell and histamine being the major mediator. Other mast cell mediators include bradykinin, prostaglandins, leukotrienes, eosinophil and neutrophil chemotatic factors, platelet-activating factor, and cytokines [2,3]. The activation of complement pathways may also cause urticaria by producing anaphylatoxins

(C3a, C4b, C5a) which can degranulate mast cells [2,3]. Urticaria may result from non-immunological triggering of mast cell release such as from chemical (radiocontrast material) or physical stimuli (cold, heat). Neuropeptides such as substance P and vasoactive intestinal peptide can activate mast cells for histamine secretion [2]. More than 80% of cases of chronic urticaria are idiopathic [1]. T lymphocytes and monocytes play a role in their pathogenesis [2].

### Diagnostic Principles

The differential diagnosis includes erythema multiforme, insect bite reactions, cutaneous vasculitis, cutaneous mastocytosis, bullous pemphigoid, and acute febrile neutrophilic dermatosis (Sweet's syndrome). A comprehensive history is essential in the evaluation and should include time of onset of disease, duration of disease and individual lesions, frequency of attacks, associated symptoms such as itch, associated illness, past or current allergies, induction by physical agents, exercise, food or drugs, previous treatment and response, and family history of atopy [4]. Signs of systemic disease and infection should be looked for. Physical examination should include a test for dermographism. Skin testing should be reserved for patients with chronic urticaria in whom an allergen-induced disorder is suspected. Skin biopsy should be considered when individual lesions persist for more than 24–48 h to rule out other skin disorders [2]. Other tests should be performed when clinically indicated.

### Therapeutic Principles

Triggering factors should be avoided if possible. Currently, the most frequently used therapy aims at blocking the release of mediators from mast cells or blocking the effects of released mediators [5]. Non-sedating $H_1$ antihistamines are the mainstays in the management [5]. In acute severe urticaria, subcutaneous epinephrine (0.01 ml of 1:1,000 epinephrine per kg, up to 0.3 ml) is indicated.

[2]Department of Otolaryngology, Tuebingen Hearing Research Center, Eberhard Karls University Tuebingen, Tuebingen, Germany

### Synonyms

USH; Retinitis pigmentosa and congenital deafness

### Definition and Characteristics

Usher syndrome comprises a group of clinically and genetically heterogeneous disorders characterized by sensorineural hearing impairment (HI), retinitis pigmentosa (RP) and vestibular dysfunction. Usher syndrome is the most common cause of combined deafness and blindness leading to a severe handicap of affected persons.

### Prevalence

The prevalence is estimated to be 5:100,000 [1].

### Genes

To date eleven loci and six genes are known to be responsible for Usher syndrome. Among these genes, MYO7A was the first one identified and accounts for up to 75% of all USH1 cases [2]. An actual overview of loci and genes involved in USH is presented by Van Camp and Smith [3].

**Usher Syndrome. Table 1**

| Type | Percentage of all USH cases | HI | Manifestation of RP | Vestibular function |
|---|---|---|---|---|
| USH1 | 33–44 | Congenital, profound | In the first decade | Absent |
| USH2 | 56–67 | Congenital, sloping audiogram | In the first or second decade | Normal |
| USH3 | Rare | Progressive | Variable | Variable |

## Molecular and Systemic Pathophysiology

Based on the severity of clinical symptoms, three types of Usher syndrome are distinguished (see Table 1).

## Diagnostic Principles

Audiogram, ERG, visuo-evaluation, vestibular testing, genetic screening only in familial cases.

## Therapeutic Principles

Hearing devices including cochlea implant, retinoic acid treatment.

# Uveal Melanoma

Nikolaos E. Bechrakis
Department of Ophthalmology, Medical University of Innsbruck, Innsbruck, Austria

## Definition and Characteristics

The term uveal melanoma comprises melanoma that occurs as a primary tumor in the entire uveal tract of the eye. These tumors can be subdivided according to their topographical location within the uveal tract into iris, ciliary body and choroidal melanomas. Uveal melanoma is the most common primary intraocular malignancy. The cell of origin is the melanocyte that occurs in the entire uveal tract and is derived embryologically from the neural crest. The average age of presentation of uveal melanomas is in the sixth decade of life at around 55 years and some epidemiologic surveys state a slight predominance in the diagnosis of uveal melanomas in males. Although some familial occurrences of uveal melanoma have been described, there is no hereditary predisposition and no gene responsible for the development of this tumor has been identified up to date. Recent studies suggest however a higher incidence of uveal melanomas in the presence of cutaneous nevi, such as in the dysplastic nevus syndrome and also in patients having increased amounts of ocular melanocytes such as in ocular melanocytosis, oculodermal melanocytosis (Nevus Ota) and neurofibromatosis. Bilateral occurrence of uveal melanomas is exceedingly rare and most probably a matter of simple coincidence and not associated with any systemic condition. In contrast to cutaneous melanoma there is no clear association of uveal melanoma and sunlight exposure and this might be due to the fact that the choroid has a lifelong UV-shield by the lens of the eye. In contrast melanomas of the iris, which lack this UV-shield occur more commonly in the inferior and temporal quadrant where exposure to sunlight is probably greatest. Several studies suggest that persons having lighter colored irides (blue or gray) are at increased risk (approximately twofold) of developing uveal melanoma. Although an increased risk has been described in women in their childbearing years and an adverse effect of pregnancy on prognosis, epidemiologic studies have failed to find a conclusive hormonal relationship in uveal melanoma. Uveal melanoma is a potentially lethal disease with an overall 5-year tumor-related mortality rate of approximately 30–35%. Unfortunately this mortality rate has remained essentially unchanged since the first systematic analysis of uveal melanoma prognosis in the late 19th century by E. Fuchs. However, several parameters have been identified having an influence on mortality and these can be subdivided into clinical, morphological and cytogenetic risk factors (see Table 1).

In the last years, cytogenetic analysis of uveal melanomas have identified that loss of heterocygosity of chromosome 3 and specific gene expression profiles are highly associated with the development of distant tumor metastases [1]. Moreover uveal melanomas are being categorized into two classes (class 1: low risk, class 2: high risk) according to their gene expression profiling [2]. Up to date no single gene has been

**Uveal Melanoma. Table 1** Factors having an adverse effect on mortality from uveal melanoma

| Clinical | Morphological | Cytogenetic |
|---|---|---|
| Increasing tumor size:<br>– Largest basal diameter<br>– Tumor thickness<br>– Tumor volume | Presence of epithelioid melanoma cells | Presence of monosomy 3/loss of heterozygosity of chromosome 3 |
| Presence of Ciliary body infiltration | Increased vascularity | Gain in 8q |
| Presence of extrascleral infiltration | Presence of closed vascular loops | Loss in 6q (controversial) |
| Increasing patient age | Higher mitotic rate | p53 downregulation |
| Detection of circulating tumor cells (RT-PCR) | Higher proliferation rate (MIB-1/Ki-67/PCNA) | |

identified for a specific gene targeted therapy strategy. Unfortunately in case of occurrence of distance metastases still life expectancy is extremely dismal, usually not exceeding 12 months.

## Prevalence

Most epidemiologic studies estimate an incidence for uveal melanoma of annually 6–7 newly diagnosed cases per 1 million Caucasian population (USA, Finland, Sweden, Denmark, Germany). The prevalence of uveal melanoma in the general Caucasian population is estimated with 7.5 cases per 10,000. In the presence of ocular or oculodermal melanosis there is an estimated threefold increase of uveal melanoma occurrence. Uveal melanoma is very rare in nonwhite race, with whites having more than eight times the risk of developing uveal melanoma as compared to blacks or Asians. Also Europeans with ancestral origin from more northern latitudes are at increased risk of developing uveal melanomas that those originating from Southern and Mediterranean Europe.

## Genes

Although specific genes have yet to be identified in the pathogenesis of uveal melanoma, loss of heterozygosity of chromosome 3, as well as gain in 8q and probably loss in 6q are linked with an increased mortality rate. These findings imply the presence of a possible tumor suppressor gene/-es on chromosome 3 and/or an oncogene on chromosome 8.

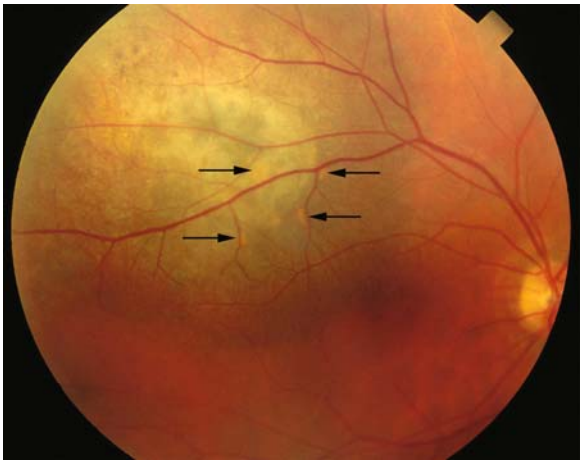
## Molecular and Systemic Pathophysiology

Cell of origin in uveal melanoma is the uveal melanocyte. Melanomas can arise from preexisting nevi and also de novo, via poorly understood molecular intracellular mechanisms involving most probably chromosomal alterations causing malignant transformation of melanocytes. Furthermore uveal melanomas exhibit a tendency towards cellular dedifferentiation from a more benign spindle cell type to a more malignant epithelioid cell type during their evolution. Whether monosomy 3 is involved in these mechanisms is still unclear. Angiogenesis and angiogenic mimicry are also involved in the pathophysiology of uveal melanoma growth. Approx. 70% of all uveal melanomas express both VEGF and various types of VEGF receptors, which correlates to the amount of tumor necrosis. Whether these findings can lead to novel antiangiogenic treatment options is under investigation. Furthermore it has been recently found that uveal melanomas express chemokine receptors CXCR4, CCR7 and CKR10 as well as the ligands CXCL12, CCL19 and CCL27, which might play a role for the hepatic affinity of uveal melanoma metastases.

## Diagnostic Principles

The principal symptom of patients with uveal melanomas is gradual deterioration of their visual acuity and/or depression of their visual field, as well as visualization of flashes or floaters. The occurrence and timing of these symptoms is a dependent on the location of the tumor within the eye. Tumors located close to structures important for central vision such as the macula and the optic nerve are diagnosed earlier as opposed to tumor located in the ciliary body that can grow significantly without being noticed by the patient and the examining ophthalmologist. The mainstay of diagnosis is clinical observation either by slit-lamp biomicroscopy in case of anteriorly located melanomas (iris, ciliary body) or by fundus indirect stereoscopic ophthalmoscopy in case of posteriorly located tumors (choroidal melanomas with or without ciliary body infiltration). Uveal melanomas are typically pigmented (although pigmentation can be heterogeneous), have lipofuscin depositions on their surface (orange pigment) and produce exsudative retinal detachments causing visual symptoms and visual field losses (Fig. 1).

These basic examinations can be complemented by ultrasound, angiography and magnetic resonance



**Uveal Melanoma. Figure 1** Pigmented uveal melanoma with orange pigment deposition (arrows) on its tumor surface.

imaging (MRI) techniques. Especially ultrasound is helpful for initial and follow-up diagnosis showing low internal tumor reflectivity in the majority of cases. The diagnostic yield with these non-invasive examination techniques is in specialized centers approx. 98%. Invasive biopsy techniques have been established for the small percentage of intraocular tumors that cannot be classified with certainty otherwise [3]. With the increasing importance of cytogenetic prognostication, that can only be obtained analyzing tumor tissue samples, minimally invasive biopsy techniques are increasingly being developed and employed even when the clinical diagnosis can be stated with certainty.

## Therapeutic Principles

The mainstay of treatment of uveal melanomas is radiation therapy. Various radiotherapeutic modalities are employed, including brachytherapy using various radionuclides (ruthenium-106, iodine-125, etc.) and teletherapy techniques either with charged particles such as protons, helium ions or carbon ions. Smaller series utilizing stereotactic radiosurgery with the gamma knife, the linear accelerator and more recently the cyberknife have also been reported. Surgical resection techniques have been developed ether by an external approach to the eye creating an external scleral window-flap over the tumor base and removing the tumor in one piece in systemic hypotension (transscleral resection) or by an internal approach from the vitreous side of the tumor by a pars plana vitrectomy (endoresection). Its has been shown that these resection techniques have favorable results in large uveal melanomas, but have to be combined with radiotherapy techniques to avoid late tumor recurrences [4]. Overall these so called "conservative" or eye-salvaging treatments for uveal melanoma result is a local tumor control of approximately 90–95% and an approximately 80–90% probability of eye retention according to the size of the tumor. In case of large non-resectable uveal melanomas, which have a poor prognosis after sole radiotherapy due to secondary irradiation complications (tumor necrosis, retinal detachment, radiation retinopathy and neuropathy), enucleation of the entire eye is advised. A large prospective randomized multicenter clinical trial (collaborative ocular melanoma study, COMS) comparing iodine-125-brachytherapy to enucleation found no difference in mortality rates between these two groups, justifying conservative eye-salvaging treatment modalities in general [5].

# Uveitis

Henry J. Kaplan, Hui Shao, Deming Sun
Department of Ophthalmology and Visual Sciences, University of Louisville, Louisville, KY, USA

## Synonyms

Iritis; Cyclitis; Pars planitis; Vitritis; Choroiditis; Chorioretinitis; Retinitis; Retinal vasculitis

## Definition and Characteristics

Uveitis is intraocular inflammation involving the uvea (iris, ciliary body, choroid) of the eye. However, inflammation of the retina – either the neurosensory retina or the retinal vasculature –is also commonly referred to as uveitis [1]. Inflammatory cells (mononuclear and/or leukocytes) are the clinical hallmark of the disease, with cells in the anterior chamber and/or vitreous cavity. However, some forms of choroiditis – e.g. ocular histoplasmosis syndrome – are associated only with chorioretinal lesions without cellular infiltration in either chamber. Some types of uveitis cause

redness, pain, and photophobia while other types may be associated with only floaters and/or blurring of vision. Young children with juvenile idiopathic arthritis are characteristically asymptomatic with a quiet, white eye. Uveitis may effect one or both eyes and occur only once; or it may be recurrent with spontaneous episodes of exacerbation and resolution; or it may be persistent (i.e. last over 3 months). The major complications of uveitis occur with recurrent or chronic inflammation. Decreased vision usually results from cystoid macular edema (CME) and/or a posterior subcapsular cataract (PSCC). A late complication may be angle-closure glaucoma (i.e. damage to the optic nerve associated with increased intraocular pressure [IOP]) from peripheral anterior synechiae. IOP is usually normal or low during an active episode although occasionally an increase in IOP is observed as a result of inflammatory obstruction of the outflow channels of the trabecular meshwork.

## Prevalence

2.8% of blindness in the US; incidence of 17/100,000 person-years; prevalence of 204/100,000 over 10 years; one recurrence in 11.3% in 5 years, with 2.5% experiencing a second recurrence [1].

## Genes

Blau syndrome: CARD15/NOD2 mutation, p.R334W substitution.

Selected HLA associations: Acute anterior uveitis – B27; Reiter's syndrome – B27; Ankylosing spondylitis – B27; Behcet's disease – B51; Birdshot retinochoroiditis – A29, A29*2; Juvenile idiopathic arthritis – DR4, Dw2, DRB1*13; POHS – B7, DR15, DQ6; Pars planitis – B8, B51, DR2, DR15; Vogt-Koyanagi-Harada's disease – DR4.

## Molecular and Systemic Pathophysiology

Since access to human tissue samples is limited, much of the understanding of the molecular and systemic pathophysiology of uveitis has been provided by the study of animal models. The mechanism of autoimmune uveitis likely involves both innate and adaptive immunity. Experimental autoimmune uveitis (EAU) is initiated by activation of antigen-specific T cells with uveitogenic antigens. Candidate antigens include S-antigen and arrestin for posterior uveitis, recoverin for cancer-associated retinopathy, alpha tropomyosin and S-antigen for Behcet's disease, Type 1 collagen for anterior uveitis, and tyrosinase-related proteins in Vogt-Koyanagi-Harada syndrome. Expansion and differentiation of activated T cells into effector T cells is accompanied by migration into the target organ. Within the eye, these T cells encounter antigen, undergo reactivation and produce large amounts of cytokines and chemokines that recruit antigen non-specific inflammatory cells (Fig. 1).

Three phenotypes of effector CD4 T cells are involved in autoimmune uveitis. Th1 T cells (cellular immunity), generated by IL-12, produce large amounts of IL-2, TNF-α and IFN-γ; thus, activating macrophages – i.e. induction of iNOS, NO and other active oxygen intermediates – as well as the immunoglobulin (Ig) switch to complement-binding and opsonizing isotypes. Th2 cells (humoral immunity), generated by IL-4, produce large amounts of IL-4, IL-5 and IL-10, and promote the Ig switch to antibodies of the non-complement binding isotypes. These two T cell subsets are mutually antagonistic and inhibit each other by virtue of the cytokines they produce. Th17 T cells, generated by IL-23 or TGF-β and IL-6, produce IL-17 and IL-22, and may be the key effector cells in autoimmune uveitis [2]. CD8 T cells recognize the same uveitogenic epitopes as CD4 T cells and are also pathogenic, suggesting that both autoreactive CD4 and CD8 T cells, rather than CD4 T cells alone, should be targeted for the treatment of uveitis [3]. Regulatory CD4 and CD8 T cells are responsible for the spontaneous remission of uveitis and the prevention of recurrences [4].

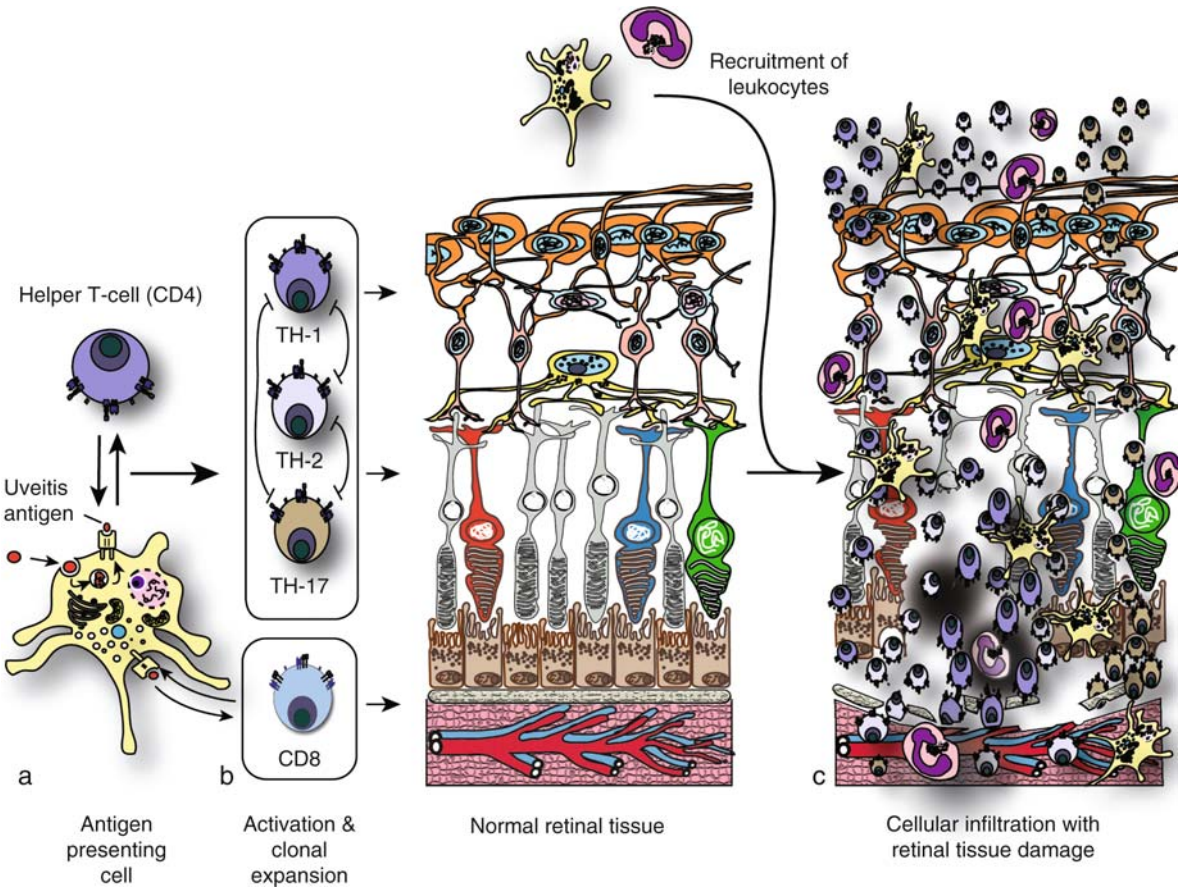
## Diagnostic Principles

Uveitis is classified by both anatomic and etiologic criteria. The anatomical classification is based on the ocular structure most involved with inflammation – i.e. anterior (iris, ciliary body), intermediate (pars plana, vitreous), posterior (choroid and/or retina) or pan (diffuse). Since uveitis can have either an infectious or non-infectious cause, the etiologic classification of uveitis is more complex. Thus, a focused laboratory evaluation suggested by the history and clinical examination is the appropriate approach. The value of a particular diagnostic test is dependent on the probability, sensitivity and specificity of the test – e.g. calculated using Bayes theorem [5].

## Therapeutic Principles

Since most cases of uveitis can not be cured, the medical management of uveitis is directed at relief of discomfort, improvement of vision and prevention of complications. Infectious uveitis should, in general, should be treated with the appropriate anti-infective pharmaceuticals (either topical, periocular and/or intravitreal) coupled with anti-inflammatory therapy with corticosteroids, to reduce the intraocular damage caused by inflammation.

*Red, painful, photophobic eye*: Topical cycloplegia and mydriasis with cyclopentalate will relieve ciliary body muscle spasm and reduce photophobia, while inhibition of cholinergic stimulation of the sphincter



**Uveitis. Figure 1** Schematic sequence of events in the pathogenesis of uveitis. (a) Uveitogenic antigens are processed and presented to antigen-specific T cells in peripheral and/or central lymphoid organs. (b) Once activated, the T cells proliferate and differentiate into uveitogenic T cells capable of migrating to the eye. (c) Following entrance into the eye, these T cells are re-activated and produce cytokines and chemokines. These chemical signals recruit antigen non-specific leukocytes and produce intraocular inflammation (i.e. uveitis).

muscle of the iris will cause mydriasis and prevention of posterior synechiae. Sun glasses will contribute to the relief of light sensitivity.

*Floaters and/or reduced vision from CME*: Inflammatory cells in either the anterior chamber or vitreous cavity may cause floaters. CME can result from inflammation confined to the anterior segment of the eye (i.e. iris and ciliary body) or the posterior segment (i.e. vitreous, retina and choroid). Topical corticosteroids will reduce the inflammation in the anterior chamber, and frequently result in an improvement of vision and the resolution of CME associated with anterior uveitis. However, periocular, intravitreal or systemic corticosteroids should be given for CME associated with intermediate, posterior or pan uveitis or for even anterior uveitis associated with persistent CME.

*Chronic uveitis*: Non-infectious uveitis is considered chronic if intraocular inflammation persists for more than 3 months. If treatment with corticosteroids is not successful in resolving uveitis, the next line of defense is immunosuppression, specifically the antimetabolites, such as methotrexate and mycophenolate mofetil. The newer biologic agents that block specific mediators of the immune response – such as TNF-α (e.g. etanercept, infliximab) and IL-2 receptor (e.g. daclizumab) – have been more recently tried in unresponsive patients.

## Van Buchem Disease and Sclerosteosis

Wendy Balemans, Wim Van Hul
Department of Medical Genetics, University and University Hospital of Antwerp, Antwerp, Belgium

### Synonyms

Autosomal recessive endosteal hyperostosis; Hyperostosis corticalis generalisata; Truswell-Hansen disease

### Definition and Characteristics

Van Buchem disease and sclerosteosis are classified among the craniotubular hyperostosis. Radiographic examination shows a generalized, progressive overgrowth and sclerosis of the skeleton. Typical features are an impressive thickening and sclerosis of the mandible and both the roof and base of the skull, often resulting in facial distortion. Facial nerve palsy, hearing disturbances, visual loss and neurological pain, caused by encroachment of the cranial foramina by hyperostotic bone, are frequently observed clinical complications. The clinical phenotype of sclerosteosis is often more severe and variable expression of congenital hand malformations and raised intracranial pressure, sometimes leading to sudden death, is observed [1].

### Prevalence

Both conditions are inherited in an autosomal recessive fashion with an equal sex distribution, and the prevalence is very low in general. Only about 40 cases of van Buchem disease and >60 affected sclerosteosis patients have been reported. The prevalence of Sclerosteosis has been estimated at 1 in 75,000 in the South African population, where the incidence is the highest, and at least 1 in every 140 Afrikaners is a carrier of the disease-causing mutation.

### Genes

Van Buchem disease and sclerosteosis result from mutations in SOST, a gene located on chromosome

17q12–q21. Thus far, six different disease-related sequence variants have been described. Three nonsense mutations, Q23X, W124X and R126X, have been found in respectively South-African, Brazilian and American patients with sclerosteosis, while two splice site variants, IVS1 + 3 A→T and IVS1 + 1 G→C, were identified in a Sclerosteosis patient from Senegal and two German siblings, respectively, diagnosed with the milder van Buchem disease. Finally, a genomic deletion downstream of SOST was found in van Buchem patients from an extended, highly consanguineous Dutch family [2].

SOST is a two-exon gene and encodes sclerostin, a 213 amino acid propeptide with a calculated molecular weight of 24 kDa including a signal sequence for secretion and two putative N-glycosylation sites. Based on amino acid sequence similarity, sclerostin belongs to the DAN subfamily of secreted proteins containing a cystine knot motif.

## Molecular and Systemic Pathophysiology

The observed amino acid sequence similarities of sclerostin with DAN family members initially suggested a role for sclerostin in antagonizing transforming growth factor (TGF)-β family members, such as bone morphogenetic proteins (BMPs). However, only weak interactions were observed with different members of the BMP family and studies demonstrated that sclerostin does not inhibit early BMP responses [3]. More recent reports showed an antagonistic effect of sclerostin on LDL receptor-related protein (LRP) 5/6-mediated canonical Wnt signaling, an important signaling cascade in osteoblastic bone formation, by direct binding to LRP5/6 [4].

The Q23X nonsense mutation present in the South-African sclerosteosis patients leads to lack of sclerostin expression in bone. Normally, sclerostin is found in osteocyte canaliculi and/or lacunae of both cortical and trabecular bone [2]. Introduction of this premature stop codon, however, does not result in increased degradation of mRNA. We anticipate that the two other nonsense mutations, W124X and R126X, similarly result in abolition of protein expression. Both, IVS1 + 3 A→T and IVS1 + 1 G→C, are likely to affect splicing of SOST. An in vitro splicing assay for the IVS1 + 3 A→T mutation showed that this variant results in the use of a cryptic splice site located 214 bp downstream of the authentic site introducing an in-frame stop codon and resulting in strongly reduced transcript processing [2]. The 52-kb genomic deletion located downstream of SOST associated with van Buchem disease in the Dutch patients contains at least one long-range enhancer specifically regulating gene transcription in bone [4]. Absence of this enhancer results in complete lack of sclerostin protein in bone biopsies of van Buchem patients. Further studies need to be performed to investigate whether this regulatory mutation also results in complete lack of SOST mRNA in these patients.

The absence of sclerostin in the bone of van Buchem and sclerosteosis patients may therefore result, at least in part, in a hyperactivation of canonical Wnt signaling and consequently lead to the bone overgrowth observed in these patients.

## Diagnostic Principles

Sclerostin deficiency can be suspected in cases with a generalized skeletal hyperostosis that is most pronounced in the skull and mandibular bones, and an autosomal recessive mode of inheritance. Narrowing of the cranial foramina by hyperostotic bone frequently results in clinical complications, including facial palsy, hearing loss and visual disturbances.

Differential diagnosis between sclerosteosis and van Buchem disease is based on the presence of congenital hand malformations (syndactyly of the digits, radial deviation of the terminal phalanges and absent or dysplastic nails), a tall stature and raised intracranial pressure in patients with sclerosteosis.

## Therapeutic Principles

At this moment, no effective therapy is available to cure patients with van Buchem disease and sclerosteosis. Surgical decompression of the neural and vascular channels and extensive decompression of the posterior fossa may help to preserve vision and fifth, seventh and eight nerve function, in the preservation of facial and cochlear nerve function, to improve cerebral venous drainage, to alleviate intracranial hypertension and to relieve pressure upon brainstem and cerebellum. Surgery has also been used to recontour the mandible.

# Van Lohuizen Syndrome

►Cutis Marmorata Telangiectatica Congenita

# Vanadium Deficiency and Excess

Marian Valko, Jan Moncol
Faculty of Chemical and Food Technology, Slovak Technical University, Bratislava, Slovakia

## Synonyms

Dietary micronutrient vanadium; Vanadium poisoning

## Definition and Characteristics

Vanadium is a trace mineral. There is no RDA for vanadium; a daily intake of 10–100 mcg is probably safe and adequate. Whether the element vanadium plays any nutritional, biochemical, or biologic role in the human is a question that has been difficult to answer.

## Prevalence

Pathophysiologically relevant vanadium deficiency and excess are probably both rare.

## Molecular and Systemic Pathophysiology

Vanadium is a trace mineral found in fish, vegetable oils, and olives. It may also be found in snap beans, dill, meat, radishes, and whole grains. Vanadium's functions are not fully understood, but it may act as a co-factor for enzymes involved in blood sugar metabolism, lipid and cholesterol metabolism, bone and tooth development, fertility, thyroid function, hormone production and neurotransmitter metabolism. Vanadium is known to stimulate glucose oxidation and transport in fat cells and glycogen synthesis in liver and muscle and inhibit liver production of glucose from fat and absorption of glucose from the gut. Vanadium enhances the stimulating effect of insulin on DNA synthesis. Vanadium appears to function like insulin by altering cell membrane function for ion transport processes, therefore vanadium has a beneficial effect in humans with glucose tolerance problems by making the cell membrane insulin receptors more sensitive to insulin. Vanadium also inhibits cholesterol synthesis; this is followed by decreased plasma levels of cholesterol and reduced aortic cholesterol.

Experiments on tissue cultures have shown that vanadium excess results in DNA damage and oxidation of lipids. Using the comet assay, it was shown that vanadyl sulfate induced DNA damage in human normal lymphocytes and in HeLa cells. Vanadyl at 0.5 and 1 mM produced DNA single- and double-strand breaks (SSBs and DSBs) in lymphocytes, whereas in HeLa cells were observed only SSBs. Vanadium-induced oxidative stress on cells, is partly due to an interaction with reactive iron. However, at this stage it is too early to conclude that these in vitro experiments and experiments on animals will translate into similar dangers in humans.

The only clearly documented effect of vanadium dust is upper respiratory tract irritation characterized by rhinitis, wheezing, nasal hemorrhage, conjunctivitis, cough, sore throat, and chest pain. Symptoms may be delayed a few days and recovery usually occurs within 3–5 days. Following more severe exposure, an acute bronchitis with dyspnea and expiratory wheezes may develop along with gastrointestinal symptoms and fatigue. Bronchitis and pneumonitis may occur after prolonged exposure, but chronic respiratory dysfunction has not been reported in clinical studies of workers exposed to vanadium compounds.

It is probable that deficiency in humans may lead to high cholesterol and triglyceride levels and increase susceptibility to heart disease. Some success in treating manic-depressive disease has actually come from diets designed to be low in vanadium. Symptoms of vanadium toxicity vary with chemical form and route of absorption.

Vanadium enters the organism by inhalation, skin and gastrointestinal tract. Vanadium oxides are usually more toxic than vanadium salts and vanadium(V) is usually more toxic than vanadium(IV) compounds. While potential mutagenic effects of vanadium are also related to the ability of vanadium to generate reactive oxygen species, cancer induction has not yet been satisfactorily confirmed. Excess ingestion of vanadium can result in decreased appetite, depressed growth, diarrhea/gastrointestinal disturbances, nephrotoxic and hematotoxic effects. Pallor, diarrhea, and green tongue are early signs of excess vanadium and have been reported in human subjects consuming about 20 mg vanadium per day. In addition, vanadium excess may cause nerve damage, liver damage and stunted growth. Animals that ingested very large doses have died. Lower, but still high levels of vanadium in the water of pregnant animals resulted in minor birth defects. Some animals that breathed or ingested vanadium over a long term had minor kidney and liver changes. Some researchers speculate that excess vanadium could also be involved in several diseases of the kidney and bone where it is known to accumulate.

## Diagnostic Principles

There are no known specific symptoms of vanadium deficiency in humans, but bone deformities, growth retardation, infertility and increased infant mortality have resulted from vanadium deficiency in animals. Deficiency in animals causes reduction in red blood cell production leading to anemia and iron metabolism defects.

## Therapeutic Principles

Vanadate supplementation reverses many of the symptoms of osteoporosis caused by high-dose glucocorticoids in adult rats.

Intravenous EDTA (ethylenediaminetetraacetic acid) chelation therapy that blocks intake of vanadium (and other metals) has been proven safe and effective approach to protect the organism against vanadium intoxication.

# Vanadium Poisoning

►Vanadium Deficiency and Excess

# Vanishing Bile Duct Syndrome

Lee A. Denson
Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

## Synonyms

Intrahepatic bile duct loss; Ductopenia; VBDS

## Definition and Characteristics

Vanishing bile duct syndrome (VBDS) represents the final, irreversible stage of a variety of ductopenic diseases due to progressive intrahepatic bile duct loss [1]. Regardless of the underlying etiology, VBDS will ultimately lead to chronic cholestasis, biliary fibrosis, and ultimately cirrhosis or liver failure.

## Molecular and Systemic Pathophysiology

The biliary epithelium under normal conditions is in a state of equilibrium between ongoing biliary epithelial cell (BEC) loss primarily due to apoptosis, and BEC renewal [2]. Intrahepatic bile duct loss may result when this balance is upset, in terms of increased BEC apoptosis without a compensatory increase in BEC renewal. The relative expression of anti-apopototic genes, including members of the Bcl-2 family, is an important factor in terms of regulating this process. A number of triggers for apoptosis have been identified; these can include Fas, tumor necrosis factor α (TNFα), oxidative stress, and retained bile acids. Depending upon the underlying disease, the bile duct loss may occur at any level of the biliary tree, in either a focal (Primary Biliary Cirrhosis (PBC) and Primary Sclerosing Cholangitis (PSC) or diffuse (hepatic allograft rejection (HAR) and graft-versus-host disease (GVHD)) fashion. A variety of immunological, ischemic, infectious, or toxic disorders may result in ductopenia [2].

*Immune-mediated Bile Duct Loss* is the mechanism of bile duct loss in PBC, PSC, HAR, and GVHD, in which autoreactive (PBC and PSC) or alloreactive (HAR and GVHD) T cells targeted against specific antigens on BECs mediate bile duct injury. In HAR, the recipient's immune response is active against allogeneic antigens on the donor BECs, while in GVHD, graft lymphoid cells target MHC-related antigens on host BECs. In the autoimmune mechanisms invoked in PBC and PSC, antigens aberrantly expressed on BECs are targeted. For PBC, this includes mitochondrial antigens such as the pyruvate dehydrogenase complex E2-subunit (PDC-E2). For PSC, this is less well established, although a colonocyte protein which is an isoform of tropomyosin has been implicated.

Infectious cholangitis In long-standing bacterial cholangitis, such as in secondary sclerosing cholangitis or chronic hepatolithiasis associated with Caroli's disease, the intrahepatic bile ducts may be progressively destroyed and replaced by fibrous tissue. This tends to be a focal process involving the most severely affected hepatic segments. While some viral infections, such as cytomegalovirus (CMV) or reovirus have been shown to involve the biliary epithelium, it is not clear whether these represent a significant cause of chronic ductopenia. Alternately, bacterial or viral infections may trigger immune-mediated injury in PBC, PSC, HAR, or GVHD, although this has not been definitively established for any single organism.

*Drug-induced and Toxic Bile Duct Loss*: There are agents such as paraquat and some anticancer drugs

when infused through the hepatic artery which may predictably cause cytotoxic injury to the biliary epithelium. However, for most drug-induced VBDS, idiosyncratic toxic or immune-mediated mechanisms may lead to progressive ductopenia [3].

*Ischemic Biliary Injury*: The bile ducts are supplied by the hepatic arterial system. Ischemic biliary injury contributes to bile duct loss in HAR, in which the hepatic arterial branches may undergo thrombosis or ongoing endothelial immune injury, and in interventional radiology therapy (IVR) involving the hepatic artery. In acute HAR, it is primarily the recipient T cells which mediate damage to the biliary tree, while in chronic HAR, both the immune-mediated and ischemic mechanisms may combine to cause progressive bile duct loss.

Other conditions which have been associated with bile duct loss include sarcoidosis, Hodgkin's disease, idiopathic adulthood ductopenia, and PFIC 3.

## Diagnostic Principles

Patients may present with jaundice and pruritis, or a more indolent anicteric cholestasis. On histology, the bile duct loss is recognized as the absence of interlobular bile ducts in at least 50% of small portal tracts, in a liver biopsy which contains at least ten portal triads. Similarly, the absence of bile ducts adjacent to hepatic arterial branches may also be quantified in establishing the diagnosis of intrahepatic bile duct loss. Additional imaging (e.g. ERCP or MRCP) and serological testing for autoantibodies and infections is then typically required to diagnose one of the specific disorders listed in the preceding section.

## Therapeutic Principles

Supportive therapy is similar to other chronic cholestatic disorders and is directed at the specific underlying disorder and complications of cholestasis and portal hypertension [4]. For drug-induced ductopenia, prompt removal of the offending agent will often lead to restoration of the biliary tree over time. For many of the other disorders, progressive duct loss leading to VBDS may occur. Fat soluble vitamin deficiency (A, D, E, and K) should be identified and treated. Infants will benefit from a formula containing medium chain triglycerides. Pruritis can be a debilitating feature of chronic cholestatic disorders; studies have indicated that this may be due to elevated circulating levels of opiods – encephalins. Accordingly, opiod antagonists including naltrexone have been used in some cases with good results. More commonly, some combination of ursodeoxycholic acid (UDCA), antihistamines including hydroxyzine, bile acid sequestering agents such as cholestyramine, or rifampicin are used. UDCA may reduce the severity of several of these disorders, if sufficient biliary enrichment is achieved with this much less toxic hydrophilic bile acid. Patients with the autoimmune type of sclerosing cholangitis may benefit from prednisone and/or azathioprine, in addition to UDCA therapy. Similarly, HAR and GVHD will benefit from specific immunosuppressive therapy, although this may not prevent progression in chronic HAR once VBDS has developed [5]. Fatigue is a common, but poorly understood complaint for which specific therapies are not available. Metabolic bone disease may be treated with calcium and Vitamin D supplementation and bisphosphonates. Liver transplantation is offered to patients who progress to biliary cirrhosis and liver failure.

# Variceal Bleeding

Maria Mela, Ulrich Thalheimer, Dimitrios Samonakis, Andrew K. Burroughs
Department of Liver Transplantation and Hepatobiliary Surgery, Royal Free Hospital, Hampstead, London, UK

## Definition and Characteristics

Bleeding from esophageal or gastric varices at the time of endoscopy or the presence of large varices with blood in the stomach and no other recognizable cause of bleeding. The episode of bleeding is considered clinically significant when the transfusion requirement is two or more units of blood within 24 h of hospital admission, together with a systolic blood pressure <100 mmHg or a postural change >20 mmHg and/or pulse rate >100/min at the time of admission. Liver cirrhosis is frequently complicated by the development of portal hypertension and the formation of portal-systemic collaterals. Among these, gastroesophageal varices are the most important since they are responsible for the main complication of portal hypertension, massive variceal bleeding which carries a mortality of 10–50% according to the severity of the underlying liver disease.

## Prevalence

At the time of diagnosis of cirrhosis, varices are present in about 60% of decompensated and 30% of compensated patients. Cirrhotics without varices develop varices at a rate of 5–15% per year. One third of patients with varices will bleed.

## Molecular and Systemic Pathophysiology

Once formed, varices tend to dilate as a function of time, persistence of portal hypertension and repeated physiological stimuli such as meals, ethanol consumption, exercise and increased intraabdominal pressure which cause abrupt rises in portal pressure and/or blood flow. Tension of the variceal wall is probably the decisive factor determining variceal bleeding; the progressive vessel distension generates an increasing resistance to further distension (wall tension). When reaching the elastic limit of the vessel, the variceal wall cannot increase its resistance to further dilatation, leading to variceal rupture [1]. Wall tension is defined by the Frank's modification of Laplace law: wall tension = (P1–P2) × radius/thickness in which P1 is the intravariceal pressure (which is a function of the increased portal pressure) and P2 is the esophageal luminal pressure. Many studies have shown that variceal rupture and bleeding is extremely rare if the portal pressure gradient (most commonly evaluated in clinical practice by the hepatic venous pressure gradient HVPG) is <12 mmHg. Also, substantial decrease of the HVPG particularly if reduced to 12mHg or less is associated with a substantial reduction in risk of bleeding. Moreover, the outcome of the bleeding episode, in terms of lack of control of bleeding and early rebleeding is worse in patients with an admission HVPG ≥20 mmHg. The risk of bleeding as defined from the above equation is directly related to the size of the varices and the wall thickness. This concept fits with clinical observations showing that large varices (as assessed by endoscopy) with endoscopic red color signs are associated with higher risk of bleeding. However, the severity of liver disease is the main risk factor for variceal bleeding, superimposed on these two risk factors.

Bacterial infections occur in up to 70% of cirrhotic patients with variceal bleeding. This association has led not only to the use of antibiotic prophylaxis in the setting of acute gastrointestinal bleeding, but also to the hypothesis that endotoxaemia plays a role in the pathogenesis of bleeding. The obvious hypothesis that could explain this connection is that gastrointestinal hemorrhage could predispose bleeding cirrhotic patients to bacteremia. However, there are data to support a different sequence of events; bacterial infection may be a critical factor that triggers gastrointestinal hemorrhage, particularly variceal bleeding [2]. In patients with varices, the high levels of endotoxin in the systemic circulation during episodes of bacterial infection result in a further increase in portal pressure through the synthesis of endothelin and contraction of hepatic stellate cells. Furthermore, endotoxin-induced nitric oxide together with prostacyclin induced by both endothelin and endotoxin could inhibit platelet aggregation; induction of cyclo-oxygenase products may also contribute. The increase in portal and subsequently variceal pressure, coupled with impairment in primary hemostasis could lead to the onset of variceal bleeding.

## Diagnostic Principles

In cirrhotic patients the clinical suspicion of variceal source of gastrointestinal bleeding is confirmed with upper endoscopy. Early endoscopy in all upper GI bleeders enables accurate diagnosis of the bleeding site and decision regarding management.

## Therapeutic Principles

Effective resuscitation, accurate diagnosis and early treatment can reduce mortality due to variceal bleeding. The aims are not only to stop bleeding as soon as possible but also to prevent early rebleeding which is associated with worsening mortality. The initial resuscitation of the patient is as important as the other specific measures to promote homeostasis. Over-transfusion must be avoided and blood should be

replaced to a modest target hematocrit 25–30%. The optimal use of clotting factors has been little studied; a practical approach is to give two units FFP after four units of blood when the PT is more than 20 s and platelets if the count is $<50{,}000 \times 10^6/mm^3$ in an actively bleeding patient. Endotracheal intubation must be considered for the encephalopathic patients or those with massive hematemesis to avoid aspiration. Prophylaxis with an oral or IV quinolone or IV cephalosporin is mandatory in cirrhotics with gastrointestinal bleeding irrespective of the suspected presence of sepsis [3]. The currently recommended treatment schedule for acute variceal bleeding is administration of a vasoactive drug (terlipressin or somatostatin) at the time of admission followed by with endoscopic treatment (sclerotherapy or band ligation) at the time of diagnostic endoscopy. The pharmacotherapy should be continued for at least 2 and preferably 5 days; this approach improves initial control of bleeding and 5-day hemostasis but to date there is no convincing evidence as to a reduction in mortality. Transjugular intrahepatic portosystemic shunt (TIPS) is indicated in patients in whom bleeding cannot be controlled or recurs after two endoscopic sessions. The therapeutic role of haemostatic agents has not been studied in variceal bleeding. Recently, the availability of haemostatic agents and specifically of the recombinant factor VIIa which is known to correct prothrombin time, has led to a large blinded study. The results are awaited.

Patients surviving the first episode of variceal bleeding are at very high risk of recurrent bleeding (70% or more at 1 year) and death (30–50%). Therefore, all patients who survive an episode of variceal bleeding must receive some effective long-term therapy to prevent further variceal bleeding and the first-line treatment is non selective b-blockers. B-blockade should be continued indefinitely. Variceal band ligation has replaced sclerotherapy as it is better tolerated with fewer side effects and is more efficacious in secondary prophylaxis. It should be used if there are contraindications or intolerance to b-blockers. The use of isosorbide mononitrate on its own is contraindicated and its use in combination with b-blockers is not sufficiently studied. The management of patients on drug therapy can include monitoring of hemodynamic response, but the evidence for this may not be as strong as initially thought. In addition, in view of the lack of non-invasive methods to measure and monitor the portal pressure, it remains clinically difficult to recommend.

Primary prophylaxis depends on the detection of varices. At present there is no standardization of screening practices but in our practice every patient with cirrhosis (except those with short life expectancy) should be offered a one-time screening endoscopy. In cirrhotics with large varices, prophylactic b-blocker therapy should be given. The available evidence does not support the combination of b-blocker and ISMN for primary prophylaxis. ISMN as monotherapy is contraindicated. Sclerotherapy does not offer any additional benefit when combined with b-blockers and it may be harmful in patients with varices who have never bled. Variceal ligation appears to be safe and may be a reasonable alternative for patients with contraindications, intolerant or non-compliant to b-blockers. However it is unlikely to be a routine prophylactic treatment as it is much more expensive and less available than b-blockers and it does not prevent from gastric mucosal bleeding.

Until further encouraging results become available, the usefulness of prevention of formation/growth of varices (pre-primary prophylaxis) in clinical practice is yet unproven.

## Synonyms

Congenital varicella-zoster syndrome; Fetal varicella syndrome; Fetal herpes zoster syndrome; Varicella embryopathy

## Definition and Characteristics

The most prominent pathognomonic feature is a hypoplastic limb with cutaneous scars in a dermatomal distribution (Fig. 1) [1].

Infants with congenital varicella syndrome are usually small for gestational age. Eye abnormalities, such as Horner syndrome, microphthalmia, and chorioretinitis are common. Horner syndrome is characterized by

**Varicella Syndrome, Congenital. Figure 1** Note cutaneous scars on the hypoplastic left forearm of this child with congenital varicella syndrome. The fingers are short and contracted.

miosis, ptosis, apparent enophthalmos with or without anhidrosis, facial flushing on the side of the lesion, and heterochromia iridis [2]. Central nervous system abnormalities are common and include microcephaly, hydrocephaly, cortical and cerebellar atrophy, mental retardation, bulbar palsy, and intracranial calcification [1]. Autonomic nervous system involvement is seen occasionally and can present as neurogenic bladder, anal sphincter dysfunction, dysphagia, or intestinal obstruction. Less frequent neuromuscular abnormalities include talipes equinovarus or calcaneovalgus deformity, a rudimentary digit, and scoliosis. Gastrointestinal tract anomalies, notably colonic atresia, and genitourinary anomalies have been occasionally reported [3,4].

## Prevalence

The incidence of varicella during pregnancy is estimated to be 0.1–0.7 per 1,000 pregnancies. About 25% of the fetuses of women who develop varicella become infected with the virus [1]. Approximately 1–2% of fetuses whose mothers developed varicella in the first 20 weeks of pregnancy are at risk for congenital varicella syndrome [5].

## Molecular and Systemic Pathophysiology

Humans are the only known reservoir for the varicella-zoster virus. The virus is transmitted by direct contact with varicella-zoster lesions or by inhalation of infected airborne droplets. In maternal varicella that results in viremia, the virus is usually transmitted to the fetus through the placenta and then spreads by a hematogenous route. Transmission to the fetus by ascending infection from lesions in the birth canal is rare. The congenital abnormalities are thought to result from the development of varicella-zoster virus infection in utero and from the associated encephalitis [1]. The varicella-zoster infection leads to dermatomal lesions and to damage to the spinal sensory ganglia, anterior spinal horn, and autonomic nervous system. The encephalitis can result in optic atrophy, chorioretinitis, microphthalmia, microcephaly, and mental retardation.

## Diagnostic Principles

Congenital varicella syndrome can be diagnosed during pregnancy by the demonstration of specific malformations on ultrasonography, detection of IgM antibody to varicella-zoster virus in fetal blood obtained by percutaneous umbilical cord sampling, or by detection of the virus by polymerase chain reaction in samples of amniotic fluid or fetal blood [5]. After birth, the criteria for the diagnosis include evidence of gestational varicella, clinical stigmata of congenital varicella syndrome, proof of intrauterine varicella-zoster virus infection by the detection of viral DNA in the infant, the presence of specific IgM in the neonatal period, persistence of specific IgG beyond 7 months of age, or the appearance of zoster during early infancy [5].

## Therapeutic Principles

There is no specific therapy for congenital varicella syndrome. Treatment is supportive and may involve multiple disciplines such as physiotherapy, occupational therapy, ophthalmology, orthopedics, and developmental pediatrics. Congenital varicella syndrome can be prevented by immunization of all susceptible individuals who are 12 months of age and older. Pregnancy should be avoided for at least 1 month and preferably for 3 months after an immunization. For mothers who develop varicella during pregnancy, varicella-zoster immune globulin, administered intramuscularly within 96 h, reduces the incidence of congenital infection.

# Varicocele

Stefan R. Bornstein
Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Definition and Characteristics

Varicoceles are defined as dilations of veins of the pampiniform plexus. A scrotal varicocele is the most

common finding in infertile man with changes in the sperm count. Varicoceles are also found in fertile men and are more common in tall men and in men with larger testes.

## Prevalence

It occurs in 30% of the adult male population with infertility and usually affects the left side in 95%. Varicoceles are detected in 15% of fertile men at routine examination.

## Molecular and Systemic Pathophysiology

Varicocele results from backflow of blood secondary to incompetent or absent valves in the spermatic veins. This valvular deficiency combined with the long vertical course of the spermatic on the left side, leads to the formation of most varicoceles on the left side (95%). Varicoceles are not commonly seen on the right side because of the obcourse of the right internal spermatic vein from the vena cava. A unilateral right varicocele suggests venous thrombosis/tumor or situs inversus. The incidence of bilateral varicoceles is less than 40%.

Men with varicoceles generally have poorer semen quality than those without varicoceles. To explain the abnormalities in spermatogenesis with varicocele, the following theories have been proposed:

1. Elevation of testicular temperature due to venous stasis
2. Retrograde flow of toxic metabolites from the adrenal or kidney
3. Blood stagnation with germinal epithelial hypoxia
4. Alterations in the hypothalamic–pituitary–gonadal axis

Until now the precise mechanisms are not clear. The semen quality in men with varicoceles varies from azoopermic to normal. No specific pattern of abnormality is seen with varicocele.

*Clinic*: Patients suffer from scrotal discomfort and the infertility manifests in limitation of the spermatic motility. Symptoms, including swelling and dragging sensation in the scrotum, are infrequent. Many men with large varicoceles are unaware of its presence. The sudden appearance of a varicocele in the adult should be taken seriously because it may be feature of renal carcinoma with extension into the left renal vein. This well known clinical association is uncommon.

## Diagnostic Principles

The diagnosis of a clinical significant varicocele is generally made on physical examination of the scrotum and its contents. The patient is examined in the supine and standing position in a warm room, which promotes relaxation of the scrotal dartos muscle and facilitates accurate evaluation for varicocele. The scrotum should be inspected carefully for any easily visible dilated veins. The spermatic cord should be palpated between thumb and forefingers for palpable vein. Both sides of spermatic cords should be palpated while the patient performs a Valsalva maneuver.

The severity of the varicoceles is graded I through III as follows:

1. Clinical (palpaple):
   - Varicocele I: Only in Valsalva maneuver palpated enlargement of the pampiniform plexus
   - Varicocele II: Prominent palpable enlargement of the pampiniform plexus
   - Varicocele III: Prominent palpable and visible enlargement of the pampiniform plexus
2. Subclinical (not palpaple):
   - Vein larger than 3 mm on ultrasound; Doppler reflux on Valsalva maneuver

Grade I varicoceles can be thought of as small, grade II, medium and grade III, large. Varicoceles should significantly diminish in size when the patient assumes the supine position. If the varicocele remains prominent with the patient supine, this finding suggests a mechanical obstruction to testicular venous outflow such as a retroperitoneal mass (sarcoma, lymphoma, or a renal tumor with venous thrombus). An abdominal ultrasound or CT scan should be obtained to evaluate the retroperitoneum in the patients.

Scrotal ultrasonography with color flow Doppler imaging may prove useful in equivocal cases or in patients with a body habitus that makes accurate physical examination of the scrotum impossible. Using ultrasonography, the diameter of the internal spermatic vein can be measured and retrograde flow through the vein during Valsalva documented. Veins that are greater than 3.5 mm can generally be detected on physical examination.

## Therapeutic Principles

The value of treatment of varicocele for infertility is controversial. One view is treatment of varicoceles may not improve infertility; therefore, varicocele should be treated only for symptoms. The other extreme is the belief that varicocele is the most important treatable cause of male infertility, so all varicoceles should be treated even if they are small. Reasons for treating varicoceles are as follows:

1. When the right testis is absent, obstructed, or atrophic and sperm in the semen come from the left testis
2. Large varicoceles
3. Semen abnormality

Treatment of the varicocele involves venographic obstruction of the incompetent veins or surgery to prevent venous backflow from the abdomen to the

pampiniform plexus. Radiographic techniques involve placement of a sclerosant, glue, or coil to promote clotting in the vein and carry a lower rate of morbidity than surgery under general anesthesia does, but failure and recurrence rates are relatively high. A variety of operations can be performed for varicocele. New inguinal and scrotal microsurgical approaches have low failure, recurrence, and hydrocele rates.

Successful venous occlusion will relieve pain and reduce the size of large varicoceles. Up to 66% of men show significant improvement in semen quality after treatment, with pregnancy rates in the female partner averaging 32%.

# Varicose Veins

Marina Aunapuu, Andres Arend
Department of Anatomy, University of Tartu, Tartu, Estonia

## Synonyms

Varicosis; Varicosity

## Definition and Characteristics

Permanently enlarged, twisted, tortuous superficial veins, most commonly seen in the legs, resulting from congenitally incomplete valves. Varicose veins of lower extremities represent the most common pathology of peripheral blood vessels [1]. Varicose veins are gnarled, enlarged veins, which develop mostly in the v. saphena magna system. The causes include hereditary weak vein wall structure with defective valves, venous hypertension, age-related changes and pregnancy. Prolonged standing and increased pressure in the abdomen may increase susceptibility to the development of varicose veins.

## Prevalence

Prevalence estimates vary widely between geographical locations. The reported range is <1–73% in females and from 2 to 56% in males. Prevalence is generally higher in more developed, industrialized countries [2].

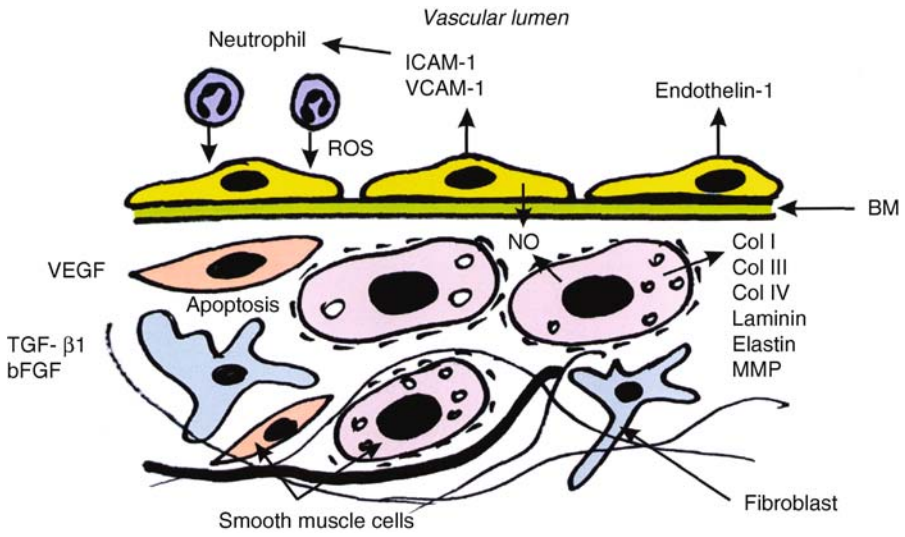
## Genes

Data confirming the genetic background of the varicosis is constantly accumulating, but the genes involved have not been identified [3].

## Molecular and Systemic Pathophysiology

Varicosis is a complex pathology characterized by venous hypertension, blood stagnation, and reflux leading to progressive venous wall remodeling. The primary cause is still unknown, but it is likely that the defect is in the wall of the lower limb veins. The valvular incompetence, also contributing to the pathogenesis of varicose veins, should be accompanied by other aspects of wall dysfunction. The resulting increased hydrostatic pressure causes structural changes in the layers of the vein wall. Variable wall structure with areas of attenuation and dilatation interspersed with focal areas of intimal thickening is characteristic for varicose veins. Along intimal invaginations, endothelial cells are elongated, thinned out and could be lost into the lumen leaving only basement membrane to form the luminal surface. The medial layer mostly contains few abnormal smooth muscle cells, which are surrounded by increased amount of connective tissue with irregular organization of collagen fibers and disruption of the elastic network around smooth muscle bundles. In hypertrophic segments, medial smooth muscle cells show marked alterations suggesting a change from a contractile to a proliferative and synthetic phenotype (Fig. 1).

Thus, the balance of smooth muscle cell proliferation and extracellular matrix deposition and degradation is perturbed involving different molecular mechanisms. Blood stasis leads to ischemia triggering the endothelium to release inflammatory mediators and growth factors including intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) [4]. These molecules recruit and activate leukocytes leading to the infiltration of the venous wall with subsequent alteration of extracellular matrix components. The inhibition of matrix metalloproteinases, accumulation of collagen type I, reduction of type II and IV collagen, abnormal collagen to elastin ratio and the loss of the regular collagen/elastic lattice of the vein wall represent part of mechanisms behind the extracellular matrix remodeling. Growth factors such as basic fibroblast factor (bFGF) and transforming growth factor-β1 (TGF-1) induce smooth muscle cell migration, proliferation and differentiation into the synthetic phenotype. An imbalanced or aberrant production of vasoactive factors



**Varicose Veins. Figure 1** Schematic drawing of molecular interactions between cells in the varicose vein wall. ROS – reactive oxygen species, ICAM-1 – intercellular adhesion molecule-1, VCAM-1 – vascular cell adhesion molecule-1, BM – basement membrane, VEGF – vascular endothelial growth factor, NO – nitric oxide, TGF-β1 – transforming growth factor - 946;1 bFGF – basic fibroblast growth factor, Col 1 – Collagen I, Col III – Collagen III, Col IV – Collagen IV, MMP – matrix metalloproteinases.

like vascular endothelial growth factor (VEGF), endothelin-1 (ET-1), prostacyclin, nitric oxide (NO) and angiotensin II are also important factors influencing vein wall disturbances. It is proposed that NO released in venous tissue by the upregulation of iNOS enhances the production of TGF-β1 in varicose veins and that apoptosis downregulation and smooth muscle cell cycle inhibition leads to structural changes in the vein wall [5].

## Diagnostic Principles

The method and extent of treatment in the case of varicosis is determined by means of ultrasound imaging. Ultrasound diagnostics allows to establish quickly and precisely the condition and permeability of deep and superficial veins, assess the valvular functioning and the speed of blood flow. Based on the results of ultrasound examination, a diagnosis is made and a rational treatment approach is developed.

## Therapeutic Principles

Conservative measures, sclerotherapy, surgical and laser treatment are used to treat varicose veins. Conservative treatment is aimed at restraining the progression of the disease. Sclerotherapy is indicated for visible expanded veins with a diameter of up to 7–8 mm. Special sclerosing solution is injected in the vein, as a result of which the varicose vein collapses. Operative treatment includes miniphlebectomy, which is removal of varicose veins through 1–2 mm incisions in the skin using special hooks, and more extensive ligation and stripping of the greater and lesser saphenous veins. In the course of the operation, the damaged veins are removed and deep veins of the lower limb will perform their functions. Newer methods, such as radiofrequency ablation and laser treatment have become more widely available.

[2]Ontario Cancer Institute, University Health Network, Toronto, ON, Canada

### Synonyms

Rapid progressive glomerulonephritis; Wegener's granulomatosis; Microscopic polyangiitis; Churg Strauss syndrome

### Definition and Characteristics

Anti-neutrophil cytoplasmic antibodies (ANCAs) are antibodies in patients sera directed against distinct proteins found in neutrophil granulocytes. Typical ANCAs react specifically with myeloperoxidase (MPO ANCA) or Proteinase 3 (PR3 ANCA). Based on the type of ANCA found, the organs involved and the histologic type of inflammation found, ANCA vasculitis is divided into clinically distinct syndromes as stated above (Synonyms).

### Prevalence

ANCA associated vasculitis is a rare disease. Wegener's granulomatosis typically affects young men. Churg Strauss vasculitis usually occurs in atopic patients.

### Genes

The expression of MPO and PR3 on the surface of circulating neutrophils is genetically determined [1].

### Molecular and Systemic Pathophysiology

ANCAs are currently believed to be directly pathogenic. First, a close association of ANCA with small vessel necrotizing vasculitis was documented in a neonate patient whose mother suffered from MPO-ANCA vasculitis. Vasculitis was induced shortly after birth and could be treated by plasmapheresis. Second, ANCAs are able to activate neutrophil granulocytes by binding to

their respective antigen on the cell surface. ANCA mediated neutrophil activation requires IgG receptors expressed by granulocytes. Lastly, Xiao et al. [2] immunized MPO knock out mice with myeloperoxidase, resulting in the formation of MPO-ANCA IgG. Serum transfer (containing ANCAs) in wild type mice (and even T cell deficient mice) induced glomerulonephritis reminiscent of ANCA associated vasculitis in man. In detail analysis showed the requirement of the alternative complement cascade for the development of necrotizing vasculitis in this murine disease model.

## Diagnostic Principles

ANCA are searched in patients with documented or suspected necrotizing small vessel vasculitis. Ften, joint pain is present due to synovitis. A typical manifestation is a rapid progressive glomerulonephritis. Wegener's disease may present as the combination of sterile otitis, sinusitis and pulmonary lesions (e.g. pulmonary hemorrhage). Another typical manifestation is mononeuritis multiplex where nerve biopsy demonstrates necotizing vasculitis. Immune-histologically, ANCA vasculitis is pauci-immune meaning that large deposits of immunoglobulins are not found.

ANCA screening is performed by immunofluoresence microscopy on commercially available granulocytes plated on microscopic slides incubated with patient's serum. Based on the emerging picture of immunofluoresence, positive sera are categorized into typical or atypical ANCAs. Only typical ANCAs are ANCAs directed against PR3 or MPO which is confirmed by specific ELISA tests. Atypical ANCAs are not associated with ANCA vasculitis however can be found in other inflammatory states such as inflammatory bowel disease. Flares of Churg Strauss Vasculitis are almost always associated by peripheral eosinophilia.

## Therapeutic Principles

Renal involvement is usually treated with cyclophosphamide combined with systemic steroids. After remission is achieved, cyclophosphamide is replaced by azathioprine. Other drugs commonly used are mycophenolate mofetil or methotrexate. Plasmapheresis or anti CD20 (rituximab) are used with success and believed to eliminate the pathogenic ANCAs.

# Vasculitis, Cerebral Forms

Arthur Melms
Department of General Neurology, and
Hertie-Institute for Clinical Brain Research,
University of Tuebingen, Tuebingen, Germany

## Synonyms

Cerebral vasculitis; Cerebral angiitis; Isolated angiitis of the central nervous system; IAC; Primary angiitis of the central nervous system; PACNS

## Definition and Characteristics

Cerebral forms of vasculits are a heterogeneous group of inflammatory vascular disorders which affect small and medium sized arterial vessels of the brain, spinal cord and meninges. *Isolated* angiitis of the central nervous system (CNS) is a primary vasculitis restricted to the CNS. Primary forms of *systemic* vasculitis are of unknown origin and may involve the CNS along with other organs [1]. Prototypic examples are giant cell arteritis, Wegener's granulomatosis, Churg Strauss syndrome, panarteritis nodosa and Behcet's disease. Secondary forms are associated with connective tissue diseases like systemic lupus erythematodes (SLE) or may be triggered by viral infections (e.g. by HBV, HCV, HIV, VZV and others) or bacteria after Lyme disease or syphilis (Fig. 1).

## Prevalence

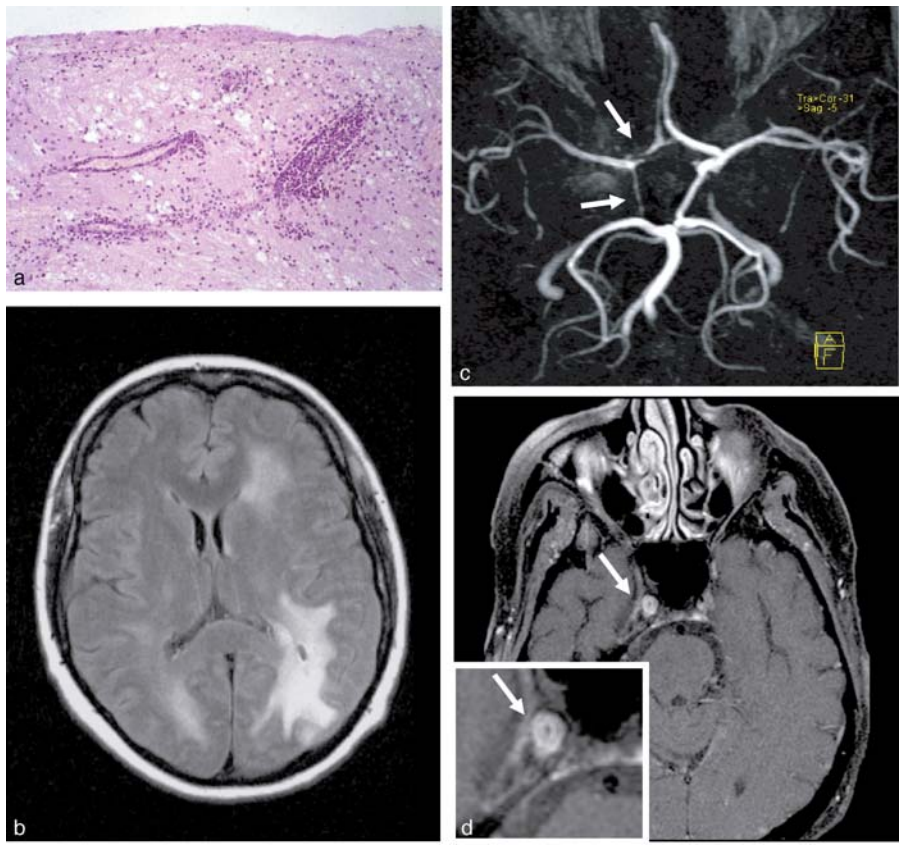
A rare cause of cerebrovascular events, data from large stroke registers suggest cerebral forms of vasculitis in less than 1% of cases. In young adults and patients without cardiovascular disease vasculitis may account for up to 5%. There are no epidemiological data for biopsy proven cerebral vasculitis with the exception of giant cell arteritis which is the most frequent *systemic* vasculitis with a high prevalence in elderly people of approximately 130 per 100,000 over age 60, but rarely affects intracranial arteries proper [2].

## Genes

No predisposing genes are known.

## Molecular and Systemic Pathophysiology

Due to the heterogeneity of vasculitis, damage to cerebral vessels is mediated by a variety of immunological mechanisms including antibodies, immune complexes, complement- and cell-mediated injury. Inflammatory activation of endothelial cells as common targets of the



**Vasculitis, Cerebral Forms. Figure 1** Features of isolated angiitis of the CNS (IAC): (a) Brain biopsy with perivascular infiltrates of mononuclear cells in a small size IAC (H&E stain, ×400). (b) MRI scan with patchy enhancing areas predominantly in the white matter (FLAIR-sequence, same patient as in a). (c) MR-angiography with segmental stenosis of the basal cerebral vessels of the circle of Willis (*arrows*) in medium-large size IAC. Note the missing signal of the carotid artery at the affected side. (d) Contrast-enhancement of the vessel wall of the internal carotid artery (ICA) in medium-sized IAC (*arrow*; same patient as in c). Insert: Focussed on the contrast-enhancing wall of the ICA. (Histology courtesy Prof. A. Bornemann, Institute for Brain Research, UKT. MRIs courtesy Prof. K. Voigt, Neuroradiology, UKT).

inflammatory pathways may lead to segmental stenosis, thrombotic vascular occlusion, necrosis of the vessel wall and occasionally to hemorrhage. Thrombosis of cerebral veins may occur in Behcet's disease [1]. The reason for the preferential involvement of certain segments of the vascular system is unknown but the differential expression of endothelial cell surface molecules is a possible explanation [3].

The analysis of biopsies from giant cell arteritis disclosed an inflammatory microenvironment in the vessel wall composed of T lymphocytes, dendritic cells and proinflammatory cytokines like IL1, IL6 and IFN-γ which in concert with matrix metalloproteases, platelet derived growth factor and vascular endothelial growth factor leads to the destruction and obliteration of the artery [4].

Clinical symptoms are caused by acute and recurrent multifocal ischemia and include chronic headache, encephalopathy and neuropsychiatric symptoms. This presentation is distinct from ischemic stroke due to atherosclerosis.

## Diagnostic Principles

Biopsy of a CNS and meningeal lesion only provides definite proof of vasculitis and is diagnostic in up to 80% of cases. Modern MRI technologies are essential in the diagnostic workup and detect cerebral lesions in small sized vasculitis which are not identified by classical angiography. Contrast enhancement in MRI of the vessel wall suggests inflammation of medium sized basal cerebral vessels [5]. There is no specific diagnostic laboratory marker for IAC. Antinuclear antibodies (ANA) and anticytoplasmic antibodies in neutrophils (ANCA) are helpful in the classification of some forms of systemic vasculitis like SLE or

Wegener's granulomatosis. Cerebrospinal fluid is abnormal in most patients however these findings are nonspecific.

### Therapeutic Principles

By analogy to severe manifestations in systemic vasculitis treatment requires immunosuppression with corticosteroids and cytotoxic drugs. The introduction of cyclophosphamide, an alkylating cytotoxic drug has changed the prognosis and outcome in cerebral vasculitis. More recently less toxic drugs like mycophenolate, azathioprine and biological response modifiers like TNF-inhibitors are being explored in clinical trials. Antiplatelet agents like acetylsalicylic acid are useful to prevent ischemia due to vascular stenosis [1,2].

## Vasculitis, Cryoglobulinaemic

Mike Recher[1], Karl S. Lang[2]
[1]Clinic for Immunology, Department of Internal Medicine, University Hospital Zurich, Zurich, Switzerland
[2]Ontario Cancer Institute, University Health Network, Toronto, ON, Canada

### Synonyms

Cryoglobulinaemia

### Definition and Characteristics

Cryoglobulins are defined as cold-precipitable immunoglobulins from serum. Three pathogenetically distinct subtypes have been described based on the type of immunoglobulins involved in the precipitate. Type I accounts for 25% and is characterized by a paraprotein (monoclonal immunoglobulin) mostly built of IgM (sometimes also IgG or IgA). Type II (25%) is characterized by a combination of monoclonal (mostly IgM) and polyclonal IgG. Type III (50%) is characterized by oligoclonal IgMs. Type II and Type III cryoglobulinemia is strongly related to chronic hepatitis C virus (HCV) infection. Type I cryoglobulins are found in diseases associated with paraproteins such as multiple myeloma or lymphomas or monoclonal gammopathy of undetermined significance (MGUS).

### Prevalence

Cryoglobulinaemic vasculitis is a rare disease. Due to the association with HCV infection, cryoglobulinemia is found more prevalently in countries with high HCV prevalence.

### Molecular and Systemic Pathophysiology

Cryoglobulinemia is mostly asymptomatic (up to 50% of HCV infected individuals), however only between 2 and 15% may develop cryoglobulinemic vasculitis due to deposition of cryoglobulins in small vessels. Clinically, a palpable purpura of the skin develops. Alternatively, a livedo racemosa with a reddish lightning-like pattern of the skin is found. The typical conventional microscopy of the affected skin demonstrates a leucocytoclastic vasculitis with vascular infiltrates of leukocytes with leucocytic cell dust (derived from nuclei). When glomeruli are involved, membrano-proliferative glomerulonephritis is typically seen with a deposition of cryoglobulin immune complexes and complement C3 in the basement membrane. Clinically, renal involvment manifests as nephritic syndrome or proteinuria. Renal insufficiency may develop.

### Diagnostic Principles

Cryoglobulins can be demonstrated after incubation of patient sera in at 4° over several days. It is essential to collect and transport the blood at 37° before centrifugation. The type of cryoglobulinemia is characterized by immune-fixation of the cryoprecipitate. Cryoglobulinaemic vasculitis found in skin biopsies is non-specific, however the detection of HCV in the inflamed vessel may lead to the diagnosis. Usually complement C3 and C4 are both low in patients sera due to the formation of complement activating immune-complexes.

### Therapeutic Principles

The asymptomatic detection of cryoclobulins is not an indication for treatment. Cryoglobulinaemic vasculitis associated with HCV infection is treated with a therapy directed against hepatitis C therapy (usually interferon alpha plus ribavirin) which is superior to conventional immunosuppressive therapy. Paraproteinaemic cryoglobulinaemic vasculitis is treated as a treatment

of the underlying disease (lymphoma or multiple myeloma). Other treatments include corticosteroids, anti-CD20 (rituximab) or plasmapheresis.

# Vasculitis, Large Vessel

Mike Recher[1], Karl S. Lang[2]
[1]Clinic for Immunology, Department of Internal Medicine, University Hospital Zurich, Zurich, Switzerland
[2]Ontario Cancer Institute, University Health Network, Toronto, ON, Canada

## Synonyms

Giant cell arteritis; Arteritis temporalis; Granulomatous arteritis; Polymyalgia arteritis; Takayasu's arteritis

## Definition and Characteristics

Large vessel vasculitis is characterized by inflammatory infiltrates in the vessel wall of large and middle sized arteries. Clinically distinct diseases are separated based on the type of vessel involved, the histologic manifestation of inflammation and the patient's age, sex and origin.

## Prevalence

Giant cell arteritis typically affects patients >50 years and is often associated with polymyalgia rheumatica. Takayasu arteritis is typically found in young female patients and is more prevalent in the south-east Asian countries.

## Genes

HLA DR4 as well as a polymorphism in the promoter region of the NOS2A gene has been linked to susceptibility to giant cell arteritis. HLA-B52 and B39.2 have been linked with Takayasu arteritis in the Japanese. Familial Takayasu's arteritis has been described.

## Molecular and Systemic Pathophysiology

The early inflammatory response in Takayasu's arteritis is characterized by lympho-plasmacellular infiltrates in the adventitia around the vasa vasorum. Later, adventitial fibrosis develops. The intima layer is thickened and fibrotic.

Giant cell arteritis is often focal and segmental showing T lymphocytes and macrophages and multinucleated giant cells typically centered on the internal lamina elastica, which subsequently becomes fragmented. Fibrinoid necrosis, which is often found in small vessel vasculitis, is not found in giant cell arteritis.

No microorganism has been convincingly demonstrated to be the causative agent. Anti aortic endothelial cell antibodies are commonly found in patients with Takayasu arteritis. IL-6, IL-12 and IL-18 have been positively correlated with disease activity. T cell derived TNF-alpha and IL-2 expression correlated well with disease activity of patients with Takayasu's arteritis. MCP-1 (monocyte chemotactic protein 1) correlates well with disease activity in giant cell arteritis.

Clinically, large vessel arteritis may result in acute vessel thrombosis with subsequent ischemia, embolism or stenosis due to chronic inflammation with fibrosis. Alternatively, the inflamed vessel may lead to an inflammatory arterial aneurism and aortic insufficiency when the inflamed vessel is located near the heart valves.

## Diagnostic Principles

Typical symptoms of giant cell arteritis are fatigue, weight loss and low grade fever combined with jaw claudication or diplopia, temporal headaches or scalp tenderness. Acute vision loss is feared due to inflammation of the retinal arteries or arteries of the optical nerve. Synovitis of the shoulders and other features of polymyalgia rheumatica may be present due to the association of polymyalgia and giant cell arteritis. The erythrocyte sedimentation rate is typically >55 mm/h. Ultrasound of the temporal arteries may identify hypoechogenic halos (vessel edema), however the sensitivity of the test is <50%. Positron emission tomography (PET) examination cannot demonstrate arteritis of the temporal arteries (due to the high background of brain glucose turnover), however may show high glucose turnover in large thoracic vessels with a high specificity and a sensitivity of >50%. Temporal artery biopsy remains the diagnostic gold standard, however, its negative predictive value is only about 90% if only one temporal artery is histological examined. Some centers therefore recommend biopsies taken from both temporal arteries. Corticosteroids may lower the bioptic diagnosis of giant cell arteritis as a function of time, however, initiation of immunosuppressive treatment should never be delayed when the suspicion of giant cell arteritis is high.

## Therapeutic Principles

Systemic corticosteroids usually show a rapid clinical response in both types of large vessel vasculitis. Acute vision loss due to giant cell arteritis is usually treated initially with 1 g methylprednisone intravenously daily. Methotrexate in higher doses has been demonstrated to be modestly successful in reducing the long-term corticosteroid dose in giant cell arteritis. TNF-alpha specific blocking antibody (infliximab) has been used

with success in corticosteroid refractory cases. Acetylsalicilate is administered to lower the risk of thrombotic events due to vasculitis.

# Vasculitis, of Medium-sized Vessels

Cord Sunderkötter, Anca Sindrilaru
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Polyarteritis nodosa (PAN) group; Classic PAN, cutaneous PAN (benign, no systemic involvement), infantile PAN (Kawasaki disease); ANCA-associated vasculitis (Wegener's granulomatosis, Microscopic polyangiitis, Churg-Strauss syndrome); PAN group

## Definition and Characteristics

The term vasculitis of medium-sized vessels denotes an inflammatory condition, in which infiltration of the wall of medium-sized blood vessels (arterioles, small veins) by leukocytes is the primary event, often coupled with compromise of the lumen. It results in necrosis of the supplied tissue area, if sufficient collateral blood flow is not available. It is a common denominator for several different systemic syndromes (Polyarteritis nodosa e.g., Kawasaki disease, Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome).

## Prevalence

Different for various forms.

## Molecular and Systemic Pathophysiology

These forms of vasculitis are mediated by immunopathogenic mechanisms. These encompass production of Antineutrophil-cytoplasmic antibodies (ANCA) and pathogenic T cell responses, often with granuloma formation [1]. Deposition of immunoglobulins is less consistently present and as yet without a clear role.

ANCA are a heterogenous group of autoantibodies. Most of them show specificity for either proteinase 3 (cANCA) or myeloperoxidase (pANCA). They are regularly found in Wegener's granulomatosis (cANCA), microscopic polyangiitis, and Churg-Strauss syndrome. A well-described effector function of these autoantibodies is stimulation of neutrophils to produce reactive oxygen species and to release proteolytic enzymes, similarly as shown for immune complexes [2]. Passive transfer of ANCA is sufficient to develop glomerulonephritis and vasculitis in an animal model. According to a hypothetical sequence of events, transient activation, e.g., by infections, leads to activation of granulocytes with subsequent release of cytokines and movement of lysosomes to the cell membrane, thereby rendering their antigenic contents accessible to ANCAs. ANCAs trigger enhanced adherence and induce respiratory burst and degranulation of granulocytes with subsequent damage to the vessel wall [3].

One of the histological hallmarks in some vasculitides of medium-sized vessels is the presence of granulomatous inflammation (Wegener's granulomatosis, Churg-Strauss syndrome) around and sometimes within vessel walls. The clonal and polyclonal CD4 + T cells derived from lesional tissue and peripheral blood of Wegener's granulomatosis exhibit a predominant TH-1 profile, while a Th2 cytokine patterns has been reported for microscopic polyangiitis which goes without granulomas. The aberrant granuloma formation in Wegener's granulomatosis could be secondary to necrotizing tissue inflammation caused by activation of neutrophils and monocytes [4]. Necrotizing inflammation of medium-sized muscular arteries, especially of internal organs, may lead to aneurysmal dilatations as observed in classic PAN.

## Diagnostic Principles

The presenting symptoms in vasculitis of medium-sized vessels in the skin and mucous membranes are faint to intense red subcutaneous nodules which usually undergo necrotic ulceration. Inflammations of the medium-sized blood vessels may also lead to livedo racemosa, a distinct type of livedo reticularis with a broken network of bluish discolorization due to disturbed blood flow with shunting of deoxygenated blood to the venular bed. Systemically, these vasculitides often cause severe symptoms depending on the pattern of involvement which differs in various forms. Among them are glomerulonephritis, pulmonary hemorrhage, disturbance of CNS functions, and the serious clinical sequela such as renal or pulmonary insufficiency, hypertension, or neuritis.

Histological diagnosis is required. Basic blood tests and additional examinations must be performed to evaluate the extent of systemic involvement (CRP, differential blood count, ANCAs, repeated urine analysis, hemoccult, blood pressure, chest X-ray).

## Therapeutic Principles

Prompt start of therapy is important. Schemes with high-dose steroids (continuous or pulsed administration) complemented by cyclophosphamide are efficacious and mandatory in induction therapy in several forms of

vasculitis of medium-sized vessels [5]. Due to the severe side effects after long-term application of cyclophosphamide, maintenance therapy is now often performed with less toxic azathioprin, methotrexate, or mycophenolate mofetil.

# Vasomotor Rhinitis

►Hyperreflectoric Rhinitis

# Vasospastic Angina

►Coronary Spasm

# VATER Association

Maria Teresa Divizia, Margherita Lerone, Roberto Ravazzolo
Laboratory of Molecular Genetics, G. Gaslini Institute, Department of Pediatrics, University of Genova, Genova, Italy

## Synonyms

VACTERL association

## Definition and Characteristics

Non-random and variable co-occurrence, in the same person, of a group of malformations including vertebral defects (V), anal atresia (A), cardiac defects (C), esophageal atresia and/or tracheo-esophageal fistula (TE), renal (R) and limb (L) defects [1]. The original definition, done by Quan and Smith in 1973 [2], was "VATER" where "R" was for radial defects; only afterwards, the acronym was expanded to include cardiac defects, renal anomalies and all types of limb defects. Today, both terms are used in the literature.

## Prevalence

VATER association has a prevalence of about 1/5,000 live births. More than 10% of the affected cases is estimated to be stillbirths.

## Genes

At present, the exact cause of VATER association remains unknown. The etiology is thought to be multifactorial with significant environmental influences, and the genetic components seem to play a limited role. There are very few reports of cases of recurrence of VATER association in the same family; to date, it is considered a sporadic defect with a low recurrence risk in first-degree relatives.

Animal models for VATER association are obtained by injection of the chemotherapic adriamicin in rats at an early gestational period; in this model, no identifiable molecular mechanism has been recognized as responsible of the multiple anomalies. Recently, it has been noted that mice carrying mutations in the Shh and Gli genes exhibit a VATER-like phenotype [3]. It has been speculated that a direct or indirect perturbation in the Shh signaling pathway during the embryogenesis could lead to VATER-like defects.

Only few reports of chromosomal imbalances in patients affected with VATER association have been published [4].

In the literature, a rare but distinct entity called "VACTERL with hydrocephalus" has been reported, for which both X-linked and recessive mode of inheritance has been described.

## Molecular and Systemic Pathophysiology

Martinez-Frias et al. suggested that VATER association is a combination of anomalies of blastogenesis [5]. During the first events of embryo development (blastogenesis), the cells are pluripotent and each of them is capable of beginning the development of the complete organism; this mass of cells constitutes a "primary developmental field." An early hit (genetic and/or environmental) occurring during the blastogenesis may cause a developmental field defect. If the hit acts in a very early stage of blastogenesis, the defect is

defined "polytopic" because it is severe and involves many organs and tissues. The authors proposed that the combination of anomalies present in the VATER association should be considered "polytopic developmental field defect" and that this term is more appropriate than "association."

Because of the clinical severity of an early anomaly of the blastogenesis, a high lethality of the conditions originated in this stage is observed; this could explain the low recurrence risk at birth and apparently high percentage of sporadic occurrence reported in cases of VATER association, which could be masked by spontaneous abortions. Some studies seem to confirm this hypothesis, as the mothers of patients affected with VATER association or other blastogenesis defects show a grater number of spontaneous abortions compared to the mothers of patients with other types of malformations or to the general population. Therefore, the recurrence risk is probably not as low as observed in live births, and the defect could be considered not always sporadic. This view is in agreement with the finding of malformations present in VATER association in first-degree relatives [1], such as isolated esophageal atresia/tracheo-esophageal fistula.

Depending on the prenatal period in which the etiological agents act, the developmental field defect can be isolated or part of a multiple congenital anomaly. This hypothesis could explain also the occurrence, in individuals affected with VATER association, of additional malformations or anomalies not included in the VATER association definition.

Two cases associated with mitochondrial defect have been described, although it is unclear whether the pathogenic mechanism can be referred to mitochondrial impairment.

Regarding the possible risk factors and environmental causes of VATER association, prenatal exposure to several potential teratogens has been analyzed, such as maternal illness (i.e. diabetes), drugs (in particular sexual hormones), radiations or other physical agents, but none has shown any significant correlation with VATER association.

## Diagnostic Principles

The co-occurrence, in the same individual, of at least three of the typical malformations of VATER association leads to the clinical diagnosis. Nevertheless, very few reports of series of VATER patients with a carefully definited clinical phenotype can be found in the literature, perhaps because of the difficulty of a clear clinical definition and the risk to consider as VATER association patients affected with a syndromic pathology. Indeed, many syndromes overlap with VATER association, such as Feingold syndrome, CHARGE syndrome and deletion 22q11 syndrome. They should be considered in the differential diagnosis of VATER association.

Usually, facial dysmorphic features, growth anomalies, microcephaly and learning disabilities are not part of VATER association; therefore, an alternative diagnosis must be considered in patient displaying one of these signs.

## Therapeutic Principles

Surgical correction of congenital malformation is the principal treatment of patients with VATER association. Esophageal and intestinal malformations often require an immediate intervention at birth. Postnatal correction of cardiac malformations is often necessary.

Vimla S. Aggarwal[1], Jelena S. Arnold[1], Anna Blonska[1,2,*], Bernice E. Morrow[1]
[1]Department of Molecular Genetics, Albert Einstein College of Medicine, New York, NY, USA
[2]Department of Pathophysiology, Wroclaw Medical University, Wroclaw, Poland

## Synonyms

VCFS; DiGeorge syndrome; 22q11 deletion syndrome; Shprintzen syndrome; Conotruncal anomaly face syndrome

## Definition and Characteristics

VCFS is associated with a wide spectrum of malformations, including 180 clinical findings. The common defects include dysmorphic facies, palate abnormalities, malformed outer ears, chronic otitis media with associated conductive hearing loss, cardiac defects, hypocalcemic hypoparathyroidism, and T-cell mediated immune deficiency. Other features include learning and speech disabilities, as well as a high incidence of psychiatric illness.

## Prevalence

The prevalence of the disorder has been estimated at 1 per 4,000 live births.

## Genes

About 90% of VCFS patients have a typical 3 Mb deletion on chromosome 22q11, which includes 40 genes. Approximately 8% of the patients have a nested distal deletion endpoint resulting in a 1.5 Mb deletion. There is no difference in the severity in patients with the 1.5 or 3 Mb deletion, suggesting the critical region is the smaller 1.5 Mb interval. A total of 27 known genes lie in the nested 1.5 Mb interval and they are conserved in the mouse as a single cluster on chromosome 16. This enabled several groups to model VCFS in mice.

Mouse models of VCFS implicate Tbx1, a transcription factor, on the 1.5 Mb region, as a major candidate for the etiology of the syndrome. Recently, mutations in TBX1 were found in rare non- deleted patients with VCFS and one of them is associated with loss of function of TBX1.

A few genes such as Fgf8 and Vegf have been identified as modifiers that enhance the phenotype of model organisms lacking Tbx1. Other genes such as Gbx2 and Raldh2 have been suggested as modifiers of VCFS as mouse models of the same phenocopy the disorder.

Even though TBX1 is the strongest candidate gene for a large number of features, animal models suggest that haploinsufficiency of Tbx1 cannot recapitulate the entire phenotypic spectrum of the disease. Other genes on the 22q11 deleted region may contribute to the full phenotype. An important candidate is CRKL, located within the common 3 Mb deletion. Crkl homozygous- null mice phenocopy VCFS and Tbx1 and Crkl genetically interact in a dosage sensitive manner in the development of structures affected. Thus, it seems possible that this disorder is a contiguous gene syndrome.

COMT and PRODH, both present on the 1.5 Mb region, may be involved in the psychiatric and behavioral phenotype of VCFS. These genes encode the enzymes catechol-O-methyl transferase (COMT) and proline dehydrogenase (PRODH), which modulate the levels of the neurotransmitter, dopamine and a putative neuromodulator, l-proline respectively. Prodh mutant mice have defects in sensorimotor gating while Comt mutant mice display impairment in emotional behavior.

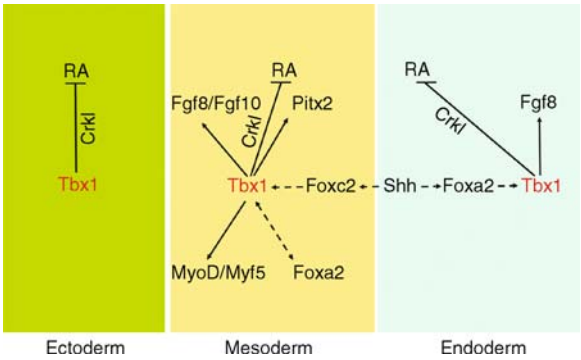
## Molecular and Systemic Pathophysiology

Molecular pathway characterization has been focused on downstream targets and upstream regulators of Tbx1, the primary candidate gene for the syndrome (Fig. 1).

*Downstream Target Genes*: Multiple members of the fibroblast growth factor family, including Fgf8 and Fgf10 have been implicated as downstream modulators of Tbx1 function. Both Fgf8 and Fgf10 are downregulated in the pharyngeal region in the absence of Tbx1, while in vitro analysis has demonstrated that Tbx1 directly activates transcription of Fgf10. Tbx1 also regulates members of the MyoD family of bHLH factors, including Myf5 and MyoD, which specify craniofacial muscle lineages throughout the embryo. Expression of both Myf5 and MyoD is downregulated in the pharyngeal arches of Tbx1 –/– embryos. Recent in vivo and in vitro studies have identified Pitx2, the gene responsible for Rieger syndrome, as a direct downstream target of Tbx1 in the cardiac outflow tract progenitors. Finally, retinoic acid (RA) signaling is ectopically activated in embryos lacking both Crkl and Tbx1, implicating the RA pathway as a modulator of Tbx1 activity.

*Upstream Regulators*: Multiple studies have noted the presence of a Tbx1 enhancer, necessary for the expression of the gene. The activity of this enhancer is dependent upon a fork-head binding site, responsive to Foxc1, Foxc2 and Foxa2. However, it has also

*Anna Blonska is the Kosciszko Foundation grantee at the Department of Molecular Genetics of Albert Einstein College of Medicine



**Velo-cardio-facial Syndrome. Figure 1** Tbx1 is expressed in the pharyngeal ectoderm (green), mesoderm (yellow), and endoderm (blue). In the mesoderm, the gene activates fibroblast growth factor (FGF) family members Fgf8 and Fgf10, MyoD and Myf5, as well as Pitx2 (arrows). Tbx1 is also implicated in an auto-regulatory loop with Foxa2 in the pharyngeal mesoderm (double-headed dashed arrows). In the endoderm, the gene activates Fgf8. *Sonic hedgehog* (Shh), from the endoderm, regulates expression of Tbx1 in the mesoderm and in the endoderm, possibly through regulation of Foxc2 and Foxa2, respectively (dashed arrows). Tbx1 together with Crkl negatively regulates activation of the retinoic acid (RA) signaling pathways in all three germ layers (arrows).

been shown that the expression of Foxa2 was reduced in the core mesoderm of Tbx1 mutants, suggesting a regulatory loop between Foxa2 and Tbx1. Finally, Sonic hedgehog (Shh) has been shown to regulate Tbx1 expression in the pharyngeal arches and in the periotic mesenchyme, although this regulation might not involve direct activation of the Tbx1 promoter.

## Diagnostic Principles

Prenatal diagnosis of VCFS can be made by ultrasound examination around the eighteenth week of pregnancy, when malformations of the heart and palate can be seen. Postnatally, VCFS is usually diagnosed shortly after birth, due to abnormal facies or cardiac manifestations. Molecular cytogenetic investigations incorporate standard FISH mapping (fluorescent in situ hybridization) with commercial region probes TUPLE 22 or N25 of amniocytes or blood cells. Other lab findings include T – cell deficiency, hypocalcemia, low parathyroid hormone levels. Thymic presence and size may be assessed by lateral-view radiograph or MRI. Cardiac abnormalities can be diagnosed with echocardiogram and with invasive techniques including cardiac catheterization.

## Therapeutic Principles

Established therapy encompasses a comprehensive, symptomatic approach. Pharyngeal flap surgery is usually performed to correct velo- pharyngeal insufficiency and resulting hypernasal speech. Control of hypoparathyroidism demands treatment of hypocalcemia by supplementation of calcium and vitamin D, as well as a low phosphorus diet. Heart defects are corrected surgically. Due to defective immune function, patients are advised to keep a sterile environment, avoid corticosteroids and immunization with live viruses, and to promptly treat all infections. More severe immunodeficiency cases are treated by transplantation of fetal thymic tissue or bone marrow. Psychiatric disorders are treated with typical therapies for all patients with psychiatric illness, depending on the condition.

# Veno-occlusive Disease

Ralf Kubitz
Clinic of Gastroenterology, Hepatology and Infectiology, University Hospital of Duesseldorf, Duesseldorf, Germany

## Synonyms

Venoocclusive disease; VOD; Venoocclusive hepatic disease; Sinusoidal obstruction syndrome; SOS

## Definition and Characteristics

VOD is a type of hepatic venous outflow obstruction which is characterized by the occlusion of terminal hepatic venules and hepatic sinusoids from zone 3 of the hepatic acinus. VOD is clinically and pathologically distinct from the Budd-Chiari syndrome.

VOD most often occurs after hematopoietic cell transplantation and chemotherapy (e.g. busulfan and melphalan), or, less common, after liver transplantation,

high dose radiation of the liver (>30 Gy) or ingestion of pyrrolizidine alkaloids (certain teas).

## Prevalence

The incidence of VOD after hematopoietic cell transplantation (bone marrow, peripheral blood progenitor cells or cord blood cells) ranges from 5% to more than 60% in children [1] and is similar in adults [2].

Risk factors for the development of VOD include pre-transplant liver diseases (e.g. risk in HCV > HBV), pre-transplant abdominal radiation, the type of cytoreductive therapy, use of certain antibiotics/virostatics before bone marrow transplantation (e.g. vancomycin, acyclovir), persistent fever during cytoreductive therapy and allogenic transplantation.

## Genes

There are no detailed studies concerning the genetic basis of VOD. Genetic polymorphisms of the thiopurine methyltransferase (TPMT) may reduce its activity and thereby may increase the risk of VOD in patients which are treated with thioguanine [3], a substrate of TPMT.

In a small study the prothrombin mutation 20210 G-A and factor V Leiden were found to be strongly associated with VOD, while in another study 20210 G-A but not factor V Leiden was associated with VOD.

Busulfan, which is often used for cytoreductive therapy and may cause VOD, is conjugated to glutathione by glutathione S-transferase A1 (GSTA1). Eight single nucleotide polymorphisms with seven of them being localized within in the promoter region of GSTA1 were identified, however, there was no association between SNP or haplotypes of GSTA1 and the development of VOD.

## Molecular and Systemic Pathophysiology

VOD is characterized by an injury of the hepatic endothelium. Because preexisting liver diseases are associated with higher risk of VOD, an impaired hepatic metabolism (leading to toxification of certain drugs) or a liver endothelitis may contribute to the development of VOD. For example, the expression of pro-coagulant factors by defective endothelium may increase the susceptibility for clotting in the sinusoids.

In early stages of VOD factor VIII and fibrinogen are found in dense deposits around the endothelium of acinar zone 3 and in small venules. Occlusion of sinusoids by these deposits is followed by erythrocytic congestion and later by centrilobular hemorrhagic necrosis. Late events are the deposition of collagens type I, III and IV and sclerosis/fibrosis of venular and sinusoidal walls.

Typically, in VOD there is a reduction in plasma levels of clotting factor VII, V and protein C. These changes bring about a procoagulant state. Furthermore, multimers of von-Willebrand factor are increased and elevated levels of D-dimers and plasminogen activator inhibitor-1 are found as a sign of activated coagulation.

## Diagnostic Principles

In general, the diagnosis of VOD is made clinically by the trias ("Baltimore criteria") of increased serum bilirubin above 2 mg/ml, right upper quadrant pain/hepatomegaly and sudden weight gain due to fluid retention. These symptoms typically occur within the first three weeks after transplantation.

Weight gain in VOD may exceed 10 kg and is due to peripheral edema (in more than 50% of patients) and ascites (>20%). Mid epigastric or right upper quadrant tenderness or pain is a typical symptom (>95%) and is associated to hepatomegaly. VOD must already be considered when bilirubin rises above 2 mg/ml (normal: <1.1 mg/dl), however, bilirubin levels (mostly conjugated) may exceed 12–18 mg/dl. Increases in liver enzymes may be moderate to severe. Thrombocytopenia is another typical finding in VOD and is related to clotting within the hepatic vessels. When renal failure develops, urea typically increases more than creatinine.

Increases in serum procollagen type III (above 100 mg/ml) and in plasminogen activator inhibitor-1 may be used in the diagnosis of VOD.

Liver biopsy may help in the diagnosis of VOD, however, sample size needs to be adequate because pathological changes may be unevenly distributed. Furthermore, feasibility of biopsy may be restricted due to thrombocytopenia and clotting defects. Histopathological changes involve structures in zone 3 of the hepatic acinus, such as (i) occluded hepatic venules, (ii) the frequency of occluded hepatic venules x degree of occlusion, (iii) eccentric luminal narrowing/phlebosclerosis, (iv) zone 3 sinusoidal fibrosis and (v) zone 3 hepatocyte necrosis [4]. The number of changes and not only the occlusion of small hepatic venules seems to correlate to the severity of VOD.

The following differential diagnoses should be considered when VOD is suspected: Budd-Chiari-Syndrom, graft versus host disease (GvHD), cardiac failure, malignant liver infiltration, sepsis (cholestasis lenta), drug toxicity, capillary leak syndrome, neutropenic colitis, total parenteral nutrition associated cholestasis, hepato-lienal candidiasis, viral hepatitis (including HBV, HCV, CMV and others).

Measurement of porto-hepatic venous gradient of more than 10 mmHg correlates with the presence of VOD with a specificity of more than 90%.

## Therapeutic Principles

Clinically VOD may be divided into mild, moderate and severe disease, the latter with a mortality as high as

90% [1]. Severe VOD is characterized by multiorgan failure with renal failure (80%), encephalopathy with confusion (80%), cardiac failure (60%) and significant bleeding (40%) with the requirement of transfusions [1]. Renal insufficiency is probably a consequence of liver injury, has features of hepatorenal syndrome with a low fractional urinary sodium excretion and is associated with a very poor prognosis. High weight gain, early jaundice, and ascites are predictors of a severe course of VOD.

The necessity of therapy depends on the severity of VOD. In mild VOD no specific therapy is required despite clinical and biochemical evidence of VOD. In moderate VOD treatment of fluid retention by sodium restriction and diuretics and of pain by analgesics is adequate.

In severe disease (by definition when hepatic dysfunction persists more than 100 days after transplant or when patients die due to VOD) the most promising treatment option is defibrotide, while treatment with systemic anticoagulation or thrombolytic therapies has been proven to be unsuccessful [5].

Defibrotide is a deoxyribonucleic acid derivative from porcine intestinal mucosa or cow lung. Its beneficial effect in VOD may be attributed to the increase of prostaglandin E2, and prostacyclin, the amplification of tissue plasminogen activator function, and the reduction of activity of tissue plasminogen activator inhibitor. Together, defibrotide inhibits platelet aggregation but has less anticoagulant activity. Survival increases from 0–20% to 30–50% [5].

## Venoocclusive Hepatic Disease

►Veno-occlusive Disease

## Venous Angioma

►Venous Malformation

## Venous Insufficiency

Takashi Yamaki
Department of Plastic and Reconstructive Surgery, Tokyo Women's Medical University, Tokyo, Japan

### Synonyms

Chronic venous insufficiency; CVI; Vein insufficiency

### Definition and Characteristics

Venous insufficiency is defined as any abnormality of the lower extremity venous system that reduces or impedes venous return. Venous insufficiency is associated with venous hypertension, and this is due to mechanical problems of venous reflux, obstruction, or combination of the two. Chronic venous insufficiency (CVI) of the lower extremity is manifested by a range of signs, the most obvious of which are varicose veins and venous ulcers. Signs also include edema, venous eczema, hyperpigmentation of skin of the ankle, atrophie blanche, and lipodermatosclerosis. In the lower extremity, there are three main venous system including superficial, deep, and perforating veins. Of these, primary valvular insufficiency with reflux in the superficial venous system is most commonly found, and varicose veins may be an integral part of the venous insufficiency. Reflux in the deep venous system may be due to postthrombotic syndrome, congenital valvular absence, or prolapse of the valves, and 65% of limbs with postthrombotic syndrome have both reflux and obstruction. Reflux in the isolated perforating vein is not common, and is commonly associated with superficial and/or deep venous insufficiency.

*Classification*: The CEAP (clinical etiology anatomy pathophysiology) classification for chronic venous disorders (CVD) was developed in 1994 by an international ad hoc committee of the American Venous Forum, and incorporated into "Reporting Standards in Venous Disease" in 1995. The CEAP classification was then revised in the late 2004 [1]. Today most published clinical papers on CVD use all or portions of CEAP. The clinical signs of the limbs are categorized into seven classes from $C_0$ to $C_6$, and limbs categorized

**Venous Insufficiency. Table 1** Revised CEAP Classification

in any clinical class may be symptomatic (S) or asymptomatic (A) (Table 1).

## Prevalence

CVD is common. A cross-sectional study of random subjects aged 18–64 from the general population in Edinburgh, Scotland found that telangiectases and reticular veins were seen in approximately 80% of men and 85% of women. Prevalence of varicose veins was 40% in men and 16% in women. Active or healed venous leg ulcers occur in approximately 1% of the general population [2].

## Genes

Some genetic defects related to thrombophilia (e.g., protein C deficiency, protein S deficiency, factor V Leiden, and prothrombin G20210A mutations) are associated with postthrombotic syndrome.

## Molecular and Systemic Pathophysiology

Increased numbers of granulocytes, monocytes, macrophages, and lymphocytes and increased matrix metalloproteinase (MMP)-2 and MMP-9 are observed in the pressurized valves. In addition, morphologic changes in the valves occur which lead to reductions in leaflet height and width, and disappearance of the valves [3]. Increased venous pressure also affects the changes of the skin, and venous ulceration is considered to be a result of CVI-induced ischemia-perfusion episodes. After venous hypertension was induced in patients with CVD, white cells marginate to the periphery of the blood stream, followed by rolling along the venous endothelial wall, and the final stage of the process is firm adhesion. The trapped white cells are mostly adherent to the postcapillary venules and veins. After accumulation of leukocytes at the endothelial surface, multiple proinflammatory factors are released as a consequence of the interactions between endothelium, platelets, and leukocytes.

In chronic ulcers, MMP expression in inflammatory cells, keratinocytes, and fibroblasts is enhanced. In particular, MMP-2 and MMP-9 are found predominantly associated with the inflammatory infiltrate. Increase in MMP activity may contribute to the breakdown of the extracellular matrix, which promotes the formation of ulcers and impairs healing. Also, activated leukocytes migrate out of the postcapillary venules and release TGF-β1 and stimulate collagen production, leading to dermal fibrosis [4].

## Diagnostic Principles

In the past, venography has been carried out for diagnostic reasons. Nowadays, duplex scanning is being performed for the evaluation of distribution and extent of venous insufficiency. Venous segments with reflux time exceeding 0.5 s are considered to be incompetent. Recent studies show that clinical severity is associated with peak reflux velocity rather than reflux time [5]. In patients with previous DVT, high peak reflux velocity in proximal deep veins seems to contribute to develop advanced CVI. Air plethysmography is also a useful tool to determine venous function. The venous filling index seems to better discriminate between patients with early CVI and those with advanced CVI [5].

## Therapeutic Principles

All stages and clinical manifestations of CVI benefit from compression therapy. Selective stripping operation is the best option for superficial venous insufficiency. Recently, more noninvasive endovenous radiofrequency and endovenous laser techniques are widely accepted. Compression sclerotherapy is applied for telangiectasias, reticular veins, and truncal varicose

veins. Because sclerosing foam offers better result, many phlebologists are now in favor of the use of foam sclerosing solution instead of the use of liquid. Direct or angioscopic valve repair of the deep venous system may be indicated for highly selected patients with primary deep venous insufficiency or postthrombotic syndrome. Subfacial endoscopic perforator surgery may be potentially useful in combination with superficial ablation for severe CVI.

# Venous Malformation

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Cavernous hemangioma; Angioma cavernosum; Cavernous malformation; Venous angioma

## Definition and Characteristics

Venous malformation is a slow-flow vascular malformation present at birth. The lesion is soft, compressible, non-pulsatile and deep blue in color (Fig. 1) [1].

Expansion with dependent positioning is a unique feature [2]. Histologically, the lesion is composed of thin-walled vessels or sinuses lined with endothelium and surrounded by a fibrous connective tissue stoma [2]. These vessels or sinuses drain to normal adjacent conducting veins. They may involve skin, subcutaneous tissue, and mucosa and may permeate deeper structures such as muscles. Venous malformations are usually segmental or focal. Most lesions are asymptomatic. They may become painful as a result of entrapment and compression of nerve fibers or from venous stasis and thrombosis [2]. Phleboliths are the hallmarks of venous malformation and result from local venous thrombosis. Other possible complications include ulceration, infection, and hemorrhage [1]. Chronic localized intravascular coagulopathy may occur due to consumption of clotting factors. Giant venous malformations may be associated with platelet sequestration, which may lead to intravascular coagulopathy or thrombocytopenia (Kasabach-Merritt syndrome) [1]. Venous malformations in the limb may be complicated by osteoporosis, diaphyseal thinning, and lytic lesions [3]. Large venous malformations can be cosmetically unsightly and may lead to psychologic disturbance. Most venous malformations are isolated although they may occur in association with Maffucci syndrome, blue rubber bleb nevus syndrome and glomuvenous malformations.

## Prevalence

The exact incidence is not known. Suffice it to say, venous malformation is the most common type of vascular anomaly [2].

## Genes

Majority of cases are sporadic. An autosomal dominant mode of inheritance has been described. Mutations in VMCM1 and Tie2 account for some cases of venous malformations. VMCM1 has been mapped to 9p21.

## Molecular and Systemic Pathophysiology

Venous malformations are the result of errors in morphogenesis within the vasculature. Vascular malformations are classified according to the predominant vasculature involved and by flow rates [4]. Capillary, venous, and lymphatic malformations are slow-flow lesions whereas arterial malformations are fast-flow lesions [4]. In contrast to infantile hemangiomas, vascular malformations are not proliferative and they grow proportional to the size of the child and do not involute. The stagnation of blood in the venous malformation may predispose to thrombosis [5].

## Diagnostic Principles

Extensive venous malformation in a limb must be differentiated from Klippel-Trenaunay syndrome. The latter is a capillary-lymphatic-venous malformation associated with hypertrophy of the soft tissue and bone and overgrowth of a limb. The diagnosis of venous malformation can usually be established on the basis of clinical features. CT and MRI can be used to delineate the extent of the lesion into the surrounding tissue.

## Therapeutic Principles

Most venous malformations are asymptomatic and can be treated conservatively with compression garments. Low-dose aspirin and anticoagulants should be

**Venous Malformation. Figure 1** A 6-month-old infant with venous malformation in the right upper limb.

considered for patients prone to thrombosis and diffuse intravascular coagulation. With larger and increasing symptomatic lesions, sclerotherapy with fluoroscopic monitoring, laser light combined with radiofrequency energy, transcatheter embolization, and surgical excision should be considered [5].

### Synonyms

Left ventricular fibrosis; Right ventricular fibrosis; Biventricular fibrosis; Cardiac scarring

## Definition and Characteristics

Ventricular fibrosis is the formation of excessive fibrous tissue in the myocardium, affecting either or both ventricles. The process may be diffuse, as seen in hypertensive heart disease, or localized as in the post myocardial infarction setting.

## Prevalence

Ventricular fibrosis represents a disordered reparative response, whereby increased extracellular matrix, primarily in the form of fibrillar collagen, types I and III, are laid down in response to of a wide range of insults that include: ischemia, hypertension, hyperglycemia, inborn errors of metabolism, infection, autoimmunity and infiltrative diseases such as cardiac sarcoidosis and amyloidosis. Fibrosis therefore represents the final common pathway of a wide variety of insults. As such, the true prevalence of ventricular fibrosis is unknown.

## Molecular and Systemic Pathophysiology

The accumulation of excessive extracellular matrix, the hallmark of ventricular fibrosis, is the result of increased synthesis of matrix proteins, principally collagen, and/or a diminution in their degradation. Cardiac fibroblasts, that account for 8–10% of cardiac cells, synthesize procollagen that once extruded from the cell aggregates in the pericellular space to form fibrils that spontaneously assemble into large fibers. Collagen degradation is primarily performed by members of the matrix metalloproteinases (MMP) family of enzymes, particularly MMPs 1, 2, 8, 9 and 13, the activity of which are in turn modulated by the tissue inhibitors of the MMPs (TIMPs), such that increased TIMP 1 will reduce MMP activity and leads to fibrosis with abnormal ventricular function [2].

The tensile strength of collagen fibers is enormous (roughly equivalent to that of steel) and they are thus well suited for their role in reducing wall stress and stabilizing the myocardium. However, alterations in quantity, quality and distribution of the heart's collagenous matrix can severely disrupt its normal functioning. For instance, increased collagen or change in the precise balance of its isotypes may lead to diminished ventricular compliance and diastolic dysfunction. Similarly, alterations of the heart's matrix superstructure may lead to systolic dysfunction, as a consequence of cardiomyocyte slippage with incoordinate contraction that results from alterations in the precise geometric alignment of collagen fibers.

A myriad of profibrotic factors may favor the development of cardiac fibrosis. These include: hypoxia as in ischemic heart disease, mechanical factors, such as cell stretch (the in vitro counterpart of hypertension), vasoactive hormones, such as angiotensin II and metabolic derangements, such as that which occur in diabetes. Common to all of these stimuli is their ability to induce the expression of transforming growth factor-ß (TGF-ß), a profibrotic growth factor that both stimulates collagen production and inhibits its degradation.

TGF-ß induces procollagen transcription by a number of different intracellular intermediaries. In its classical signaling pathway, TGF β1 binds to its cognate receptors (TGF β receptor I and II) that have intrinsic kinase activity and phosphorylate the transcription activating Smad (Smad=Mothers against decapentaplegic) proteins 2 and 3. The resultant phospho-Smad 2/3 complex then associates with Co-Smad 4 and translocates as a heterotrimer to the nucleus where it activates collagen transcription (Fig. 1).

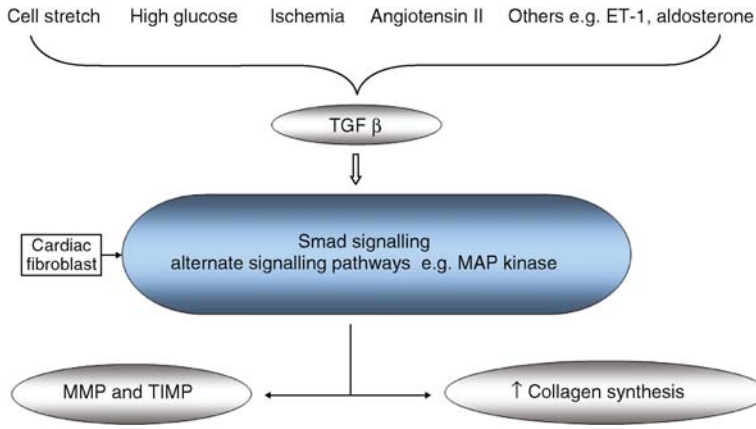
## Diagnostic Principles

Given the morbidity and mortality associated with cardiac biopsy, the assessment of ventricular fibrosis in humans is mostly achieved by cardiac imaging or inferred by the measurement of peripheral (plasma) markers. Cardiac magnetic resonance imaging with intravenous gadolinium can detect large quantities of scar tissue, as seen in the post myocardial infarction setting or in hypertrophic cardiomyopathy, where the presence of delayed hyperenhancement correlates with the degree of ventricular fibrosis. Echocardiographic techniques such as integrated backscatter may also detect the presence of fibrosis.

The terminal amino-terminal propeptide of procollagen type I (PINP) and type III (PIIINP) and the carboxy-terminal telopeptide of collagen type I (CITP) can be measured by a variety of immunologically-based techniques such as radioimmunoassay and ELISA. These assays, whilst not specific for myocardial collagen, are elevated in conditions of increased myocardial stiffness and scarring, presumably reflecting the increased collagen turnover in these disease states.

## Therapeutic Principles

Ischemic and hypertensive heart disease remain the commonest causes of ventricular fibrosis, such that therapies aimed at preventing hypertension and myocardial infarction are key strategies in reducing ventricular fibrosis. Given the role that the tissue based renin-angiotensin-aldosterone system (RAAS) and TGF β1 play in the development of ventricular scar formation, pharmacological therapy directed at these targets represent major targets of current and future therapies. For instance, angiotensin converting enzyme inhibitors and angiotensin II type 1 receptor blockers have been



**Ventricular Fibrosis. Figure 1** Pathways involved in the profibrotic process. TGF β may be induced by a number of extracellular factors including hyperglycemia, cell stretch, ischemia and effector molecules of the renin-angiotensin system. TGF-β receptor mediated induction of Smad phosphorylation along with the activation of other signaling pathways, such as the MAP Kinases result in enhanced collagen synthesis and reduced degradation. The end result is increased collagen production, reduced degradation and alterations in the properties of the extracellular matrix.

shown to reduce ventricular fibrosis in animal models of myocardial infarction. Similarly, mineralocorticoid receptor antagonists such as epleronone and spironolactone have also demonstrated antifibrotic actions that are independent of their hemodynamic effects. Whether a combination of the listed RAAS blockers or the addition of newer strategies such as direct renin inhibition may exert additional anti-fibrotic effects beyond single agent treatment remains to be determined.

Also of recent interest are strategies that target TGF-ß. For instance, tranilast, (n-[3,4-dimethoxycinnamoyl] anthranilic acid), an agent used in Japan for the treatment of excessive dermal scarring has been demonstrated to not only reduce cardiac and renal fibrosis, but also improve cardio-renal function by attenuating the actions of TGF β1. Other compounds that inhibit TGF-ß activity include pirfenidone, pentoxifylline and antagonists of the TGF-ß type 2 receptor kinase (ALK-5).

# Ventricular Flutter and Fibrillation

Lucia K. Ma[1], Patrick T. S. Ma[2], Alexander K. C. Leung[3]
[1]Royal College of Surgeons, Dublin, Ireland
[2]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Ventricular fibrillation (VF) is a very rapid (150–500 bpm) irregularly irregular disorganized ventricular rhythm of varying configuration; with time, the amplitude of the fibrillation wave becomes progressively smaller, particularly immediately before death. Ventricular flutter (VFL) is a very rapid (180–250 bpm) and regular ectopic ventricular rhythm with undulations of equal amplitude and usually rapidly degenerates to VF. In both VF and VFL the separation of QRS complex from ST segment and T wave is not possible, and is always associated with a fall in or lack or cardiac output, blood pressure and pulse. VFL and VF are usually preceded by ventricular tachycardia (VT). Idiopathic (primary) VF occurs in patients with normal cardiac structure. Primary VF has been estimated to account for 5% of cases of sudden cardiac death (SCD) with the mean age 36 years, and the male to female ratio

of 2.5:1 [1]. Survivors have a 30% recurrence rate of VF, syncope, and cardiac arrest. Without prompt and aggressive therapy, VF and VFL are uniformly lethal.

## Prevalence

VF is the most common immediate cause of SCD. The incidence of SCD ranges from 36 to 128 per 100,000 persons per year. Recently, a major decline in the incident of out-of-hospital VF was observed, the annual decline rate of VF was 56% [2]. In prediatric cardiac arrests, VF was the first identified rhythm in 6–19% of patients. The incidence of VF arrest in patients 40 years old or younger is 1:2 in 10,000 and is usually secondary to ►hypertrophic cardiomyopathy (HC), ►dilated cardiomyopathy (DC), and ►arrhythmogenic right ventricular dysplasia (ARVD).

## Molecular and Systemic Pathophysiology

VF results from multiple localized areas of microreentry without any organized electrical activity. The most likely mechanism is rotating spiral waves. This almost always occurs in diffuse structural heart disease resulting in heterogeneity of depolarization and the dispersion of repolarization. This disparity of electrophysiologic properties is a precondition for reentry. A triggering event is usually necessary to precipitate the arrhythmia in the vulnerable heart. The diversity in conduction and recovery parameters (myocardial heterogeneity) results in fragmentation of the impulse as it travels through the myocardium, producing multiple areas of localized reentry or multiple spiral myocardial activation wavelets. Since there is no organized electrical activity or myocardial depolarization, there is no uniform ventricular contraction. This results in the failure of the heart to generate a cardiac output. As the duration of VF increases, progressive cellular ischaemia and acidosis develop, resulting in electrophysiologic deterioration, manifested by an increase in fibrillation cycle length and prolonged diastole duration between fibrillation action potentials. The fibrillatory waves rapidly become finer and more irregular in amplitude, duration, and cycle length. Over a period of several minutes, the fibrillatory waves become so fine that there does not appear to be any electrical activity before death. Approximately, 65–70% is secondary to ischaemic heart disease, 10% secondary to other types of structural heart diseases, and the remaining secondary to noncardiac causes such as trauma, bleeding, drug intoxication, intracranial haemorrhage, pulmonary embolism, drowning, central airway obstruction, electrolyte abnormalities (hypokalaemia, hypomagnesaemia), drug intoxication (digitalis, cocaine, pro- and antiarrhythmic drugs), commotio cordis, and accidental electric shock. VF and VFL are commonly associated with acute myocardial infarction (MI), when it occurs within 48 h of the MI, it is regarded as the epiphenomena of the MI and it would not predispose the patient to VF after discharge. However, late VT or VF (48 h post MI) reflects the presence of myocardial scarring and permanent arrhythmic substrate capable of reentrant circuits, and predisposes the patient to future VF. The incidence of VT or VF is much higher when a post MI patient has a left ventricular ejection fraction of less than 30–35%. This also applies to symptomatic patients with nonischaemic DC.

## Diagnostic Principles

The twelve lead ECG is most important in formulating differential diagnosis during and following VFL and VF arrests. Work up in patients who have been resuscitated from VF aims at determining any preventable triggers or risk factors for ventricular arrhythmia that can degenerate into VF. Tests include electrolyte levels, blood gases, drug levels, (particularly medications that may prolong QT-interval, proarrhythmic agents, anti-arrhythmic agents), and toxicology screen (cocaine, amphetamines, phencyclidine, LSD, ecstasy, marijuana). Other tests include the signal average electrocardiogram, chest x-ray, echocardiogram, cardiac MRI, Holter monitoring, exercise or nuclear stress tests, event monitoring and electrical physiologic studies.

## Therapeutic Principles

The management of patients with VFL and VF is immediate epicardial blow to the sternum, electrical defibrillation, basic life support, and advanced life support [3].

V

## Definition and Characteristics

Left ventricular mass index (LVMI, $g/m^2$) above the 97.5th percentile of the LVMI distribution in normotensive, normal-weight individuals. Usually occurs in response to increased hemodynamic load or in the autosomal-dominant disorder, hypertrophic cardiomyopathy (HCM).

## Prevalence

Sixteen percent of Caucasians and 33–43% of African–Americans, with a greater prevalence with age, hypertension, obesity and diabetes. HCM occurs in 0.05–0.2% of the population.

## Genes

In hemodynamic overload, there are multiple changes at the level of gene expression involving increases or decreases in transcription, and changes in LV gene expression profiles (isogene switching). The physiologically most important subcellular change is increased muscle fiber deposition (myofibrillogenesis or sarcomerogenesis). In man and experimental animals (mainly rodents), increased transcription of atrial- and B-type-natriuretic peptide genes (ANP and BNP, respectively) coincides with LVH and may be useful as prognostic markers. In rodents, there is increased expression of immediate response genes (e.g. c-myc and c-fos) and, for myofibrillar proteins, isogene switching to skeletal muscle α-actin and β-myosin heavy chain (β-MHC). There are changes in the expression of $Ca^{2+}$ -handling proteins (e.g. transcription of the sarcoplasmic reticulum $Ca^{2+}$ pump, SERCA2, is decreased). Some of these changes are likely to occur early in the development of LVH in man. In the mutationally-induced forms of LVH (familial HCM), a mutation in one of the myofibrillar proteins (β-MHC, cardiac troponins T and I, α-tropomyosin, myosin light chains, myosin-binding protein C) is the initiating factor [1].

## Molecular and Systemic Pathophysiology

Though it remains controversial, LVH can be viewed as an initially- adaptive mechanism that enables the heart to maintain cardiac output in the face of the increased mechanical load. During the first phase of pressure- or volume-overload LVH, the changes normalize systolic LV wall stress [Laplace's Law: wall stress is proportional to (pressure x radius)/wall thickness] thereby maintaining systolic function. Over time, however, a large number of changes (including interstitial fibrosis and myocyte loss) prevent the heart from relaxing and contracting normally. Initially, diastolic dysfunction ensues which is characterized by increased myocardial stiffness, decreased ventricular compliance, delayed relaxation, increased LV end diastolic pressure, LV dilatation, decreased rate of early diastolic filling, and prolonged late filling phase. Abnormalities in excitation-contraction coupling (e.g. increased action potential duration) occur because of changes in $Ca^{2+}$ handling in the sarcoplasmic reticulum and plasma membrane. Clinically, LVH is an independent risk factor for coronary artery disease, congestive heart failure, cerebrovascular accidents, ventricular arrhythmias and sudden cardiac death.

Multiple factors contribute to LVH. These changes are detected by intracellular signaling pathways (often involving reversible protein phosphorylation and dephosphorylation) which lead to the phenotypic changes. The hypertrophic effects of increased hemodynamic loading may be mediated by mechanical stretch and deformation of the cardiomyocyte plasma membrane which activate (poorly-characterized) mechanosensitive ion channels. Increases in neurohumoral factors (endothelin-1, sympathetic tone, angiotensin II) act in a juxtacrine-, autocrine or paracrine fashion to activate their cognate sarcolemmal G-protein coupled receptors receptors (GPCRs) [4]. In turn, GPCR signaling stimulates membrane phospholipid-dependent signaling pathways resulting in phosphatidylinositol 4,5-bisphosphate ($PIP_2$) hydrolysis and activation of protein kinase C. This leads to activation of the ERK1/2 mitogen-activated protein kinase (MAPK) cascade. Other "stress-activated" MAPK cascades may also be activated by poorly-understood mechanisms. Phosphorylation of $PIP_2$ to $PIP_3$ by the lipid kinase phosphoinositide 3-kinase leads to activation of the protein kinase B/Akt signaling pathway [3]. Changes in $Ca^{2+}$ handling leads to activation of $Ca^{2+}$ -regulated protein phosphatases (calcineurin) and protein kinases (CaMKs). These intracellular signals are transmitted to and integrated in the nucleus by transcription factors to alter the rates of transcription of individual genes and to the translational machinery resulting in increased protein synthesis.

Because mammalian cardiomyocytes lose their ability to proliferate in the perinatal period, growth can only occur by the hypertrophy of pre-existing cells. In response to loss of myocardial tissue or increased mechanical work (pressure- or volume-overload), the cardiomyocytes lay down sarcomeres and grow in an attempt to maintain cardiac output. Regional LVH ("remodeling") may occur in the surviving myocardium following the regional loss of a proportion of the myocardium following myocardial infarction. For hemodynamic overload, two different anatomical phenotypes of LVH exist [5]. Concentric hypertrophy is caused by pressure-overload (e.g. hypertension or aortic stenosis)

and is characterized by increased LV wall thickness without chamber enlargement, hence increasing LV wall thickness:chamber radius ratio. Eccentric hypertrophy is caused by volume-overload (e.g. aortic insufficiency) and is characterized by chamber expansion with an equivalent proportional increase in wall thickness, thus preserving LV wall thickness:chamber radius ratio. These two different phenotypes involve differences in the patterns of accumulation of sarcomeres in the myofibrils. Furthermore, cardiac fibroblasts, which are responsible for collagen production, are capable of hyperplasia. Thus, during LVH, alterations within the extracellular matrix (ECM) also occur, with increased connective tissue deposition. Chronic LVH involves interstitial fibrosis and "myocardial stiffness" which probably contributes to myocardial failure. Hence, the increase in LVMI which occurs in LVH is a result of a combination of myocyte hypertrophy, fibroblast hyperplasia and ECM deposition.

## Diagnostic Principles

Echocardiography with LVMI threshold values >131 g/m$^2$ in men and >100 g/m$^2$ in women and relative wall thickness (interventricular septum + posterior wall thickness/left ventricular internal diameter) >0.45 [2]. Electrocardiography with voltage criteria of S in V1 + R in V5 or V6 ≥ 35 mm.

## Therapeutic Principles

Therapy includes reduction of pressure load (lowering systemic blood pressure) and volume load (diuretics). Moreover, therapy may be directed to reverse remodeling (see ventricular remodeling) or to support cardiac contraction, e.g. by a Left Ventricular Assist Device. Ultimately cardiac transplantation main remain the only therapeutic option.

UMDNJ, Newark, NJ, USA

## Synonyms

RVH

## Definition and Characteristics

Right ventricular hypertrophy (RVH) is defined as a concentric or eccentric enlargement of the right ventricle resulting from increased workload and subsequent hypertrophy of the cardiac myocytes composing the right ventricle. If untreated, the condition will evolve from an adaptive (compensatory hypertrophy) into a maladaptive state (progressive loss of contractility) resulting in right heart failure. RVH results from chronic overload of the right ventricle, due most often to the causes of pulmonary hypertension shown in Table 1, including chronic lung disease, congenital heart defect with left-to-right shunt (such as patent ductus arteriosus or ventricular septal defect), high-altitude hypoxia, and idiopathic pulmonary hypertension.

Another cause of chronic overload of the right ventricle without pulmonary hypertension is right ventricular myocardial infarction. The right ventricle can also be exposed to acute overload during pulmonary embolism, which will result in RVH only if repetitive (congenital coagulation disorders, cancer).

**Ventricular Hypertrophy, Right. Table 1** Most common causes of pulmonary hypertension

| | |
|---|---|
| **Primary hypertension** | Idiopathic, familial, high altitude |
| **Secondary hypertension** | |
| Due to systemic disease | Collagen vascular disease, HIV-1, toxins |
| Due to heart disease | Left ventricular dysfunction, congenital disease with left-to-right shunt |
| Due to lung disease | Chronic bronchitis, severe asthma, emphysema |
| Due to vascular disease | Thrombo-embolism |

## Prevalence

Between 10 and 30% of hospital admissions for heart failure in the United States are due to cor pulmonale. Approximately 40% of patients with chronic lung disease have clinical or pathological signs of cor pulmonale.

## Genes

Right ventricular hypertrophy may result from genetic alterations leading to congenital heart disease with left-right shunt, or from genetic causes of dilated cardiomyopathy.

## Molecular and Systemic Pathophysiology

The right ventricle receives deoxygenated blood from the right atrium and ejects into the pulmonary artery, which divides into the lungs where blood is reoxygenated before reaching the left atrium. Compared to the left ventricle, the wall thickness of the right ventricle is relatively modest because the right ventricular cavity is exposed to low filling pressure (preload, or pressure with which the right atrium fills the right ventricle) and low ejection pressure (afterload, or pressure with which the right ventricle ejects into the pulmonary artery). Any increase in workload will result in additional thickening of the right ventricular wall due to hypertrophy of the cardiac myocytes, which accumulate more sarcomeres to match the increased work demand. Increased workload of the right ventricle can be due to either an increase in preload (such as right ventricular infarction), resulting in eccentric RVH, or increased afterload (pulmonary hypertension), which results in concentric RVH. After an initial phase of compensation where ventricular function is maintained, the hypertrophied right ventricle will dilate, because of the progressive death by necrosis and apoptosis of the overloaded cardiac myocytes. Cell death is due not only to the chronic exposure of the myocytes to overload but also to the progressive deterioration of the coronary flow reserve. This process, known as ventricular remodeling, will be accompanied by a regurgitation of blood from the right ventricle to the right atrium through an insufficient tricuspid valve. As a consequence, the right ventricular cardiac output will decrease, leading to the condition of heart failure when the cardiac output becomes insufficient to match the needs of the organism. The neurohormonal response to the right ventricular dysfunction may also induce an alteration of the left ventricular dynamics.

## Diagnostic Principles

Echocardiography is the most practical method for the measurement of right ventricular function, dimensions, regional dynamics, thickness and tricuspid regurgitation. This technique can be completed by magnetic resonance imaging (MRI) for measurement of ventricular volumes and ejection fraction. On the X-ray, RVH is better seen on the lateral view as a retrosternal enlargement. The electrocardiogram will show an increased R wave in the right precordial leads and electric signs of right ventricular myocardial infarction if present. Thermodilution by pulmonary artery catheterization will determine the right ventricular cardiac output and the developed pressure. Right ventriculography will show the ventricular volumes and regional dynamics, which can also be diagnosed non-invasively by radionuclide ventriculography. The measurement of the N-terminal B-type natriuretic peptide concentration (NT-proBNP) in the plasma is a useful and non-invasive prognosis factor.

## Therapeutic Principles

The treatment of the disease depends on the cause. The prognosis of primary pulmonary hypertension is usually poor because the disease is incompletely relieved by the treatment, which includes high-dose calcium channel blockers, diazoxide, corticosteroids, sildenafil, nitric oxide donors, prostacyclin analogs, and, ultimately, heart-lung transplantation. Gene delivery of prostacyclin synthase and inhibition or Rho-kinase by fasudil have been used successfully in an experimental model of pulmonary hypertension but these therapeutic avenues are not approved yet for clinical application. The clinical use of rapamycin or statins showed disappointing results. Administration of carvedilol reduces the extent of RVH. Secondary pulmonary hypertension due to lung disease (cor pulmonale) requires an aggressive treatment of the cause (oxygen, antibiotics, bronchodilators, mucolytics). The prognosis of cor pulmonale is also poor because the causal disease is usually very advanced when cardiac symptoms develop. Treatment of right ventricular myocardial infarction includes beta-blockers and inhibitors of angiotensin convertase. Pulmonary embolism is treated with anticoagulants, thrombolytics or surgery, depending on the cause and severity of the symptoms. Congenital abnormalities with subsequent RVH require repair by surgery or catheterization.

# Ventricular Remodeling

Joseph B. Selvanayagam
Department of Cardiovascular Medicine, Flinders Medical Centre, Bedford Park, SA, Australia

## Definition and Characteristics

Left ventricular remodeling refers to the regulation of ventricular size, shape, and function by mechanical, hormonal, and genetic factors [1]. Remodeling may be physiological and adaptive during normal growth or pathological due to myocardial infarction, cardiomyopathy, pressure volume overload.

## Prevalence

Pathophysiologically relevant ventricular modeling in heart disease is frequent, affecting >10% of the common population with increased prevalence in advanced age, hypertension, obesity and diabetes.

## Genes

No single or cluster of genes have been identified in the direct pathogenesis of remodeling. A number of genes that encode transcriptional and growth factors have been implicated in the genesis of hypertrophy (see below).

## Molecular and Systemic Pathophysiology

Conceptually, the pathophysiology of ventricular remodeling can be best considered in the setting of left ventricular myocardial infarction. This is the most common scenario that leads to pathological ventricular remodeling. The loss of heart muscle results in an sudden elevation in loading conditions that induces a unique pattern of remodeling involving the infarcted border zone and remote non-infarcted myocardium. Myocyte necrosis and the resultant increase in ventricular load trigger a cascade of biochemical intracellular signaling processes that initiates and subsequently modulates changes in ventricular geometry and conformation. These include dilatation, hypertrophy, and the formation of a discrete collagen scar. Ventricular remodeling may continue for weeks or months until the distending forces are counterbalanced by the tensile strength of the collagen scar. This balance is determined by the size, location, and transmurality of the infarct, the extent of myocardial stunning, the patency of the infarct-related artery, and local tropic factors.

Postinfarction remodeling has usually been divided into an early phase (within 72 h) and a late phase (after 72 h). The early phase involves expansion of the infarct zone, which may result in early ventricular rupture or aneurysm formation. Late remodeling involves the left ventricle globally and is associated with time-dependent dilatation, the distortion of ventricular shape, and mural hypertrophy. The failure to normalize increased wall stresses results in progressive dilatation, and deterioration in contractile function.

*Early Remodeling*: Infarct expansion results from the degradation of the intermyocyte collagen by proteases released from neutrophils. Infarct expansion usually occurs within hours of myocyte injury, results in wall thinning and ventricular dilatation, and causes the elevation of diastolic and systolic wall pressure [2]. The increased wall stress is then a powerful stimulus for hypertrophy mediated by mechanoreceptors and transduced to intracellular signaling, partly via angiotensin II (Ang II) release, which initiates the increased synthesis of contractile assembly units.

Non-infarcted, remote myocardium has adaptive responses that try and preserve stroke volume. Infarct expansion causes the deformation of the border zone and remote myocardium, which alters Frank/Starling relations and augments shortening. Disturbances in circulatory hemodynamics are the main trigger for the activation of the sympathetic nervous system, and the resulting catecholamine release, activates the renin-angiotensin-aldosterone system, and stimulates the production of atrial and brain natriuretic peptides (ANP and BNP). Increased myocardial fiber shortening and elevated heart rate from sympathetic stimulation result in hyperkinesis of the noninfarcted myocardium and (temporary) circulatory compensation

*Late Remodeling*: Remodeling involves myocyte hypertrophy and alterations in ventricular architecture to distribute the increased wall stresses more evenly as the extracellular matrix forms a collagen scar to stabilize the distending forces and prevent further deformation. Myocyte hypertrophy is demonstrable microscopically, with an up to 70% increase in cell volume and mural hypertrophy by in-series sarcomeric replication, without a change in sarcomere length.

*Remodeling and Hypertrophy*: Hypertrophy is an adaptive response during postinfarction remodeling that offsets increased load, attenuates progressive dilatation, and stabilizes contractile function. Genes for transcriptional factors, such as c-fos, c-jun, c-myc, Egr-1, natriuretic peptides (ANP, BNP), smooth muscle and skeletal α-actins, and myosin light chains 1a and 2a, enzymes (angiotensin-converting enzyme [ACE], ßARK), and growth factors (including insulin-like growth factor-1, transforming growth factor [TGF]-ß1), are induced and regulated by hypertrophic stimuli [3]. Myocyte hypertrophy is initiated by neurohormonal activation, myocardial stretch, the activation of the local tissue renin-angiotensin system (RAS), and paracrine/autocrine factors.

*Neurohormonal Activation*: Neurohormonal activation has been established to be an important mechanism for ventricular remodeling and progression of heart failure [4]. The neurohormonal systems are stimulated even before the development of clinical heart failure. In patients with overt clinical heart failure, activation of these neurohormones continues. Neurohormonal activation appears to be initiated by myocyte/myocardial and global and regional left ventricular dysfunction including increased wall stress. Myocyte and myocardial remodeling associated with neurohormonal activation result in decreased bioenergetics, altered $Ca^{2+}$ handling, abnormal architecture and fetal gene induction.

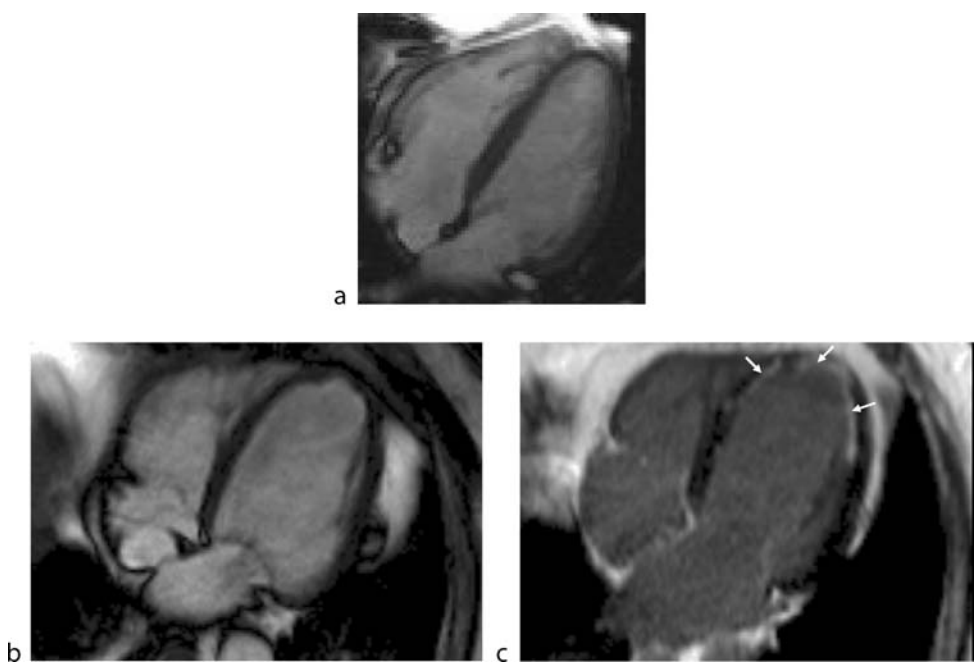
The neurohormonal systems that are activated in systolic heart failure can be broadly categorized into those that promote vascular and cardiac remodeling and those that have the potential to cause reverse remodeling (see Table 1).

**Ventricular Remodeling. Table 1** Neurohormonal systems that are activated in systolic heart failure categorised into those that promote remodelling and those that potentially reverse modelling

| Adverse remodeling | Reverse remodelling |
|---|---|
| Renin | Natriuretic peptides (ANP, BNP) |
| Angiotensin II | Vasaactive intestinal peptides |
| Aldosterone | Substance P |
| Endothelins | Growth hormone |
| Catecholamines | Calcitonin gene related peptide |
| Neuropeptide Y | |

## Diagnostic Principles

Non-invasive imaging, particularly 2D echocardiography, and nuclear techniques have provided insights into the mechanisms by which biochemical and cellular changes are translated into alterations in ventricular architecture and function during remodeling. Clinical outcome analyses and reliable, objective, non-invasive measurements of ventricular structure and function currently provide a template for assessing new therapies. Cardiac MRI has rapidly become the imaging method of choice and the gold-standard in the assessment of ventricular remodeling. Given its 3D nature and order of magnitude greater signal-to-noise ratio, CMR is highly superior to 2D echocardiography [5]. This has allowed reductions of study sizes of 80–97% to achieve the same statistical power for demonstrating given changes of left ventricular volumes, ejection fraction, or cardiac mass (Fig. 1).



**Ventricular Remodeling. Figure 1** Cardiac MR images from a patient 2 days and 1 year following an acute antero-septal and apical myocardial infarction. (a) End-diastolic horizontal long axis (HLA) cine MR image 2 days post MI showing normal LV dimensions and wall thickness (EDV 122mls, ESV 51 mls, EF 55% and mass 116 g). (b) End-diastolic HLA cine MR image at 1 year post MI showing increased LV dimensions and wall thickness (EDV 190 mls, ESV 121 mls, EF 41% and mass 146g). (c) "Delayed enhancement" (technique for imaging myocardial scar) HLA image at 1 year shows the location of irreversible myocardial injury in the antero-septal and apical myocardium (*arrows*).

## Therapeutic Principles

In patients with ischemic cardiomyopathy, as infarct size and the degree of depression of LV systolic function are the major determinants of remodeling, limiting the infarct size should be considered as an essential therapeutic goal. In patients with AMI early, effective and adequate reperfusion of the ischemic myocardium is the best strategy to decrease the extent of myocardial injury and preserve LV systolic function.

*Reverse Remodeling Therapy*: This can be broadly divided into pharmacological and non-pharmacological therapy. A number of pharmacologic agents have been shown to produce reverse remodeling and some of them have been shown to improve not only the clinical status but also prognosis. Many prospective clinical trials have documented their beneficial effects.

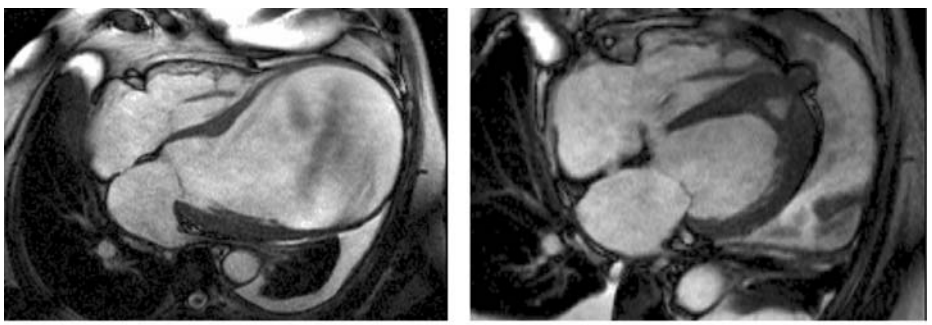
*Angiotensin Converting Enzyme Inhibitors (ACEI)*: Long-term use of ACEIs results in decrease of end-systolic and end-diastolic volumes and mass of LV and an increase in its ejection fraction. These beneficial reverse remodeling effects are observed in patients irrespective of the underlying etiology of adverse remodeling or the presence/absence of symptoms. The ACEIs relieve symptoms of heart failure, improve exercise tolerance and quality of life in the majority of patients although the magnitude of improvement is variable. The most consistent systemic hemodynamic effect is reduction in right atrial and pulmonary capillary wedge pressures, although cardiac output tends to increase in a substantial proportion of patients. Prospective randomized clinical trials have also documented a substantial survival benefit of ACEIs in patients with chronic systolic heart failure.

*Angiotensin-II Receptor Blockers*: Angiotensin-II ($AT_2$ -Subtype 1) receptor blocking agents also attenuate ventricular remodeling. There is an increase in LV ejection fraction along with a decrease in LV end-diastolic volume. Angiotensive receptor blocking agents also decrease morbidity and mortality of patients intolerant to ACEIs.

Complete angiotensin blockade with combined ACEIs and $AT_1$ blocking agents have been shown to decrease the risks of cardiovascular deaths and morbidity such as rates of hospital admission for congestive heart failure, non-fatal myocardial infarction and stroke in patients with mild to moderately severe systolic heart failure.

*Beta Blockers*: Chronic long-term β-blocker therapy is associated with reverse remodeling. There is a decrease in end-systolic and end-diastolic volume as well as in LV mass and an increase in the sphericity index. A number of prospective randomized controlled studies have documented that chronic β-blocker therapy improves survival of patients with mild, moderate and even severe heart failure.

*Aldosterone Antagonists*: The aldosterone antagonists attenuate adverse ventricular remodeling. A substantial reduction occurs in LV end-diastolic and end-systolic volumes and LV mass. It also reduces collagen turnover and myocardial fibrosis. Aldosterone antagonists increase nitric oxide bioavailability, improve endothelial vasodilatory function and decrease conversion of vascular $AT_1$ to $AT_2$. In patients with heart failure, there is also a decrease in norepinephrine and BNP levels. Thus, aldosterone antagonists not only decrease the deleterious remodeling effects of aldosterone, directly by blocking the aldosterone receptors but also by their anti-angiotensin and antiadrenergic effects. These agents have also been shown to improve vascular compliance, decrease myocyte hypertrophy, and possibly because of this, reduce cardiovascular and overall mortality.



**Ventricular Remodeling. Figure 2** Cardiac MR images from a patient with adversely remodeled left ventricle secondary to large, non-reperfused myocardial infarction, before (*left*) and after (*right*) an endoventricular patch plasty repair (Dor procedure). MR images are in the horizontal long axis plane and show a grossly dilated LV with increased mass prior to surgery with dramatic improvement in LV volumes and mass after surgery. *EDV* indicates end-diastolic volume; *ESV* end-systolic volume; *SV* stroke volume; *EF* ejection fraction (adapted from Selvanayagam J et al. (2003) Circulation 107:e71).

*Other Agents*: The newer neurohormonal modulators have failed to meet the expected promise. In prospective randomized clinical trials, the use of intravenous prostacyclin, TNF-α antagonists, endothelin antagonists and vasopeptidase inhibitors all have been associated with neutral or even adverse outcomes. Only intravenous B-type natriuretic peptide (brain natriuretic peptide) has been shown to produce favorable hemodynamic and clinical responses in patients with decompensated systolic failure. However, the impact of BNP therapy on ventricular remodeling has not been adequately investigated.

*Non-pharmacological Interventions*: Non-pharmacologic interventions such as chronic resynchronization therapy, with or without defibrillator has been reported to attenuate ventricular remodeling and to improve prognosis. LV assist devices also have the potential for improving prognosis of patients with refractory heart failure. Ventricular volume reduction surgery, revascularization and LV reconstruction (see Fig. 2), myoblast implantation and gene therapy are under investigation.

# Ventricular Scar

Annika Burow, Etienne Delacrétaz
Swiss Cardiovascular Center Bern, University Hospital, Bern, Switzerland

## Definition and Characteristics

Ventricular scar typically forms when a section of the myocardial wall is deprived of blood and undergoes necrosis with replacement of cardiomyocytes by fibrous tissue. Less often, an inflammatory and/or degenerative process can cause ventricular necrosis and scarring.

## Prevalence

Ventricular scars are frequent. In most cases ventricular scars are caused by myocardial infarction, but they can be seen in relation to ►myocarditis, ►sarcoidosis, ►arrhythmogenic right ventricular cardiomyopathy (ARVC), Chagas' disease, ►dilated cardiomyopathy (DCM), ►hypertrophic cardiomyopathy (HCM) and ►congenital heart disease.

## Genes

Risk factors for atherosclerosis and ischemic heart disease include genetic predisposition. At this stage however, it has not been associated with specific gene mutations. A few diseases occur partly due to a familial linkage such as DCM, HCM and ARVC. About 35% of patients with DCM have an inherited form related to a genetic mutation [1]. Most familial cases show autosomal dominant transmission but autosomal recessive, X-linked and mitochondrial inheritance have also been demonstrated. Genetic mutations have been shown in genes coding for cytoskeletal and nuclear envelope proteins and sarcomeric contractile proteins. HCM presents as familial disease with autosomal dominant inheritance in about 50% of patients. It is caused by mutations in genes that encode sarcomeric proteins or intrasarcomeric cytoskeletal proteins. ARVC, characterized by replacement of myocytes by fibrofatty tissue prevailing in the right ventricle, presents an autosomal dominant inheritance in at least 30% of cases. In a few families mutations in the cardiac ryanodine receptor gene have been identified [1,2].

## Molecular and Systemic Pathophysiology

A scar develops following myocardial injury that is typically due to acute myocardial infarction, but may be due to a number of causes that result in increased pressure or volume overload of the heart and less commonly occurs as a result of inflammatory and/or degenerative processes. Myocardial scars are composed of collagen and fibroblasts which do not contract, leading to a regional loss of contractile function. Scarring is associated with progressive ventricular remodeling of surviving myocardium that may ultimately lead to progressive heart failure [3]. Cells with abnormal electrical activity may be present in the border zone of scars, causing arrhythmias including ventricular premature beats, and non sustained ventricular tachycardia. Furthermore, ventricular scars may be the substrate for sustained reentrant ventricular tachycardia. The mechanism is a reentry circuit within

a region of abnormally conducting tissue, usually at the border zone of a relatively large scar [4]. Ventricular tachycardia can cause sudden cardiac death due to hemodynamical collapse and secondary ventricular ischemia and ventricular fibrillation. Other clinical manifestations include palpitations, syncope and heart failure.

## Diagnostic Principles

Ventricular scars can be detected by routine tests including electrocardiogram (ECG) and echocardiography. Contrast-enhanced magnetic resonance imaging has a higher sensibility and specificity to demonstrate smaller or nontransmural lesions. Endomyocardial biopsy is usually performed when an inflammatory process is suspected. Left ventricular ejection fraction is a measure of the contractile function, and can be determined by several methods, including echocardiography and ventriculography. Ventricular arrhythmias can be diagnosed with ECG recordings. Identification of the mechanism and delineation of the reentry circuit is possible using catheter-based mapping techniques.

## Therapeutic Principles

Since myocardial cells do not spontaneously regenerate, ventricular scarring is permanent. Recently, studies in animal models of myocardial infarction and heart failure have demonstrated that stem cells from bone marrow can regenerate functional cardiomyocytes with improvement in cardiac structure and function [5]. However, no medication or procedure used clinically has shown efficacy yet in replacing the myocardial scar with functioning contractile tissue. Blockade of the renin–angiotensin system and blockade of beta-receptors improve myocardial performance and decrease mortality. In patients with coronary artery disease, the need for coronary revascularization should be assessed, and risk factors for atherosclerosis should be aggressively treated. Patients with scar-related ventricular tachycardia are at risk of sudden cardiac death and should receive an implantable defibrillator. In some patients who are not eligible for this therapy or in those with recurrent defibrillator intervention, catheter ablation of ventricular tachycardia may be performed.

# Ventricular Septal Defect

Zhuang Chen, Weinian Shou
Department of Pediatrics, Biochemistry and Molecular Biology, Indiana University School of Medicine, Herman B Wells Center for Pediatric Research, Indianapolis, IN, USA

## Synonyms

Interventricular septal defect; VSD

## Definition and Characteristics

Ventricular septal defects (VSD) represent a group of cardiac anomalies that exhibit one or more holes in ventricular septum that divides right and left ventricular chambers. VSDs are one of the most common forms of congenital heart disease (CHD), which can occur as an isolated form or in association with other congenital heart malformations.

## Prevalence

About 1% of babies are born with this condition.

## Genes

Genetically modified mouse mutants strongly suggest that VSD is not a single-gene defect. Table 1 summarizes candidate genes that have been associated with VSDs. More genes are certainly expected to be added to this list.

## Molecular and Systemic Pathophysiology

VSDs may be located in muscular (outlet, inlet, trabecular) or membranous septal regions. As with most forms of CHD, the etiology of VSDs can be multifactorial and is not always clear. Identification of

**Ventricular Septal Defect. Table 1** Genes potentially associated with VSDs

genetic causes of VSDs through human genetic studies has thus been difficult, and the molecular mechanisms responsible for various types of VSDs remain largely unknown. The heterogeneous composition of the normal ventricular septum suggests a variety of possible mechanisms could be involved in the development and/or morphogenesis of these defects.

### Diagnostic Principles

VSD patients commonly exhibit murmurs. Other symptoms include shortness of breath, paleness, fast heartbeat, failure to gain weight, and frequent respiratory infections in children. Laboratory tests include ECG, chest radiograph, echocardiography (definitive diagnosis), and cardiac catheterization.

### Therapeutic Principles

In mild cases, treatment is not usually required as there is a good chance that the hole closes as the child grows. In the severe cases, surgical closure is required by direct suture or with a patch, and some VSDs can be repaired via transcatheter devices.

### Synonyms

Common warts

### Definition and Characteristics

HPV-induced reactive epithelial hyperplasia (acanthosis, hyperkeratosis) with affection of the connective tissue papillary body (papillomatosis), restricted to skin and mucous membranes. Common warts prone to develop more frequently at acroasphyctic areas as well as mechanically exposed parts of the body (i.e. hands and feet). Virus infection also seems to take place more easily in children with atopy and dry skin.

Frequently spontaneous regression. Heals without scarring, generally confers immunity.

### Prevalence

The worldwide incidence per year is ca. 10% and shows a peak in the second decade. Distinct increase among immunosuppressed patients (HIV/AIDS, organ transplant patients).

### Genes

HPV 2, 27, 57 and rarely 1, 4, 7, 26, 28, 29, 60, 65, 75–78

### Molecular and Systemic Pathophysiology

Papilloma viruses are host specific and can be transmitted from humans to humans but normally not from animals to humans. It occurs in almost all domestic animals (e.g. cattle, dog, horse, rat). The incubation data ranges between weeks and years.

The immune system is responsible for the high recurrence rate.

The HPV infection enters the skin via micro-lesions and infects basal keratinocytes. Expression of viral proteins mainly occurs in the stratum spinosum (early proteins) and granulosum (late proteins) of squamous epithelium [1].

After certain latency, HPV causes an increased cell growth, which is histologically described as an akanthopapilloma. Together with an increased cellular expression of viral particles, shed off keratinocytes might serve as new sources of infection.

## Diagnostic Principles

Clinical inspection. The initial wart is about the size of a pinhead and is seen as a protuberant, hard, skin-coloured nodule. As the wart enlarges, its surface develops a yellowish-gray hyperkeratosis with punctuate black spots due to some dirt or due to blood deposits. Daughter warts might develop through autoinoculation.

The structure of the warts depends upon its particular localisation and can be found for example on fingers and backs of the hands, eyelids, and mucous membranes (i.e. condylomata plana).

Immune defects or immunosuppressive treatment might lead to a dissemination of warts (verrucosis generalisata, eczema verrucatum).

For further diagnostic options, particularly with regard to differentiation of HPV types see chapter on ►Human Papilloma Virus.

## Therapeutic Principles

Pharmacological therapy, such as cytotoxic agents (i.e. podophyllin, trichloroacetatic acid,), keratolysis, 5-fluorouracil (5-FU), immunotherapy, interferons, immunomodulators (i.e. imidazoquinolones like imiquimod), antiviral therapy, retinoids, cidovir (see [2,3]).

Dietary therapy such as Indole-3-carbinol (constituent of cruciferous vegetables) and other treatments, local destruction (i.e. cryotherapy, laser vaporisation), excision, photodynamic therapy (PDT), homeopathy,suggestion, hypnosis, hot water (up to 52).

Warts have a high rate of spontaneous regression. (i.e. 63% within 2 years).

# Vertigo: Vestibular Neuritis

Thomas Brandt, Michael Strupp, Diethilde Theil
Department of Neurology, Ludwig-Maximilians-University, Klinikum Großhadern, Munich, Germany

## Synonyms

Vestibular neuronitis

## Definition and Characteristics

Vertigo and dizziness are among the most frequent presenting symptoms, not only in neurology. These two terms do not, however, indicate unique disease entities, but are used to cover a number of multisensory and sensorimotor syndromes of various etiologies and pathogeneses (Table 1).

Benign paroxysmal positioning vertigo is the most frequent vestibular disorder in which detached otoconia lead to canalolithiasis of the posterior > horizontal or > anterior semicircular canal. Phobic postural vertigo, a somatoform disorder of stance and gait, is the second most common form of dizziness. Central vestibular vertigo/dizziness is caused by lesions occurring along the vestibular pathways, which extend from the vestibular nuclei and the integration centers in the rostral midbrain to the vestibulo-cerebellum, the dorsolateral thalamus and – rarely – multisensory vestibular areas in the temporo-parietal cortex.

Vestibular migraine is the most common cause of spontaneous recurrent episodic vertigo.

Ménière's disease develops from endolymphatic labyrinth hydrops with periodic ruptures or leakage of the membrane separating the endolymph from the perilymph space.

Bilateral vestibular failure is a rare disorder of the labyrinths and/or the vestibular nerve of various etiologies. Vestibular paroxysmia is due to neurovascular cross-compression of the VIIIth nerve with ectopic discharges. The most frequent form of "perilymph fistula" is a bony dehiscence of the superior

**Vertigo: Vestibular Neuritis. Table 1** Frequency of different vertigo syndromes in 6473 patients seen in a neurological outpatient dizziness unit

| Diagnosis | Frequency | % n |
|---|---|---|
| Benign paroxysmal positioning vertigo | 1197 | 18.4 |
| Phobic postural vertigo | 1007 | 15.6 |
| Central vestibular vertigo/dizziness | 821 | 12.7 |
| Basilar or vestibular migraine | 657 | 10.2 |
| Menière's disease | 609 | 9.4 |
| Vestibular neuritis | 483 | 7.4 |
| Bilateral vestibulopathy | 276 | 4.3 |
| Vestibular paroxysmia | 239 | 3.7 |
| Psychogenic vertigo (other than phobic postural vertigo) | 215 | 3.3 |

semicircular canal. Familial episodic ataxias EA1 and EA2 and vestibular neuritis (see below) are among the best studied vestibular disorders as regards their underlying molecular mechanisms.

Acute unilateral vestibular neuritis (VN) accounts for about 8% of patients who present to a neurological dizziness unit (Table 1). The main symptoms of an acute unilateral vestibular deficit are sustained violent rotatory vertigo, oscillopsia and gait and postural imbalance with a tendency to fall as well as nausea and vomiting. All of these symptoms have an acute or subacute onset and last for a few days or weeks. Hearing disorders or other neurological deficits are not present. Recovery is the result of a combination of central compensation of the peripheral vestibular tonus imbalance, substitution of the functional loss by the contralateral vestibular system as well as by somatosensory (neck proprioception) and visual afferents and restoration of the peripheral labyrinthine function (frequently incomplete). Patients with VN exhibit a permanent non-responsiveness (20%) or hyporesponsiveness (50%) to caloric irrigation. The rate of permanent paresis of the VIIIth nerve is considerably higher than in patients with Bell's palsy, in which severe, permanent palsy occurs in 4% and mild or moderate in 70% [1].

## Prevalence

The incidence of VN in the normal population was calculated to be 3.5 per 100,000 [2]. In a long-term follow-up (103 patients, mean 9.8 years) a second VN of the contralateral ear occurred in only two patients (1.9%) [1]. Thus, the frequency of recurrence is low but considerably higher (odds ratio of 55) than in the normal population. Unlike Bell's palsy or sudden hearing loss, a relapse in the same ear did not occur.

## Genes

Vestibular neuritis.

## Molecular and Systemic Pathophysiology

Molecular biological studies have presented strong evidence that VN is caused by a reactivation of latent herpes simplex virus type 1 (HSV-1) in the cranial nerve ganglia [3]. After primary infection of the epithelium (stomatitis aphtosa), HSV-1 enters the axon terminals and is carried by retrograde axonal transport to human trigeminal and geniculate ganglia. There it remains latent until certain stimuli reactivate HSV-1 by switching its viral state from latent to lytic. The latent state is characterized by expression of latency-associated transcript (LAT). During reactivation in the trigeminal ganglia, the entire viral genome is expressed and virus particles are transported back to the entry site, causing herpes labialis. When reactivated in the geniculate ganglia, the virus may spread via the facio-vestibular anastomosis to the vestibular ganglia, causing VN [1]. A persisting CD8-T-cell infiltration and the elevated cytokine/chemokine expression in trigeminal ganglia demonstrate that latent herpes viral infection in humans is accompanied by a chronic inflammatory process at an immunoprivileged site without causing any neuronal destruction [4]. The chronic immune response seems to control viral latency and influence viral reactivation. HSV-1 DNA was also found in the vestibular labyrinth (semicircular canals and macula organs), the potential significance of which is twofold: (i) inflammation in VN could also involve the labyrinth and thereby cause acute unilateral deafferentation and (ii) as benign paroxysmal positioning vertigo often follows VN in close temporal relationship, it could be a sequella of viral labyrinthitis.

## Diagnostic Principles

The following four conditions have to be met: (i) a history of acute/subacute onset of severe prolonged rotatory vertigo, postural imbalance and nausea; (ii) horizontal spontaneous nystagmus toward the unaffected ear with a rotatory component and a pathological head-impulse test; (iii) hyporesponsiveness or nonresponsiveness of the horizontal canal of the affected ear during caloric irrigation at 30°C and 44°C,

with an asymmetry between both sides of more than 25% according to the Jongkees' vestibular paresis formula; and (iv) displacement of the subjective visual vertical and ocular torsion (measured by fundus photography or laser scanning ophthalmoscopy) toward the affected ear but no vertical divergence of the eyes. Exclusion criteria are (i) additional cochlear symptoms, (ii) central ocular motor or vestibular dysfunction, (iii) any brainstem or cerebellar signs or symptoms and (iv) pathological findings on MRI and/or CT of the vestibular nuclei or the root entry zone of the VIIIth nerve or the vestibulo-cerebellum.

## Therapeutic Principles

In the acute phase lasting 1–3 days, antivertiginous drugs can be given to suppress nausea and vomiting. Drugs should be stopped as soon as the patient no longer vomits, as they prolong the time required to achieve central compensation.

A prospective randomized study of 141 patients assigned to placebo, methylprednisolone, valacyclovir and methylprednisolone plus valacyclovir groups showed that monotherapy with corticosteroids significantly improved the recovery of peripheral vestibular function of patients with VN (follow-up time: 12 months). The mean improvement in peripheral vestibular function at 12-month follow-up was 39.6 percentage points in the placebo group, 62.4 percentage points in the methylprednisolone group, 36.0 percentage points in the valacyclovir group and 59.2 percentage points in the methylprednisolone plus valacyclovir group [5]. Thus, there was no evidence of synergy between methylprednisolone and valacyclovir despite the assumed viral etiology. It is conceivable that the replication of HSV-1 in the vestibular ganglia had already occurred by the time that the antiviral agent was applied, i.e. within 3 days after symptom onset. This is supported by studies on HSV-1 encephalitis, which showed that the most relevant prognostic factor is early acyclovir treatment within 2 days after admission to the hospital.

# Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency

Brage Storstein Andresen
Institute of Human Genetics and Research Unit for Molecular Medicine, Aarhus University, Aarhus, Denmark

## Synonyms

Long-chain acyl-CoA dehydrogenase deficiency; VLCAD

## Definition and Characteristics

Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency is a defect of the mitochondrial betaoxidation of long-chain fatty acids.

There are three major clinical forms of VLCAD deficiency [1]. The severe childhood form is characterized by early (often neonatal) onset of symptoms. There is a very low tolerance of fasting, leading to recurrent disease episodes often with coma and a high mortality. Cardiomyopathy is a common clinical finding in these patients.

The milder childhood form is characterized by a later onset of symptoms and a lower mortality. The metabolic stress accompanying a feverish illness or fasting may result in metabolic decompensation and disease manifestation in these patients. Hypoketotic hypoglycemia is usually observed at clinical presentation, whereas cardiomyopathy is rare in this group. In both the severe and the milder childhood forms of the disease hepatomegaly and hypotonia are frequently observed. In some patients, who initially presented with the milder childhood form of the disease the clinical symptoms change towards more muscular symptoms as they get older.

The adult form of VLCAD deficiency is characterized mainly by skeletal muscle involvement. Disease manifestation is usually caused by exercise or fasting. Symptoms are recurrent episodes of muscle pain, rhabdomyolysis, and myoglobinuria. Rhabdomyolysis and myoglobinuria may result in acute renal failure.

## Prevalence

VLCAD deficiency is an autosomal recessive inherited disease. Because VLCAD deficiency is included in newborn screening programs in Europe, Australia and USA its prevalence can be estimated from the number of newborns identified in these programs to be approximately one in 100,000 births.

## Genes

Initially patients with a defect in dehydrogenation of long-chain acyl-CoAs were believed to have mutations in the long-chain acyl-CoA dehydrogenase (LCAD) gene, ACADL, but it has now turned out that all patients instead have mutations in the VLCAD gene, ACADVL. ACADVL is located on chromosome 17p11.13–p11.2. It consists of 20 exons, which encode 655 amino acids [2,3].

Close to 200 different mutations distributed to all twenty exons of the gene are known [1,4]. There are no prevalent mutations, but many of the mutations are present in more than one unrelated family. The most frequently identified mutation is c.848T>C, which is located in exon 9, and results in a change from valine to alanine at position 243 of the mature protein (V243A).

## Molecular and Systemic Pathophysiology

There is a rather clear correlation between VLCAD genotype and clinical presentation (Fig. 1) [1,4].

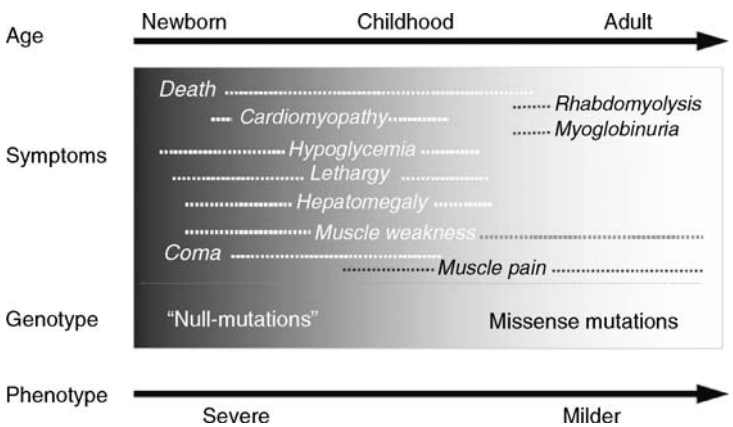
In the severe childhood form of the disease, most of the identified mutations are "null" mutations, such as frameshift, splicing and stop mutations, that result in no residual enzyme activity. In patients with two "null" mutations, the complete absence of VLCAD activity will affect many tissues, in particular heart and liver, which are heavily dependent on energy from fatty acid oxidation. This leads to cardiomyopathy and hepatomegaly and the tolerance to a metabolic stress is very low.

In the milder childhood and the adult forms of the disease, the vast majority of alleles harbor missense mutations or single amino acid deletion mutations that may result in some residual enzyme activity. Most of these mutations are folding/stability mutations, which dependent on temperature (for instance fever) will result in mutant VLCAD proteins with varying levels of residual enzyme activity.

Patients with this type of mutations, in at least one of their alleles, may have sufficient residual VLCAD activity to avoid liver and cardiac symptoms if they are not metabolically stressed. In addition they do not undertake sufficient sustained exercise, in childhood, to precipitate severe muscle symptoms. During infections or fasting, however, the residual enzyme activity may no longer be sufficient to sustain the increasing demand on hepatic fatty acid oxidation, leading to hypoketotic hypoglycemia. It is also possible that compromised folding/stability conditions are a contributing factor in disease precipitation. It could be speculated if, for instance, during febrile illness or due to increased temperature in exercising skeletal muscle, the partially functional mutant proteins loose all or most of the residual enzyme activity. As the patients get older, metabolic decompensation becomes less of a problem, but they also start to undertake more sustained exercise. Because muscle depends heavily on fatty acid oxidation as energy source this leads to muscle symptoms becoming a more frequent clinical symptom with increasing age.

## Diagnostic Principles

VLCAD deficiency may be difficult to diagnose since the clinical presentation and the findings from standard laboratory tests from patients show extensive overlap with other long-chain fatty acid oxidation defects. This is further complicated by the fact that many of the abnormal laboratory parameters may be normal or close to normal between episodes of metabolic decompensation. VLCAD deficiency may be indicated by tandem mass spectrometry screening of blood or blood spots for elevated levels of several long chain acylcarnitines (C16:0, C14:0 and C14:1). This procedure is used for routine screening of newborns in several countries worldwide. If urine is collected from a child during disease manifestation urine organic acid analysis will reveal dicarboxylic aciduria. During periods of low



**Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency. Figure 1** Genotype – phenotype correlation in VLCAD deficiency.

V

or no metabolic stress biochemical diagnosis may be very difficult, since such biochemical markers (and also the acylcarnitine profile) from patients with the milder forms of this disease may be normal. A definitive diagnosis can be obtained by demonstration of mutations in the ACADVL gene or by demonstration of decreased VLCAD enzyme activity in patient cells.

### Therapeutic Principles

Acute episodes of metabolic decompensation may be corrected by intravenous glucose. Dietary treatment consists of avoidance of fasting, reducing the amount of long-chain fat in the diet and supplementing with medium chain triglycerides or triheptanoin. In small children overnight continuous tube feeding or provision of uncooked cornstarch before bedtime may be necessary in periods with febrile illness or vomiting. Because plasma carnitine levels may be low in VLCAD deficiency, L-carnitine is frequently prescribed, although the benefits of carnitine therapy still remains unclear. The adult, muscular, form of VLCAD deficiency can be managed by restricting physical activity and by high carbohydrate intake prior to exercise. Very recent studies indicate that increasing ACADVL gene expression by bezafibrate therapy may be beneficial to patients, who possess at least one allele with an ACADVL missense mutation [5].

►Vesicular Stomatitis Virus Infection

## Vesicular Stomatitis Virus Infection

Amei Ludwig, Hartmut Hengel
Institute for Virology, Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany

### Synonyms

Vesicular stomatitis (VS)

### Definition and Characteristics

Vesicular stomatitis, a viral disease caused by vesicular stomatitis virus (VSV), naturally infects livestock, but in rare cases humans are also affected. Vesicular stomatitis virus belongs to the family of Rhabdoviridae, genus Vesiculovirus. As an arbovirus, short for arthropod-borne virus, vesicular stomatitis virus is restricted to biting insects (i.e. mosquitoes or sand flies) and mammals. The insects not only act as vectors, but are also supposed to be a natural reservoir for VSV.

Two groups of at least 14 serotypes can be separated based on geographic distribution. On the one hand there are serotypes found in the Americas including the Indiana (IND) and New Jersey (NJ) serotypes, on the other hand there are those found in the eastern hemisphere (India, Eastern Europe and the Middle East) including the serotypes Chandipura, Isfahan and Yug Bogdanovac. In North America epizootic outbreaks are sporadic, in parts of Central and South America enzootic outbreaks appear in the dry season from November to March [1]. Infection with one serotype does not protect against infection with another strain.

Vesicular stomatitis in livestock is characterized by fever, vesicles and subsequent erosions in the mouth and epithelium of teats and feet. Symptoms usually

**Vesicular Stomatitis Virus Infection. Table 1**

| Protein | Function | |
|---|---|---|
| N protein | Nucleoprotein | Associates with viral RNA to generate the viral nucleocapsid, which serves as functional template for viral transcription and replication |
| G protein | Glycoprotein | G protein trimers form spikes on the viral envelope that provide attachment of virus particle to host cell receptors and enables viral entry. |
| M protein | Matrix protein | Multiple functions (i.e. regulation of viral transcription, inhibition of host cell gene expression and virus budding) |
| L protein | Large protein | Association of L and P protein forms functional viral RNA polymerase (with transcriptase and replicase functions) |
| P protein | Phosphoprotein | |

resolve in 10–14 days and VSV is not readily transmitted from animal to animal. Secondary bacterial infection can lead to mastitis. Lameness can develop with foot lesions [1]. Vesicular stomatitis has significant economic effects caused by decreased production and restriction on transport and sale of animals. The most important differential diagnosis of vesicular stomatitis is foot-and-mouth disease, a picornavirus infection.

VSV-susceptibility of humans is low and transmission occurs in contact with infected animals. In humans, VSV-infection is asymptomatic or may cause an Influenza-like illness with fever, headache, myalgia and oral herpes-like lesions. In most of the cases the disease course is four to seven days.

## Prevalence

The seroprevalence of VSV in humans is generally very low and restricted to the geographical occurence of vesicular stomatitis. Seroprevalence of animals is higher in enzootic areas (Southern Mexico, Central America) and antibody detection in these areas can reach levels up to 80% [2].

## Genes

The virion is a large bullet-shaped (65–185 nm) negative sense RNA virus. The ribonucleoprotein core is surrounded by a lipid envelope that originates from host cell plasma membrane. The non-segmented RNA of 11162 bp length encodes five major viral proteins (see table 1). All neutralizing antibodies are directed toward the VSV-G protein [2].

## Molecular and Systemic Pathophysiology

Cytolytic infections in mammalian hosts and transmission by insects are the two steps in natural VSV infection. Intercellular edema in the stratum spinosum leads to cell dissociation and necrosis. In insects and insect cell lines, infections are non-cytolytic and persistent. Transovarial transmission has been shown to occur in the sand fly (Lutzomyia shannoni) and the black fly (Simuliidae).

VSV is one of the most-studied nonsegmented negative strand RNA viruses. VSV-G protein shows the ability to bind numerous cell types. Replacing envelope proteins in other viral vectors with VSV-G protein expands the host range of the vectors and therefore broadens the use of these vectors for gene transduction. In addition numerous studies have been performed to design and develop recombinant VSV vectors (rVSV) as experimental vaccine vectors against human infectious diseases, e.g. HIV. Reasons to develop rVSV as vaccine vector include low seroprevalence in humans and the ability of rVSV to establish a stable expression of foreign antigens [3].

## Diagnostic Principles

Lesions caused by VSV-infections resemble those of foot-and-mouth disease and demand urgent diagnosis. Antibodies can be detected on the basis of ELISA-technology. Vesicular stomatitis is accompanied by a transient viremia, but PCR diagnosis following reverse transcription may be more successful in specimens taken from saliva or vesicular fluids. Cultivation of VSV is possible in a broad range of cells [1].

## Therapeutic Principles

Vesicular stomatitis is a disease with mild symptoms and therapy is generally restricted to symptomatic therapy. Secondary bacterial infections need to be treated appropriately. VSV-IgG confers serotype specific protection against VSV-infection. A vacciniation for animals is in development.

### Definition and Characteristics

VIPomas are rare neuroendocrine tumors that produce the neuromodulator and neurotransmitter vasoactive intestinal polypeptide (VIP). Majority of these tumors are located within the pancreas. They usually occur as isolated tumors, but are in 5% of patients as part of the multiple endocrine neoplasia syndrome type 1. In children, VIPomas occur in sympathetic ganglia and in the adrenal gland. Apart from these, other VIP-secreting tumors have been reported including bronchogenic carcinoma, colon carcinoma, ganglioneuorblastoma, hepatoma, and adrenal tumors. Approximately 60–80% of VIPoma have metastasized by the time of diagnosis.

The VIPoma syndrome is caused by unregulated secretion of VIP by the tumor and characterized by watery diarrhea associated with hypokalemia, hypochlorhydria and symptoms related to dehydration and hypokalemia such as lethargy, muscle weakness, and muscle cramps. The stool volume usually exceeds 700 ml/day in all patients but is up to 3 l/day and more in 70% of patients. In about 20% of patients flushing episodes are observed. Hypercalcemia and hyperglycemia might also be caused by unregulated VIP release [1,2].

### Prevalence

VIPoma are rare neuroendocrine tumors with an annual incidence of less than 1/10 million of the general population. In 5% of patients, VIPoma is part of MEN1 which by itself has a prevalence of 2/100,000 [1–3].

### Genes

The gene encoding VIP is on chromosome 6. Gene defects responsible for the pathogenesis of VIPoma have been described particularly in the context of MEN1. Genetic linkage analysis implicated a region on the long arm of chromosome 11 (11q13) as the site of the MEN1 gene. In about 75% of unrelated MEN kindreds mutations are located within the MEN1 gene which encodes for a product termed “menin” [3].

### Molecular and Systemic Pathophysiology

VIP is a 28 amino acid polypeptide processed from its precursor by cleavage of a 22 amino acid containing signal peptide. Mature VIP binds to high-affinity G protein-coupled receptors on intestinal epithelial cells, leading to activation of cellular adenylate cyclase and cAMP production. Due to its wide distribution, VIP has effects on many organ systems. In particular, VIP mediates the following biological activities representing the molecular basis for the clinical appearance of VIPoma, thus VIP:

- Stimulates gastrointestinal epithelial secretion and inhibits absorption of sodium, chloride, and water
- Stimulates potassium secretion in the large bowel

- Promotes fluid and bicarbonate secretion by cholangiocytes
- Inhibits gastric acid secretion, induces vasodilation, stimulates bone resorption and enhances glycogenolysis

Under physiological conditions VIP serum levels are low and do not appreciably change with food intake. Unregulated release of VIP by VIP-producing tumors (VIPoma) results in extensive stimulation of gastrointestinal epithelial cells and bile duct cholangiocyte secretion leading to a net fluid and electrolyte secretion into the lumen resulting in watery diarrhea, hypokalemia, and hypochlorhydria or achlorhydria [4,5].

### Diagnostic Principles

A VIP-producing tumor should be considered when an otherwise unexplained high volume secretory diarrhea is present, which is characterized by a low osmotic gap. Repeated detection of serum concentrations of VIP in excess of 75 pg/ml makes the diagnosis of a VIP-producing tumor likely. In most cases tumors can be identified by CT scan, MRI, and ultrasound examination. Furthermore endoscopic ultrasound, angiography, and radiolabeled pentetreotide scintigraphy might be necessary for exact diagnosis and staging [1,2].

### Therapeutic Principles

Replacement of fluid loss and correction of electrolyte abnormalities is vitally important. Diarrhea can be controlled by treatment with the somatostatin analogue octreotide (50–100 µg subcutaneously every 8 h) or the depot form lanreotide, which decreases VIP secretion. The addition of IFN-α to octreotide may control symptoms in patients with refractoriness to octreotide monotherapy. Although surgery undertaken with curative intent is not successful in the majority of cases, symptoms of hormone hypersecretion can be effectively palliated by surgical debulking and often prolongs survival. Alternatively or in addition to surgery, particular hepatic metastases can be treated by therapeutic embolization of the accommodative artery or by radiofrequency ablation or cryoablation [1,2].

## Viral Hepatitis, Acute

Andreas Erhardt
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University of Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

Major hepatotropic viral agents are hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and hepatitis E virus (HEV). Virus-induced hepatitis is considered acute within the first 6 months after inoculation or onset of symptoms. Characteristics of the hepatitis A–E viruses and infection course are shown in Table 1 [1–5]. The clinical course of acute viral hepatitis is mild and asymptomatic in the majority of cases. Propensity of symptomatic and fulminant courses is virus-dependent. In adults, symptomatic hepatitis occurs in upto 35% of hepatitis B infections but only in upto 10% of hepatitis C infections. Most hepatitis A infections occur in early childhood and are asymptomatic at this time point, but symptomatic in 70% of adults who acquire the disease. Fulminant courses are seen in about 0.1% of HAV infections, 1% of HBV/HDV infections, 0.5% of HCV infections, and up to 2% of HEV infections. Fulminant HEV infection in pregnancy may reach mortality rates up to 20%. Chronicity rates of 5–10% for HBV and 60–80% for HCV infection have been reported in adults. Chronicity rates of up to 90% are seen after perinatal hepatitis B infection. In HDV superinfection to hepatitis B chronic outcomes are reported in over 90% of cases. Chronic infections with HAV or HEV do not occur.

### Prevalence

It is estimated that 350 million people are infected by HBV and 170 million people by HCV worldwide. Seroprevalence of anti-HAV antibodies in the general population varies from 15% to almost 100% in different parts of the world. The prevalence of antibody to HEV has been reported to vary between

| Incubation (days) | 15–45 | 30–180 | 15–180 | 30–180 | 15–60 |

3–26% in endemic and 1–3% in nonendemic regions. HDV infection affects about 15 million persons worldwide in all age groups. Prevalence of the different hepatitis A–E infections shows enormous geographical variations, with higher rates in the developing countries.

## Genes

Host genetic factors for susceptibility to viral infection have not been identified. Host genes involved in virus clearance and chronification are the protein kinase R (PKR), suppressor of cytokine signaling (SOCS), and endogenous IFN genes [5]. There might be a role for TNF-α and Il-10 polymorphisms for disease progression. In chronic hepatitis B, polymorphisms in the basic core promoter (BCP; nucleotide exchange G1764A) and the precore region (G1896A nucleotide exchange) have been associated with fulminant courses [4].

## Molecular and Systemic Pathophysiology

Immunopathogenesis is the major disease mechanism in most acute viral hepatitis (A–E) infections. HBV-related liver disease is mainly related to lysis of infected hepatocytes by cytotoxic T-lymphoctes. In acute self-limiting hepatitis B, a vigorous, polyclonal, HLA-I restricted cytotoxic T-lymphocyte response against multiple epitopes in the envelope, nucleocapsid, and polymerase regions is noted. A strong TH1 response with increase of Il-2, IFN-γ is seen in patients with acute hepatitis C and spontaneous virus clearance whereas a TH2 cytokine profile seems to promote chronic infection [4]. Neutralizing antibodies are produced during HCV infection against B-cell epitopes within the core-, envelope-, NS3-, and NS4- proteins but are mostly ineffective due to occurence of viral mutations. The pathogenic role of the HCV core and NS3 protein in the pathogenesis of acute HCV is not well defined. In a cell culture model, transforming activity has been demonstrated for both viral proteins. So far, there is no evidence for a direct cytopothic effect of HAV or HEV. In contrast, viral cytotoxicity has been implicated as important pathogenic mechanism in acute HDV infection.

## Diagnostic Principles

Asymptomatic courses of acute infection are often missed. Symptomatic course typically presents with initially rather unspecific symptoms like fatigue, malaise, anorexia, nausea, and abdominal discomfort followed by hepatomegaly, jaundice, and dark urine. Symptomatic hepatitis is accompanied by elevation of liver transaminases, predominantly alanine aminotransferase (ALT), and bilirubin. Severe liver dysfunction may be indicated by decrease of albumin or prothrombin time.

The different forms of acute hepatitis are clinically hard to distinguish from each other. The etiological diagnosis of hepatitis is made by detection of specific antibodies/antigens and can be confirmed by detection of specific viral DNA or RNA. Detection of HBsAg (Hepatitis B surface antigen) is the diagnostic hallmark of HBV infection. Presence of anti-HBc-$I_g$M (Core) is confirmatory of acute HBV infection. Detection of HBV DNA (by PCR, branched DNA assay, and hybridization assay) can precede serological tests by 2–4 weeks [4]. As HDV requires the presence of HBsAg, HDV antibodies and HBsAg should be detectable in acute HDV infection. HDV RNA detection can be an alternative to serological tests for diagnosis of acute HDV.

Enzyme immunosorbent assays (EIA) for identification of specific antibodies are highly sensitive for the diagnosis of chronic hepatitis C infection but may miss the early phase of acute HCV infection. Anti-HCV $I_g$M antibodies are no reliable markers of acute infection as they are present in 50–70% of patients with chronic HCV infection. Testing for HCV RNA (e.g., by PCR, branched DNA assay, transcription mediated assay) is the diagnostic gold standard for

acute HCV allowing detection of HCV RNA 1–3 weeks after inoculation.

Diagnosis of HAV and HEV is made by the demonstration of $I_gM$ antibodies to HAV or HEV in serum. Detection of the virus or viral antigens in stool is not used for routine diagnosis.

### Therapeutic Principles

Active immunization is available for hepatitis A and hepatitis B. Postexposure prophylaxis for hepatitis A with immunoglobulin at a dose of 500 IU i.m. has been shown to be 85% effective when administered within 2 weeks after inoculation. Postexposure prophylaxis for hepatitis B should be given within 24 h after inoculation by the combination of immunoglobulin at a dose of 6–12 IU/kg i.m. and active vaccination.

Monotherapy with interferon-α (IFN-α) or pegylated interference for 12–24 weeks in acute hepatitis C achieves viral elimination rates of upto 90%. Because of high spontaneous resolution, IFN treatment is not recommended in acute hepatitis B. There are no therapeutic recommendations for acute HDV/HBV superinfection. Because of self-limiting disease, there is no indication for antiviral treatment apart from supportive treatment in acute HAV, HEV, and simultaneous acute HDV/HBV coinfection.

Liver transplantation may be required in fulminant courses of viral hepatitis. Nucleos(t)id analogs (e.g., lamivudine) can be beneficial in fulminant hepatitis B.

### Synonyms

Viscero atrial situs (solitus, inversus, ambiguous); Heterotaxia or heterotaxy syndrome; Asplenia and polysplenia syndrome; Right and left isomerism; Bilateral or double right and left sidedness; Right and left laterality; Laterality abnormalities; Right-left axis malformations; Visceral symmetry; Ivemark syndrome

### Definition and Characteristics

Human body is characterized by a typical left–right asymmetry or laterality, which is normally defined situs solitus. Variation in the development of the normal left–right asymmetry, of the thoracoabdominal organs, may either result in complete mirror image arrangement, situs inversus, or in apparently chaotic arrangement, termed situs ambiguous or heterotaxy (from the Greek words heteros = other and taxis = order).

We may refer to situs visceroatrialis because in nearly all cases situs atrialis and situs visceralis are concordant.

Situs inversus totalis is the mirror image arrangement of all thoracoabdominal organs. It may or may not be part of the "immotile cilia syndrome" or Kartagener's syndrome, clinically presenting with chronic sinusitis, bronchiectasis, and male infertility.

Heterotaxy or situs ambiguous, typically involves the following: rotation of the entire gastrointestinal tract, lobation of the lungs, lobation and position of the liver, atrial appendage's morphology, and development of the spleen. Heterotaxy may tend, more or less, to "isomerism." In other words, the complete failure to break bilateral asymmetry can result in two apparently right body sides (right atrial isomerism, asplenia syndrome), or in two apparently left body sides (left atrial isomerism, polysplenia or Ivemark syndrome). Characteristics of asplenia and polysplenia are not constant and are summarized in Table 1 [1,2].

**Viscero Atrial Situs Abnormalities. Table 1** Characteristics of asplenia and polysplenia

| | Solitus | Inversus | Ambiguous (asplenia) | Ambiguous (polysplenia) |
|---|---|---|---|---|

| *Cardiac anomalies* | 0.8% | 3–5% | Nearly 100% | More than 90% |
| Seno atrial node | | | Often double | Often absent |
| Atrio ventricular canal | | | 85% | 40 % |
| Total anomalous pulmonary venous return | | | 70% (extra cardiac) | 40% (intra-atrial) |
| Pulmonary stenosis/atresia | | | 90% | 30% |
| Transposition of the great arteries/ double outlet right ventricle | | | 80% | 20% |
| Azygos continuation of the interrupted inferior vena cava | | | Rare | 85% |
| Bilateral superior vena cava | | | 50% | 40% |
| Dextrocardia | | | 40% | 40% |
| Functional single ventricle | | | 50% | 20% |
| Left heart obstruction | | | Rare | 40% |

## Prevalence

1. Situs viscero atrialis solitus = normal
2. Situs viscero atrialis inversus = 1:10,000/20,000 births. 20–25% of them have Kartagener's syndrome.
3. Situs viscero atrialis ambiguous = 1:4,000/10,000 births. 1–3% of all the congenital heart diseases.

## Genes

Familial situs abnormalities occur with autosomal dominant, recessive, X-linked, and multigenetic inheritance. All possible situs variants such as solitus, inversus, ambiguous can occur among different members of the same heterotaxy family [3].

1. iv/iv mice (mapped on human chromosome 12) has been identified in some forms of autosomal recessive familial heterotaxy.
2. Mutations in connexin 43 have been recognized in some other autosomal recessive familial cases of heterotaxy. Connexin 43 (to chromosome 6) codes a protein involved in gap junctions, which may play a main role in the embryo organ development by

mediating the exchange of morphogenetic cell to cell signals.
3. Mutations of nodal gene, mapped in the humans to 10q21-q23, account for some cases of human heterotaxy
4. Mutation in the ZIC3 gene (to Xq26.2), encoding a putative zinc-finger transcription factor is described as X-linked inheritance mechanism of heterotaxy.

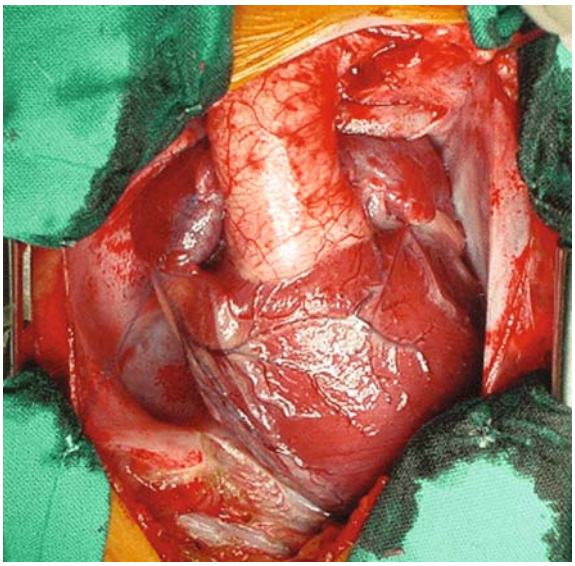
## Molecular and Systemic Pathophysiology

How the mutations translate into situs inverdsis is incompletely understood. Situs inversus totalis may or may not be part of the "immotile cilia syndrome" that is characterized by the absence or abnormalities of the dynein arms, connecting the nine pairs of microtubules of cilia and clinically presenting with chronic sinusitis, bronchiectasis, and male infertility.

Gap junctions may play a main role in the embryo organ development by mediating the exchange of morphogenetic cell-to-cell signals.

## Diagnostic Principles

Viscero atrial situs abnormalities may be suggested by the position of the cardiac apex, bronchi length and direction, stomach bubble, and liver shadow on the plain thoracic and abdominal radiographs. Ultrasound, CT and MR imaging, contrast gastrointestinal studies, echocardiography and angiocardiography may be required to evaluate fully all the features of these anomalies. Howell-Jolly bodies on peripheral blood smear found at birth may suggest asplenia syndrome (Fig. 1). Presence or absence of spleen tissue is anyhow best defined in children with heterotaxy with hepatoiminodiacetic acid (HIDA) scan in conjunction with radiocolloid scan.



**Viscero Atrial Situs Abnormalities. Figure 1** {A,D,D} Common inlet left ventricle with pulmonary atresia and total anomalous pulmonary venous return in asplenia syndrome or right isomerism. This intraoperative view clearly shows both atrial appendages to be morphologically right, with the characteristically broad base of implant and the typical pyramidal shape. Pulmonary atresia is a recurrent feature in asplenia syndrome and is clearly recognizable in this patient as well.

## Therapeutic Principles

The heart is the organ that most frequently leads to clinically detectable abnormalities.

Mortality in the first year of life: 79% asplenia, 61% polysplenia.

Therapy is basically surgical and is mainly focused on the treatment of congenital heart disease.

Abdominal complication such as midgut volvulus, due to gut malrotation and malfixation, may require urgent surgical treatment.

# Vitamin A Deficiency

Hans K. Biesalski
Department of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

## Synonyms

Vitamin A deficiency disorders; VADD

## Definition and Characteristics

The major cause of vitamin A deficiency is either a low dietary intake of preformed vitamin A or an imbalanced amino acid supply (resulting in impaired RBP synthesis), frequently appearing in developing countries. Health consequences of vitamin A deficiency include mild to severe systemic effects on innate and acquired mechanisms of host resistance to infection and growth. Vitamin A deficiency results in typical early clinical signs affecting anterior and posterior segments of the eye. In the posterior segment, unavailability of retinol causes night blindness because the steady loss of rhodopsin, of which vitamin A is an essential component, during the rod visual cycle cannot be sufficiently replaced. In the anterior segment xerophthalmia develops. Xerophthalmia is a clinical syndrome of vitamin A deficiency that includes night blindness, conjunctival xerosis with and without Bitot spots and corneal xerosis. Finally, as a result of prolonged vitamin A deficiency, keratomalacia including corneal ulceration and potential subsequent blindness, as well as degeneration of the pigment epithelium may occur. The loss of goblet cells and terminal differentiation of epithelial cells (squamous metaplasia) reflect the changes in epithelial architecture throughout the body. As a consequence the barrier function of mucous membranes in the respiratory and urogenital tracts is impaired. Health consequences of vitamin A deficiency include mild to severe systemic effects on innate and acquired mechanisms of host resistance to infection and on growth and an increased burden of infectious morbidity.

## Prevalence

Vitamin A deficiency is frequently present throughout the developing world, especially affecting the health and survival of infants, young children and pregnant and lactating women. Approximately 127 million preschool aged children and seven million pregnant women are vitamin A deficient. In developed countries, despite adequate food sources, subclinical vitamin A deficiency is described in pregnant women and the elderly. Globally, 4.4 million preschool children have xerophthalmia and 6 million mothers suffer night blindness during pregnancy. Both conditions are associated with increased risk of morbidity and mortality. Reductions of child mortality of 19–54% following vitamin A treatment have been frequently reported.

## Genes

Plasma RBP concentrations remain constant except during prolonged insufficient dietary vitamin A intake, extreme protein-energy malnutrition (e.g., kwashiorkor), disease (e.g., measles or kidney and liver diseases) or genetically modified TTR (transthyretin). The latter results in FAP (familial amyloid neuropathy), which is a consequence of a point mutation in TTR, (more than 40 have been detected) encoded by a gene located in chromosome 18. FAP is a variable clinical syndrome that includes progressive sensorimotor polyneuropathy, autonomic failure, cardiomyopathy and vitreous deposits of variable severity. There are also amyloid deposits in other organs, most notably in the kidney and digestive tract, but also in subcutaneous fat, the meninges and the spleen, with variable clinical manifestations.

The genetic basis of a naturally occurring mutation in RBP in two German sisters and their mother and its resulting effects on plasma concentrations of retinol and RBP was identified and characterized for the first time by Frank et al. Sequence analysis of cloned PCR products spanning exons 3 and 4 revealed that these mutations were present on different alleles. DNA sequence analysis of the RBP gene of the healthy mother identified the point mutation in exon 3 (T1282A), whereas no mutation was present in exon 4. The RBP gene of the mother had a mosaic structure, i.e., only one allele was affected with the mutation in exon 3 and the other allele showed no mutation. Although the paternal RBP gene was not available for genomic analysis, it is conceivable that both siblings inherited the mutation in exon 4 from their father. The presence of two mutations in both affected siblings resulted in complete loss of RBP function; as a result, plasma concentrations of retinol and RBP were extremely low. The single mutation in exon 3 (Ile41 → Asn) of the maternal RBP gene or likely exon 4 (Gly74→ Asp) of the paternal RBP gene did not result in severely decreased RBP concentrations because of the normal DNA sequence of the corresponding allele. The Ile41Asn mutation was also found in the mother and the unaffected sister, whereas no mutations were present in the unaffected brother. Both mutations concerned amino acid positions conserved in evolution and were absent from 100 healthy control subjects (200 chromosomes).

## Molecular and Systemic Pathophysiology

Vitamin A and its active metabolites (retinoic acids) regulate cellular growth and development in a couple of different areas. All trans- and 9-cis exert their effects via a family of nuclear receptors (RAR, RXR) belonging to the superfamily of steroid–thyroid hormone receptors. Retinoic acid receptors (RAR) in partnership with retinoid X receptor (RXR) appear to be the important retinoid receptor transcription factors regulating vitamin A function at the gene level during development via the physiological ligand all-trans- and 9-cis-retinoic acid. In cases of vitamin A deficiency, terminal differentiation of epithelial cells leading to a squamous phenotype occur. Beside the alterations in the anterior and posterior segments of the eyes, focal loss of cilia and metaplastic areas occur in the respiratory tract and contribute to the increased morbidity due to infections.

Vitamin A is essential for embryonic development. Early studies of embryos from marginally vitamin A deficient (VAD) pregnant rats revealed a collection of defects called the vitamin A deficiency syndrome. Vitamin A requirement begins at the time of formation of the primitive heart, circulation and specification of hindbrain. The lack of vitamin A at this critical time results in gross abnormalities and early embryonic death. Major target tissues of vitamin A deficiency include the heart, central nervous system and structures derived from it, the circulatory, urogenital and respiratory systems and the development of skull, skeleton and limbs. These abnormalities are also evident in mouse mutants from retinoid receptor knockouts; they have revealed both morphological and molecular aspects of vitamin A function during development. Homeostasis of retinoic acid is maintained by developmentally regulated vitamin A metabolism enzyme systems. Inadequate vitamin A nutrition during early pregnancy may account for some pediatric congenital abnormalities.

## Diagnostic Principles

Xerophthalmia classification was traditionally used to identify populations with vitamin A deficiency. Currently, night blindness and dark adaptometry have been proposed as population assessment methods. While eye signs and function tests are still used in areas where vitamin A deficiency is severe, a subclinical vitamin A deficiency is more prevalent. Serum and breast milk retinol concentrations are used to identify vitamin A deficiency risk. However, in healthy individuals, serum retinol concentrations are homeostatically controlled and do not begin to decline until liver reserves of vitamin A are nearly exhausted. Moreover, serum retinol and retinol binding protein (RBP) concentrations fall during times of infection. The RBP:transthyretin ratio may help to determine if serum retinol concentrations are depressed by infection. However, recent data question the usefulness of this ratio in detecting persons at risk of vitamin A deficiency. The relative dose response and modified relative dose response tests involve giving a small dose of retinyl or dehydroretinyl ester respectively and determining a response in the serum after about 5 h. The dose response tests lack utility in defining the total body reserve of vitamin A. Taken together, vitamin A deficiency can be diagnosed if clear clinical signs occur. Before clinical signs, systemic and more or less unspecific effects of marginal deficiency as described above are present and have a massive impact on mortality. However, marginal deficiency cannot be clearly detected with laboratory methods.

## Therapeutic Principles

The most important step in preventing vitamin A deficiency is ensuring that children's diets include adequate amounts of carotene containing cereals, tubers, vegetables and fruits. An overall strategy designed to prevent and control vitamin A deficiency, xerophthalmia and nutritional blindness may be defined in terms of action taken in the short, medium and long term. A short term, emergency measure includes the administration to vulnerable groups of single, large doses of vitamin A on a periodic basis. In the medium term, the fortification of a dietary vehicle (e.g., sugar or monosodium glutamate) with vitamin A can be initiated. Increased dietary intake of vitamin A through home gardening and nutrition education programs comprises the long-term solution to this problem. The World Health Organization plans to launch a 10-year program of support to countries where vitamin A deficiency is a significant public health problem.

## Synonyms

Vitamin A toxicity

## Definition and Characteristics

Vitamin A toxicity may occur due to acute or chronic high intake with the diet (preformed vitamin A) or supply with retinoic acid derived from drugs only. The latter is not addressed in this review. Unfortunately, the term retinoids as a general term for vitamin A and metabolites is used to describe retinoic-acid-derived toxicity as well as vitamin A-derived toxicity. Retinoic acid, however, is not present in food; it is only available as a prescribed drug. Humans normally obtain preformed vitamin A mainly as retinyl esters and a few percent as retinol from animal products in the diet. The provitamin A β-carotene from fruits or vegetables contributes more or less to the individual vitamin A status. In contrast to preformed vitamin A, there is no risk of overloading with retinol derived from β-carotene. Depending on the diet, up to 75% of dietary vitamin A in industrialized nations is derived from preformed vitamin A [1]. Beside animal products, sources of preformed vitamin A are multivitamins, fish liver oil, and fortified foods (e.g., milk, margarine, breakfast cereals). Depending on the individual diet, an accumulation and at least toxicity due to hypervitaminosis A becomes evident in different individuals. In a couple of recent reviews, the different aspects of vitamin A toxicity have been extensively described [2,3].

## Prevalence

*Acute Toxicity*: Data for acute toxicity symptoms have been obtained from public health programs related to vitamin A deficiency in childhood. From the expanded program of immunization (EPI), data exist that an acute dose of 50,000 IU (15 mg) of vitamin A is safe for children before 6 months. In young children, doses between 100,000 and 300,000 IU may produce vomiting (up to 6%) and diarrhea (up to 16%). In adults, 400,000 IU were without side effects if compared to a placebo group in postpartum women. Typical side effects of acute vitamin A toxicity are nausea and vomiting, headache, blurred vision, and lack of muscular coordination. In infants, an excessive dose can cause transient bulging of the fontanelle.

*Chronic Toxicity*: Ingesting at least 30 mg (40-fold of the RDA) preformed vitamin A for month or years may lead to liver damage. Depending on other components related to liver diseases such as chronic alcohol intake, overweight with fat liver, or chronic drug intake, lower levels of vitamin A may be harmful.

Tolerable upper levels (UL) were recommended by different organizations (EFSA; US Institute of medicine) (Table 1 adapted from [4]).

## Genes

Up to now, there are no data related to vitamin A toxicity, e.g., polymorphism that increases sensitivity against vitamin A. However, it has to be considered that the nuclear receptors of vitamin A (RAR, RXR) exert their function by heterodimierization with nuclear receptors of the steroid/thyroid hormone family and especially with nuclear vitamin D receptors.

## Molecular and Systemic Pathophysiology

Cases of acute toxicology are relatively rare. Beside headaches and nausea, the symptoms are more or less unspecific and disappear within a short time if the intake is stopped. Headaches and increased

**Vitamin A Excess. Table 1** Tolerable upper level (UL) for vitamin A intake (μg/day) and criteria on which they are based

| Group | NOAEL or LOAEL | Uncertainty factor | UL | Criterion |
|---|---|---|---|---|
| <1 year | 6,000 | 10 | 600 | Bulging fontanelle other symptoms |
| l–3 years | | | 600 | Extrapolated from adults |
| 4–8 year | | | 900 | Extrapolated from adults |
| 9–13 years | | | 1,700 | Extrapolated from adults |
| 14–18-year male | | | 2,800 | Extrapolated from adults |
| 14–18-year female | 4,200 | 1.5 | 2,800 | Teratogenicity |
| 14–50-year female[a] | 4,500 | 1.5 | 3,000 | Teretogenicity |
| Other adults | 14,000 | 5 | 3,000 | Liver toxicity |

LOAEL, lowest-observed-adverse-effect level; NOAEL, no-observed-adverse-effect level.
[a]For women at risk of becoming pregnant.

cerebrospinal pressure may be a result of an increased formation of cerebrospinal fluid. It has been assumed that retinol stimulates the secretory activity of the plexus choreoideus.

Chronic intoxication is manifested as drying, ulceration, and desquamation of the skin, anorexia, anemia, and bone loss. Liver damage leading to fibrosis and hepatic stellate cell activation has been described in patients with hypervitaminosis A. Upon activation, hepatic stellate cells lose their capacity to store retinyl esters and secrete collagen that results in the formation of cirrhosis.

*Teratogenicity*: Retinoic acid is a strong teratogen, but it does not occur in human food. The formation of retinoic acid from preformed vitamin A is strictly controlled, and there is no evidence that critical levels of retinoic acid can be formed after ingestion of high amounts of preformed vitamin A. The teratogenic effect of preformed vitamin A is critically discussed whether such an effect really exists. Nevertheless, women who may get pregnant are advised to avoid high doses (>3 mg). In the second and third trimenon, there is no reason to avoid vitamin A that is important for childhood development.

## Diagnostic Principles

Serum retinol concentrations under normal conditions are between 1 and 3 μmol/l with small interindividual variations due to a homoeostatic regulation even in case of high intakes. The homoeostatic regulated plasma concentration can be different between individuals but varies a little with widely disparate vitamin A intakes. In cases of renal insufficiency, plasma level increases due to an impaired degradation of the apoRBP in the kidney. High apoRBP, however, signals increased tissue demand, and consequently, hepatic RBP synthesis increases and more retinol-RBP is delivered to the blood stream. In cases of hepatic diseases, protein synthesis might be impaired and consequently plasma levels decrease.

Consequently, determination of retinol in blood is not a reliable marker to detect vitamin A overdose. Furthermore, high levels of retinol in blood are either due to an impaired apoRBP cleavage or might be an unknown polymorphism of a gene involved in either RBP synthesis, vitamin A release from liver stores, or apoRBP degradation. The latter is of importance if plasma levels are chosen to explain side effects of vitamin A intake, as it is the case in the presumed interactions of vitamin A on bone. Several human studies have suggested an association between chronic high intakes of preformed vitamin A and bone loss that potentially leads to osteoporosis [5]. However, mean intake in these observational studies is far below the chronic high intake in studies that indeed suggested that vitamin A affects bone. Studies are needed to assess true vitamin A status, bone turnover markers, bone mineral density, and bone fracture incidence by using measures specific in addressing vitamin A status. Nevertheless, a high serum retinol is a risk factor for a lower bone mineral density. However, a high serum retinol is not necessarily a consequence of a high intake of preformed vitamin A, but far more a sign of impaired homoeostatic regulation. The latter has to be addressed as a major aspect to understand chronic vitamin A toxicity.

## Therapeutic Principles

The major therapeutic principle in cases of overdosing is cessation of intake of preformed vitamin A.

# Vitamin A Toxicity

►Vitamin A Excess

# Vitamin B Deficiency

Hans-Jürgen Gdynia, Albert C. Ludolph
Department of Neurology, University of Ulm, Ulm, Germany

## Definition and Characteristics

*Vitamin B1*: Deficiency causes "dry beriberi" with peripheral neurological changes (sensomotoric axonal polyneuropathy) and Wernicke-Korsakoff's syndrome,

which is clinically characterized by nystagmus, ataxia, ophthalmoplegia and neuropsychiatric features (mental confusion, confabulation).
*Vitamin B6:* Deficiency causes peripheral neuropathy and convulsions in infants.
*Vitamin B12*: Clinical manifestations of Vitamin B12 deficiency are a peripheral axonal sensomotor neuropathy, funicular myelosis (axonal damage and demyelination of dorsal columns and corticospinal tract) and neuropsychiatric features, i.e. irritability, personality change, mild memory impairment and depression.

## Prevalence

*Vitamin B1 and B6 deficiency*: The true prevalence of vitamin B1 and B6 deficiency is unknown.
*Vitamin B12 deficiency*: The true prevalence of vitamin B12 deficiency in the general population is unknown. In one study 15% of adults older than 65 years had laboratory evidence of vitamin B12 deficiency [1].

## Molecular and Systemic Pathophysiology

*Vitamin B1 deficiency*: The coenzyme thiamine pyrophosphate, the active form of thiamine, participates in carbohydrate metabolism through decarboxylation of alpha-keto acids. Thiamine also acts as coenzyme to the apoenzyme transketolase in the pentose monophosphate pathway for glucose. Primary thiamine deficiency is caused by inadequate intake (malnutrition), secondary deficiency is caused by an increased requirement, as in hyperthyroidism, pregnancy, lactation or fever, impaired absorption, as in prolonged diarrheas, or impaired utilization, as in severe liver diseases. Neurological symptoms are caused by degeneration of the nerve fibers and their myelin sheath, the molecular mechanisms of which are not sufficiently understood. The most advanced neural changes occur in the distal portions of the peripheral nerves, particularly of the legs. Degeneration can also occur in the posterior columns. Lesions of hemorrhagic polioencephalitis occur when deficiency is severe. Wernicke encephalopathy most commonly is associated with chronic alcohol abuse, although it can occur in any individual suffering from a poor nutritional state, especially in elderly patients with a high carbohydrate intake.

*Vitamin B6 deficiency*: Vitamin B6 is the collective term for a group of three related compounds, pyridoxine, pyridoxal and pyridoxamine [2]. They are metabolized to pyridoxal phosphate, which is involved in a wide range of biochemical reactions, including metabolism of amino acids, synthesis of nucleic acids and the synthesis of the neurotransmitters serotonin, dopamine, norepinephrine and gamma-aminobutyric acid. Primary deficiency is rare, secondary deficiency may result from alcoholism, malabsorption or inactivation by drugs (e.g. isoniazid).

*Vitamin B12 deficiency*: Two biochemical reactions depend on vitamin B12, a folate-dependent reaction in which the methyl group of methyltetrahydrofolate is transferred to homocysteine to form methionine and a conversion of methylmalonyl CoA to succinyl CoA. Causes for vitamin B12 deficiency are inadequate absorption (e.g. ileal resection), absence of intrinsic factor (e.g. pernicious anemia, gastrectomy), lack of B12 in food, altered intestinal utilization or congenital transcobalamin deficiency. The pathogenesis of neurological manifestations of cobalamin deficiency is not well understood. Demyelination may play a role, but the way in which cobalamin deficiency leads to demyelination remains unclear. Elevated methylmalonic acid may be involved in axonal damage.

## Diagnostic Principles

*Vitamin B1 deficiency*: If "beriberi" is suspected, electrophysiological studies will show an axonal sensory and motor bilateral symmetric polyneuropathy. Elevated blood pyruvate and lactate and diminished urinary thiamine excretion are consistent with the diagnosis of beriberi. Erythrocyte transketolase activity diminishes before and increases after administration of thiamine pyrophosphate and is a sensitive indicator of tissue stores. Variations in apoenzyme levels in some cases may complicate interpretation of the test. Wernicke-Korsakoff's syndrome remains a clinical diagnosis with no characteristic abnormalities in diagnostic studies of cerebrospinal fluid, brain imaging or EEG, but only one third of patients present with the classic triad of ocular abnormalities, global confusional state and ataxia. The diagnostic sensitivity of cerebral MRI is not clear; it might be not very high.

*Vitamin B6 deficiency*: There is no generally accepted test of vitamin B6 status. Erythrocyte glutamic pyruvate and oxaloacetic transaminase activities are decreased, but due to a wide range of values in healthy controls, this decrease is diagnostically not very helpful.

*Vitamin B12 deficiency*: Diagnostic tests may be divided into those that screen for deficiency and those that determine the cause of deficiency. The diagnosis of deficiency is established by the serum levels of vitamin B12, homocysteine and methylmalonic acid. Determination of the cause of deficiency necessitates screening for malabsorption syndromes, which may be caused by autoimmune disease, chronic pancreatitis, Crohn's disease and more. The use of the Schilling test for the detection of pernicious anemia has been supplanted for the most part by serologic testing for parietal cell and intrinsic factor antibodies.

## Therapeutic Principles

*Vitamin B1 deficiency*: For mild polyneuropathy 10–20 mg/day thiamine is given in divided doses for

2 weeks. For Wernicke-Korsakoff's syndrome, thiamine 50–100 mg i.v. must usually be given for several days, followed by 10–20 mg daily until a therapeutic response is obtained. Recovery from neurological deficits is often incomplete in beriberi. The mortality rate in Wernicke-Korsakoff's syndrome is 10–20%; treatment may correct all abnormalities.

*Vitamin B6 deficiency*: Deficiency in adults usually responds to pyridoxine 50–100 mg/day p.o. For pyridoxine-dependent seizures in infants, the initial dose is 50–100 mg daily i.m. or i.v. for 1 week followed by oral doses tapered over 1 week to 25 mg. Vitamin B6 hypervitaminosis is to be avoided.

*Vitamin B12 deficiency*: The treatment is based on vitamin B12 substitution. Initially 1,000 mg intramuscularly should be given daily for 3–7 days, then weekly for 4 weeks. Maintenance therapy should be managed with monthly intramuscular injections of 100–1,000 mg, quarterly intramuscular injections of 1,000 mg, weekly intranasal administration of 500 mg or daily oral administration of 1,000 mg. The effect of therapy should be monitored by measuring the serum concentration of methylmalonic acid. The maintenance therapy should be continued for life [3,4].

# Vitamin $B_6$

Roland Bitsch
Institute of Nutrition, Friedrich-Schiller-University Jena, Jena, Germany

## Synonyms

Pyridoxine; Derivatives of 2-methyl-3-hydroxy-5-hydroxymethyl-pyridine

## Definition and Characteristics

This group comprises the naturally occurring pyridoxol (PN), pyridoxal (PL), and pyridoxamine (PM) and their 5′-phospsphates, which are metabolically interconverted (see Fig. 1 in the chapter ►Pyridoxine deficiency).

Pyridoxal-5′-phosphate (PLP) and pyridoxamine-5′-phosphate serve as coenzymes in more than 100 enzymatic reactions, predominantly in the amino acid metabolism.

## Prevalence

Eucaryotic cells.

## Genes

Amino acid (AA) decarboxylases, AA transferases, AA lyases, and synthases.

## Molecular and Systemic Pathophysiology

Key reactions of AA metabolism are as follows:

1. Amino acid decarboxylations, resulting in the formation of biogenic amines, that operate, e.g., as neurotransmitters, such as γ-aminobutyric acid (GABA), dopamine, and noradrenaline.
2. Amino group transfer reactions, transferring reversibly α-amino groups with ultimate formation of an α-keto acid, as e.g., the conversion of aspartate to ketoglutarate or alanine to pyruvate. These enzymes provide the important connection between the amino acid, the carbohydrate, and the energy metabolism. In most cases, α-oxoglutarate is the end acceptor of amino groups, conveying them to the urea cycle.
3. Amino acid splitting and synthesizing reactions, which catalyze the breakage of tryptophan to kynurenine and kynurenic acid, leading to the biosynthesis of niacin (see Fig. 2 in the chapter ►Pyridoxine deficiency).
4. The condensation of glycine and succinyl-CoA followed by decarboxylation yields δ-amino-levulinic acid as the precursor of the heme biosynthesis. This reaction may be the clue to the $B_6$-responsive anemia in severe deficiency. Serine palmitoyl transferase in the sphingolipid biosynthesis and other PLP-dependent enzymes in the phospholipid metabolism may account for changes in the linoleic and arachidonic acid levels in vitamin $B_6$-deficient animals [1–3]. There are also relationships between pyridoxine and the cell-mediated immune response, probably by affecting 1-carbon metabolism via the PLP-dependent serine transhydroxymethylase. Some evidence exists for a PLP-mediated modulation of the steroid hormone action by its binding to receptors, but the exact mechanism remains to be elucidated [4].

Pyridoxic acid (PA) is the vitamin inactive metabolite, excreted besides minor amounts of active pyridoxine derivatives in the urine. Usually, under normal dietary habits about 40% of the ingested vitamin $B_6$

is metabolized to PA and excreted. This inactive metabolite can so be taken as biomarker of the nutritional status [1,2].

Pyridoxine-dependent enzymes, such as cystathionine synthase and γ-cystathionase, are involved in the homocysteine metabolism. Apart from folate and vitamin $B_{12}$, the circulating level of this atherogenic metabolite is therefore dependent on the adequate status and supply of pyridoxine too (see Fig. 1 in the chapter ►Pyridoxine responsive diseases).

*Absorption and Storage*: Unphosphorylated vitamers are absorbed by a nonsaturable passive diffusion, predominantly from the jejunum; phosphorylated derivatives are hydrolyzed by intestinal phosphatases before absorption. In plasma, the albumin bound PLP and PL are the main transport metabolites. Apart from the PLP-dependent enzymes, PLP in erythrocytes is bound to hemoglobin, too, modulating its oxygen affinity. Storage pool is the muscle tissue, and the majority of vitamin $B_6$ is bound as PLP to muscle glycogen phosphorylase. The total body pool is estimated to about 200 mg (1,000 μmol) [1,2,5].

*Bioavailability*: Pyridoxine is contained in a great variety of plant and animal foodstuffs. In many plants, however, pyridoxine vitamers are glucosidically bound as 5′-O-β-D-glucopyranosyl pyridoxine with deteriorated availability for man in contrast to the $B_6$ vitamers in most animal products that are efficiently absorbed. Only in processed and canned products, the availability may also be limited by formation of ε-*N*-(4′-pyridoxyl)-lysine, so called Schiff bases, which may be reduced to rather stable aldamines [1,2,5].

## Diagnostic Principles

Reference values of dietary requirements amount to 0.02 mg $B_6$/g protein intake, corresponding to 0.5 mg/day (newborn) up to 1.3 mg/day (adults) and 1.7 mg/day (elderly) [5].

*Status Assessment*: A variety of static and functional parameters are available. The most frequently used indicator of the $B_6$ status is the plasma PLP level. A linear dose response over a wide range of oral $B_6$ intake exhibits also the urinary 4-PA-excretion. Besides these static indicators, the erythrocytic aspartate amino transferase (EAST) and its activation coefficient (AC) serve as functional tests of the $B_6$ status. In population surveys, there is also the noninvasive, easily handled tryptophan load test as functional parameter practiced, measuring the urinary catabolites of tryptophan after a loading dose (Fig. 2). Interactions with nutritive and metabolic factors, which may affect the various tests of status assessment, are described elsewhere. Because flavin enzymes are involved in the interconversion of pyridoxine vitamers, the riboflavin supply may affect the $B_6$ status [1,5].

## Therapeutic Principles

Tolerable upper intakes of $B_6$ supplements for the chronic treatment of a variety of diseases should not exceed 80 mg/day [5].

## Synonyms

Ascorbic acid

## Definition and Characteristics

Vitamin C deficiency causes a disease known as scurvy. The diagnosis of scurvy is based mainly on symptoms. Scurvy develops after 60–90 days of vitamin C deficiency when the total body pool is depleted below 300 mg of vitamin C.

## Prevalence

During the sixteenth century many sea voyagers and British soldiers died due to scurvy disease. The sailors and British Navy on sea for several months suffered from scurvy because of deficiency of vitamin C in view of diet of nonperishable foods and lack of fresh fruits and vegetables. Scurvy is of rare occurrence today due to consumption of diet containing fruits and vegetables. But cases of scurvy were reported due to alcoholism, food faddism, psychiatric disorders, or social isolation [1].

## Molecular and Systemic Pathophysiology

Ascorbic acid also known as vitamin C is an important water-soluble vitamin essential for human life. Most of the plants and animals synthesize ascorbic acid. However, humans can not synthesize ascorbic acid due to lack of an enzyme L-gulunolactone oxidase. Hence, humans derive ascorbic acid through food or supplementation. Vitamin C is found in fruits such as oranges, lemons, grapefruit, mango, pineapple, strawberries and vegetables including tomatoes, green and red pepper, cabbage, cauliflower, and parsley. Ascorbic acid is heat labile and lost during cooking/processing. Both natural and synthetic ascorbic acid are chemically identical and have the same bioavailability and biological activities. Ascorbic acid present in foods or tablets are easily absorbed in the intestine but not stored in the body. The average half life of ascorbic acid in the adult human is about 10–20 days. Hence, it has to be regularly supplemented through food to maintain the ascorbic acid pool in the body.

Ascorbic acid is an essential vitamin and needed for many normal physiological functions of the body. The vitamin is known to aid in absorption and bioavailability of iron and also its conversion from nonheme sources. Bile acid formation and cholesterol degradation are dependent on ascorbic acid and its deficiency leads to accumulation of cholesterol in liver and formation of cholesterol gall stones. It promotes synthesis of neurotransmitters. Ascorbic acid plays an important role in the maintenance of collagen, which forms the major body protein and helps in wound healing by stimulating collagen synthesis. It is a very important water soluble dietary antioxidant. Ascorbic acid neutralizes/scavenges an array of reactive oxygen species viz., hydroxyl, alkoxyl, peroxyl, superoxide anion, hydroperoxyl, nitrogen dioxide, nitroxide, peroxynitrite and also helps to regenerate antioxidants such as α-tocopherol, urate, and β-carotene.

Symptoms of scurvy disease include bleeding, inflamed gums, loose teeth, poor wound healing, pain in the joints, anemia, and fatigue. Initial symptoms are nonspecific and feature malaise, weakness, myalgia, diarrhea, and depression. Cutaneous manifestations include follicular hyperkeratosis associated with coiled corkscrew hairs on the arms, back, and lower legs. Blood vessel fragility leads to perifollicular hemorrhages, petechiae, purpura, and extensive ecchymoses. Oral manifestations of scurvy are ulcerative gingivitis, chronic periodontitis and mucosal hemorrhages, and anemia [2].

## Diagnostic Principles

Blood tests can detect a very low level of vitamin C.

## Therapeutic Principles

Adequate vitamin C replenishment in patients with scurvy is essential for complete resolution of symptoms. Oral supplementation of ascorbic acid at 10 mg/day can prevent occurrence of scurvy. In severe cases, dietary supplementation of ascorbic acid at 400 mg twice daily for 2 weeks completely cured scurvy due to malnutrition and alcoholism in a case study in UK [1]. An intake of 100 mg/day is reported to saturate vitamin C body pool in healthy individuals. Smokers need higher ascorbic acid requirement in view of the increase metabolic turnover of vitamin C due to oxidative stress by free radicals, reactive oxygen species and nitrogen species in cigarette smoke. The recommended daily intake (RDA) of 140 mg/day is suggested for smokers and 100 mg/day for nonsmokers [3].

# Vitamin C Excess

Naidu K. Akhilender
Department of Biochemistry and Nutrition, Central Food Technological Research Institute, Mysore, India

## Definition and Characteristics

High dose of vitamin C has been advocated for prevention and treatment of cold. However, clinical trials showed that vitamin C in excess of 1.0 g/day did not reduce the duration or severity of cold symptoms in healthy adult volunteers compared with a vitamin C dose less than the minimum recommended daily intake [1].

## Prevalence

The practice of taking mega doses of vitamin C is wide spread.

## Molecular and Systemic Pathophysiology

The practice of taking mega doses of vitamin C is not clinically proven to be beneficial to treat cold. Further excess intake of vitamin C was reported to form kidney stones. High doses of ascorbic acid (2.0 g/day) were reported to increase the risk of formation of calcium oxalate in individuals without a history of stone formation [2].

Mega doses of ascorbic acid (10 g/day) were given to treat cancer and it was reported to improve the quality of life and also increase the longevity of cancer patients. However, current evidences suggest that vitamin C/derivatives alone may not be active and effective against cancer but it can be used as adjuvant in cancer therapy. Thus supplementation of high doses of vitamin C (1–2.0 g/day) against RDA dosage should be considered cautiously as there are no special health benefits but could increase the risk of side effects of vitamin C.

## Diagnostic Principles

Blood tests reveal the level of vitamin C.

## Therapeutic Principles

Excess of vitamin C is treated by discontinuation of excessive intake.

# Vitamin D Deficiency

Armin Zittermann
Department of Thoracic and Cardiovascular Surgery, Heart and Diabetes Center NRW, Ruhr University Bochum, Bad Oeynhausen, Germany

## Definition and Characteristics

Vitamin D deficiency is characterized by a lack of the active vitamin D metabolite calcitriol (1,25-dihydroxyvitamin D) in its target cells leading to hypocalcemic rickets in infants and to osteomalacia in adults [1]. The defect in vitamin D action can occur secondarily as a consequence of an inadequate vitamin D supply or primarily as the result of two hereditary forms of rickets that lead to impaired vitamin D action: The two forms are vitamin D-dependent rickets type I (VDDR I) and VDDR II [2,3].

## Prevalence

A high prevalence of inadequate vitamin D supply (up to 50% and more) is observed in elderly people, coloured people living in the Northern Hemisphere, and in veiled women [1]. In contrast, the prevalence of VDDR I and II is extremely rare.

## Genes

Human 1α-hydroxylase gene and the vitamin D receptor gene are both located at the same region of chromosome 12q13-14.

## Molecular and Systemic Pathophysiology

Orally ingested or cutaneously synthesized vitamin D is converted into 25-hydroxyvitamin D (25OHD) in the liver and into calcitriol in the kidney and also

in various extrarenal tissues. Physiologic circulating 25OHD levels are necessary to satisfy the tissue's requirement to produce an adequate amount of calcitriol. Thus, secondary vitamin D deficiency occurs as the consequence of an inadequate ultraviolet light B-mediated skin synthesis and/or an inadequate dietary vitamin D intake, resulting in a deficit of the calcitriol precursor 25OHD. VDDR I is the phenotype of several inactivating mutations in the 1alpha-hydroxylase gene. VDDR II is caused by mutations in the gene of the vitamin D receptor such that calcitriol cannot exert its physiologic genomic action in target cells. In all these cases, absent calcitriol action leads to severe hyperparathyreodism, calcium malabsorption, hypocalcemia, bone diseases, myopathy, and probably to an up-regulation of pro-inflammatory cytokines and a suppression of anti-inflammatory cytokines. Patients with VDDR I and II are often growth retarded. Patients with VDDR II may also have alopecia.

### Diagnostic Principles

In subjects with normal vitamin D metabolism, serum calcitriol levels do not reliably reflect tissue availability of the vitamin D hormone. There is general agreement that secondary vitamin D deficiency can best be assessed by circulating 25OHD concentrations. Levels of 25OHD below 25 nmol/L reflect vitamin D deficiency. In patients with VDDR I and II, however, 25OHD levels are often in the normal range. Patients with VDDR I have very low serum calcitriol levels, while calcitriol levels are markedly elevated in patients with VDDR II.

### Therapeutic Principles

Patients with secondary vitamin D deficiency need therapeutic doses of vitamin D or 25OHD. Calcitriol doses of 0.25–3 μg/day are recommended for patients with VDDR I. Pharmacological oral doses of vitamin D or calcitriol are required in patients with VDDR II. In severe cases of VDDR II, long-term intravenous calcium infusions are necessary.

## Vitamin D Excess

Armin Zittermann
Department of Thoracic and Cardiovascular Surgery, Heart and Diabetes Center NRW, Ruhr University Bochum, Bad Oeynhausen, Germany

### Definition and Characteristics

Vitamin D excess can be the result of a very high oral vitamin D intake [1]. Moreover, vitamin D excess has been described in patients with sarcoidosis [2].

### Prevalence

Several case reports of vitamin D intoxication due to very high therapeutic doses of vitamin D, overfortification of foods with vitamin D, and over-the-counter supplements with an excessive vitamin D content are known [1]. Approximately 11% of patients with sarcoidosis have a disturbed calcium/vitamin D metabolism [2].

### Genes

Human 1α-hydroxylase gene and the vitamin D receptor gene are both located at the same region of chromosome 12q13-14.

### Molecular and Systemic Pathophysiology

Orally ingested or cutaneously synthesized vitamin D is converted into 25-hydroxyvitamin D (25OHD) in the liver and into calcitriol in the kidney and also in various extrarenal tissues. Vitamin D excess results in intestinal calcium hyperabsorption and increased net bone resorption leading to hypercalcaemia and hypercalciuria. In patients with sarcoidosis hypercalciemia is the result of a dysregulated calcitriol production by activated macrophages.

### Diagnostic Principles

In subjects with normal vitamin D metabolism, serum calcitriol levels do not reliably reflect tissue availability of the vitamin D hormone. Oral vitamin D excess is associated with serum 25OHD levels above 300 nmol/L. In patients with sarcoidosis hypercalcemia is related to elevated serum calcitriol levels.

### Therapeutic Principles

Avoidance of vitamin D-rich foods and sunlight exposure (sunscreen!) is mandatory. Glucocorticoids must possibly be given.

## Synonyms

Hypovitaminosis E; Vitamin E deficiency; AVED; FIVE

## Definition and Characteristics

The vitamin E group contains α- β–γ– and δ-tocopherols, which vary in the extent to which – and position where the chromanol ring is methylated. RRR-α-tocopherol is the most potent naturally occurring stereoisomer (1.49 IU/mg); the racemic synthetic tocopherols have less biologic activity (1.1 IU/mg) and in the acetate ester form it is used as international standard (1.0 IU/mg). In vitro tocopherols prevent peroxidation of polyunsaturated fatty acids and independent of this effect they show cell regulatory properties [1]. The plasma α-tocopherol concentration is 11.6–23.2 μmol/L (5–10 μg/mL). Decreased α-tocopherol uptake (see vitamin E excess) is at the basis of the disease manifestations. The decrease can be the consequence either of fat malabsorption (α-tocopherol is absorbed with lipids) or of mutations of the α-tocopherol transfer protein in the liver (α-TTP) responsible for α-tocopherol retention. Diminished α-tocopherol concentrations in plasma have been associated with atherosclerosis progression and with the growth of some tumors [1].

## Prevalence

Vitamin E deficiency occurs rarely in humans. Only a handful of families with clinically evident vitamin E deficiency due to a mutation of the α-TTP (autosomal recessive inheritance) have been described. The disease is more frequent in North Africans and other Mediterranean populations. Among Italian patients presenting with Friedreich's ataxia-like phenotype, AVED accounts for 5% of the cases. The prevalence of less drastic abnormalities in α-TTP, or the occurrence of heterozygotes for α-TTP gene defects, is not known [2].

## Genes

The chromosomal location for α-TTP is 8q13.1–q13.3

## Molecular and Systemic Pathophysiology

The signs of deficiency are different in different animal species and include necrotizing myopathy (all species), fetal death and resorption (rat, mouse, guinea pig, cow, sheep, etc.) and lipofuscin accumulation in uterus, intestine and adipose tissue (rat, dog, pig, etc). Chickens develop encephalomacia, with hemorrhages and necrosis localized in the cerebellum. In rats, 56 genes are up-regulated in response to vitamin E deficiency including muscle structure and extra cellular matrix genes, as well as anti-oxidative, anti-inflammatory and anti-fibrotic genes [3]. In newborns (and even more premature infants) there is a state of relative vitamin E deficiency, with plasma α-tocopherol levels lower than 11.6 μmol/L (5 μg/mL). Low levels of α-tocopherol at birth (a situation that improves with age) may be due to limited placental transfer. In children, having fat malabsorption due to abetalipoproteinemia (Bassen-Kornzweig syndrome), chronic cholestatic hepatobiliary disease, celiac disease, or a genetic abnormality in vitamin E absorption the main manifestations of vitamin E deficiency are mild hemolytic anemia associated with progressive neuropathy and retinopathy in the first two decades of life and a spinocerebellar syndrome, caused by lack of vitamin E absorption consequent to fat malabsorption and steatorrhea [4]. In human adults, ataxia, areflexia, dysarthria, pigmentary retinopathy, proprioceptive sensory loss,

paraesthesia, xanthelasmata and tendon xanthomas, are the major symptoms of vitamin E deficiency, either caused by abetalipoproteinemia or by mutations in the gene coding for α-TTP. The latter disease, with presentation similar to Friedreich's ataxia, is named ataxia with vitamin E deficiency (AVED).The mechanism of the onset of the disease is not clear. It may be attributed to either the lack of the antioxidant properties of α-tocopherol or the dysregulation of signal transduction and gene expression pathways under the control of the vitamin [1].

## Diagnostic Principles

In newborns and premature infants, hemolytic anemia (hemoglobin levels ranging from 7 to 9 g/dL) and very low (<9.28 μmol/L (<4 μg/mL)) to undetectable plasma vitamin E levels are indicative of vitamin E deficiency. Muscular weakness, creatinuria, and necrosis in muscle biopsies are also present. In children with chronic cholestatic hepatobiliary disease or cystic fibrosis the neurological syndrome of vitamin E deficiency (spinocerebellar ataxia with loss of deep tendon reflexes, of vibration and position sense) may be present. In adults spinocerebellar ataxia, without fat malabsorption, associated with low plasma vitamin E (<11.6 μmol/L (<5 μg/mL)) is in most cases diagnostic for a mutation of the α-TTP gene in the liver.

## Therapeutic Principles

Low amounts of tocopherol 5 mg/kg for newborns and 5–10 mg/kg for premature infants are used orally to prevent deficiency. In case of existing deficiency 15–25 mg/kg/day are used. Neuropathy treatment requires higher doses if caused by fat malabsorption (100 mg/kg/day) and at a dosis of 800 mg/day in AVED [5]. Treatment usually arrests the progression of the disease.

# Vitamin E Excess

Angelo Azzi, Yesim Negis
Vascular Biology Laboratory, JM USDA Human Nutrition Research Center on Ageing at Tufts University Boston, Boston, MS, USA

## Synonyms

Hypervitaminosis E; Vitamin E poisoning; Vitamin E toxicity

## Definition and Characteristics

The vitamin E group contains α- β- γ- and δ-tocopherols (cf. Vitamin E deficiency). Dietary Reference Intakes for Vitamin E are shown in Table 1. The Reference Daily Intake (RDI) is the value established by the Food and Drug Administration (FDA) for use in nutrition labeling. The Upper Limit (UL) is the highest level of intake considered to be safe [1] (Table 2).

There is no evidence of adverse effects from the consumption of the limited amounts of vitamin E naturally present in foods. The only possible source of vitamin E excess is via supplementation. There are no known toxicities with vitamin E. Large amounts of vitamin E (400–800 mg/day) taken for months to years are without any apparent harm. From clinical trial evidence that vitamin E supplements appear safe for most adults in amounts of > 1,600 IU (1,073 mg RRR-alpha-tocopherol or the molar equivalent of its esters) [2]. Transient nausea and gastric distress have been observed in a few patients taking high dosages of vitamin E (2,000–2,500 mg/d). Diarrhea and intestinal cramps have been reported at a dosage of 3,200 mg/d. Non-specific adverse effects, which have been reported rarely, include fatigue and muscle weakness. The most significant toxic effect of vitamin E is its antagonism to vitamin K action and the enhancement of the effect of oral coumarin anticoagulants which may result in overt hemorrhage [3]. Patients on anticoagulant therapy should be monitored when taking vitamin E supplements [1].

A recent meta-analysis has claimed that high dose vitamin E supplementation may slightly increase the risk of all-cause mortality in adults with chronic diseases [4]. This result, not generally accepted by the scientific community, can not be in any case extended to healthy adults.

## Molecular and Systemic Pathophysiology

Vitamin E is not mutagenic, carcinogenic, or teratogenic. In human studies with double-blind protocols

Modified from http://ods.od.nih.gov/factsheets/vitamine.asp.

and in large population studies, oral vitamin E supplementation resulted in few side effects even at doses as high as 3,200 mg/d. The presence in the liver of the α-tocopherol transfer protein limits the uptake of α-tocopherol. The maximal amounts that can be reached after supplementation with 900 mg α-tocopherol for 4 weeks doubles the plasma vitamin E concentration from 31.2 to 63.7 +/−14.5 micromol/L. The oral median lethal dose found in several species is 2 g/kg. The importance of a pro-oxidant role of vitamin E in vivo has yet to be demonstrated [5]. Vitamin E can prolong the prothrombin time (corrected by administration of vitamin K) by inhibition of vitamin K–dependent carboxylase. Vitamin E at dosages of 1,600 mg/d reduces platelet thromboxane production and depresses leukocyte oxidative bactericidal activity and mitogen-induced lymphocyte transformation. High doses of α-tocopherol compete for the uptake of γ-tocopherol [5].

### Diagnostic Principles

Vitamin E excess is diagnosed by taking the history of vitamin supplementation.

### Therapeutic Principles

If vitamin E excess is suspected, the supplementation should be reduced accordingly.

## Synonyms

Vitamin K1 – phylloquinone (plant); Vitamin K2 – menaquinone (animal); Vitamin K3 – menadione; Active vitamin K – dihydroquinone

## Definition and Characteristics

Vitamin K (VK), a lipid soluble vitamin, is the generic term for derivatives of naphthoquinones that have coagulation activity. Humans are unable to synthesize VK and therefore it must either be acquired from: (i) dietary sources, mainly leafy green vegetables (VK1 – phylloquinone) or, (ii) as a metabolic product through synthesis by intestinal bacteria (VK2 – menaquinones) [1]. VK is an important co-factor in blood coagulation and in bone metabolism. Deficiency of VK results in impaired coagulation and increased incidence of hemorrhage and can also lead to significant osteoporosis [1].

## Prevalence

VK deficiency is rare in adults due to the abundant VK in plants and synthesis of this vitamin by the intestinal flora. However, in cases of poor dietary intake, such as trauma, surgery, or broad-spectrum antibiotic treatment, deficiency can develop. Other causes are malabsorption, as in celiac disease or Crohn's disease; or administration of certain drugs, such as aspirin, that can interfere with VK function [1].

VK deficiencies are most common in newborns. Breast milk contains low concentrations of VK. Most newborn hemorrhagic diseases occur 1–7 days postpartum.

## Genes

γ-Glutamyl carboxylation is a post-translational modification essential for the activity of the vitamin K dependent coagulation factors II, VII, IX, X, protein C and protein S and therefore for normal homeostasis [1]. During the carboxylation reaction, vitamin K hydroquinone is converted to vitamin K 2,3 epoxide which is then reduced back to vitamin K hydroquinone by the microsomal enzyme vitamin K 2,3 epoxide reductase (VKOR) (Fig 1). Inherited deficiencies of vitamin K dependent coagulation factors can occur either as a result of a molecular defect in the gamma glutamyl carboxylase gene or secondary to one or more defects in proteins of the VKOR complex [2]. Patients with the common, functionally defective 2 and 3 allelic variants of the cytochrome P-450 enzyme 2C9 (CYP2C9) require significantly lower maintenance doses, have longer times to dose stabilization, and are at higher risk for serious and life-threatening bleeding than are patients without these variants [3].

An inherited deficiency of combined molecular defects has also been described [4]. Hereditary combined vitamin K–dependent (VKD) coagulation factor deficiency is an autosomal recessive bleeding disorder associated with defects in both, the carboxylase gene and the VKOR complex, resulting in impaired function in hemostatic factors not restored by vitamin K administration [4].

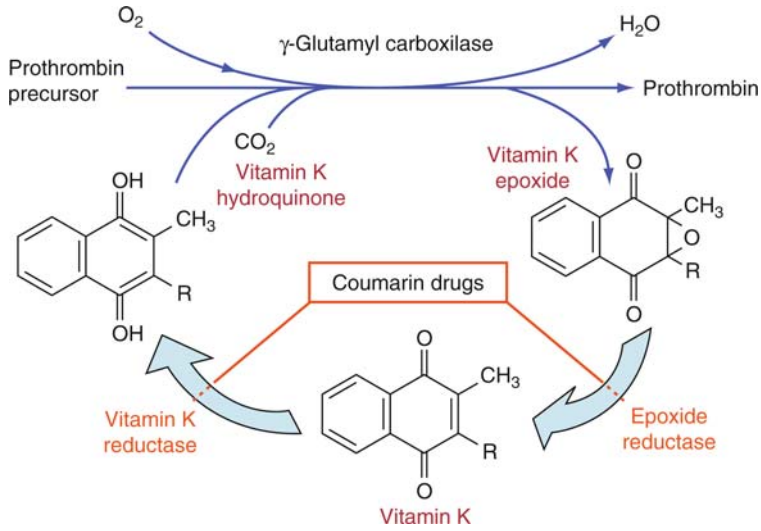
## Molecular and Systemic Pathophysiology

VK activates the carboxylation of γ-carboxyglutamic amino acid of VK-dependent proteins such as prothrombin (factor II); factors VII, IX, and X; anticoagulation proteins such as protein C and protein S; and proteins found in bone (bona gla, matrix gla protein, and osteocalcin) that increases the affinity of glutamic acid residues for calcium [1]. Calcium is necessary for the formation of coagulation complexes and in increasing bone density. VK epoxide is the product of a carboxilation reaction (Fig. 1), and is recycled to its active form (VK hydroquinone) by a two step enzymatic reduction [1]. Coumarin drug anticogulants, such as wafarin, act as antagonists to the reduction reaction, thus blocking the two enzymes responsible for recycling VK (Fig. 1).

Bone matrix proteins, specifically osteocalcin, undergo similar gamma carboxylation in the presence of VK, explaining the increased incidence of osteoporosis secondary to VK deficiency [1].

## Diagnostic Principles

The classic sign of vitamin K deficiency is a prolonged PT (prothrombin time) and increased incidence of spontaneous hemorrhage, such as heavy menstrual bleeding, gastrointestinal bleeding or unexplained anemia. Since vitamin K is stored in the liver, clinical deficiency is rare. Conditions associated with vitamin K deficiency include fat malabsorption, liver disease (as with other fat-soluble vitamins), and chronic antibiotic therapy. Diagnosis of vitamin K deficiency is based on a history of



**Vitamin K Deficiency. Figure 1** Vitamin K carboxilation-reduction pathway.

malabsortion, hemorrhagic diathesis, clinical symptoms, or measurements of prolonged PT and vitamin K values in the plasma [1]. Excess vitamin E can inhibit vitamin K activity and precipitate signs of deficiency [1].

Regarding bone metabolism, the Framingham Heart Study found a lower incidence of hip fractures in subjects with normal VK intake compared with subjects with a low intake. However, the investigators found no association between dietary vitamin K intake and bone mineral density [5].

## Therapeutic Principles

Phylloquinone (phytonadione) is the preparation of choice. Severe hypoprothrombinemia, especially, following coumarin drugs improves after SC (subcutaneous) or IM (intramuscular) phytonadione administration.

For prophylaxis, a diet rich in VK is recommended, including green leafy vegetables and oils, such as olive, canola, and common vegetables, such as green peas and beans, asparagus, spinach, and broccoli. For newborns, phytonadione 0.5–1 mg IM is routinely recommended to prevent hypoprothrombinemia and reduce the incidence of intracranial hemorrhage. Pregnant women taking anticonvulsants should receive phytonadione 20 mg/day PO for 2 weeks before delivery in order to prevent fetal hemorrhage.

# Vitamin K Excess

Arie Markel[1], Nir Kfir[2]
[1]Department of Internal Medicine A, Haemek Medical Center, Afula, Israel
[2]Tel Hai College, School of Bio-Technology, Upper Galilee, Israel

## Synonyms

Vitamin K1 – phylloquinone (plant); Vitamin K2 – menaquinone (animal); Vitamin K3 – menadione; Active vitamin K – dihydroquinone

## Definition and Characteristics

Vitamin K (VK), a lipid soluble vitamin, is the generic term for derivatives of naphthoquinone that have coagulation activity. Humans are unable to synthesize VK and therefore it must either be acquired from: (i) dietary sources, mainly leafy green vegetables synthesis (VK1 – phylloquinone) or, (ii) as a metabolic product through synthesis by intestinal bacteria (VK2 – menaquinones) [1]. VK is an important co-factor in blood coagulation and in bone metabolism.

## Prevalence

Excessive intake of VK rarely occurs. Excess doses (>1,000 times the requirement) can promote thrombogenesis and hemolysis. These doses of VK can also increase risk of jaundice. Hypervitaminosis K, or VK toxicity, is fairly rare as the natural forms of VK, phylloquinone and menaquinone, are non toxic at very high dosage levels.

## Genes

In contrast to genetically determined cases of warfarin sensitivity, there are rare cases of warfarin resistance. A potential pharmacodynamic mechanism underlying warfarin resistance has been elucidated with the recent discovery of the warfarin target gene, which encodes VK epoxide reductase complex 1 (VKORC1) [2,3,4].

This complex recycles VK, which is essential for the post-translational gamma-carboxylation of VK–dependent clotting factors: II (prothrombin), VII, IX, and X. Several rare mutations that lead to amino acid changes in the VKORC1 protein have been discovered in warfarin resistant patients [3,4]. VKORC1 haplotypes can be used to stratify patients into low-, intermediate-, and high dose warfarin groups and may explain differences in dose requirements among patients of different ancestries. High dose haplotype required 6.2 ± 0.3 mg per day, in contrast to a requirement of 2.7 ± 0.2 mg per day in the low dose haplotype [4].

In a different study, a VKORC1 Asp36Tyr polymorphism was identified. This polymorphism was present in 7 of 15 resistant patients but in none of 8 sensitive cases ($P$ = 0.026). Carriers of Asp36Tyr required significantly higher warfarin doses of 80.9 ± 10.1 mg/wk compared with 42.7 ± 7.5 mg/wk in noncarriers [5].

## Molecular and Systemic Pathophysiology

VK activates the carboxylation of γ-carboxyglutamic amino acid of VK-dependent proteins such as prothrombin (factor II); factors VII, IX, and X; anticoagulation proteins such as protein C and protein S; and proteins found in bone (bona gla, matrix gla protein, and osteocalcin) which increases the affinity of glutamic acid residues for calcium [1]. Calcium is necessary for the formation of coagulation complexes and in increasing bone density. (see Fig. 1 in the chapter ►Vitamin K deficiency).

## Diagnostic Principles

VK influences prothrombin time.

## Therapeutic Principles

In the rare conditions with excess VK the intake of the vitamin needs to be decreased accordingly.

# Vitiligo

Johannes Bayer, Stefan Beissert
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Definition and Characteristics

Vitiligo is an acquired, idiopathic hypomelanotic disorder in which a progressive loss of melanocytes from the epidermis and hair follicles results in well-circumscribed cutaneous depigmented macules [1].

## Prevalence

Vitiligo is the most common pigmentary disorder worldwide. The prevalence is 0.5–2% without a predilection for age, sex or race.

### Genes

Several candidate genes have been proposed for vitiligo susceptibility, including genes important for melanin biosynthesis, response to oxidative stress and/or regulation of autoimmunity [2,3]. However, none of these vitiligo susceptibility genes has yet been identified. Case-control studies examining human leukocyte antigens (HLA) have shown a positive association with HLA DR4 and a negative association with HLA DR3 [4].

### Molecular and Systemic Pathophysiology

The mechanisms leading to the loss of pigment cells are not yet fully understood. Melanocytes could be destroyed by necrosis, apoptosis or transepidermal elimination of melanocytes [5]. There are multiple hypotheses to explain the aetiology of vitiligo: autoimmune, autocytotoxic, neural, environmental and genetic factors.

### Diagnostic Principles

An immunohistopathology of the skin should be drawn and associated autoimmune disease should be excluded (thyroid studies, antinuclear antibodies (ANA), other organ specific antibodies, fasting blood glucose levels and a complete blood count).

### Therapeutic Principles

Vitiligo is a challenging disease to treat, but there are several options. First line treatments include topical corticosteroids, topical calcineurin inhibitors, or phototherapy (UVB UVA1, PUVA). Novel therapeutic approaches include pseudocatalase with UVB.

Janice Y. Chou[1], Brian C. Mansfield[2]
[1]Section on Cellular Differentiation, Heritable Disorders Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA
[2]Correlogic Systems, Inc., Rockville, MD, USA

### Synonyms

Glycogen storage disease type I (GSD-I); GSD-Ia (MIM232200); GSD-Ib (MIM232220)

### Definition and Characteristics

Von Gierke disease is a group of autosomal recessive disorders of glucose metabolism. The primary defect is

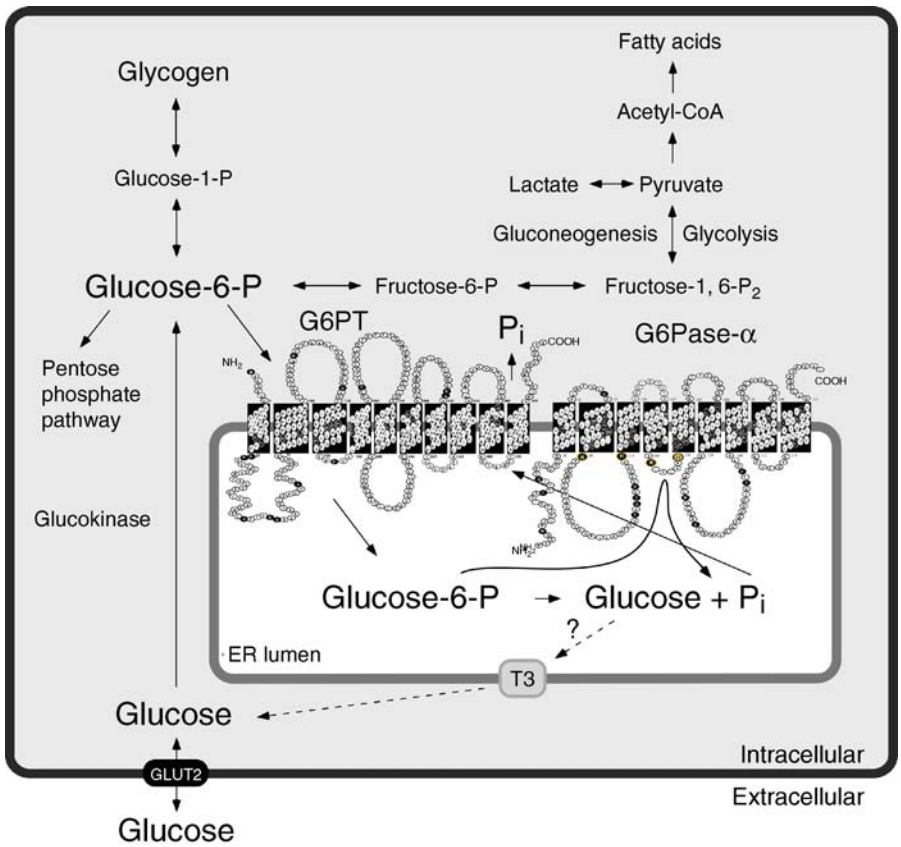
in the impaired conversion of glucose-6-phosphate (G6P) to glucose and phosphate due to mutation of either glucose-6-phosphatase-α (G6Pase-α, synonym G6PC) in GSD-Ia, or the G6P transporter (G6PT, synonym SLC37A4) in GSD-Ib [1]. Only a single G6Pase activity, expressed primarily in the liver, kidney and intestine [1], was known until 2003 when a second ubiquitous G6P hydrolase activity was identified. The original G6Pase is now designated G6Pase-α, the second, G6Pase-β (synonym G6PC3). G6Pase-β is not currently implicated in von Gierke disease, although it impacts glucose metabolism in neutrophils. GSD-I patients manifest fasting hypoglycemia, hepatomegaly, nephromegaly, hyperlipidemia, hyperuricemia, lactic acidemia, and growth retardation [1]. In the longer term, complications include short stature, osteoporosis, gout, pulmonary hypertension, renal disease, and hepatic adenomas that can become malignant. GSD-Ib patients exhibit the additional complications of neutropenia and myeloid dysfunctions [1]. Untreated, both diseases are fatal in early life.

## Prevalence

1:100,000 in GSD-I. Of these, GSD-Ia represents 80% of cases and GSD-Ib 20%.

## Genes

G6Pase-α is encoded by G6PC, a single copy, ~12 kb gene, on chromosome 17q21, composed of five exons that encodes a 357 amino acid hydrophobic glycoprotein [2] anchored in the endoplasmic reticulum (ER) by 9-transmembrane helices (Fig. 1). The catalytic center,



**Von Gierke Disease. Figure 1** The primary anabolic and catabolic pathways of G6P in the liver. The G6Pase-α system, an enzyme complex essential for interprandial glucose homeostasis, is comprised of a G6Pase-α catalytic subunit, a G6PT that transports G6P in and phosphate out of the ER, and a putative glucose transporter (T3), shown to anchor in the membrane of the ER in contact with both the cytoplasm and ER lumen. The spatial representation is illustrative only; the proteins probably exist as a multi-protein cluster. Molecular genetic studies have confirmed that inactivating mutations in the G6PC and SLC37A4 genes cause GSD-Ia and GSD-Ib, respectively [1]. Amino acids in G6Pase-α and G6PT altered by missence mutations are marked in black. T3 has not been characterized at the molecular level and its existence is currently unclear. The GLUT2 transporter, responsible for the transport of glucose in and out of the cell, is shown embedded in the plasma membrane.

which includes $Arg^{83}$, $His^{119}$, $Arg^{170}$, and $His^{176}$, lies within the ER lumen (Fig. 1). $His^{176}$ is the phosphate acceptor forming the phosphohistidine-G6Pase-α intermediate during catalysis. To hydrolyze G6P, G6Pase-α must couple with G6PT [1,3]. A total of 84 separate G6PC mutations, including 54 missense, 10 nonsense, 17 insertion/deletion, and 3 splicing, spread through the coding and exon–intron junction regions have been associated with GSD-Ia [1]. The R83C mutation has a particularly high prevalence in Ashkenazi Jews with a carrier frequency of 1.4%.

G6PT is encoded by SLC37A4, a single copy, ~5 kb gene, on chromosome 11q23, composed of nine exons. The gene is transcribed into two mature RNAs encoding a 429 amino acid G6PT [4] and a 451 amino acid variant G6PT. G6PT (Fig. 1) and variant G6PT are both hydrophobic, ten transmembrane domain ER proteins. G6PT transports cytoplasmic G6P into the ER lumen for hydrolysis and phosphate out [1]. A total of 79 SLC37A4 mutations, including 33 missense, 11 nonsense, 19 insertion/deletion, and 16 splicing, spread through the coding and exon–intron junction regions have been associated with GSD-Ib [1].

## Molecular and Systemic Pathophysiology

The G6Pase-α-G6PT complex hydrolyzes G6P to glucose and phosphate in the terminal steps of gluconeogenesis and glycogenolysis (Fig. 1) in the liver, kidney, and small intestine.

These pathways are critical for the maintenance of blood glucose levels between meals. The hallmark of GSD-I patients is hypoglycemia following a short fast [1]. Loss of glucose homeostasis results in the accumulation of elevated levels of G6P in the cytoplasm, driving conversion of G6P to glycogen for storage. Excessive accumulation of glycogen in the liver and kidney promotes progressive hepatomegaly and nephromegaly. Accumulation of fat droplets in the liver also contributes to hepatomegaly. Excess G6P also enters the glycolytic pathway, generating chronic lactic acidemia, hyperuricemia and hyperlipidemia.

The mechanisms for immune deficiency in GSD-Ib are unclear but enhanced neutrophil apoptosis is observed. Neutrophils lacking G6PT also have intrinsic defects in respiratory burst, chemotaxis, and $Ca^{2+}$ mobilization [5].

## Diagnostic Principles

Historically, GSD-I was diagnosed symptomatically, supported by clinical biochemistry, and confirmed by G6Pase activity assays of liver biopsies [1]. Gene-based diagnostic tests for GSD-I are now available and also useful for carrier testing of at-risk families and prenatal diagnosis.

## Therapeutic Principles

There is no cure for GSD-Ia or GSD-Ib. Many disease symptoms are managed or improved using a dietary therapy augmented by drugs [1]. Infants receive nocturnal nasogastric infusion of glucose. Older patients eat uncooked cornstarch. GSD-Ib patients also receive granulocyte colony stimulating factor therapy to restore myeloid functions [1]. However, the underlying disease remains untreated and patients continue to suffer hyperlipidemia, hyperuricemia, hypercalciuria, hypocitraturia, and lactic acidemia. Allopurinol and lipid lowering drugs are used to control hyperuricemia and hyperlipidemia, respectively. Angiotensin converting enzyme inhibitors are beneficial in treating microalbuminuria, an early indicator of renal dysfunction in GSD-I patients.

Orthotopic liver transplantation is advocated for patients failing to respond sufficiently to dietary therapy, or with multiple liver adenomas [1]. Patients with, or at risk of, renal failure, may consider combined liver and kidney transplantation.

Animal models of GSD-Ia and GSD-Ib are available and being used to investigate alternative treatments, such as somatic gene therapy, which are showing promise [1].

## Synonyms

VHL-S

## Definition and Characteristics

The von Hippel-Lindau-Syndrome (VHL-S) is an autosomal dominant inherited familiar cancer syndrome and characterized by the development of capillary hemangioblastoma of the central nervous system and retina, clear cell renal cell carcinoma (CCRCC) and pheochromocytoma. Other rare extrarenal manifestations of VHL are neuroendocrine tumors, pancreatic tumors and cysts, endolymphatic sac tumors of the inner ear and epididymal and broad ligament cystadenomas. The diagnostic criteria for VHL-S are based on the diagnosis of capillary hemangioblastomas of the CNS or retina and additionally the occurrence of one of the typical VHL-associated extraneural tumors or a pertinent family history.

Two types of VHL-S are distinguished:

- Type1: Occurrence of CCRCC only
- Type 2: Additional occurrence of pheochromocytoma
  - 2a: Without CCRCC
  - 2b: With CCRCC
  - 2c: Familiar pheochromocytoma as only manifestation

In clinically defined VHL-S, germline VHL mutations can virtually always be detected. Approximately 3–4% of all CCRCC develop in patients with VHL-S. The mean age of manifestation is 37 years (5 years earlier than sporadic CCRCC) with a 70% chance of developing CCRCC by the age of 70 years. Frequently renal cysts are found. All renal cell carcinomas developing in VHL-S are of clear cell type with frequent cystic differentiation, bilateral and multifocal occurrence and a relatively good prognosis (Fig. 1).

Several hundred CCRCC and cysts can develop in the kidney of patients with VHL-S. The most important extrarenal manifestation are hemangioblastomas of the CNS and retina, which develop frequently earlier as CCRCC (25–30 years of age), thus allowing an early diagnosis. These tumors are benign and rarely life threatening. Pheochromocytoma may constitute a major clinical problem, particularly in families with predisposition to the development of these tumors (VHL type 2).

## Prevalence

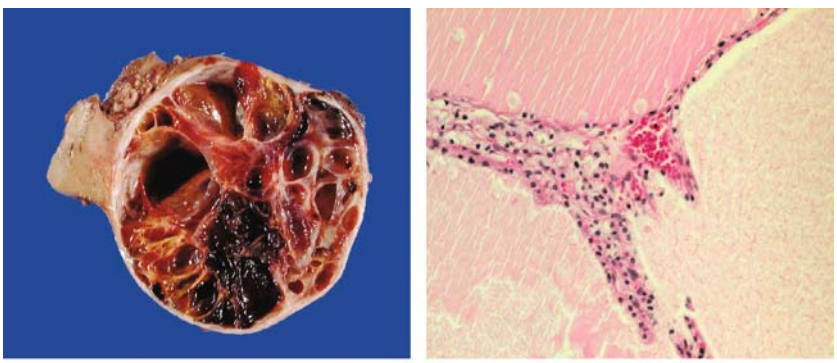
VHL-S is one of the most frequent hereditary cancer syndrome and estimated to occur at rates of 1:36,000 to 1:45,000 population [1].

## Genes

In 1993 germline mutations of the VHL gene at chromosome 3p25–26 were detected in patients with VHL-S [1]. In the tumors of these patients, the wild-type allele is frequently deleted. Somatic VHL mutations are also the most frequent genetic alteration in sporadic CCRCC, occurring in 60–80% of tumors. The VHL tumor suppressor gene has three exons and a coding sequence of 639 nucleotides. The VHL gene is expressed in a variety of human tissues, in particular epithelial cells of the skin, the gastrointestinal, respiratory and urogenital tract, and endocrine organs, but also in neurons, including the Purkinje cells of the cerebellum. More than 150 different germline mutations in VHL are described in all three exons [2]. Missense mutations are most common, but truncating mutations (nonsense, deletion/insertions/splice site mutations) are also described. The spectrum of clinical manifestations of VHL-S reflects the type of mutation (genotype-phenotype correlation) [3]. VHL type 2 families with high risk of pheochromocytomas have almost invariable missense mutations (most frequently at codons 712 (C > A, type 2A) or codons 505 (T > C) and 658 (G > T, Type 2B), whereas many different types of mutations have been linked to type 1 VHL (most frequent mutation 686 T > C).

## Molecular and Systemic Pathophysiology

The VHL gene product has multiple functions including regulation of angiogenesis and cell cycle and



**Von Hippel-Lindau-Syndrome. Figure 1** (a) Gross macroscopic appearance and (b) histopathology (HE, ×200) of a typical cystic renal cell carcinoma in a patient with VHL-S.

ubiquitin-mediated protein degradation [4]. The VHL protein is part of a ubiquitin ligase complex that targets the alpha-subunits of the heterodimeric transcription factor hypoxia-inducible factor (HIF) for polyubiquitylation and proteosomal degradation, when oxygen is available. In VHL-defective CCRCC, HIF-α accumulates and leads to transcriptional activation of a variety of genes involved in acute or chronic adaptation to hypoxia, including VEGF, PDGFB, TGFα or erytropoitin. New therapeutic approaches for CCRCC aim to inhibit HIFα or HIF-responsible gene products, as already demonstrated for VEGF antagonists with clinical activity in metastatic disease.

Additional functions of the VHL protein may contribute to malignant transformation and the evolution of the phenotype of VHL-associated lesions. This includes the control of cell cycle exit through regulation of the CDK inhibitor p27 and the increase of invasion capacity through regulation of HGF/TIMP-2.

## Diagnostic Principles

The median life expectancy of VHL-S patients is 49 years. In order to detect VHL-associated tumors at an early stage, analyses for germline VHL mutations has been recommended in every patient with retinal or CNS hemangioblastoma, especially in those with young age at diagnosis and multiple tumors.

The following prophylactic procedures are recommended in patients with germline VHL mutations:

1. Yearly clinical and neurological examination
2. Yearly opthalmological examination
3. Periodical measurement of Hb/Hk to exclude polycythemia as symptom of hemangioblastomas and renal cell carcinomas
4. Yearly urine examination (cytology, metanephrine, VMA)
5. MRT examination of CNS at age 10–12 years
6. Yearly CT scan and ultrasound of kidneys and pancreas, beginning not later than age 18 years.

## Therapeutic Principles

Because of the good prognosis and the bilateral and multifocal occurrence of CCRCC in VHL-S patients, surgery is frequently only used in patients with large tumors. Metastases do not occur in patients with tumors smaller than 4 cm. Partial nephrectomy and conservative surgery allow the preservation of renal function over long periods of time in many patients.

## Synonyms

Von Willebrand factor deficiency; Von Willebrand factor, included; VWF, included; vWD

## Definition and Characteristics

The gene product is a 2,813-amino acid protein comprised of a signal peptide (pre-peptide), a large pro-peptide of 741 amino acids, and a mature vWF molecule of 2,050 amino acids. vWf is made by endothelial cells and stored in specialized organelles, the Weibel-Palade bodies. vWF is constitutively secreted from the cells into blood but its secretion can also be stimulated with specific agonists such as desmopressin. Weibel palade body-stored vWF consists of unusually large multimers that are being processed by a specific protease in plasma, now identified as ADAMTS 13 [1]. vWF is also found in megakaryocytes and platelets, and is also present in subendothelial matrix where it is bound to collagen.

## Prevalence

vWD is the most frequent bleeding disorder with an estimated prevalence of 4–10 cases per 100,000 and a number of symptomatic cases of at least 100 per million people, but in the few studies in which specific groups were screened the prevalence was about 1% without ethnic differences [2]. In such screening studies the large majority of cases detected have a mild phenotype without any previous need for hemostasis investigations. The most prevalent subtype is thought to be type 1; however, the original estimate of 65% may have been an overestimation due to mistyping in a significant number of cases.

## Genes

Autosomal, usually dominant (type 1) bleeding disorder with variable phenotype and penetrance due to defective and/or deficient von Willebrand factor (vWF) molecules [3].

*Gene Map Locus*: 12p13.3.

*Classification*: Two major subtypes are recognized, the quantitative (types 1 and 3) and qualitative (type 2) vWF defects. Type 1 vWD shows a partial quantitative deficiency of vWF, type 3 a virtual complete lack of vWF. Type 2 can be distinguished into several subtypes: 2A: qualitative variants with decreased platelet-dependent function associated with the absence of high-molecular weight vWF multimers. 2B: qualitative variants with increased affinity for platelet GpIbα. Type 2M: qualitative variants with decreased platelet-dependent function not caused by the absence of high-molecular weight vWF multimers. Type 2N: qualitative variants with markedly decreased affinity for factor VIII.

## Molecular and Systemic Pathophysiology

The gene for vWF has been cloned and located at chromosome 12p13.3. It comprises about 178 kilobases with 52 exons. A highly homologous pseudogene has been located at chromosome 22, spanning the sequence between exons 23 and 34. Knowledge of the functional domains has improved the identification of mutations underlying vWD. In type 1 the genetic basis is still unknown in most cases, although several factors may be involved [3]. In type 2 disease several mostly missense mutations have been identified (updated on www.shef.ac.uk/vwf). These mutations result in either of two dysfunctional pathways: group 1 mutations show impaired secretion of HMW multimers and group 2 mutations show normal production and secretion of protein but probably enhanced proteolysis in vivo. In type 3 vWD partial or total gene deletion may be found. Mutations may be found throughout the gene.

vWF has two important functions in hemostasis. First, it mediates platelet–subendothelium interaction by binding of a region in the A1 domain in vWF to the platelet GpIbα receptor and the same molecules are involved in platelet–platelet interactions. The latter process is also accelerated by interactions among vWF, GpIIb/IIIa, and fibrinogen. The second function of vWF is to protect factor VIII from proteolysis, stabilizing its action in blood. Thus, any change in concentration of vWF results in concurrent changes in factor VIII. In general, the main defect in VWD is in platelet adhesion and platelet–platelet interaction, required for proper aggregation and thrombus formation. Thus, the principal result is impaired primary hemostasis.

*Clinical Features*: The clinical phenotype is usually mild in type 1 with increasing severity in types 2 and 3 and with variable penetrance per family. Mucocutaneous bleeding predominates, in women vWD may be the sole cause of severe menorrhagia. Bleeding may occur following dental extraction. Severe bleeding after delivery is rare in type 1 disease. In type 2 vWD severe bleeding postpartum may occur. In type 3 severe bleeding may occur sometimes resembling hemophilia. Preventive measures to limit blood loss after delivery or surgery may be needed in type 2 and is warranted in type 3 vWD.

## Diagnostic Principles

The diagnosis of type 1 vWD is hampered by both the variable clinical presentation and the fact that vWF concentrations are linked to blood group but also to acquired conditions, including stress, pregnancy, inflammation, and the diagnosis may require repeated blood samples and tests. Upon screening, the platelet count is usually normal or mildly lowered in type 2B. The bleeding time is usually prolonged, while clotting times are normal in case of prothrombin time, or mildly prolonged in case of APTT when factor VIII is also reduced. In the final diagnosis of vWD, vWF antigen and ristocetin cofactor activity are relevant to detect any discrepancies between protein and function of vWF. Multimer analysis further discriminates the specific type 2 subtypes.

## Therapeutic Principles

Management aims at limiting or preventing bleeding complications. Desmopressin (DDAVP), a synthetic analogue of vasopressin, raises both factor VIII and vWF levels in plasma and can be applied in patients with mild hemophilia but is the cornerstone of treatment of VWD. Since the first clinical trial in 1977 DDAVP has been widespread and successfully used [4]. DDAVP is usually given intravenously, is comparably inexpensive and safe as compared with transfusions of protein concentrate. In addition, antifibrinolytics such as epsilon aminocaproic acid or tranexaminic acid may be used to limit mucosal bleeding. Estrogens are not widely used anymore except in the form of combined contraceptive agents that are quite useful in women with menorrhagia. In patients unresponsive to DDAVP transfusion therapy with cryoprecipitate or factor VIII/vWF concentrates may be warranted.

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Type 3 Waardenburg syndrome (WS) (also known as Klein-Waardenburg syndrome); Type 4 WS (known as Shah-Waardenburg syndrome)

## Definition and Characteristics

A hereditary, mostly autosomal dominant auditory–pigmentary syndrome consisting of four clinical subtypes (WS1-4) [1]. Pigmentary abnormalities (white forelock) and congenital non-progressive sensorineural hearing loss are consistent features of all WS types.

## Prevalence

Waardenburg syndrome accounts for between 2 and 5% of cases of congenital deafness [2]. The estimated prevalence is 1 in 10,000–20,000 of the population. The highest incidence is among Kenyan Africans.

## Genes

WS1 (MIM#193500) and WS3 (MIM#148820): *PAX3* at 2q35; WS2 (MIM#193510) is genetically heterogeneous with one locus at 3p14.2–p12.3. For WS4 (MIM#277580) several loci have been mapped at 20q13.2–q13.2, 22q13 and 13q22.

## Molecular and Systemic Pathophysiology

WS1 is autosomal dominant (with haploinsufficiency) and is caused by a wide range of mostly private mutations (nonsense, missense, frameshift, splice-site mutations) of PAX3 resulting in loss of function of the encoded transcription factor [3]. Identical PAX3 mutations can lead to variable clinical expression. PAX3 is predominantly active in the embryonic neural crest and regulates the expression of microphthalmia transcription factor (MITF), a master gene for melanocyte development and pigmentation, as well as of Met and MyoD, genes involved in limb development. Variations in the PAX3 interacting proteins may explain the clinical phenotype of WS3 (autosomal dominant but mostly sporadic). PAX3 is homologous to murine Pax3. Mutations in this gene result in the lethal Splotch mouse while patients with WS3 and homozygosity for a PAX3 mutation survive. WS2 is also autosomal dominant. In 10% mutations of MITF have been reported [4]. Other candidate genes include SLUG (SNAI2) encoding a zinc-finger transcription factor. The murine homologue of SLUG is Slugh which is expressed in migratory but not premigratory neural crest cells [5]. WS4 is genetically heterogenous including homozygotes for EDN3 and EDNRB (encoding endothelin-3 and the endothelin receptor type B) as well as heterozygotes for SOX10 (encoding a transcription factor of the high-mobility group-domain SOX family), all genes fulfilling crucial roles in differentiation of neural crest-derived melanocytes and glia.

## Diagnostic Principles

According to the Waardenburg consortium WS1 is diagnosed, if at least two major criteria (dystopia canthorum, congenital sensorineural hearing loss, white forelock, pigmentation abnormalities of the iris, affected first degree relative), or one major plus two minor criteria (early hair graying, pigment dilution of the skin, synophrys, hyoplasia of the ala nasae, broad high nasal root) are present. WS2 is defined negatively by the absence of dytopica canthorum. WS3 is characterized by features of WS1 plus hypoplasia of the upper limb muscles and mild contractures of the elbows and fingers. WS4 describes a heterogeneous group of neurocristopathies in which defects of melanocytes and enteric neurons are present resulting in a combination of WS2 with Hirschsprung disease.

## Therapeutic Principles

Genetic counseling is advised and prenatal diagnosis is possible for WS1. In patients with WS1 it is necessary to screen the entire *PAX3* gene sequence for mutations. There is limited prediction of the potential hearing loss.

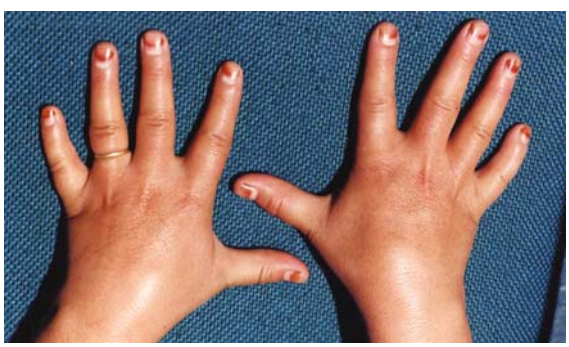
## Synonyms

GEMSS syndrome; Glaucoma, ectopia, microspherophakia, stiff joints, short stature syndrome; microspherophakia (for dominant form)

## Definition and Characteristics

A very rare congenital disorder presenting with skeletal anomalies as brachymorphy, brachycephaly, physically short (pyknic) stature with minor facial abnormalities, rounded face in stiff attitude, hypertelorism, depressed nasal bridge, osteoporosis, short and stubby hands, fingers, feet, and toes (brachydactyly; Fig. 1), restricted articular movements (hypoextendable joints or the fingers that cannot be fully made into fist) with joint prominence and stiffness especially in the hands, thickened skin, muscular build, and broad thorax [1].

Ocular abnormalities are typical and include progressive microspherophakia (a crystalline lens with a small diameter and spherical shape that is considered a prerequisite for the diagnosis) and/or bilateral ectopia lentis (a displaced or malpositioned lens) that occurs in about half of the cases, tending to occur later in life after birth (postnatally) rather than being present congenitally in origin [1]. The lens usually displaced partially (subluxated) downwards with the lens in the pupillary area. Severe lenticular myopia and astigmatism with decreased vision along with the loss of accommodation develop [1]. Secondary chronic, angle-closure, or pupillary block glaucoma may develop by forward movement of the lens to become entrapped in the pupil or as a result of congenital angle anomaly with narrow and occludable anterior chamber angle during the teens or early twenties in either sex [1,2]. The lens may completely dislocate forward into the anterior chamber as the lens zonules are weaker than normal that can rupture with abnormalities in the ciliary body structure, which is hyperplastic (enlarged due to an increase in the number of cells), causing not only inflammation but also reverse pupillary block with the pupil compressed against the back of the lens. Carpal tunnel syndrome may result from fibrous tissue hyperplasia. Occasional findings may be cardiopulmonary abnormalities and slight mental handicap. A less frequent finding is asymmetric axial lengths associated with presenile vitreous liquefaction [1].



**Weill-Marchesani Syndrome. Figure 1** Short hands and stubby fingers in a 27-year old female patient with Weill-Marchesani syndrome.

## Genes

Although sporadic cases of Weill–Marchesani syndrome occur, both autosomal dominant and recessive mode of inheritance has been reported with partial expressivity in the heterozygote. A candidate gene for the autosomal dominant form is linked to mutation within the fibrillin-1 gene on chromosome 15q21.1 whereas the autosomal recessive form is mapped to fibrillin-3 on chromosome 19p13.3-p13.2 with additional null mutations in a member of the extracellular matrix protease family of the ADAMTS10 gene [3–5].

## Molecular and Systemic Pathophysiology

A systemic connective tissue disorder including the bone associated with fibrous tissue hyperplasia as the primary lesion with an impairment of extracellular matrix structure and cytoskeleton anomaly, and abnormal microfilaments from fibrillin gene mutation, causing the alterations of its protein that is the major component of microfibrils, which plays a role in tropoelastin deposition and elastic fiber formation with a deteriorated fibrillin in the skin, skeleton and chondrocytes, dermal–epidermal junctions, and in the papillary dermis. Therefore, it is a mesodermal dystrophy, especially of the anterior segment of the eye. Microspherophakia may be either primitive or secondary to zonular dysplasia with insufficient traction.

## Diagnostic Principles

Measurements for height, arm span, lengths of the hand and foot, skeletal X-ray studies for brachymorphy and brachydactyly (brachymetacarpia), ocular examinations for lenticular changes and phacodonesis, gonioscopy for angle abnormalities, B-mode ultrasound for axial length.

### Therapeutic Principles

Medical treatment may be insufficient to control glaucoma that necessitates surgical interventions such as trabeculectomy, lensectomy, peripheral iridectomy or laser iridotomy, and anterior vitrectomy to decrease the intraocular pressure with or without intraocular lens implantation, thus preventing primarily the pupillary block that can lead to angle-closure and scarring of the angle.

### Synonyms

Progeria adultorum; WRN

### Definition and Characteristics

Autosomal recessive disorder. Clinical characteristics start to appear after the age of two with scleroderma like skin changes especially on the extremities, cataract formation, subcutaneous calcification, premature arteriosclerosis, diabetes mellitus, wizened and prematurely aged face with beaked nose. The characteristic habitus includes short stature, slender limbs and stocky trunk. There is increased incidence of malignancies.

### Prevalence

A prevalence of $1:10^5$ has been estimated.

### Molecular and Systemic Pathophysiology

Mutations in the WRN gene (8p12–p11), a RecQ-type homolog, cause Werner Syndrome. The WRN gene encodes a protein with exonuclease and helicase domains and a nuclear localization signal [1]. Reported mutations disrupt this signal leading to ineffective transfer into the nucleus as well as reduced mRNA stability [2,3]. Cell lines derived from WRN patients have a decreased number of population doublings and show an increased rate of chromosomal aberrations. The function of the WRN protein has been implicated in a number of processes including DNA replication, homologous recombination, telomere maintenance and repair of double strand DNA breaks, all of these with a wide range of influence in age-associated decline of cellular function and carcinogenesis [4,5].

## Diagnostic Principles

The typical clinical appearance leads to the diagnosis. A further indication of WRN can be raised by immunoblot analysis employing monoclonal antibodies against the WRN gene product. Sequence analysis confirms the mutations leading to a truncated WRN protein.

## Therapeutic Principles

Each different symptom (diabetes mellitus, atherosclerosis, cataract, subcutaneous calcification) occurring in WRN needs to be treated separately. Frequent medical examinations are advisable to detect malignancies early.

# Wernicke Korsakoff Syndrome

Irene Guerrini, Allan D. Thomson, Hugh M. Gurling
Molecular Psychiatry Laboratory, Windeyer Institute of Medical Sciences, Department of Psychiatry and Behavioural Sciences, Royal Free and University College London, London Medical School, London, UK

## Synonyms

Wernicke encephalopathy; *Korsakoff psychosis*; Amnestic disorder; WKS

## Definition and Characteristics

The Wernicke Korsakoff Syndrome (WKS) is a neurodegenerative disorder caused by the deficiency of vitamin B1 (thiamine). In the Western countries, the syndrome frequently occurs in combination with alcohol misuse and/or poor nutrition. It has classically been described as presenting with an acute onset, Wernicke encephalopathy (WE), characterized by nystagmus, ophthalmoplegia, ataxia and global confusion, occurring together or in various combinations. WE can be prevented and treated successfully with parenteral thiamine before the onset of irreversible brain damage. It is thought that patients can suffer recurrent episodes of WE, some of which might be subclinical, leading to a more chronic form of the disease [1]. Many of these patients develop a severe amnesic syndrome that is known as Korsakoff psychosis (KP). Autopsy studies have shown that the diagnosis of KP and WE is not made during life, in 80% of cases [1].

## Prevalence

Post-mortem studies of 26,691 patients in general hospitals from different countries estimated that 1.4% of subjects have lesions of WE i.e. macro and microscopic lesions in the periaqueductal gray matter, the mammillary bodies, medial thalamus and the superior vermis of the cerebellum of the brain [2]. The prevalence increased to between 12.5 and 35% in alcohol misusers. Furthermore, the syndrome occurs more frequently in patients with gastrointestinal disorders associated with recurrent vomiting/chronic diarrhea, hyperemesis gravidarum, cancer and during chemotherapy, renal diseases in particular during dialysis, AIDS, after bariatric surgery, and, in general, in the case of unbalanced nutrition (re-feeding syndrome, anorexia nervosa) due to thiamine deficiency alone. The Wernicke encephalopathy occurs more frequently in males than in females (1.7:1) with a mortality rate of 17% [2].

## Genes

In fibroblasts of individuals affected by WKS, the enzyme transketolase showed less affinity for thiamine diphosphate than normal and a genetic abnormality in the tranketolase gene on 3p14.3 was postulated but no mutations were identified in the transketolase coding region of two individuals affected by WKS [2].

The GABA-A receptor subunit on 5q33 was associated with both alcohol dependence and WKS. A mutation screening analysis identified three genetic variants in the 3′ UTR of the SLC19A2 (high affinity thiamine transporter) on 1q23.3 in WKS patients [2]. It has been demonstrated in human subjects that both alcohol and malnutrition can severely inhibit the

absorption of thiamine hydrochloride from the intestine and therefore thiamine needs to be given intravenously or by intra muscular injection in malnourished subjects [1].

## Molecular and Systemic Pathophysiology

The involvement of a thiamine deficiency in the pathogenesis of the Wernicke Korsakoff Syndrome was first postulated in the early 1940s by Alexander and co-workers (1940). Anatomical studies of the brains of WKS patients and experimental rat or mouse models of thiamine deficiency have demonstrated acute and chronic neuronal damage with evidence of hemorrhages, demyelinization, gliosis and neuronal loss localized to the mammillary bodies, thalamic nuclei and cerebellum with relative sparing of cerebral cortical structures [2]. The importance of thiamine or thiamine diphosphate, the active form of thiamine, to the central nervous system is shown by its key role in glucose metabolism. 80% of brain thiamine is in the form of thiamine diphosphate, a cofactor for three classes of thiamine-dependent enzymes important in brain cell metabolism – α-ketoglutarase, transketolase and pyruvate dehydrogenase enzymes [3] (Fig. 1).

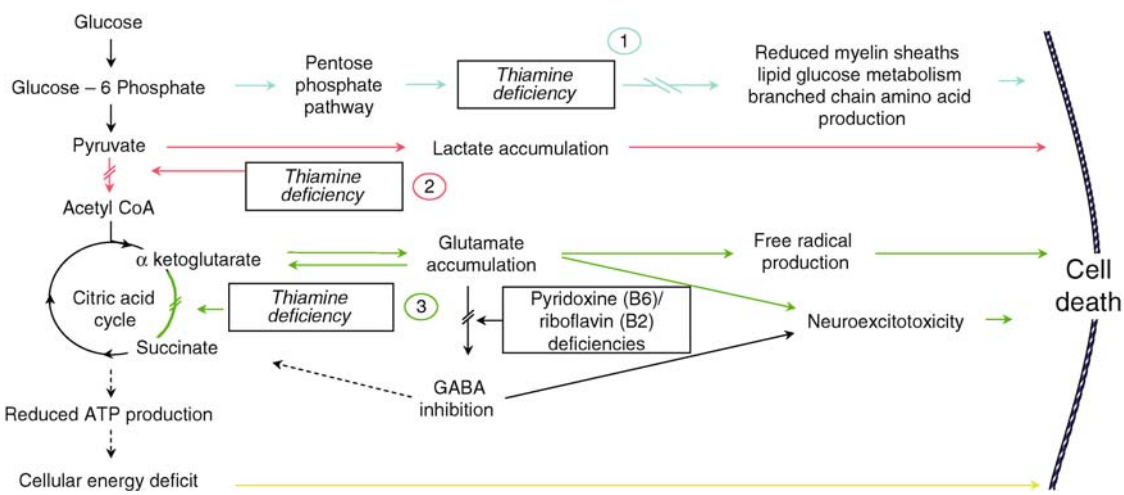
In humans, thiamine cannot be synthesized and must therefore be obtained from exogenous sources, through absorption in the intestine. Healthy adults require 1.4 mg of thiamine daily; requirements are higher in children, in pregnancy and in critically ill patients. The cellular transport of thiamine is mediated by specific carriers, recently identified and biochemically characterized: the Thiamine Transporter-1 and Transporter-2, respectively the products of the SLC19A2 and SLC19A3 genes. Gene expression studies have shown that the thiamine transporters are well expressed in several tissues such the intestine, placenta, kidneys and brain [3].

Several mechanisms have been implicated in the pathogenesis of thiamine deficiency such as oxidative stress, glutamate-mediated excitotoxicity and focal lactic acidosis.

In fact in thiamine deficient rodents it is possible to demonstrate that selective cell death is caused by chronic oxidative abnormalities and inflammation. The inflammation is characterized by microglial activation, induction of endothelial nitric oxide synthase, an altered blood–brain barrier, microglial accumulation of iron and ferritin, and increased levels of inducible nitric oxide synthase [4].

The glutamate transporter (GLAST) is down-regulated in astrocytes under conditions of thiamine deficiency by inducing increased phosphorylation of GLAST. These findings support the hypothesis that glutamate accumulation and toxicity are important factors in the degeneration of selective brain regions in conditions involving thiamine deficiency such as WKS [4].

Thiamine deficiency also results in lactate accumulation in the brain, a finding that has been consistently observed in various experimental models. The most likely explanation for the increased brain lactate is a reduction of pyruvate oxidation resulting from decreased activities of the thiamine-dependent dehydrogenases. It has been suggested that the focal accumulation of lactate in structures vulnerable to thiamine deficiency could result in alterations of cellular pH and contribute to neuronal death. Autoradiographic studies reveal significant acidosis in mammillary bodies, thalamic and pontine structures of thiamine-deficient rats [4].



**Wernicke Korsakoff Syndrome. Figure 1** The figure illustrates the potential mechanisms leading to brain damage. The numbers in the diagram refer to the thiamine dependent enzymes: (1) Transketolase; (2) Pyruvate Dehydrogenase Complex; (3) α-ketoglutarate complex.

## Diagnostic Principles

High performance liquid chromatography (HPLC) measures all four forms of thiamine (thiamine, thiamine monophosphate, thiamine diphosphate, thiamine triphosphate). This technique has demonstrated that current alcohol misuse causes low circulating levels of all forms of thiamine except monophosphate compounds and that liver cirrhosis is associated with decreased thiamine diphosphate concentrations and impaired thiamine phosphorylation [1]. However, there is no laboratory test that will diagnose WKS, although low circulating levels will indicate the patients who are at particular risk.

It should be noted that low circulating levels of thiamine have been reported in 30–80% of alcoholic patients [1]. The incidence and the extent of depletion vary from one group to another, depending on the degree of malnutrition, liver damage, and alcohol intake.

## Therapeutic Principles

The successful treatment of Wernicke's encephalopathy (WE) depends upon providing the depleted brain cells with adequate levels of thiamine (vitamin B1) before any permanent brain damage, Korsakoff's psychosis (KP), has occurred. A number of prodromal signs and symptoms of thiamine depletion have been identified such as anorexia, weight loss, recurrent vomiting, fatigue/weakness etc [5]. Using these criteria patients should be given 250 mg of thiamine hydrochloride IM prophylactically for 3–5 days. Criteria have also been identified for making a presumptive or definite diagnosis of WE. Some patients require 1.0 gm of thiamine a day and lower doses have not been reliably effective at preventing KP. Therefore, patients should be given 500 mg of thiamine IV in saline over a period of 30 min three times daily for 3 days, followed by 250 mg IV daily for a further 5 days [5].

Thiamine therapy is associated with a small risk of anaphylaxis/anaphylactoid reactions and giving it by slow IV infusion reduces the risk. It is also important to correct any other nutrient deficiencies required for normal brain function especially Mg++ levels. The recommendations for thiamine therapy are the result of clinical experience and not determined by dose-ranging controlled trials [5].

# West Syndrome

Gerhard Kurlemann, Bärbel Fiedler
University of Muenster, Children's Hospital, Muenster, Germany

## Definition and Characteristics

West syndrome and infantile spasms (in German BNS-epilepsy, an acronym for "Blitz-Nick-Salaam" derived from the seizure semiology) is an age-related epileptic encephalopathy syndrome with an average or peak onset time around the sixth month of life (range 3rd to 12th month).

West syndrome is an epileptic syndrome in infancy characterized by brief flexor/extensor spasms, often in clusters, symmetric or asymmetric, with a peculiar form of electroencephalographic findings named hypsarrhythmia. This condition comprises chaotic high voltage polyspike and slow wave discharges with multifocal spikes and slow waves varying with the underlying cause of the syndrome. It was first described by Gibbs and Gibbs in 1952. Onset of spasms is often associated with arrest or regression of psychomotor development. About 80% of infants have a symptomatic form with an underlying neurological disease: hypoxic ischemic encephalopathy, a number of neurodegenerative disorders, periventricular leucomalacia, migration disorders from cortical dysplasia to lissencephalia, neurocutane disorders in most cases tuberous sclerosis, Aicardi syndrome and some metabolic disorders are etiologic factors for West syndrome. Even among infants without an underlying disease – idiopathic/cryptogenic West syndrome – many of them develop severe cognitive impairments and other types of seizures later in childhood. There is no clear gender preponderance.

## Prevalence

The average prevalence value is 0.25/1,000 children with a range of 0.14–0.52/1,000 children. The wide

range appears to be largely correlated with geographical region: 0.14–0.18/1,000 in Japan, 0.20–0.25/1,000 in Saudi Arabia and the United States and 0. 30–0.52/1,000 children in Finland and Denmark.

## Genes

Especially in cases with symptomatic West syndrome some monogenic diseases are causative of a complex brain malformation as the reason for West syndrome. For example: lissencephaly: 17p13.3 (LIS1 or PAFAH1B1), schizencephaly: 10q26.1 (EMX2), Tuberous Sclerosis Complex: 9q34 (TSC1) and 16p13.3 (TSC2), Trisomy 21. (For details on these syndromes or diseases see the respective chapters.)

In a small group, West syndrome follows an X-linked recessive pattern without underlying malformations of the brain: Mutations were found in the ARX gene (Xp 22.13) in nearly all patients with X-linked West syndrome. In a few cases, mutations were found in the CDKL5/STK9 gene (Xp 22.3) with a more severe retardation [1].

## Molecular and Systemic Pathophysiology

The complexity in the development of the cortex is a product of carefully orchestrated interactions of genes in which ARX plays a crucial role in a special time pattern during development, also in later stages. The ARX gene (aristaless related homeobox gene) is a paired class homeobox gene located on human chromosome Xp22.13 and consists of five exons encoding a protein of 562 amino acids [2]. The protein has four polyalanine tracts in which 7–16 alanine residues are sequentially repeated. Three of the four polyalanine tracts are encoded in exon 2; the first and second polyalanine tracts are mutation hot spots causing mental retardation and epilepsy, including West syndrome: two thirds of patients with West syndrome show an expansion mutation of the first polyalanine tract of ARX. ARX may regulate neuroepithelial cell proliferation and timing of neuronal regulation; one part of the network are GABAergic interneurons. The disorganization of the neuronal network with dysfunction of the signaling pathway and/or neuronal morphogenesis in form of an interneuronopathy seems to be one cause in West syndrome based on polyalanine expansion mutations, particularly as the brain MRI of these patients is normal. Defects in lissencephaly and schizencephaly genes give rise to defects in inhibitory GABAergic neurons, tangential neurons and hippocampal abnormalities in symptomatic West syndrome. The precise function of CDKL5 is still unknown, but there is an overlap of expression of Cdkl5 in mouse brain with Mecp2, which is mutated in 80% of patients with Rett syndrome [3].

Based on the observations that infants with West syndrome have a reduction of rapid eye movement sleep (REM), West syndrome may be a disturbance of interaction between cortex and brain stem structures as a result of rostral pontine tegmentum instability. In this complex integrity, the brain adrenal axis may play a key role: corticotrophin releasing hormone (CRH) secretion is increased in West syndrome causing a cortical hyperexcitability resulting in hypsarrhythmia and spasms. This hypothesis of pathogenesis is triggered by the response of West syndrome to treatment with ACTH/steroids in which ACTH is superior to oral steroids [4].

## Diagnostic Principles

Age of infant, clinical picture with flexor/extensor spasms, EEG with hypsarrhythmia, seldom only during non REM sleep, and arrest of development are key points for West syndrome. Demonstration of hypsarrhythmia in EEG is essential, there are only very few cases in literature without hypsarrhythmia. Classification as symptomatic or idiopathic form of West syndrome is secondary.

## Therapeutic Principles

The optimum treatment for infantile spasms has yet to be established. Because of the not fully understood pathogenesis of West syndrome, the management remains largely empirical and a challenge to every pediatric neurologist. Several antiepileptic drugs have been introduced for the therapy of West syndrome, many without adequate randomized studies.

ACTH has been the gold standard for the last 40 years. Besides ACTH, sulthiame, prednisone and valproate have been evaluated in larger groups than the new antiepileptic drugs, such as topiramate, lamotrigine or levetiracetam. Vigabatrine seems to be the medication of first choice in the treatment of West syndrome in tuberous sclerosis complex. Ketogenic diet is proven to be effective in single cases, even pyridoxine in a high dosis. Immunglobuline therapy and thyrotropin releasing hormone have also been used for treatment. In case of focal cortical dysplasia, surgery should be considered, especially in cases of tuberous sclerosis with a leading epileptic tuber [5].

## Whipple's Disease

Matthias Wenning
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

### Synonyms

Intestinal lipodystrophy

### Definition and Characteristics

Whipple's disease is a rare chronic infectious disorder first described in 1907 by G. H. Whipple. The disorder is caused by the bacterium Tropheryma whipplei, which was first identified in 1991. T. whipplei appears intra- as well as extracellulary and can be detected by a periodic acid Schiff (PAS) staining of intestinal biopsies within infected macrophages, indicated by a deep red color representing the bacteria or parts of their cell wall. Despite the identification of the bacterium, details about the pathogenesis of Whipple's disease are still far from clear, but there are several hints for a genetic or acquired immunological predisposition [1,2]. Although the presence of T. whipplei is presumed to be ubiquitous, Whipple's disease occurs mainly in middle aged individuals (mean age at diagnosis about 50 years). Specific environmental factors or habits have not yet been associated with the disorder. Whipple's disease may affect different organs and symptoms vary in terms of their severity. The organs most frequently affected are the joints and the gut and in the further course the heart, lung, brain, and eyes. In many cases, patients complain about pain and swelling of the joints first, which may be misdiagnosed as rheumatoid arthritis. Frequently, intestinal involvement occurs with abdominal pain and diarrhea, which leads to weight loss, malnutrition, and anemia. Relapsing fever and lymph node enlargement are possible symptoms as well. Chest pain or cough may occur if the pleura is involved. Possible heart problems become apparent as edema, disturbed cardiac rhythm, or heart valve disease if this organ is infected. In some cases the infection spreads to the brain, which leads to loss of memory, confusion, or disturbances in the gait or the mobility.

### Prevalence

Whipple's disease is rare and there is no valid estimate of its actual prevalence. Only about 1,000 cases have been reported to date. In postmortem studies, the frequency of the disease is less than 0.1% [1].

### Genes

Some familial cases have been reported, and a genetic susceptibility might be suggested, since about 26% of patients (three to four times more than expected) are positive for HLA B27 [3]. Taken together, these observations suggest that a host factor, putatively of an immunological nature, plays an important role in the occurrence of the disease. However, no causal association with any specific genetic factor has been demonstrated so far, and some studies do not support the existence of genetic risk factors [1,2].

### Molecular and Systemic Pathophysiology

The most probable theory is that a defect in cellular immune responses predisposes patients for an infection with T. whipplei. This presumed immunological defect is likely to be quite specific for T. whipplei, since patients are not generally affected by infections with other organisms. Massive infiltration of infected tissues by macrophages on microscopy typifies Whipple's disease [1]. Replication of T. whipplei in macrophages is associated with apoptosis of the host cell, which may be crucial for bacterial dissemination and may also relate to increased interleucin-16 production, which correlates with the activity of Whipple's disease. Antibodies neutralizing interleukin-16 inhibit the growth of T. whipplei in macrophages. Although macrophages from affected patients phagocytose bacteria normally, they appear to be unable to degrade bacterial antigens efficiently [1,2]. This inability to degrade bacterial antigens is related to inadequate production of interleukin-12, which may lead to diminished interferon-γ production

by T-cells and defective macrophage activation. The loss of interleukin-12 production decreases an effective type 1 helper T-cell immune response and would favor a shift toward a type 2 helper T-cell response [1,4]. In support of this hypothesis, the gene expression profile of macrophages in intestinal lesions from one patient with classic Whipple's disease indicated that genes encoding CCL18 and interleukin-10 were uniquely upregulated in intestinal lesions [1,3]. A similar pattern in upregulated genes has been associated with macrophage 2, also known as alternatively activated macrophages, reflecting a predominance of type 2 helper T-cells in the local immune response [1]. The persistent defect of cellular immunity involve activation and interaction of macrophages and T-cells and results in disturbed phagocytosis and intracellular degradation of T. whipplei and allow invasion of the bacillus from the gastrointestinal mucosa to peripheral organs [2,3].

## Diagnostic Principles

Historically the diagnosis is made by histopathology of the infected tissue. In the majority of cases, a gastroscopy and the investigation of intestinal duodenal biopsy sample is the preferred sample, but according to clinical presentation, other samples should be tested, including cerebrospinal fluid (CSF), cardiac valve tissue, lymph node, and synovial tissue. The basic histological finding is characterized by presence of granular foamy macrophages. The inclusions in macrophages are typically stained purple with PAS and are diastase-resistant. In spite T. whipplei is phylogenetically related to the gram positive bacteria phylum, its appearance on gram stain is gram negative. However, as it is poorly stained and this staining is not specific, gram staining is not used for histological study. Bacteria may be visualized using electronic microscopy that shows a typical three layer membrane, but this technique is not convenient for routine use. Immunohistochemistry using mouse or rabbit polyclonal antibodies has demonstrated to be of help as a complement of PAS staining as it may avoid false positive results due to PAS. Immunohistochemistry was also successfully used for detection of T. whipplei in circulating macrophages. Since the determination of 16S rRNA gene sequence, polymerase chain reaction (PCR) amplification of T. whipplei gene tends to become a reference technique for the laboratory diagnosis of Whipple's Disease. Since the first descriptions of usefulness of this technique using partial amplification of 16S rRNA gene, other target genes have been used such as 16S-23S internal transcribed spacer (ITS), 23S rRNA, rpoB, or randomly cloned ORF. The recent sequencing of two T. whipplei genomes now allows to choose between hundred of genes for PCR diagnosis. Quantitative PCR procedure using real time PCR has been developed. The same samples used for histology may be tested by PCR but also synovial fluid and vitreous humor. Samples are best conserved at −80°C before sending it to molecular biology laboratory. Cultivation of T. whipplei from various samples can be achieved, but this technique is not generally available. Today, the diagnosis of Whipple's disease is commonly based on the results of PAS staining and PCR techniques parallel [1,5].

## Therapeutic Principles

Management of Whipple's disease is empirical. In 1952 it was first shown that Whipple's disease can be treated successfully by antibiotics. The recommended treatment is oral administration of 160 mg of trimethoprim and 800 mg of sufamethoxazole twice a day for 1–2 years (alternatively doxycyclin 100 mg/day), usually preceded by parenteral administration of streptomycin (1 g/day) together with penicillin G (1.2 million U/day) or ceftriaxone (2 g/day) for 2 weeks [1].

# White Plague

►Tuberculosis

# Whooping Cough

Noel W. Preston
Microbial Immunology, University of Manchester, Manchester, UK

## Synonyms

Pertussis (=severe cough)

## Definition and Characteristics

Typically, after 1–2 weeks' incubation period, a simple cough marks the "catarrhal" phase of about a week. The "paroxysmal" phase follows, with many severe bouts of coughing each day, and no pause for air-intake within a bout; but there is increasing cyanosis and a final inspiratory effort causing a high-pitched whoop, and often also vomiting. Between bouts, the patient may not appear ill. This phase usually lasts for many weeks, and is followed by an equally long "convalescent" phase.

The illness may be mild and atypical, especially in adults and adolescents, in partially immunized younger children, and in tiny infants with some maternal antibody protection [1]. In such cases, laboratory confirmation of diagnosis is necessary.

Fever suggests secondary infection with pyogenic bacteria and the need for appropriate antibiotic therapy.

## Prevalence

Pertussis affects all ages worldwide. It is one of the major lethal infections of childhood in developing countries; but in some countries it has been virtually eliminated by effective, often compulsory, vaccination [2]. It is caused by the solely human pathogen Bordetella pertussis, rarely by Bord. parapertussis [1]. The usual source is a child with copious secretions [2].

## Genes

Molecular research on Bord.pertussis has concentrated on the genetic control of virulence-factors involved in the infection of inappropriate animal models, but not on the control of the spontaneous variation of the adhesins vital for human disease [3].

However, as with smallpox eradication in the 1970s, genetic understanding of pathogenicity is unnecessary for pertussis eradication. We have the data and resources now. We need only the global will to use them.

## Molecular and Systemic Pathophysiology

*Bord.pertussis* produces three agglutinogens (Aggs). Agg 1 is common to all strains; but the three serotypes pathogenic to man (types 1,2; 1,3; 1,2,3) produce also Agg 2 or Agg 3 or both. These two type-specific Aggs are adhesins of the respiratory mucosa. Agg 2 is fimbrial, giving types 1,2 and 1,2,3 a colonizing advantage. Agg 3 is an outer membrane protein, and type 1,3 infection occurs only when the other types are suppressed by antibody 2.

After colonization, various toxins are produced [3]. Tracheal cytotoxin paralyses the mucosal cilia, so that paroxysmal coughing is required to remove the increased mucus. Other products are pertussis toxin (PT), filamentous hemagglutinin (FHA) and pertactin (adenylate cyclase toxin, ACT); but a role for these has been shown only in experimental rodents. Moreover, unlike the natural (human) host, mice can be infected with (degraded) type 1 organisms which possess neither Agg 2 nor Agg 3.

As with cholera, antitoxin has no role in pertussis immunity [3]. Protection is by the prevention of adhesion, with antibodies against Agg 2 and Agg 3.

## Diagnostic Principles

The gold standard is still bacterial culture [4]. If every published detail is observed [1] culture is not only 100% specific but is highly sensitive, yielding positive results up to 3 months from onset if coughing persists. It has the unique advantage of revealing the serotype of the infecting organism, thus allowing correction of any vaccination failure [2]. The techniques are neither difficult nor costly, and are successful even in developing countries [5].

Except with stringent controls, serology is prone to false-positive results, and does not distinguish between current infection, past infection and previous vaccination [1]. Polymerase chain reaction is demanding and costly and maybe too sensitive – detecting even transient colonization before elimination by an immune host who poses no threat to contacts [1].

Because similar coughing, though of shorter duration, may be caused by other bacteria and viruses, pertussis should not be diagnosed without positive culture, unless severe coughing has persisted for at least 3 weeks.

## Therapeutic Principles

Most antibiotics have little or no effect when pertussis is well established; but clarithromycin or other macrolide may reduce the severity of disease if given before the paroxysmal stage, and may eliminate the organism if given for 14 days [1]. Palliative treatment, given cautiously, may suppress the paroxysms. But, with no really effective therapy, prophylaxis is essential – by the widespread use of pertussis vaccine.

Whole-cell vaccine is safe and highly effective, provided that it contains *both* of the type-specific *Aggs 2 and 3*, and includes adjuvant to enhance the antibody response (especially to Agg 3 which is a weaker immunogen), and is given in at least three doses at monthly intervals *starting no earlier than age 3 months*, to maximize the immune response and minimize adverse reactions [2].

Acellular vaccines containing the mouse-virulence factors PT, FHA and ACT give few adverse reactions but low efficacy. A large Swedish trial with reliable diagnosis by bacterial culture [2] showed better protection when fimbriae were included, but the highest efficacy was seen with whole-cell vaccine. Moreover, acellular vaccine is unnecessarily costly, especially for developing countries, where the need is greatest.

Eradication of pertussis is undoubtedly achievable, by the use of an optimal schedule of good whole-cell

vaccine to establish herd immunity which protects infants too young for active immunization.

# Wiedemann-Beckwith Syndrome

Alessandra Baumer
Institute of Medical Genetics, University of Zurich, Scherzenbach, Switzerland

## Synonyms

Beckwith-Wiedemann syndrome; BWS (MIM 130650); and the nowadays rarely used designation "Exomphalos-macroglossia-gigantism syndrome"; EMG syndrome

## Definition and Characteristics

BWS is an "overgrowth syndrome." The syndrome is due to disruption of a balanced expression of paternally and maternally imprinted genes at 11p15.5. The main characteristics of BWS include exomphalos, pre-and postnatal overgrowth, and macroglossia.

## Prevalence

The BWS is a rare genetic disorder affecting approximately 1 in 15,000 live births. The syndrome usually occurs sporadically although familiar transmission has been estimated to account for about 15% of cases.

## Genes

A number of genes in the critical region at 11p15.5 have been described to be imprinted. The following genes have been shown to play an important role in BWS: CDKN1C, KCNQ1OT1, IGF2, and H19.

## Molecular and Systemic Pathophysiology

Loss of imprinting at the chromosome region 11p15.5 causes the Beckwith-Wiedemann syndrome. The balanced expression of the genes IGF2 (expressed from the paternal allele) and CDKN1C (alias $p57^{KIP2}$, expressed from the maternal allele) appears to be crucial. The expression of the two genes is regulated separately, whereby two further imprinted genes play important regulatory roles: the maternally expressed H19 gene modulates the expression of IGF2 and the paternally expressed KCNQ1OT1 (alias LIT1) regulates the expression of CDKN1C [1–4].

A range of genetic defects are known to underlie the syndrome: i.e., abnormal methylation at KCNQ1OT1, at H19, or at IGF2; mosaic paternal uniparental disomy for at least 11p15 (patUPD11p), duplications, translocations, and inversions; and, in certain human populations, mutations in the CDKN1C gene.

## Diagnostic Principles

The clinical symptoms of BWS may range from rather mild to severe, the clinical diagnosis is based on the occurrence of typical features such as exomphalos, pre- and postnatal overgrowth (often asymmetric), macroglossia, and typical ear-lobe creases. The clinical diagnosis is usually made in early infancy, at times prenatally, and, due to the fact that the symptoms usually ameliorate within the second decade of life, only rarely in adulthood.

The molecular investigation of BWS is rather complex and includes the analysis of the methylation status at KCNQ1OT1, H19, and IGF2; as well as microsatellite analysis for the investigation of a possible patUPD11p and duplications. The detection of inversions, duplications, and translocations usually relies on conventional cytogenetic investigations.

## Therapeutic Principles

No therapy is available. At birth BWS patients often present with hypoglycemia, requesting a close monitoring of the levels of glucose in blood. Due to the increased risk for most BWS patients to develop childhood cancer (e.g., Wilms tumor), screenings need to be performed on a regular basis. The only group of patients with no particular increase in tumor susceptibility appears to be that of patients with an isolated abnormal methylation pattern at KCNQ1OT1, thus larger intervals between screenings could be performed for such patients [5].

# Wilms Tumor, Aniridia, Genitourinary Anomalies and Mental Retardation Contiguous Gene Deletion Syndrome

Yoji Nagashima[1], Yohei Miyagi[2]
[1]Department of Molecular Pathology, Yokohama City University Graduate School of Medicine, Yokohama, Japan
[2]Molecular Pathology and Genetics Division, Kanagawa Cancer Center Research Institute, Yokohama, Japan

## Synonyms

WAGR

## Definition and Characteristics

Clinical association of *W*ilms tumor, *a*niridia, *g*enitourinary anomalies, and mental *r*etardation, caused by a de novo deletion in the distal band in chromosome 11p13, which encodes the WT1 (Wilms tumor 1) gene and the PAX6 ocular development gene [1]. Because of occasional association with gonadoblastoma, some investigators have cited that "G" of WAGR should stand for gonadoblastoma [2].

## Prevalence

The prevalence of heterozygotes is reported for Swedish and Italian populations to exceed 1%.

## Genes

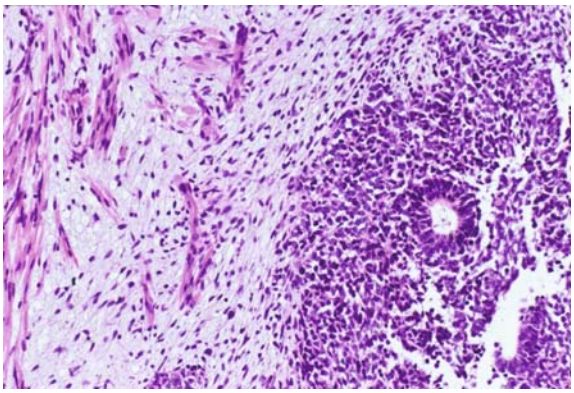
In WAGR syndrome, the patients present a contiguous deletion of chromosome 11p13, including PAX6 coding for a transcription factor essential for ocular development, localized on chromosome 11p13 [3], and WT1 coding for a transcription factor essential for genitourinary development, localized on chromosome 11p13 [1].

## Molecular and Systemic Pathophysiology

The WT1 protein is a transcription factor essential for genitourinary development, which negatively regulates expression of EGR1, IGF2, PDGF, and PAX2 genes. It has also been known as a tumor suppressor gene for Wilms tumor. Actually, in mice, disruption of the WT1 gene causes genitourinary malformation, which interprets the symptoms of WAGR syndrome. On the other hand, the PAX6 gene encoded in the neighboring locus is also involved in this syndrome. PAX6 is an important gene for ocular development. Combined chromosomal deletion of these genes is considered to be the cause of WAGR syndrome.

## Diagnostic Principles

In the neonate, the combination of sporadic aniridia along with genital anomalies alerts the clinician to consider the possibility of WAGR syndrome, although genitourinary anomalies may not be present, particularly in girls. In older children, clinical diagnosis can be made when aniridia and one of the other features are present. When WAGR syndrome is suspected,



**Wilms Tumor, Aniridia, Genitourinary Anomalies and Mental Retardation Contiguous Gene Deletion Syndrome. Figure 1** Representative histology of Wilms tumor. The tumor is composed of blastemal, organoid, and stromal elements. In this case, the stromal element showed differentiation to the striated muscle [4].

a combination of lymphocyte high resolution chromosome study and molecular cytogenetic fluorescent in situ hybridization is recommended to demonstrate the characteristic deletion and confirm the diagnosis [1].

## Therapeutic Principles

The therapeutic principles for WAGR syndrome are basically symptomatic, that is, plastic surgery for genitourinary malformation, periodic survey for each symptom (especially for Wilms tumor), and support for the patient and family. Once the diagnosis of WAGR syndrome is confirmed, ultrasound screening for Wilms tumor is usually initiated and continued until age 6 [1].

# Wilson Disease

Peter Ferenci
Department of Internal Medicine III, Gastroenterology and Hepatology, Vienna Medical University, Vienna, Austria

## Definition and Characteristics

Wilson disease (WD) is an autosomal recessive inherited disorder of copper metabolism resulting in pathological accumulation of copper in many organs and tissues.

WD may be present under a variety of clinical conditions, the most common ones being liver disease and neuropsychiatric disturbances. A characteristic clinical finding is Kayser-Fleischer rings, which are present in 95% of patients with neurologic symptoms, in 50–60% of patients without neurologic symptoms, and in only 10% of asymptomatic siblings. The ring is not always detected by clinical inspection but requires a slit lamp examination.

Liver disease may mimic any forms of liver conditions, ranging from asymptomatic transaminasemia to acute hepatitis, fulminant hepatic failure (about one out of six patients with hepatic presentation), chronic hepatitis, and cirrhosis with all of its complications. Frequently, Kayser-Fleischer rings are absent and plasma ceruloplasmin is in the normal range. Chronic liver disease may precede neurologic disease by many years. Patients can present with liver disease at any age from below the age of 3 up to patients in their seventies [1].

Neurologic symptoms usually develop in mid-teenage or in the twenties but may occur much later in life. The most common symptoms are dysarthria, dysphagia, apraxia, and a tremor-rigidity syndrome. About one third of patients present with psychiatric abnormalities.

## Prevalence

By a population-based approach, the incidence of WD was estimated to be at least 1:30,000–50,000 with a gene frequency of 1:90 to 1:150. Among selected groups of patients, WD is certainly more frequent. About 3–6% of patients transplanted for fulminant hepatic failure and 16% of young adults with chronic active hepatitis of unknown origin have WD.

## Genes

The WD gene is localized on human chromosome 13 and codes for a copper transporting P-type ATPase, ATP7B. The functionally important regions of the WD gene are six copper binding domains, a domain involved in the transduction of the energy of ATP hydrolysis to cation transport, a cation channel and phosphorylation domain, an ATP-binding domain, and eight hydrophobic regions predicted to span the cell membrane.

Close to 400 mutations occurring throughout the whole gene were documented so far (http://www.medicalgenetics.med.ualberta.ca/wilson/WND%20mutation%202.16.1web.xls). Mutations include missense and nonsense mutations, deletions, and insertions. Some mutations are associated with a severe impairment of copper transport resulting in severe liver disease very early in life; other mutations appear to be less severe with disease appearance in mid-adulthood. While most reported mutations occur in single families, a few are more common. The H1069Q missense mutation occurs in 30–60% of patients of Eastern-, Northern-, and Central-European origin [2]. The Arg778Leu mutation is present in 27% of Taiwanese patients, but not found in non-Oriental patients.

## Molecular and Systemic Pathophysiology

The basic defect in WD is the impaired biliary excretion of copper resulting in the accumulation of

copper in various organs including the liver, the cornea, and the brain (for review, see [3]). Excess copper in tissues leads to the production of free radicals and to DNA-cleavage. Probably the greatest source of damage is through the production of free radicals. Copper overload affects mitochondrial respiration and causes a decrease in cytochrome C activity. Damage to mitochondria is an early pathological effect in the liver. Hepatocellular damage due to increased lipid peroxidation and abnormal mitochondrial respiration was shown both in copper-loaded dogs and in patients with WD. The mechanisms triggering copper-induced lipid peroxidation are unknown, but it is conceivable that hepatic copper accumulation renders patients with WD susceptible to any oxidative stress. Copper may be directly toxic to neurons or may exert its effects by selective inhibition of brain MAO-A. Copper is an essential component of enzymes such as lysyl oxydase, superoxyde dismutase, cytochrome C, tyrosinase, and DOPA-ß-mono oxygenase. Dietary copper intake (about 1–4 mg/day) far exceeds the trace amounts required. Most of the ingested copper is taken up by the liver by an insaturable, carrier-mediated, energy-independent mechanism. Because hepatic uptake of dietary copper is not saturable, hepatic copper accumulation can easily be induced. Toxicity of copper, however, depends on its molecular association and subcellular localization rather than on its concentration in the liver. Metallothionein-bound copper is nontoxic. Excess copper is secreted into the bile. One of the pathways involves ATP7B. ATP7B is located in the trans-Golgi network and may also function in the intrahepatic copper trafficking coupled with the synthesis of ceruloplasmin and excretion into the bile.

## Diagnostic Principles

The diagnosis of WD can be made, if two of the three symptoms, namely, Kayser–Fleischer rings, typical neurologic symptoms, and low serum ceruloplasmin levels, are present [4] (Table 1). Brain magnetic resonance imaging (MRI) is useful to document the extent of changes in the central nervous system. The common abnormalities are changes in signal intensity of gray and white matter, and atrophy of the caudate nucleus, brain stem, cerebral, and cerebellar hemispheres. Diagnosis is far more complex in patients presenting with liver diseases. None of the commonly used parameters alone allow a certain diagnosis of WD. Usually a combination of various laboratory parameters is necessary to establish the diagnosis [5].

*Kayser-Fleischer rings* may be absent in up to 50% of patients with Wilsonian liver disease and even in a higher proportion in fulminant WD.

*Serum ceruloplasmin* is decreased in most patients with neurologic WD, but is in the low normal range in up to 45% of patients with hepatic disease. Even a low ceruloplasmin level is not diagnostic for WD in the absence of Kayser–Fleischer rings. Thus, in patients with liver disease, a normal ceruloplasmin level cannot exclude, nor is a low level sufficient to make the diagnosis of WD.

*Urine copper excretion* is markedly increased in patients with WD, however, its usefulness in clinical practice is limited. On the other hand, urinary copper excretion is also increased in any disease with extensive hepatocellular necrosis.

*Hepatic copper content* is more than fivefold increased in WD. In the absence of other tests suggestive for abnormal copper metabolism, diagnosis of WD cannot

**Wilson Disease. Table 1** Routine tests for diagnosis of WD

| Test | Typical finding | False "negative" | False "positive" |
|---|---|---|---|
| Serum ceruloplasmin | Decreased | Normal levels in pts. with marked hepatic inflammation | Low levels in: |
| | | | – Malabsorption |
| | | Overestimation by immunologic assay | – Aceruloplasminemia |
| | | | – Liver insufficiency |
| | | | – Heterozygotes |
| 24-h urinary copper | >100 µg/day | Normal: | Increased: |
| | | – Incorrect collection | – Hepatocellular necrosis |
| | | – Children without liver disease | – Contamination |
| Serum "free"copper | >10 µg/dl | Normal if ceruloplasmin overestimated by immunologic assay | |
| Hepatic copper | >250 µg/g dry weight | Due to regional variation | Cholestatic syndromes |
| | | – In pts with active liver disease | |
| | | – In pts with regenerative nodules | |
| Kayser–Fleischer rings by slit lamp | Present | – In up to 40% of patients with hepatic WD | Primary biliary cirrhosis |
| | | – In most asymptomatic siblings | |

be made based or excluded on an increased hepatic copper content alone.

*Liver biopsy findings* are generally nonspecific and not directly helpful for the diagnosis of WD. The detection of focal copper stores by the Rhodanin stain is a pathognomic feature of WD but is only present in the minority (about 10%) of patients. The ultrastructural abnormalities include changes of mitochondria and peroxisomes.

*Mutation analysis*: Direct moleculargenetic diagnosis is difficult because of the occurrence of many mutations, each of which is rare. Because of the complexity in identifying the many mutations in WD, haplotypes can be used to screen for mutations and to examine asymptomatic siblings of index patients. Today, mutation or haplotype analyses are the only reliable tools for family screening.

## Therapeutic Principles

D-Pen acts by reductive chelation: it reduces copper bound to protein and decreases thereby the affinity of the protein for copper. The usual dose of D-Pen is 1 to 1.5 g/day. Once the clinical benefit is established, it is possible to reduce the dosage of D-Pen to 0.5 to 1 g/d. Supplementation with pyridoxine (50 mg/week) prevents deficiency induced by D-Pen. A major problem of D-Pen is its high level of toxicity. Immunologic mediated side-effects like leukopenia, thrombocytopenia, systemic lupus erythematodes, immune complex nephritis, and Goodpasture syndrome require immediate cessation of D-Pen.

Trientine is also a copper chelator with fewer side effects. In the early phase of treatment trientine appears to be more potent to mobilize copper than penicillamine, but cupriuresis diminishes more rapidly than with penicillamine.

Ammonium tetrathiomolybdate has two mechanisms of action. First, it complexes with copper in the intestinal tract and prevents thereby absorption of copper. Second, the absorbed drug forms a complex with copper and albumin in the blood and renders the copper unavailable for cellular uptake. There is very limited experience with this drug. Tetrathiomolybdate appears to be the useful form of initial treatment in patients presenting with neurologic symptoms.

Zinc interferes with the intestinal absorption of copper by blocking the Zn–Cu carrier and by zinc inducing metallothionein in enterocytes and hepatocytes. Data on zinc in the treatment of WD are derived mostly from uncontrolled studies using different zinc preparations at different doses (75–250 mg/day). It appears safe to switch D-pen decoppered patients to zinc for maintenance therapy. The role of zinc as first line therapy given alone or in combination with chelation therapy remains to be established.

Liver transplantation is the treatment of choice in patients with fulminant WD and in patients with decompensated cirrhosis. Besides improving survival, liver transplantation also corrects the biochemical defect underlying WD. However, the role of this procedure in the management of patients with neurological WD in the absence of hepatic insufficiency is still uncertain.

# Wiskott-Aldrich Syndrome

Julian Ilcheff Borissoff, Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

WAS; Eczema-thrombocytopenia-immunodeficiency syndrome; Immunodeficiency 2; IMD2

## Definition and Characteristics

WASp is an intracellular protein expressed in hematopoietic stem cell derived lineages. It belongs to a family of signal transduction proteins related to the actin cytoskeleton. WASp is an effector protein for CD42, a member of small GTP-binding proteins. The absence of WASp leads to defective cell mobility and phagocytosis [1].

## Prevalence

Rare disease. Incidence approximately 1: 250,000 in a European population.

## Genes

X-linked disease due to mutations in a gene located on the short arm of chromosome X that encodes a 502 amino acid protein (WASp).
*Gene map locus*: Xp11.23-p11.22.

## Molecular and Systemic Pathophysiology

More than 100 different mutations have been identified, most of which are amino acid substitutions.

There is no clearcut association between genotype and phenotype. However, nonsense and frameshift mutations have been more frequently associated with severe immunodeficiency. The pathophysiological association is based on the effects of WASp on cell contractility and function. The bleeding tendency is due to a combination of reduced platelet count in peripheral blood (differentiation at stem cell level probably normal) and platelet size. The small dysmorphic platelets are destroyed by the spleen, worsening the bleeding risk [2].

*Clinical Features*: Patients with WAS suffer from a bleeding tendency in combination with a severe immune deficiency that worsens during childhood. The bleeding tendency ranges from minor purpura to major and life-threatening bleeding in brain or intestines. Immune dysfunction is characterized by increased rates of infections, eczema, autoimmune conditions, vasculitis, arthritis, inflammatory bowel disease and lymphoproliferative disorders. The median survival is around 15 years [1]. Female carriers are usually asymptomatic due to preferential inactivation of the mutated X chromosome.

## Diagnostic Principles

The disease is suspected on the basis of the indicated clinical features. Laboratory diagnosis is supported by thrombocytopenia (44% of patients have a count $<20 \times 10^9$ platelets/l) in conjunction with small platelet volume (MPV < 5 fl). Bleeding time may be prolonged more than would be expected based on platelet counts. A moderate storage pool deficiency is demonstrable. In time a progressive decrease in numbers and function of T-lymphocytes is noted. Serum IgM decreased, IgA and IgE increased.

## Therapeutic Principles

Splenectomy has been shown to raise the platelet counts and bleeding complications may become less frequent and better manageable. The addition of prophylactic antibiotics and intravenous immunoglobulins may improve prognosis substantially. Bone marrow transplantation has been carried out in a number of patients with WAS [3].

## Synonyms

Deletion 4p; Monosomy 4p; 4p-Syndrome

## Definition and Characteristics

Multiple congenital anomalies/mental retardation syndrome with pre-postnatal growth deficiency, hypotonia, typical craniofacial features consisting of "Greek warrior helmet appearance" of the nose, microcephaly, high forehead with prominent glabella, ocular hypertelorism, epicanthus, highly arched eyebrows, short philtrum, downturned mouth, micrognathia, and poorly formed ears with pits/tags (Fig. 1) [1].
Seizures occur in most patients.

## Prevalence

Estimates place the prevalence of WHS at about 1/50,000 births, with a 2:1 female/male ratio.

## Genes

A molecular approach has been utilized to define the size of the critical region of WHS. A series of cosmids spanning 4.5 Mb from the 4p telomere to the marker D4S81 was used to analyze metaphase spreads from individuals with WHS. Using this technique, the WHCR was reduced to 165 kb [2]. The 165-kb WHCR lies between the markers D4S166 and D4S3327 and contains two genes of unknown function, WHSC1 and WHSC2. Using the landmark cosmid set and a series of second-tier cosmids, the deletion in an individual can be defined with a high degree of confidence. Two patients have been identified that have ~1.9-Mb deletions which overlap with the current distal breakpoint of the WHCR. In both these cases, it is likely that the function of WHSC1 will be disrupted. At present, the only gene that appears to be affected in all WHS patients is WHSC1. However, the variation in severity of the clinical phenotype suggests possible roles for additional genes, including WHSC2 and LETM1, which are located proximally and distally to WHSC1, respectively.

## Molecular and Systemic Pathophysiology

WHSC1 is a novel gene that spans a 90-kb genomic region, two-thirds of which maps in the telomeric end of the WHCR [3]. The temporal and spatial expression of WHSC1 in early development and the protein domain identities suggest that it may play a significant role in normal development. Its deletion is likely to be involved in WHS.

WHSC2 spans a 26.2-kb genomic region and is ubiquitously expressed. Its location in the WHCR and the identification of a mouse homologue, Whsc2h, suggest that it encodes a protein that may play a role in WHS.

LETM1 has been suggested as a candidate gene for the neuromuscular aspects of the phenotype in WHS, and its position immediately distal to the WHCR means

**Wolf-Hirschhorn Syndrome. Figure 1** A 3 year-4-month-old girl with Wolf-Hirschhorn syndrome.

it is deleted in almost all patients. In yeast, it has been shown to be involved in mitochondrial $K^+$ homeostasis.

Much work is still to be done to identify the function of WHSC1, WHSC2, and LETM1 in both normal development and in WHS, and to characterize any remaining genes in the WHCR. Only WHSC1 is affected in all patients, but the genes that are located both proximally and distally to WHSC1 are deleted in many patients and may play a role in some aspects of the phenotype. As detailed breakpoint analysis of deletions becomes available, it may be easier to define genotype–phenotype correlations for small deletions. This may allow further understanding of the role that genes both within and outside the WHCR play in this condition. Mice were generated bearing deletions of varying sizes that spanned the WHCR syntenic region. The phenotype of these animals was variable, including seizures, midline, craniofacial, and ocular defects.

## Diagnostic Principles

The association of distinctive facial features ("Greek warrior helmet appearance"), microcephaly, pre-postnatal growth deficiency, psychomotor delay/mental retardation, hypotonia, and seizures points to the disorder. Deletion of the Wolf–Hirschhorn critical region, on chromosome 4p16.3, is the only known cause of the disorder. Seventy five percent of individuals with WHS have a de novo deletion of 4p16; about 13% have deletion of 4p16 as the result of having inherited an unbalanced chromosome rearrangement from a parent with a balanced rearrangement; 12% have either a ring chromosome 4, 4p- mosaicism, or a sporadic unbalanced translocation [4,5].

## Therapeutic Principles

Adequate caloric intake (by increased caloric formulas and/or oral or nasogastric tube feeding, or gastrostomy) is necessary to improve poor growth. Phenobarbital or valproic acid are useful to control clonic or tonic-clonic seizures; valproic acid, alone or in combination with ethosuccimide, is the first choice drug to control atypical absences; i.v. benzodiazepines can control clonic, tonic-clonic, absence or myoclonic status epilepticus. Antibiotic prophylaxis is indicated in all cases of vesicoureteric reflux. A trial of hearing aids is suggested in children with abnormal audiological evaluation. Treatment of eye, dental, and musculoskeletal anomalies follows standard practice. Intravenous immunoglobulin infusions or prophylactic antibiotics may benefit those children with immunodeficiency. Physical therapy is needed to improve the reduced muscle tone. Referral to early intervention programs is recommended in the ongoing care of these children, together with enrollment in an individualized rehabilitation program covering motor aspects, cognition, communication, and socialization. Appropriate school placement is of paramount importance. Planning for transition to adulthood should begin in adolescence [5].

## X and Y Polysomies, in Males

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

### Synonyms

48, XXYY

### Definition and Characteristics

48, XXYY is characterized by addition of an extra X and Y chromosome to a male 46,XY karyotype.

### Prevalence

The estimated prevalence is 1:50,000 newborns. Up to now, about 100 cases have been reported in the literature [1].

### Genes

Karyotype is 48, XXYY.

### Molecular and Systemic Pathophysiology

Except for tall stature and longish habitus, physical features are rather unspecific. They include mild craniofacial dysmorphisms, macrocephaly, minor skeletal anomalies, obesity and genital hypoplasia. Like patients with Klinefelter syndrome, 48, XXYY males show

atrophic testes and variable features with respect to penis size, hair distribution, gynecomastia and body contour. Mental retardation occurs in the majority of cases with a widespread variation of IQs. Psychosocial development and behavioral disturbances of 48, XXYY males represent an overlap between the 47, XXY and 47, XYY phenotype: they are, on one hand, shy and have difficulties in forming relationship; on the other hand, they often suffer from severe behavioral difficulties (temper tantrums, psychotic episodes, violent and impulsive reactions, etc. ) [2].

In conclusion, 48, XXYY males do not present with distinctive physical stigmata but show characteristic features with respect to psychosocial development and behavior [3].

### Diagnostic Principles

Diagnosis is made by karyotyping.

### Therapeutic Principles

Supportive treatment.

## X Chromosome Trisomy and Tetrasomy

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

### Synonyms

48, XXXY; 49, XXXXY

### Definition and Characteristics

X chromosome trisomy and tetrasomy in males represent a distinct group of disorders and should not be regarded as "Klinefelter variants." The most significant effects of additional X chromosomes on the phenotypes are lowering of IQ and an increase in somatic malformations [1].

### Prevalence

Tetrasomy X in men is more common than trisomy X and occurs with an incidence of about 1:85,000 male live births.

### Genes

48, XXXY; 49, XXXXY.

### Molecular and Systemic Pathophysiology

*48, XXXY*: The phenotype of trisomy X in men is characterized by mild facial dysmorphisms (coarse face with epicanthic folds and prognathism), moderate mental retardation, distinct genital hypoplasia and skeletal anomalies (radioulnar synostosis, kyphosis). Puberty is often delayed and mean height is normal. 48, XXXY karyotype is often associated with severe behavioral problems. Reports to date show that the extra sex chromosomes always originate from the same parent [2,3].

*49, XXXXY*: The clinical features include typical facial features (quadrangular head shape, full round face, epicanthic folds, upward slanting palpebral fissures, ocular hypertelorism, a broad and depressed nasal bridge, prognathism), variable degree of mental impairment (ranging in adulthood from moderate to profound), severe speech disturbances, particular habitus (eunnuchoid appearance, long, thin and tapering arms and legs), skeletal (radioulnar synostosis, scoliosis and kyphosis), genital (hypogonadism) and cardiac (most common PDA) abnormalities. Prenatal growth is reduced but growth is average or increased postnatally. In infancy, boys are often misdiagnosed as having Down syndrome, but the facial features and body habitus change over the years [2,3].

### Diagnostic Principles

Diagnosis is made by karyotyping.

### Therapeutic Principles

Supportive treatment.

Trisomy X; Triple X; Tetrasomy X; Pentasomy X; 47, XXX; 48, XXXX; 49, XXXXX

## Definition and Characteristics

47,XXX is characterized by an extra X chromosome that is of maternal origin in the majority of cases [1]. Females with X trisomy cannot be identified at any age by specific physical or behavioral features and might not come to medical attention, therefore, in the majority of cases. Trisomy X results from non-disjunction in meiosis I or II and rarely from post-zygotic non-disjunction. The mechanism underlying tetrasomy X and pentasomy seems to be successive non-disjunction in maternal meiosis I and II [2].

## Prevalence

It has been estimated that 47, XXX occurs in approximately 1:1,000–1,200 female newborns. Unlike in 45, X, prenatal loss of 47, XXX fetuses after mid-gestation is rare. Only about 40 individuals with tetrasomy X have been described so far. Pentasomy X is even more rare.

## Molecular and Systemic Pathophysiology

47, XXX: While birth weight tends to be low, the majority of girls reach height above the 75th centile during adolescence. Relative microcephaly and minor dysmorphisms might be present (epicanthic folds, hypertelorism, depressed nasal bridge, clinodactyly of the fifth fingers). Rare findings include malformations of the heart and urogenital system (cloacal exstrophy, renal anomalies). Puberty usually occurs uneventfully. Most women with trisomy X have normal reproductive capacities. However, premature ovarian failure has been repeatedly reported. The risk of giving birth to children with sex chromosome aneuploidy does not appear to be substantially increased for women with the 47, XXX karyotype. Delayed acquisition of gross motor skills and mild language and cognitive disabilities are often observed in triple X girls. They tend to be rather passive and are prone to behavior problems such as depression. However, the variability in intelligence and behavior is much larger than originally suspected [3,4].

48, XXXX are usually tall and microcephalic. Facial dysmorphisms include epicanthic folds, hypertelorism, and a flat nasal bridge. Radio-ulnar synostosis is often reported. Genitalia are generally normal but secondary sexual characteristics are incompletely developed. Mental retardation (ranging from mild to moderate) has consistently been reported and problems of behavior are frequent.

49, XXXXX show intrauterine and postnatal growth retardation and a more severe somatic and developmental phenotype than girls with tetrasomy X. The clinical features include microcephaly, coarse facial features, and a short and broad neck. Congenital heart defects, malformations of the kidneys, radio-ulnar synostosis, and joint laxity have been reported. Puberty is delayed and there are no data about fertility of females with pentasomy X. Mental retardation is always present.

## Diagnostic Principles

Karyotyping discloses the disorders.

## Therapeutic Principles

If necessary, management includes treatment of associated abnormalities and supportive measures fostering mental development and providing psychological support.

# X Polysomy, in Males

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

## Synonyms

Klinefelder Syndrom

## Definition and Characteristics

Klinefelter syndrome is characterized by addition of one extra X chromosome to a male 46, XY karyotype. Consistent clinical features include increased mean height and infertility. The extra X chromosome results from non-disjunction of sex-chromosomes during the

first (or less frequently the second) meiotic division in either parent. It is contributed slightly more often by the mother than the father [1]. There is an age effect for the cases where both X chromosomes originate from the mother.

## Prevalence

Klinefelter syndrome is the most common sex chromosome aneuploidy in men, the estimated frequency is 1:500–1:1,000 male births.

## Genes

Klinefelter syndrome is due to addition of one extra X chromosome (47, XXY).

## Features and Natural History

### *Somatic phenotype*

*Infancy and childhood*: Newborns usually show no significant dysmorphisms. Weight, height and head circumference at birth are within normal ranges.

*Pre-pubertal boys*: Height velocity is already increased during childhood. By adolescence, the height usually lies above the 75th centile. Mean head circumference remains average and the boys show a long face with narrow forehead. Before puberty, sexual development (penile length, testicular volume, testosterone and gonadotropin levels) are normal.

*Puberty*: Onset of puberty is normal, but by mid- to late-adolescence most males are hypergonadotropic with normal to low levels of testosterone. As a consequence, penile growth is decreased and testicular growth arrested. In this stage, testes are small and firm and hyalinization and fibrosis of seminiferous tubules develops. The capacity of Leydig cells to produce testosterone decreases. Facial, axillary and body hair increase during puberty, but to a lesser degree than in 46, XY males. Muscle mass is normal but muscle strength is reduced.

*Adolescence and adulthood*: Physical features include increased mean height, sparse facial and body hair and gynecomastia (15–30%). Testes are small and ejaculate most often reveals azoospermia. Paternity of non-mosaic men with 47, XXY karyotype has only been reported occasionally.

Sexual functioning is normal

### *Behavioural phenotype*

Motor developmental is unremarkable in most infants with 47, XXY karyotype, and fine motor skills are usually well developed. However, cognitive difficulties (which are largely verbal) are common and the expressive verbal skills of the majority of 47, XXY boys lag behind their non-verbal skills. In addition, they often display poor attention and concentration and show more difficulties in social interactions. In adolescence, they tend to be shy, unassertive, more passive and less confident than their peers. Adult adaptation and work performance are poorly studied, but there is evidence for a remarkable catch up in social adjustment and cognitive abilities in adulthood [2]. Many men with 47, XXY karyotype marry. Whether there is an increased incidence of psychiatric difficulties is still controversially discussed [2,3].

### *Specific problems*

Without replacement therapy, the low level of testosterone increases the risk for developing osteoporosis in adulthood. The risk for developing extra-gonadal germ cell tumors and breast cancer is increased [4,5]. Men with 47, XXY karyotype also show a higher incidence of vascular insufficiency, leg ulceration, deep vein thrombosis and pulmonary embolism. In addition, the risk for several auto-immune disorders seems to be slightly increased.

## Diagnostic Principles

Diagnosis is made by karyotyping.

## Therapeutic Principles

Testosterone replacement therapy, supportive treatment.

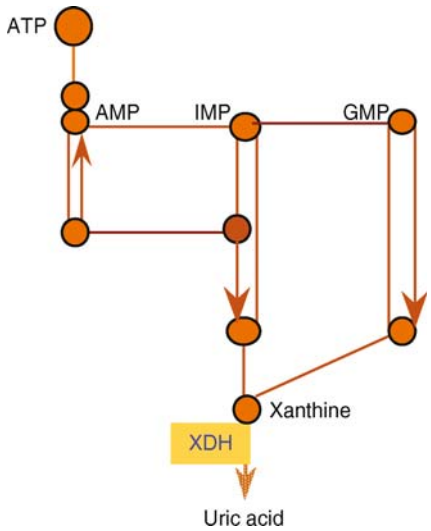
# Xanthine Dehydrogenase Deficiency

Anthony M. Marinaki, H. Anne Simmonds
Purine Research Laboratory, Department of Chemical Pathology, Guy's Hospital, London, UK

## Synonyms

Xanthine oxidase deficiency; Xanthine oxidoreductase deficiency; Hereditary xanthinuria; XDH



**Xanthine Dehydrogenase Deficiency.**
**Figure 1** Routes of ATP, AMP and GMP breakdown.

## Definition and Characteristics

Autosomal recessive. Xanthine and hypoxanthine replace uric acid in plasma and urine (Fig. 1). This illustrates the normal role of XDH (located principally in intestinal mucosa and liver in humans) in degrading xanthine to uric acid and hence the accumulation of xanthine in XDH deficiency [1].

## Prevalence

Rare, but reported from 22 countries, so not confined to any specific ethnic group. However, only 50% of UK patients are of Caucasian origin. At least 20% are asymptomatic and detected only by the low to absent plasma uric acid, during screening for an unrelated disorder. More frequent in hot climates (around the Mediterranean) than in Northern Europe [1].

## Genes

The XDH gene is located on chromosome 2p22–23. Two types of defect have been reported, Type I where patients lack only XDH activity, but have normal activities of aldehyde and sulphite oxidase (AOX, SO) and Type II (up to 50% of cases) where patients lack both functional XDH and AOX but have normal SO activity. In some Type II patients, a mutation has been reported involving a C to T base substitution at nucleotide 1255 causing a CGA (Arg) to TGA (Ter) nonsense substitution at codon 419 in the molybdenum cofactor sulphurase gene. This deletes the activity of XDH and AOX, but leaves SO intact [2].

## Molecular and Systemic Pathophysiology

Both types I and II are relatively benign. Severe pathology usually occurs only in molybdenum cofactor (MOCO) deficiency, which renders sulphite oxidase (SO) inactive also. However, MOCO can present with milder neurological deficits and renal problems and is diagnosed eventually from the low plasma urate. Whether XDH, because of its localisation, principally in liver and intestinal mucosa in humans, really has a role in ischaemia-reperfusion damage (as some propose) remains to be proven [3].

Types I and II are clinically similar, often presenting with acute renal failure, which unrecognised can lead to end-stage renal disease. Symptoms in 40% of patients include irritability, haematuria, urinary tract infection, renal colic, crystalluria or urolithiasis and sometimes myopathy due to xanthine crystals. All symptoms relate to the extreme insolubility and high renal clearance of xanthine and can manifest from birth to the 80s; 50% of cases are children. Presentation after a bout of diarrhoea, infection or intense physical activity is common. Adults with renal complications often have a history of urolithiasis dating back to childhood. Duodenal ulcers, myopathy or arthropathy have been reported in 10%. Muscle symptoms develop later. The nephrotoxicity of xanthine is supported by studies in pigs fed guanine and allopurinol. This precipitated acute renal failure due to xanthine deposits in distal tubules, epithelial damage, interstitial oedema, inflammation and eventually permanent renal damage.

Likewise, secondary xanthinuria occurs during treatment with allopurinol in disorders associated with endogenous uric acid overproduction, e.g., hypoxanthine–guanine phosphoribosyltransferase (HPRT) deficiency or in patients given allopurinol to prevent uric acid nephropathy during aggressive therapy for different malignancies [4].

## Diagnostic Principles

Both plasma and urine uric acid are low to absent, uric acid being replaced in urine by xanthine (Fig. 1) and to a lesser extent hypoxanthine (ratio approximately 4:1). Preferential accumulation and excretion of xanthine results from (i) extensive hypoxanthine recycling by HPRT for which xanthine is not a substrate in humans, excess xanthine deriving from guanine via guanase and (ii) high renal clearance of xanthine. Confirmation of the enzyme defect involves invasive techniques such as intestinal or liver biopsy, which are intrusive and rarely done. Pitfalls in diagnosis involve bacterial infection, which results in significant uric acid being found in the urine. Measurement of both plasma and urine uric acid is thus essential. Clinical consequences relate to the extreme insolubility of xanthine at any pH (0.5 mmol/l at pH 5.0, 0.9 mmol/l at pH 7.0) [4].

## Therapeutic Principles

A high fluid intake and a low purine diet is the only therapy. Vigorous exercise should be avoided. In many

patients lithotomy has been essential and extracorporeal shock wave lithotripsy with sonographic stone localisation has been used.

Genetic counselling and ante-natal diagnosis is inappropriate, except for the cofactor deficiency.

### Synonyms

Kynureninase deficiency; Hydroxykynureninuria

### Definition and Characteristics

Autosomal recessive disorder of tryptophan metabolism, consisting of excessive output of xanthutrenic acid, 3-hydroxykynurenine and kynurenine in urine following the oral loading of tryptophan.

### Prevalence

Unknown.

### Genes

A defect in the gene of kynureninase (KYNU).

### Molecular and Systemic Pathophysiology

The disorder is due to a defect in kynureninase, a vitamin $B_6$ dependent enzyme in the catabolic pathway of tryptophan metabolism. Both $B_6$-responsive and $B_6$-unresponsive types are known. Knapp [1] first described the disorder in three families and postulated disrupted tryptophan metabolism in patients. Tada et al. [2] reported this disorder in a brother and sister with mental retardation. The parents were first cousins. The patients excreted excessive amounts of xanthutrenic acid, kynurenic acid, 3-hydroxykynurenine and kynurenine in urine following tryptophan loading. The levels of pyridoxal phosphate in sera from the patients were found to be within normal limits. The disturbance in tryptophan metabolism was temporarily normalized by large doses of vitamin $B_6$. It was found that the activity of kynureninase in the liver of the patient was markedly reduced without addition of pyridoxal phosphate but the activity was restored to a considerable extent by the addition of an excess of pyridoxal phosphate [3]. Christensen et al. [4] identified a homozygous missense KYNU mutation in a boy with xanthurenic aciduria.

### Diagnostic Principles

Increase in xanthrenic acid in urine after tryptophan loading and the effect of vitamin $B_6$ on xanthrenic aciduria.

### Therapeutic Principles

Administration of vitamin $B_6$ and/or nicotinamide.

### Synonyms

Excision repair cross complementing in mice; ERCC

### Definition and Characteristics

Autosomal recessive disorder with seven subgroups called complementation groups (XP A-G) with heterogeneous clinical severity. Clinical features include extreme photosensitivity, dry skin, telangiectasia, freckling, hypo- and hyper-pigmentation and, most importantly, an up to 1000-fold increased risk for skin cancer. Neurological abnormalities occur in some complementation groups [1].

### Prevalence

In Western European populations the incidence is 0.9 per 1 million livebirths [2].

### Molecular and Systemic Pathophysiology

The disease is caused by a defect in the repair system nucleotide excision repair (NER). NER removes bulky DNA damage such as ultraviolet radiation-induced cyclobutylpyrimidine dimers, 6–4 photoproducts, Dewar isomers and cis-platin-induced DNA damage. XP proteins are essential components of the NER which repairs DNA lesions in transcribed (transcription-coupled repair) and untranscribed DNA (global genome repair). Genetic mutations in the XP genes cause XP [3]. Localisation of XP genes: XP-A: 9q22.3; XP-B 2q21XP-C: 3p25; XP-D: 19q13.2–q13.3, XP-E: 11p12–p11; XP-F: 16p13.3–p13.13 XP-G 13q33. One complementation group (XP variant) is defective in so called translesion synthesis of polymerase η past DNA damage and NER is normal (6p21.1–p12) [4]. Some XP proteins (XP-B and XP-D) are subunits of the basal transcription factor TFIIH and thus are also involved in basal gene transcription. Defective repair of UV-induced DNA lesions causes a hypermutable phenotype with a drastically enhanced risk to develop melanoma and non-melanoma skin cancer. Furthermore, immunological defects (impairment of NK cell function) have been reported which also supports carcinogenesis.

### Diagnostic Principles

Extreme photosensitivity with development of sunburn after short periods of sun-exposure already present in early infancy (first clinical hint). With increasing age freckling and development of (multiple) skin tumors starting in early childhood. The diagnosis is confirmed by measurement of the repair capacity in fibroblasts from the patient by unscheduled DNA synthesis (UDS), except the variant group where UDS is normal (see above). Diagnosis of complementation groups is done by cell fusion of fibroblasts from patients and known complementation groups or by transfection/microinjection of known XP plasmids into patients' cells. If UDS of fused cells is still abnormal cells and constructs, respectively, are of the same complementation groups. For diagnosis of XP-variant sequence analysis reveals mutations in the pol η gene.

### Therapeutic Principles

A new therapeutic principle is the topical application of xenogenic repair enzymes (T4N5 endonuclease, photolyase) in liposomes which reduce UV-induced DNA damage [5]. In addition, absolute protection from exposure to UV radiation (limited outdoor activities, protective clothing, plastic window-covers filtering UV radiation, ultrapotent sunscreens) is warranted.

# Y Polysomies, in Males

Deborah Bartholdi, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

## Synonyms

47, XYY; 48, XYYY

## Definition and Characteristics

47, XYY is characterized by addition of an extra Y chromosome to a male 46,XY karyotype. Since this aneuploidy is not characterized by distinctive physical features nor reduced fertility or a recognizable developmental pattern, the vast majority of 47,XYY individuals do not come to medical attention. The additional Y chromosome derives from nondisjunction during paternal meiosis II or (less frequently) postzygotic mitotic nondisjunction [1]. The condition is not associated with increased paternal age and it is not subject to negative selection before birth. Individuals carrying poly-Y karyotypes with three Y chromosomes are usually identified by tall stature and behavioral disturbances.

## Prevalence

47, XYY occurs in 1:1000 male births, 48, XYYY Poly-Y karyotypes containing three Y chromosomes are very rare.

## Molecular and Systemic Pathophysiology

*Growth and physical development*: Weight and length of newborns with an extra Y-chromosome (47, XYY) are indistinguishable from 46, XY newborns. Mild but unspecific dysmorphisms of the face or limbs (clinodactyly) might be present. There is no increase in the incidence of malformations. Rare findings include lymph edema, renal malformations, and radioulnar synostosis. Accelerated linear growth might be present already in early childhood and by adolescence, the majority of 47, XYY males reach the 75th centile.

*Intelligence and behavior*: The commonest indication for karyotyping in boys with 47, XYY are tall stature in combination with developmental delay and/or behavioral difficulties. Population-based studies have repeatedly shown mild developmental delay and intellectual abilities lower than those of their siblings in 47, XYY males. However, it remains open, to which degree these observations result from ascertainment bias [2,3]. During school age, learning disabilities, expressive and receptive language difficulties, hyperactivity and temper tantrums are often observed in 47, XYY boys. In adolescence, a predisposition to behavioral problems in settings of stressful environment becomes manifest and 47, XYY adults show a higher frequency of "antisocial" behavior and of criminal convictions than controls. It seems, however, that these features are mediated through lowered intelligence [4,5].

*Fertiliy*: Pubertal development, testicular histology, and spermatogenesis are normal in the majority of 47, XYY males. The risk of chromosomally abnormal offspring to 47, XYY males is only minimally increased, which has been hypothesized to be due to elimination of the extra Y chromosome during spermatogenesis in the majority of cells.

48, XYYY individuals are tall and present with major behavioral disturbances (impulsive, low frustration tolerance), developmental delay, and low-normal to subnormal intelligence. The physical findings (with the exception of clinodactyly and inguinal hernia) are inconsistent. Features reported in single patients include abnormal dentition, radioulnar synostosis, strabismus, myopia. 48, XYYY males usually show hypergonadotropic hypogonadism and azoospermia seems to be common.

## Diagnostic Principles

Diagnosis is made by karyotyping.

## Therapeutic Principles

Supportive treatment.

## Zinc Deficiency and Excess

Ananda S. Prasad
Department of Medicine, Division of Hematology-Oncology, Wayne State University, University Health Center, Detroit, MI, USA

### Definition and Characteristics

Zinc deficiency in humans was first recognized and characterized in 1963 [1]. Growth retardation due to zinc deficiency affecting children, adolescents, infants and fetuses, has been observed in many countries. Other manifestations of zinc deficiency include hypogonadism mainly affecting adolescent males, rough and dry skin, mental lethargy, poor appetite, delayed wound healing, frequent inter-current infections and abnormal neuro-sensory disorders. ►Acrodermatitis enteropathica (AE) that usually occurs in infants of Italian, Armenian or Iranian lineage is a lethal, autosomal, recessive trait disorder, caused by severe deficiency of zinc, resulting from genetically determined decreased zinc absorption. The gene for AE has now been characterized [2]. The clinical manifestation of AE includes bullous pustular dermatitis, blepheritis, conjunctivitis, corneal opacities, neuro-psychiatric disorders, weight loss, growth retardation, repeated severe inter-current infections and death if not treated with zinc [3]. Nutritional deficiency of zinc is prevalent in developing countries where the diet consists of mainly cereal proteins rich in phytate, an organic phosphate compound which binds zinc resulting in decreased absorption and availability of zinc for physiological and biochemical functions. Zinc deficiency has been also observed in many diseased conditions and in the elderly. Excess ingestion of zinc (50 mg of elemental zinc daily) for 12 weeks or more causes copper deficiency and is manifested by microcytic anemia and neutropenia. Industrial exposure to zinc fumes results in acute clinical manifestations such as fever, nausea, vomiting and generalized weakness.

### Prevalence

It is estimated that nearly 2 billion subjects mainly in the developing countries may have a nutritional deficiency of zinc. A combined nutritional deficiency of both zinc and iron is fairly common inasmuch as both zinc and iron are made unavailable for absorption by high levels of phytate contained in cereal proteins. Toxicity due to excess zinc is uncommon.

### Genes

The AE gene ZIP4 encodes a tissue specific, zinc regulated zinc transporter. AE gene in human (hZIP4, SLC 39A4) is located on chromosome 8 q 24.3.

### Molecular and Systemic Pathophysiology

Over 300 enzymes require zinc for their functions. Over 2,000 transcription factors require zinc for maintenance of their structure and their binding to DNA. Thus zinc is involved in many biochemical functions [4]. It is required for cell division, cell proliferation, protein synthesis and apoptosis. Many growth factors are zinc dependent. Zinc deficiency results in cell-mediated immune dysfunctions and there is a shift from Th1 to Th2 functions [5]. This results in frequent infectious episodes.

### Diagnostic Principles

Plasma zinc is commonly used for the diagnosis of zinc deficiency. Measurement of zinc in lymphocytes and granulocytes is more sensitive than plasma zinc

for the diagnosis of zinc deficiency. Decreased gene expression of IL-2 in Th1 cells correctible with in vitro zinc addition may be a specific diagnostic test.

### Therapeutic Principles

Nutritional deficiency of zinc is corrected by oral zinc supplementation with 15–45 mg of elemental zinc. For prevention of blindness in patients with age related macular degeneration, 80 mg of elemental zinc daily orally was administered. Two mg of copper was also administered in order to prevent copper deficiency due to excess zinc. The major side effect of zinc excess in humans is copper deficiency, which can be treated effectively with oral administration of 2 mg copper daily.

## Zinsser-Engman-Cole Syndrome

►Dyskeratosis Congenita

## Zollinger-Ellison Syndrome

Roland Reinehr, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, University Hospital Duesseldorf, Duesseldorf, Germany

### Synonyms

Gastrinoma; ZES

### Definition and Characteristics

Zollinger and Ellison described a syndrome characterized by ulcerations in the upper jejunum, hypersecretion of gastric acid, and non-beta islet cell tumors of the pancreas [1]. Gastrin produced by those tumors called gastrinoma has been identified as the humoral agent responsible for this syndrome. Today, in most of the cases, diagnosis is established before development of the complications of peptic ulcer disease or spread of a malignant gastrinoma, and therapy that modifies the course of the disease is almost always possible. Mortality largely depends on tumor dignity and the extent of disease involvement.

### Prevalence

The Zollinger-Ellison syndrome (ZES) has an incidence of up to 1% in patients with a peptic ulcer disease [2]. Gastrinomas can either be sporadic or associated with so-called multiple endocrine neoplasia (MEN) type 1, an autosomal dominant predisposition to tumors of the parathyroid glands, anterior pituitary, and pancreatic islet cells.

### Molecular and Systemic Pathophysiology

Gastrinomas are derived from multipotent stem cells of endodermal origin, are known as enteroendocrine cells and are usually well differentiated. Gastrin is the predominant peptide within the secretory granules of gastrinoma cells, but other neuroendocrine peptides such as vasoactive intestinal peptide (VIP) and glucagon can sometimes be identified as well. Seventy percent of gastrinomas are located in the duodenum; the remainder, with rare exception, arise in the pancreas or as a rarity, in lymph nodes adjacent to the pancreas.

Excessive gastrin secretion from a gastrinoma results in a high gastric acid output for two reasons: first, gastrin has trophic actions on parietal cells and histamine-secreting enterochromaffin-like (ECL) cells and second, gastrin stimulates parietal cells largely via the release of histamine. Therefore, more than 90% of patients with ZES develop peptic ulcers mostly in the first portion of the duodenum. Diarrhea can also be a prominent symptom of ZES because a high rate of gastric acid secretion results on the one hand in a volume load that cannot be fully reabsorbed by the gut and on the other exceeds the neutralizing capacity of pancreatic bicarbonate secretion. In addition, an exceptionally low pH of the intestinal contents inactivates pancreatic digestive enzymes, interferes with the emulgation of fat by bile acids, and damages intestinal epithelial cells and villi. Thus both, maldigestion and malabsorption may result in steatorrhea. Metastatic disease is evident at the time of diagnosis in approximately one-third of patients. The liver is the most common site of spread; bone metastases

also occur, but only in those patients with hepatic metastases [3].

## Diagnostic Principles

Two tests for the diagnosis of ZES syndrome are routinely used in the clinical setting: determination of fasting serum gastrin concentration and secretin stimulation test. Additional gastric acid secretion studies may still have an adjunctive role. Furthermore, serum chromogranin A serves a general marker for neuroendocrine tumors and is therefore elevated in most patients with gastrinomas. After the diagnosis of the ZES is made, two major modalities are used in order to locate the tumor: first, endoscopic ultrasound, which is especially valuable in imaging small pancreatic endocrine tumors, and permits fine needle aspiration for histological examinations; and second, somatostatin receptor imaging using 111-Indium-penetreotide-SPECT, which has a higher sensitivity than all other imaging modalities, and is particularly useful in identifying liver and bone metastases [3]. Data concerning PET-related visualization of tumor location and spread in ZES is limited.

## Therapeutic Principles

With respect to treatment of ZES, it is important to limit the clinical manifestations and complications of peptic ulcer disease. Proton pump inhibitors (PPIs) effectively block acid secretion by irreversibly binding to and inhibiting $H^+/K^+$-ATPase that resides on the luminal surface of parietal cells. While PPIs are able to control gastric acid secretion, somatostatin analogs such as octreotide can inhibit secretion of gastrin. However, due to the unpredictability of the response, they are not first-line agents for symptomatic patients with hypergastrinemia. Patients with a sporadic gastrinoma with no evidence of metastatic spread should undergo exploratory laparotomy and resection with a curative intent. The probability for a surgical cure is especially high for extrapancreatic gastrinomas while, in contrast, laparotomy is not routinely recommended for patients with ZES as part of MEN type 1, since the multifocal nature of the tumors in this disorder almost uniformly precludes cure of gastrin hypersecretion [4,5]. Although surgery may decrease the incidence of hepatic metastases and improves survival, long-term cure is achieved in less than 30% of the cases.

Metastatic gastrinoma is the predominant cause of morbidity and mortality in ZES. Unfortunately, current treatment modalities are of limited benefit. Somatostatin analogs, like octreotide, can reduce gastrin levels and related symptoms but evidence of anti-tumor activity is rare. Treatment of hepatic metastases includes hepatic resection, hepatic artery embolization, radiofrequency- and cryo-ablation. Palliative systemic chemotherapy with streptozotocin/doxorubicin is of limited efficacy, while toxicity is not negligible. Novel approaches like angiogenesis inhibitors or so-called small molecules like tyrosine kinase inhibitors are currently under investigation.
