Preface

Psychopharmacology is the study of the effects of psychoactive drugs on the functioning of the central nervous system at all levels of analysis, thus embracing cognition, behaviour, psychological states, neurophysiology, neurochemistry, gene expression and molecular biology. It includes, as integral parts of its domain, the medicinal and social uses of the substances, the interaction of environmental and genetic factors with the actions of psychoactive drugs, their use for probing the functionality of the central nervous system, and drug dependence and abuse.

The modern science of psychopharmacology was developed in the second half of the 20th century as a consequence of innovative "blue-skies" laboratory research, and the parallel recognition of the specific therapeutic effects of a new generation of drugs that brought about the so-called "psychopharmacological revolution". This Encyclopedia of Psychopharmacology attempts to bring together much of this knowledge that has been acquired in the last fifty years in a format that makes it accessible to a diverse range of non-specialists and students. It facilitates the dissemination of what has been learned to a broader population of researchers, clinicians and advanced students. The level of the entries is typically mid-way between articles for informed laypeople and reviews for specialised biomedical experts. The diversity of disciplinary areas of which psychopharmacology is comprised means that it is a useful educational resource when specialists need to extend their role into areas beyond their primary fields of expertise. People in related fields, students, teachers, and laypeople will benefit from the information on the most recent developments of psychopharmacology.

The scope of the product is defined by the definition above and by the scope of the journal Psychopharmacology, a premier peer-review journal for publication of original research and expert reviews. The aim is to provide detailed information on psychopharmacology and its sub-disciplines, such as clinical psychopharmacology, molecular neuropsychopharmacology, behavioural pharmacology in laboratory animals, and human experimental psychopharmacology. Nevertheless, the interdisciplinary nature of the field has engendered very different ideas about the meaning of the word "psychopharmacology", and there is probably no definition that could meet with universal and permanent acclaim. It is like the proverbial story of the blind men and the elephant. Some see psychopharmacology primarily as the scientific study of the psychological and behavioural effects of substances in normal subjects. Others regard it as mainly concerned with the development and evaluation of pharmacotherapies for psychiatric states. Yet a further important group of scientists have been engaged in defining the actions of psychoactive drugs across the huge range of disciplines of which neuroscience is composed including, among others, neurochemistry, neurophysiology and molecular biology. It is hoped that the project will help to shed light on the interconnections between the different parts of the elephant, showing how the effects of drugs within the intact conscious, behaving organism are related to their properties at the levels of molecules, cells and neural systems.

The wide-ranging entries in the Encyclopedia of Psychopharmacology are written by leading experts, including basic and clinical scientists in academia and industry. The entries fall into several main categories. Target essays include descriptions of fundamental psychological and biological processes that are influenced by psychoactive drugs; here the emphasis is at the behavioural and psychological level, although important functions in the neuropharmacological and psychosocial domains are included. Targets at the molecular and cellular levels constitute the primary domain of the Encyclopedia of Molecular Pharmacology (Offermanns and Rosenthal, Eds. Springer 2008) that may be seen as a parallel endeavour. Those entries named according to psychiatric disorders describe the role of pharmacotherapy in treatment, with reference to differential therapies for subclasses of a disorder, with cross-references to essays on the drugs used. Conditions where drug treatment is not normally used are excluded except for substance use disorders, where the main characteristics of all the disorders are pertinent even though there is no pharmacotherapy for some of them. Drugs are the stock-in-trade of psychopharmacologists and therefore many entries are named according to drugs or drug classes. These essays review their general pharmacology, with an emphasis on psychotropic and other central nervous system effects; their neuropharmacological mechanisms of action are described in relation to receptor or enzymatic targets, key events that occur downstream from the receptor, and brain regions, with cross-references to the psychiatric states in which the drugs are used most often. Other essays focus upon the key methods used in the field, describing the main

features of the techniques and outlining their roles in psychopharmacology, the types of information obtained and why they are needed; the advantages and limitations of a technique may also be summarised.

The essays are complemented by more than 1,150 short definitions; essays and definitions cross-reference each other and other relevant entries. Entries appear in an alphabetical sequence that makes the printed encyclopedia easy to use. Users of the online version benefit from hyperlinks that correspond to the cross-references in the printed version.

I thank the many members of the publisher's staff who have participated in this project and have supported it so ably. Throughout the enterprise I have also enjoyed the support of an outstanding team of Field Editors, all of whom have sustained internationally recognized records of scholarly activity in psychopharmacology. The team includes individuals based in pharmaceutical industry as well as in academia, reflecting the frequent and often essential collaborations between these sectors. It would not have been possible to produce the Encyclopedia of Psychopharmacology without their guidance on its content and their assistance with the selection of authors and reviews of the submitted entries. I also thank the hundreds of individual authors whose exceptional work forms the substance of the product and who have given so generously of their time and expertise.

ABC Transporters

Definition

Adenosine triphosphate (ATP)-binding cassette (ABC) transporters constitute a superfamily of primary active transport systems that are present from prokaryotes to humans. ABC transporters hydrolyze ATP to transport various substrates across cellular membranes. 48 ABC transporters are present in humans and are classified in seven subfamilies. The human ABCB1 or P-glycoprotein is responsible for multiple drug resistance (MDR) in pumping chemotherapeutic drugs out of the cell. A few ABCC members, also known as MRP (multiple drug resistance associated protein), and ABCG2 or BCRP (breast cancer resistance protein) are like, P-gp, expressed at the BBB where they play a protective role for the brain against xenobiotics.

Abuse Liability

Synonyms

Abuse potential

Definition

Abuse liability is a term used to denote properties of a drug that would lead to abuse and dependence in humans if it were to become available as a prescription medication or through illicit routes. It is assessed primarily from the ability of a drug to produce positive outcomes in laboratory tests predictive of abuse and dependence in humans. Clinical and epidemiological data are also taken into account when available. Abuse liability also depends upon other factors such as the formulations in which the drug becomes available, its cost, and the ease of synthesizing it.

Abuse potential

Definition

The abuse liability of a drug or a class of drugs is their propensity to be abused and produce adverse public health consequences. Although much of what constitutes abuse liability of a drug arises from the pharmacological properties of the drug itself (i.e., its ability to produce psychoactive effects associated with risk for abuse and/or addiction, also known as abuse potential), it can also be affected by social and cultural factors and may change from time to time as one drug or class of drug gain popularity in a particular culture. Individual products, even those containing the same generic drug, can differ in abuse liability, which may be determined by the specific formulation, the indication for which it is used and such things as its market penetration.

Current Concepts and State of Knowledge

Background

One of the principal strategies for drug abuse prevention is to place regulatory controls on the manufacture, distribution, sales, and possession of drugs with abuse liability. This strategy is embodied in international treaties and in the drug abuse control laws of individual countries. The simplest level of control for medications is to require a physician prescription for their use. Drug abuse control treaties and laws place additional requirements on drugs that have demonstrated abuse liability. Consequently, it is essential for the function of this drug abuse prevention strategy that there be a means of establishing which drugs have abuse liability and should be subjected to such regulations. In addition, the existing regulations call for differential restrictions on drugs based on differences in their abuse liability; therefore, it is also necessary to have a means of ranking this propensity.

At the international level, drug abuse control resides in two treaties, the Single Convention on Narcotic Drugs and the Convention on Psychotropic Substances (http://www.unodc.org/unodc/en/treaties/index.html). The United Nations has been given the authority to implement these treaties. Most countries are signatory to these treaties and among their obligations are to control manufacture, distribution, sale and possession of drugs at least as strictly as called for in the treaties. The drug abuse control laws differ somewhat among countries, so to illustrate how abuse liability impacts on drug abuse control, we will use as an example the ▶ Controlled Substances Act (CSA) in the US (http://www.usdoj.gov/dea/pubs/csa.html).

Under the CSA, drugs with abuse liability are placed in one of the five schedules (I-V), with Schedule I having the most restrictions and Schedule V the least. The intent is for the drugs with the greatest abuse liability and potentially causing the greatest public health concerns to be in Schedule I, with successively lower Schedules used for progressively less dangerous drugs. There is controversy about whether or not the existing classifications of drugs are consistent with this intent.

The remainder of this article will focus on how abuse liability is measured scientifically. The CSA specifies eight factors which should be assessed in determining abuse liability, but these factors do not easily translate into specific scientific assessments, so we will use a more scientifically based analysis. In this regard, it is important to distinguish between the assessment of abuse liability of drugs which are widely available to the public already and new drugs or medications, where data on actual abuse are not available but assessments of their abuse potential need to be made prior to their approval or a scheduling decision. In the former, methods from epidemiology are of paramount importance in assessing the actual abuse of the drugs. For new products, data from laboratory and clinical testing are usually the main source of information on abuse liability. Several regulatory agencies and scientific organizations have proposed strategies for abuse liability assessment (Balster and Bigelow 2003), which include chemical properties, animal test procedures (Negus and Fantegrossi 2008), human laboratory testing (Preston and Walsh 1998), and information that can be obtained from clinical efficacy trials.

Chemical Properties and Formulation

New medications that are based on analogs of existing drugs of abuse are often presumed to have abuse liability. Knowledge of structure-activity relationships can also be used to predict sites of action in the brain that might mediate abuse-related effects of drugs. Medications that are metabolized to known drugs of abuse or that can be

easily converted to an abusable drug can be considered to have abuse potential. Water soluble drugs and formulations are at increased risk for injection use. In some cases, it is possible to formulate drugs in ways that reduce their abuse liability and that are relatively tamper proof. Delayed or sustained formulations may have less abuse liability than their immediate release counterparts.

Animal Laboratory Testing of Abuse Liability

Knowledge of the pharmacological properties of a novel medication is an important first step in predicting their abuse potential. Indeed, binding assays and other means of determining a drug's cellular sites of action in the brain are typically used to assess if the drug acts on receptor systems or neural circuitry known to mediate the abuse-related effects of known drugs of abuse.

In general, the more similar a new drug is to known drugs of abuse the more likely it is to have abuse liability. The concept has often been referred to as pharmacoequivalence, and standard pharmacological tests of the properties of drugs can be used to establish pharmacoequivalence. For example, opioids, depressants, amphetamine-like stimulants, hallucinogens, and other classes of abused drugs can produce typical, class-specific profiles of pharmacological properties in animal tests. Often, developers of new medications are attempting to retain therapeutic properties (e.g., analgesia, sedation, etc), while reducing abuse potential.

► Drug discrimination testing in animals is a useful means of assessing pharmacoequivalence particularly because the discriminative stimulus effects of drugs are related to the nature of their acute subjective effects (Holtzman 1990). For abuse liability testing, novel drugs are typically tested in animals that have been trained to discriminate one or more known drugs of abuse from placebo. For example, animals trained to discriminate morphine from vehicle could be used to test a novel analgesic for morphine-like discriminative stimulus effects employing ► stimulus generalization procedures. With the use of appropriate training drugs, it is possible to characterize discriminative stimulus effects with high specificity. For example, mu and kappa opioids can be distinguished from one another, as can the various subtypes of GABA agonists.

Drug ► self-administration is also widely used for abuse liability assessment in laboratory animals. This procedure directly measures the reinforcing effects of drugs using standardized procedures, and has been used in rodents and nonhuman primates. One commonly used form of self-administration is the drug substitution procedure in which animals are trained to self-administer a known drug of abuse under limited access conditions, typically using fixed-ratio schedules of reinforcement and the intravenous route of drug administration. When rates of self-administration become reliable from day to day, a test drug is substituted to determine if animals will maintain responding. It is essential to test a range of doses of the test drug. More advanced self-administration procedures have also been used to measure reinforcement efficacy to compare the relative abuse liability of various drugs. For example, in progressive ratio procedures animals are required to make more lever presses for subsequent injections, and the maximal number of presses they make is used as the measure of reinforcement efficacy.

Testing for the development of a ► physical dependence syndrome can also be done in animals (Aceto 1990). Physical dependence is a feature of many, but not all, drugs of abuse. It is related to abuse potential because it may increase the likelihood of further drug-taking as well as being an adverse consequence of drug use. Physical dependence testing is used predominantly for opioids and depressants because the withdrawal syndromes are most pronounced with these classes of drugs. Cross-dependence can also be used to determine the extent to which a novel drug resembles a known drug of abuse. There are two primary models. One, which is often referred to as single dose suppression, utilizes animals that have already been made dependent on a known drug of abuse, such as morphine or pentobarbital, and then a test drug is administered during withdrawal to see if it suppresses the withdrawal signs that would normally emerge. If a test drug exhibits ► cross dependence in this procedure, it is very likely to produce dependence by itself. For example, a drug that suppresses withdrawal signs in morphine-withdrawn animals will probably produce dependence of the opiate type. The other common methodology is the assessment of primary physical dependence in which the test drug is administered repeatedly (or continuously by infusion) for a week or more. During treatment, animals can be injected with an antagonist (e.g., naloxone) to determine if precipitated withdrawal occurs or the drug administration can be discontinued and animals observed for spontaneous withdrawal signs.

Other animal test procedures that have been used for abuse liability assessment include the assessment of ► tolerance or ► cross tolerance, ► conditioned place preference, and altered thresholds for electrical self-stimulation of the brain.

Human Laboratory Testing of Abuse Liability

Abuse liability assessment studies conducted with humans typically occur prior to approval and marketing of a novel compound and/or new formulation of an existing

compound, but only after comprehensive safety evaluations of the new agent have been conducted in nonhumans and humans (Phase 1). Whether specific abuse liability testing in humans is needed depends on existing knowledge of the abuse potential for the test compound and pharmacologically related compounds, and the outcomes of animal abuse liability screening.

Standardized laboratory-based procedures have been developed to assess abuse potential in humans (Preston and Walsh 1998). Typically these studies are conducted using paid volunteers who are experienced with the class of drug under evaluation. Experienced drugs users provide a sensitive indicator of the positive mood effects of their drug of choice. When appropriate, abuse liability studies are sometimes conducted in normal (i.e., nondrug using individuals) and patient populations. Participants in these studies are screened for physical and mental health, cognitive ability to provide consent and answer questionnaires, and for recent drug use that would interfere with testing.

The most widely used approach for human abuse liability testing is the controlled assessment of the subjective experience of drug effects through structured and unstructured questionnaires (i.e., subjective effect reports). Key design elements for these studies include (1) testing a broad range of doses of the study agent in a controlled environment, (2) inclusion of a placebo control, (3) testing multiple doses of a positive control drug (i.e., a known drug from the same class with well characterized abuse potential), and (4) randomized dosing and double-blind procedures. Questionnaires are presented before and at regular intervals after the drug is administered (typically as an acute dose) in order to capture the onset, magnitude, and duration of drug action. The procedure produces a dose-effect of subject-reported responses associated with the test drug relative to a drug with known abuse potential.

Several standardized self-report measures are used to assess abuse liability. One measure is the visual analog scale, which allows subjects to rate their state in relation to specific questions or descriptors on a line labeled "not at all" and "extremely." Typical questions are for example, "How much do you like the drug?" "How strong is the drug?" or "Do you feel nauseous?" Other measures are adjective-rating scales, which employ a Likert-rating (e.g., ratings on a 0–10 scale), such as an opioid rating scale with effects such as nodding and itchy. The Single Dose Questionnaire (Fraser et al. 1961) is an opioid-specific questionnaire originally developed at the ►Addiction Research Center located at the ►U.S. Narcotics Prison Farm in Lexington, Kentucky where much of the seminal work in this research area was originally developed. Another widely used questionnaire (also developed at the Addiction Research Center) was a large empirically-derived battery known as the ►Addiction Research Center Inventory (ARCI; Haertzen 1966). This battery was derived after administration of drugs from a wide array of pharmacological classes, including ►opioids, ►alcohol, ►sedatives, ►psychostimulants, and ►hallucinogens. The original version has 550 true–false items subdivided into numerous subscales, with each sensitive to a specific drug-induced subjective state (e.g., the Morphine–Benzedrine Group scale (MBG) is used as a proxy for the euphoric effects produced by opioids and amphetamines; the Weak Opioid Withdrawal scale is sensitive to withdrawal symptomatology). A shortened version with only 49 items of the ARCI is most commonly employed in contemporary studies (Martin et al. 1971). Numerous other validated or locally developed questionnaires are also used.

Observer-rated measures yield additional information on observable signs of drug intoxication of which the subject may be unaware and are free of the potential bias/experimental noise that can result from drug intoxication. Cognitive and psychomotor test procedures may also be used to evaluate the impairing effects of the study drugs. These tests may include simple assessments such as balance, reaction time, and standard sobriety tests or more sophisticated cognitive measures which capture direct effects on cognitive processing and memory.

Drug discrimination and self-administration procedures have been adapted from the animal laboratory for use in humans. While these procedures are not typically used for abuse liability screening, they may provide additional relevant information. Human drug discrimination outcomes are generally concordant with those from the animal studies. Drug self-administration procedures are used most commonly with marketed agents to compare abuse liability among drugs or to evaluate potential pharmacotherapies for drug abuse treatment (Comer et al. 2008).

Evaluation of physical dependence capacity in humans was historically conducted using direct addiction studies. In early studies, subjects were exposed to repeated dosing with the test drug and then tested for signs of a withdrawal syndrome. However, these direct addiction studies are no longer conducted for ethical reasons. Instead, physical dependence is studied in currently dependent humans using substitution and withdrawal suppression procedures. For example, methadone-maintained subjects may be enrolled to examine the ability of another opioid to substitute for their maintenance dose or marijuana-dependent individuals may be maintained experimentally on equivalent oral THC doses during study participation.

Abuse Liability Assessment in Clinical Trials

Abuse liability is not typically assessed in clinical trials, which are usually designed to assess efficacy on a specified therapeutic outcome. Nevertheless, ► Phase I trials can produce information about the nature of the intoxication after administration of high doses (Brady et al. 2003). The adverse events in ► Phase II and ► Phase III trials can be a source of information about drug liking or other abuse-related phenomena, and escalation of use, or missing test medication might indicate a propensity for diversion.

Definition

Acamprosate, marketed under the brand name Campral, is an orally administered drug approved in the USA and throughout much of the world for treating ► alcohol abuse and dependence.

Pharmacological Properties

History

Alcohol-use disorders, which include both alcohol abuse and dependence, make up one of the most prevalent categories of substance use disorders in the USA, affecting almost 18 million Americans. The Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition (DSM-IV; APA 1994) characterizes alcohol dependence as a maladaptive pattern of drinking leading to clinically significant impairment, as manifested by a compulsion to drink, a lack of control over the amount of alcohol consumed and continued drinking, despite a realization of the problems associated with it. Physiological symptoms of tolerance and withdrawal may also be present. One of the most challenging aspects of recovering from alcohol dependence is maintaining abstinence after acute withdrawal and avoiding

subsequent relapse to drinking (Koob and Le Moal 2006). The goal of maintaining abstinence can be undermined by acute stressors like anger, loneliness, or hunger or by more chronic conditions such as cognitive impairment, polysubstance abuse, and mood and sleep disturbances. Supplementing counseling approaches with medications targeted to treat the biological aspects of drinking behavior can help in the maintenance of abstinence.

Three medications are currently approved for the treatment of alcohol dependence – ► disulfiram, ► naltrexone (oral and injectable extended release), and acamprosate (Koob and Le Moal 2006). A number of other therapeutic agents are under investigation; these include serotonergic agents, anticonvulsants, GABA receptor agonists, cannabinoid receptor antagonists, and corticotrophin-releasing factor antagonists. Disulfiram has been available for decades; however, high rates (up to 80%) of nonadherence to this aversive medication have contributed to its decreased use by the treatment community. Naltrexone has been available since 1994; however, it has not been readily adopted by practitioners to treat alcohol dependence. The recent Food and Drug Administration (FDA) approvals of acamprosate (2004) and an injectable extended formulation of naltrexone (2006) offer new pharmacologic options for treating this disorder.

Acamprosate is a safe and well-tolerated pharmacotherapy that has been studied in numerous clinical trials worldwide. It has been used successfully for over 15 years in 28 countries and has been prescribed for more than 1.5 million alcohol-dependent patients. Clinical trials have consistently shown that acamprosate is effective in maintaining abstinence in recently detoxified patients, especially when patients are motivated to be abstinent (Mason and Crean 2007). Current research also indicates that acamprosate has a unique mechanism of action, which may have implications for its therapeutic use (De Witte et al. 2005). In contrast to disulfiram, which causes aversive behavior through negative physical effects, or naltrexone, which tempers the pleasurable effects of alcohol, acamprosate acts to normalize dysregulation in neurochemical systems that have been implicated in the biological mechanisms of alcohol dependence.

Mechanism of Action

Acamprosate is an analog of amino acid neurotransmitters such as taurine and homocysteic acid and it has been demonstrated that acamprosate binds to a specific spermidine-sensitive site that modulates the NMDA receptor in a complex way. The NMDA receptor is one of the ► glutamate receptor subtypes. This work suggests that acamprosate acts as a "partial co-agonist" at the NMDA receptor, such that low concentrations enhance activation when receptor activity is low, and high concentrations inhibit activation when receptor activity is high. This may be particularly relevant to the success of acamprosate as a pharmacotherapy given that chronic exposure to ethanol results in an upregulation of ► NMDA receptors and an upregulation in the density of ► voltage-dependent calcium channels (Littleton 2007). Thus, sudden alcohol abstinence causes the excessive numbers of NMDA receptors to be more active than normal, and to produce the symptoms associated with acute ► alcohol withdrawal, such as ► delirium tremens and seizures and with the more persisting symptoms associated with early abstinence, such as craving and disturbances in sleep and mood (Tsai and Coyle 1998). Withdrawal from alcohol induces a surge of excitatory neurotransmitters like glutamate, which in turn activates the NMDA receptors (Tsai and Coyle 1998). Conversely, acamprosate promotes the release of taurine in the brain (Dahchour and De Witte 2000). Taurine is a major inhibitory neuromodulator/neurotransmitter and an increase in taurine availability would also contribute to a decrease in hyperexcitability. Thus, each of these changes produced by acamprosate may contribute to a decrease in the neuronal hyperexcitability commonly observed following acute alcohol withdrawal and that may underlie symptoms associated with relapse, like craving, negative affect and insomnia. Therefore, it has been hypothesized that acamprosate may promote abstinence by minimizing or normalizing some of the physiological changes produced by chronic heavy ethanol exposure.

Animal Models

Acamprosate has been shown to reduce ethanol consumption in rodents that have an extended history of ethanol exposure or are ethanol-dependent (Spanagel et al. 1996). It also has been shown to reduce the increased ethanol consumption associated with a period of enforced abstinence from ethanol (the alcohol deprivation effect) in rats (Heyser et al. 1998; Spanagel et al. 1996). In contrast, acamprosate appears to have less of an effect on alcohol consumption in alcohol naïve and nondependent rats (Heyser et al. 1998). Acamprosate also has been reported to attenuate some of the behavioral and neurochemical events associated with ethanol withdrawal (Dahchour and De Witte 2000). For example, acamprosate reduces the hyperactivity and elevated glutamate levels observed during the first 12 h of ethanol withdrawal. However, not all aspects of withdrawal are reduced by acamprosate, such as withdrawal-induced hypothermia. In addition to the direct effects on ethanol consumption, acamprosate

has been shown to inhibit cue-induced ► reinstatement of alcohol-seeking behavior in an operant conditioning model (Bachteler et al. 2005). Taken together, these results provide support for the use of acamprosate specifically as an anti-relapse medication following acute alcohol withdrawal.

Pharmacokinetics

The recommended dosage of acamprosate is two 333-mg tablets taken three times daily, with no dose adjustment required for body weight or gender (Campral package insert, 2005). Acamprosate is absorbed via the gastrointestinal tract, with pharmacokinetic linearity in terms of dose and time. Absolute bioavailability of acamprosate under fasting conditions is approximately 11%; after food intake, bioavailability decreases by approximately 20%, but this decrease lacks clinical significance (Wilde and Wagstaff 1997). Plasma protein binding is negligible. Importantly, acamprosate is not metabolized in the liver and approximately 90% of the drug is excreted unchanged in the urine (Wilde and Wagstaff 1997). Therefore, the pharmacokinetics of acamprosate are not altered in patients with mild to moderate hepatic impairment and no dose adjustment is required in such patients. Since there is a risk of accumulation of acamprosate with prolonged administration of therapeutic doses in renally impaired patients, the use of acamprosate is contraindicated in patients with severe renal impairment. The pharmacokinetics of acamprosate have not been evaluated in pediatric or geriatric populations.

Because acamprosate is not metabolized by the liver, it is unlikely to cause drug–drug interactions via cytochrome P450 inhibition. Its pharmacokinetics are not altered by co-administration with ► diazepam, ► disulfiram, ► antidepressants, or ► alcohol – substances that are often taken by patients with alcohol dependence. In pharmacokinetic studies with human subjects, co-administration with naltrexone increased the rate and extent of acamprosate absorption. These results suggest that combination therapy may improve the ► bioavailability of acamprosate without compromising its tolerability (Mason and Crean 2007).

Efficacy

Acamprosate was initially studied in Europe, and more recently, in Brazil, Korea, Australia, and the USA. The acamprosate double-blind, placebo-controlled clinical trial database included over 6500 outpatients from 15 countries and is reported in 23 published studies (Mason and Crean 2007). Nineteen of these trials used relatively equivalent methodology in terms of entry criteria, treatment, handling of drop-outs, outcome measures, and assessment of compliance. Patients received the psychosocial intervention typical of their treatment setting. Treatment duration ranged from 2 to 12 months with 13 trials 6 months or longer in duration. Patients were generally recently detoxified and typically had been abstinent for about 5 days at entry into the trials. In these studies, the principal ► efficacy measure was abstinence, which was assessed as the rate of patients completing the trial with no consumption of alcohol at all, the cumulative proportion of the study duration when the patients remained abstinent, and/or the time to first drink.

The results have been consistent in the majority of published studies, and generally show a significant beneficial effect of acamprosate on abstinence outcomes relative to placebo. A factor of 2 in the difference in the proportion of patients achieving stable abstinence was observed in approximately one-third of studies. A beneficial effect on the time to first drink was also frequently observed.

Overall, the published placebo-controlled studies demonstrate the efficacy of acamprosate for supporting abstinence over a broad range of patients in association with a variety of different psychosocial interventions. A number of these studies assessed the persistence of a treatment benefit after the study medication was stopped, and found acamprosate efficacy was maintained for up to 12 months post-treatment relative to placebo. In addition, the result of a recent multi-center, ► double-blind, ► placebo-controlled clinical trial of acamprosate conducted in the United States showed that the benefits of acamprosate were optimized in patients who had a clearly identified goal of abstinence at the start of treatment (Mason and Crean 2007).

Safety and Tolerability

The safety profile of acamprosate appears favorable. The only adverse event consistently reported across trials more frequently in acamprosate-treated patients with respect to placebo-treated patients was mild and transient diarrhea. Across clinical trials, the rate of early terminations due to drug-related adverse events did not differ between acamprosate and placebo-treated patients. Pharmacovigilance subsequent to the commercialization of acamprosate in 1989 has not identified any health risk associated with acamprosate use in over 1.5 million patients. Clinical investigations show no evidence of ► tolerance, ► dependence, or the emergence of a ► withdrawal syndrome or rebound drinking when treatment is ceased (Mason and Crean 2007). Comprehensive safety guidelines may be reviewed in the package insert for acamprosate (Forest Pharmaceuticals, Inc. 2005).

Conclusion

Acamprosate appears to be useful in the treatment of alcohol dependence above and beyond the effects of counseling alone. Acamprosate appears to work by normalizing the dysregulation of NMDA-mediated glutamatergic neurotransmission that occurs during chronic alcohol consumption and withdrawal, and thus attenuates one of the physiological mechanisms that may prompt relapse. Acamprosate requires around a week to reach steady-state levels in the nervous system and its effects on drinking behavior typically persist after the treatment is completed.

Studies into the efficacy of acamprosate in alcohol-dependent patients are generally favorable. Clinical studies and post-marketing experience indicate that acamprosate is typically safe when used as approved by the FDA in alcohol-dependent patients, including those dually diagnosed with psychiatric disorders. The majority of randomized controlled trials of acamprosate given in conjunction with counseling show significantly improved alcoholism treatment outcome relative to counseling administered with placebo. This evidence base suggests that acamprosate should be routinely considered by medical professionals for patients entering alcoholism treatment, taking into account the patient's treatment goals and preferences as well as the safety considerations outlined above.

Acetaldehyde

Synonyms

ADH; Ethanal

Definition

Acetaldehyde is an intermediate by-product in normal carbohydrate metabolism. It is known to psychopharmacologists as the first metabolite of alcohol that is eliminated primarily through oxidation by the enzyme alcohol dehydrogenase in the liver. Acetaldehyde, in turn, is converted to acetate by aldehyde dehydrogenase. Acetaldehyde has pharmacological effects on the cardiovascular system, the liver, monoamine neurotransmitter metabolism, brain function, and behavior. At high levels, it can be toxic, causing headache, facial flushing, nausea and vomiting, tachycardia, headache, sweating, dizziness, and confusion.

Acetylcholine

Definition

A neurotransmitter in the brain and peripheral nervous system involved in the mediation of motor and autonomic functions, and in the mechanisms of cognitive events such as memory functions.

Acetylcholinesterase and Cognitive Enhancement

Synonyms

Anti-Cholinesterases

Definition

Acetylcholinesterase inhibitors are molecules that inhibit the acetylcholinesterase enzyme from metabolizing (hydrolyzing) acetylcholine, thus increasing both the level and duration of action of the neurotransmitter acetylcholine.

Pharmacological Properties

Cholinergic System Effects on Cognitive Functioning

Several decades of research support the critical role of CNS cholinergic systems in cognition in humans, particularly in learning and memory formation and attention. Beginning with studies by Drachman (1977), temporary blockade of ▶ muscarinic receptors produced impairments of learning and memory that resembled changes associated with normal aging and was proposed as a model of the cognitive deficits in ▶ Alzheimer's disease (AD). Such findings were supported by animal studies showing that cognitive performance of younger animals after the administration of ▶ scopolamine was similar to older untreated animals (Bartus et al. 1982). These studies were extended by Newhouse et al. (1988) who showed that when elderly normals and depressed patients were given scopolamine, their performance declined to a level similar to AD patients. There is thus an age- and disease-related functional decline in muscarinic cholinergic system resources that matches the decline in cell number and other cholinergic markers seen in autopsy studies. Investigations of CNS nicotinic cholinergic receptors have shown qualitatively similar findings. Newhouse et al. (1994) have shown that blocking CNS ▶ nicotinic receptors with the antagonist ▶ mecamylamine in humans produces measurable cognitive impairment with a similar age- and disease-related increase in sensitivity. These studies showed that cognitive impairment followed the blockade of central nicotinic receptors, which partially modeled cognitive impairment that occurs with aging and degenerative disorders (e.g., AD). Studies of both nicotinic agonists and antagonists (Newhouse et al. 2004) have helped to establish the importance of CNS nicotinic receptors in human cognitive functioning and justified efforts to develop therapeutic agents aimed at these receptors. Thus, the effects of acetylcholinesterase inhibitors on cognitive functioning must be contextualized with an appreciation of effects on both cholinergic receptor systems (muscarinic and nicotinic).

In humans, the cholinergic system has been implicated in many aspects of cognition, including the partitioning of attentional resources, ▶ working memory, inhibition of irrelevant information, and improved performance on effortful tasks. Warburton and Rusted (1993) have proposed that the cholinergic system modulates processes that are supported by a limited capacity central executive and that the cholinergic system influences information processing during tasks that engage the control processes for the allocation of attentional resources. Cholinergic system manipulation appears to affect performance on resource demanding tasks as well as during the allocation of attention.

More recently, advances in basic animal research, cognitive pharmacology, and functional imaging have allowed a reformulation of the cholinergic hypothesis of cognitive functioning. Sarter et al. (2005) proposed that the cholinergic system modulates attentional functioning in two ways: first it serves to optimize bottom-up, signal-driven detection processes. Second, the cholinergic system also optimizes top-down, knowledge-based detection of signals, and the filtering of irrelevant information. Thus, the cholinergic system will be involved whenever a task is difficult or relevant and/or irrelevant information is difficult to discriminate, requires partitioning of attentional resources, inhibition of irrelevant information, or increased cognitive effort.

Human functional brain imaging studies have shown that cholinergic stimulation increases cortical activity in extrastriate and intra-parietal sensory areas during encoding and facilitates visual attention-associated activity in extrastriate cortex. Nicotinic cholinergic stimulation enhances reorienting of attention and alters parietal lobe activity associated with this process (Thiel et al. 2005) and may enhance the activity of a distributed neural network. Nicotinic cholinergic stimulation also specifically improves inhibitional attentional functioning (Potter and Newhouse 2004). By contrast, muscarinic cholinergic blockade reduces learning-related activity in the hippocampus (Sperling et al. 2002) and alters prefrontal and perirhinal cortical activity specifically associated with novelty. Studies have shown that muscarinic and nicotinic receptor-specific antagonists cause task-related alterations in activation in frontal and parietal areas during working memory tasks (Dumas et al. 2008).

These data support the concept that cholinergic system activation is phasic rather than tonic and serves to interrupt ongoing activity in the cortex in the context of an attentional requirement (top-down) or a signal requiring reorienting (bottom-up). A hypothesis suggested by

prior neuroimaging studies suggests that nicotinic and muscarinic systems may be responsible for different aspects of task performance; e.g., nicotinic stimulation may affect attentional modulation, rather than simply acting as a general signal gain enhancing system, whereas muscarinic effects may be more tied to stimulus processing or encoding (Thiel et al. 2005).

Studies of ► acetylcholinesterase inhibitors support these hypotheses regarding cholinergic functioning. Studies have shown that during the attentionally demanding N-back task, subjects with ► mild cognitive impairment (MCI) had increases in frontal activation after donepezil treatment relative to control subjects without MCI. In these patients with MCI, frontal regions were recruited during this task with the aid of the pro-cholinergic drug. Other pharmacological functional magnetic resonance imaging (fMRI) studies investigating the treatment of MCI with galantamine have found increased recruitment of task-related brain areas, including bilateral frontal areas and the hippocampus during semantic association, attention, and spatial navigation tasks following treatment. Donepezil treatment in AD subjects improved performance on an attention task of target cancelation while showing no effects on memory tasks (Foldi et al. 2005). Studies of the acetylcholinesterase inhibitor physostigmine have shown increased cortical activity after physostigmine compared to placebo while performing a working memory task in extrastriate and intraparietal areas during encoding but not during retrieval. Physostigmine administration also facilitates visual attention by increasing activity in the extrastriate cortex during a repetition priming task.

Thus, experimental studies using acetylcholinesterase inhibitors suggests that cholinergic system activity modulates stimulus-specific processing of sensory information in selected cortical areas. In addition, the activity of brain regions involved in memory processing such as the hippocampus and frontal lobe may be modulated by cholinergic system activity. The effects of acetylcholinesterase inhibitors on sensory areas may reflect the role of the cholinergic system in modulating attentional processes, and effects on memory-related processing areas similarly suggest effects of cholinergic modification of encoding-related activity for long-term storage.

Neuroimaging methods such as ► functional magnetic resonance imaging (fMRI) have increasingly been used by investigators as a tool to study neural processes involved in human cognitive function. Several functional imaging studies using healthy volunteers have found that enhancing acetylcholine activity via acetylcholinesterases can enhance the effect of selective attention within the extrastriate visual cortex, but not all stimulus processing regions or stimulus types are affected in a similar fashion. Based on the findings that brain activity related to both selective attention and emotional processing can be independently enhanced with physostigmine in the fusiform gyrus, and that physostigmine decreases differential activation due to attention in the posterolateral occipital cortex, cholinergic projections may modulate attention-related and emotion-related activity in distinct parts of the extrastriate and frontoparietal cortices. It has been found that physostigmine effects stimulus-selectivity and attention-related brain activation differently in patients with AD compared to healthy controls. Physostigmine partially reversed impaired stimulus activity in extrastriate visual cortices in AD patients, but negatively affected face-selectivity in the right fusiform cortex in both patients and controls. In contrast to physostigmine's reversal of impairment seen in the Alzheimer's patients, it was found to impair stimulus-related and task-related activity in controls. This finding may reflect a region-specific loss of functional cholinergic inputs in AD and/or regional variations in cortical AD neuropathology. Patients classified as cholinesterase inhibitor (ChEI) responders (based on changes in Clinical Interview Based Impression of Change and Mini Mental State Exam scores) showed a restoration of regional brain function using fMRI in the same areas used by elderly controls while performing semantic association and working memory tasks following 20 weeks of ChEI treatment (Vanneri et al. 2009). In those patients classified as nonresponders, activation patterns appeared less like the elderly controls and there was a reduction in task-related activation. Thus, recent studies tend to suggest that cholinergic stimulation with ChEI agents appears to increase task-related activation and decrease activity in areas of cortex that are unrelated to normal task activity.

Current Acetylcholinesterases

Cholinesterase inhibitors can be described as being either reversible (tacrine, ► donepezil, huperzine, and ► physostigmine), pseudoirreversible (► rivastigmine, metrifonate), or irreversible (soman, sarin, and VX). The latter class has not generally been found to have clinical applications, and are primarily toxic nerve agents or used as pesticides. Four cholinesterase inhibitors have been approved for the symptomatic treatment of AD (see Table 1): tacrine (an aminoacridine), donepezil (a benzylpiperidine), rivastigmine (a carbamate), and ► galantamine (a tertiary alkaloid). Physostigmine was the cholinesterase inhibitor most studied in the early phases of antidementia drug development, but is now generally used only as an investigational tool and for the treatment of glaucoma and myasthenia gravis. Another inhibitor of clinical

importance is huperzine, a lykopodium alkaloid isolated from the Chinese herb Huperiza serrata.

Tacrine was the first reversible acetylcholinesterase inhibitor to be studied and approved for the treatment of AD, and is about four times more potent in its action on butyrylcholinesterase than on acetylcholinesterase. The therapeutic effects of tacrine do not seem to be correlated closely with its anticholinesterase activity, so it is thought that other neurochemical actions of the drug may be contributing to its behavioral activity. Tacrine is also known to produce problematic side effects in many patients, including hepatotoxicity.

Physostigmine is an alkaloid isolated from the seed of a perennial plant of West Africa (the Caliber bean), and is classified as a carbamate acetylcholinesterase and reversible inhibitor (Giacobini 2000). Physostigmine is the most potent of the carbamate derivatives, which also includes rivastigmine. Both of these agents are more selective for butyrylcholinesterase than for acetylcholinesterase.

Rivastigmine is a pseudo-irreversible cholinesterase inhibitor, and is found to specifically inhibit the acetylcholinesterase subtype found primarily in the hypothalamus and cortex. This particular subtype is implicated in the accumulation and maturation of amyloid plaque.

Donepezil was approved as a treatment for AD in 1996, and is known to be more selective for acetylcholinesterase versus butyrylcholinesterase (Giacobini 2000). Donepezil is a reversible inhibitor but due to its long pharmacokinetic half-life (about 100 h), it produces long lasting inhibition. The rate of onset of pharmacodynamic activity, however, is slow because the drug is relatively slowly absorbed.

Galantamine is a reversible acetylcholinesterase and competitive inhibitor, but unlike other agents, can also act on nicotinic receptors by allosteric modulation. As it is a weak cholinesterase inhibitor, this allosteric modulation of nicotinic receptors has been postulated to be a significant contributor to the activity of the drug. It has been proposed that modulation as opposed to agonism may protect against down regulation of post-synaptic receptors and thus allow the drug to have a more sustained action.

Huperzine is a potent, highly specific, reversible inhibitor of acetylcholinesterase. It has been found that the potency of Huperzine A is similar or superior to other inhibitors currently being used in the treatment of AD, based on in vitro and in vivo comparison studies.

Behavioral Effects of Acetylcholinesterase Inhibitors

Due to the extensive distribution of cholinergic pathways in the brain, anticholinesterase activity affects a wide range of behavior in animals and in humans. Although acetylcholine was not identified as a brain transmitter until 1914, physostigmine was isolated as a natural product and used as clinical therapy as early as 1877 (Giacobini 2000). The most recent neuropharmacological application of these agents has been as antidementia drugs. Tacrine was the first drug approved for the treatment of AD and was shown to improve memory, language, praxis, and activities of daily living.

In patients with AD, it is thought that cholinergic deficits in limbic and paralimbic structures contribute to the development of abnormal behavior, and human pharmacology data support the concept that stabilization of cholinergic function could improve both behavioral symptoms and cognitive deficits (Giacobini 2000). Most clinical trials have shown that acetylcholinesterase inhibitors improve scores on cognitive subscales of the AD Assessment Scale, the Mini-Mental State examination, and global scales such as the Clinical Interview-Based Impression of Change (CIBIC). For noncognitve domains, scales such as the AD Assessment Scale (ADAS-noncog) and the Neuropsychiatric Inventory (NPI) scale have most consistently demonstrated the ability of AChEIs to improve noncognitive behavioral problems including apathy, disinhibition, abberant motor behaviors, and anxiety. These agents temporarily improve, stabilize, or reduce the rate of decline in memory and other intellectual functions relative to placebo.

Comparison Between Acetylcholinesterase Inhibitors

In a meta-analysis done by Hansen et al. the affects of three major acetylcholinesterase inhibitors on behavior and cognition in 26 different studies were reviewed. Two trials directly comparing donepezil and galantamine showed conflicting results; the longer 52-week, fixed dosed trial found no significant differences between the agents in cognition for treated patients, while the shorter 12-week trial using flexible doses of drug showed significant differences in cognition and function favoring donepezil. In a 2-year double blinded randomized trial comparing flexible doses of donepezil and rivastigmine, treated patients had similar favorable changes in cognition and behavior as measured by Severe Impairment Battery (SIB) and Neuropsychiatric Inventory (NPI). Patients treated with rivastigmine had significantly better functional and global assessment outcomes. In a shorter, 12-week open label trial comparing flexible doses of donepezil and rivastigmine, no statistically significant differences were seen in cognition. For donepezil, rivastigmine, and galantamine, Hansen et al. concluded that the meta-analyses of placebo-controlled data support modest overall benefits for stabilizing or slowing decline in cognition, function, behavior, and clinical global change (Hansen et al. 2008). In another review of 24 trials, it was found that donepezil improved cognition and global functioning for patients with AD and ► vascular dementia. In 10 studies investigating galantamine versus placebo, there was consistent evidence that patients being treated with galantamine showed a positive effect on cognition and global assessment. There is less consistent evidence for a significant difference in cognition for tacrine versus placebo.

Treatment with cholinergic agents may also show beneficial behavioral and cognitive responses in other disorders with cortical cholinergic abnormalities such as ► Lewy body dementia, Parkinson's disease with dementia, olivopontocerebellar atrophy, vascular dementia, Down's syndrome, and traumatic brain injury. It has also been hypothesized that the cognitive deficits seen in ► schizophrenia could be in part secondary to dysfunction within the cholinergic system. Although findings have been negative, this concept is under investigation with the use of cholinergic agents, e.g., nicotinic agonists, as possible treatments.

Cholinesterase inhibitors have also been reported to prevent and/or reduce common behavioral disturbances seen in patients with AD, including apathy, agitation, and ► psychosis (hallucinations and delusions). Visual hallucinations and apathy are the most commonly reduced symptoms. Anxiety, disinhibition, agitation, depression, delusions, and aberrant motor behavior are also found to improve in some studies but not all.

Factors that may Affect Acetylcholinesterase Effect

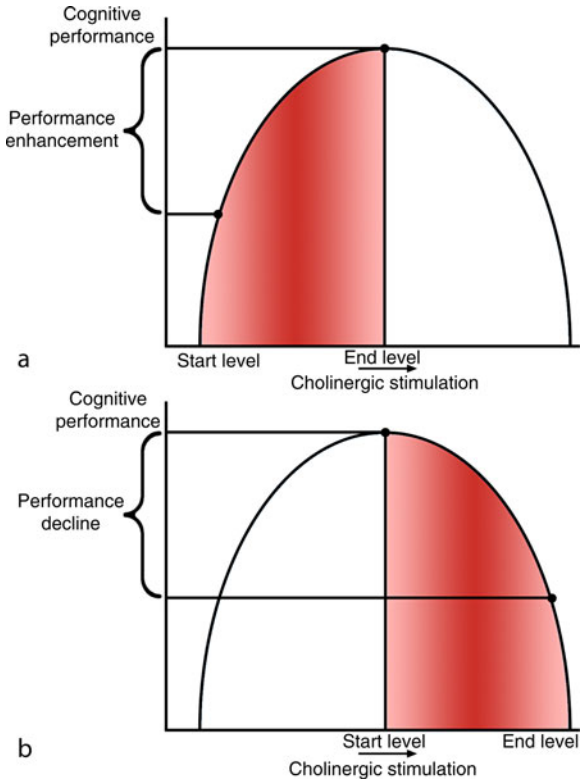
For procholinergic drugs, as the dose is increased, efficacy increases. However, side effects may become a limiting factor more rapidly than loss of efficacy, with an upside down U-shaped curve describing the relationship between cholinergic stimulation and cognitive benefit. Also, due to the phasic properties of cortical acetylcholine function, it is often difficult for increased acetylcholine in the synaptic cleft to result in stimulation of post-synaptic receptors independently from pre-synaptic activity. The ability of pre-synaptic neurons to respond to signaling may also be reduced by excessive autoreceptor stimulation. A wide range of response to treatment is seen, and may be due to variations in cholinergic deficit between patients. There may be a potential role for the ► apolipoprotein E4 genotype, as its presence is linked with late-onset AD, though the effect of this allele on the degree of Alzheimer neuropathology is not clearly understood. These individuals have less brain ► choline acetyltransferase and nicotinic receptor binding, which may contribute to developing cognitive dysfunction from cholinergic deterioration. It is clear that differences in age, disease severity, and genotype may all influence ► cholinergic deficits, and thus, the response to acetylcholinesterase therapy will vary between individuals.

Contradictions Regarding Effects of Acetylcholinesterase Inhibitors on Human Cognitive Functioning

A review of the effects of acetylcholinesterase inhibitors on cognitive functioning and performance in humans demonstrates both performance enhancement and impairment. A careful look at the nature of these disparate studies reveals clues to understanding the seemingly contradictory nature of research in this area.

Studies which tend to show impairment generally use normal unimpaired subjects. These studies tend to conclude that blocking acetylcholinesterase does not improve cognitive functioning and may impair it. By contrast, studies which tend to show improvement generally utilize clinical populations or normal subjects who have been artificially impaired. These studies generally demonstrate and/or conclude that acetylcholinesterase inhibitors have cognitive-enhancing effects. These disparate results can be resolved by considering that the findings reflect the differing populations utilized for the experiments. These populations can be expected to show quite different responses to nicotine based on principles of rate dependency or

baseline effects of cholinergic agents (e.g., the Yerkes-Dodson principal) (Fig. 1). Cognitive performance can be envisioned as a parabolic function related to cholinergic stimulation with intermediate levels of stimulation producing optimal performance and either low or high levels of stimulation impairing performance. If an individual subject who is performing suboptimally due to a disease state or impairment (e.g., AD), his performance will be enhanced by increased cholinergic stimulation via acetylcholinesterase inhibition (Fig. 1a). However, if an individual subject is already performing at or near their optimal level of performance, increasing cholinergic stimulation following acetylcholinesterase inhibitor administration will produce deterioration in cognitive functioning (Fig. 1b). The same analysis may apply if the individual is normal but the task demands are severe.



Acetylcholinesterase and Cognitive Enhancement. Fig. 1. Effects of cholinergic stimulation through acetylcholinesterase blockade are dependent on baseline performance and are subject to nonlinear effects. (**a**) Baseline performance is low and cholinergic augmentation through produces improvement in performance. (**b**) Baseline performance is normal/high and cholinergic augmentation impairs performance.

If the task is demanding enough in terms of attention, especially over a period of time, then the individual may move back to the left in terms of the performance curve and optimal performance may require enhanced cholinergic stimulation.

Studies of normal volunteers are thus unlikely to show cognitive improvement with cholinergic stimulation due to the fact that these individuals are likely to be operating at or near their optimal level of performance, particularly in the setting of experimental paradigms with pre-training for cognitive tasks, financial incentives, etc.

The preponderance of evidence is that stimulation of cholinergic receptors is most easily detected by effects on attentional systems and to some extent psychomotor speed. The most well-documented effect of cholinergic augmentation is on intensifying or sustaining attention to stimuli or tasks over a prolonged period of time. In addition, there is evidence from studies of individuals with disorders such as schizophrenia and ADHD that nicotinic cholinergic stimulation enhances selective attention, sensory detection, and inhibitional processes in attention. Positive effects of nicotinic stimulation, via acetylcholinesterase inhibitors on learning in memory may be mediated by effects on attentional functioning. Learning and memory require acquisition, encoding, storage, and retrieval. However, attention is the "front end" of this process, and adequate attentional functioning is a primary requirement for higher order processing.

Attention and related processes may be thought of as an endophenotype for cholinergic stimulation and consequently drug development. Attention, central processing impairment, and executive dysfunction may be orthogonal to the underlying neuropsychiatric diagnoses and should be considered as an independent target for drug development across diagnostic categories. Particular attentional deficits in different diagnoses may still respond to cholinergic stimulation with acetylcholinesterase inhibitors, however, the parameters for assessing improvement may be quite different between disease states and will require careful attention to particular specific agents, dosing regimens, and outcome measures for experimental studies. Paying careful attention to the issue of baseline dependency in treatment response will be vital to ensuring appropriate interpretation of experimental results, both for studies of normals and individuals with disease states. Targeting specific populations that are already impaired is much more likely to reveal potential benefits of cholinergic stimulation. Studies of normal or unimpaired individuals with acetylcholinesterase inhibitors are unlikely to show cognitive benefits except under extreme task demands.

Action Potentials

Nerve impulse; Nerve spikes

Definition

Action potentials are pulse-like waves traveling along excitable membranes. Action potential initiation occurs when the voltage of the membrane increases sufficiently (depolarizes), thus activating (opening) voltage-gated sodium channels. Since the concentration of sodium channels outside the cell is much larger than the inside, sodium ions rush into the cell and represent the fast upstroke portion of the action potential wave. The Na channels close as the voltage peaks, and potassium channels then open allowing potassium ions to flow out of the cell since the concentration of potassium ions is much larger on the inside of the cell than the outside. This represents the falling phase of the action potential

waveform, and thus repolarizes the membrane ready for the next action potential.

Active Avoidance

Marie-Louise G. Wadenberg
Department of Natural Sciences, University of Kalmar, Kalmar, Sweden

Synonyms

Conditioned avoidance response; two-/one-way active avoidance

Definition

Active avoidance refers to experimental behavioral paradigms where subjects (mainly rodents) are trained to, following the onset of a conditioned stimulus (CS), move from a starting position to another position in the testing apparatus within a fixed amount of time (avoidance). Failure to move within the given time frame, results in the onset of a negative reinforcer, usually a weak electric shock in a grid floor, until a correct move is performed (escape). In animals performing at a high level of correct response following training, drugs that are effective as antipsychotics, but not other classes of drugs, show a unique ability to selectively suppress the avoidance behavior, within a clinically relevant dose range, while leaving escape behavior intact. Because of this robust marker for the prediction of antipsychotic activity, the active avoidance test is primarily used, and considered an important screening tool, for the detection of novel potentially ► antipsychotic drugs.

Principles and Role in Psychopharmacology

Background

It was found early that antipsychotic drugs for the treatment of ► schizophrenia had the ability to produce a selective suppression of active avoidance/conditioned avoidance behavior in rats (Cook and Weidley 1957). Later, as more antipsychotic drugs came on the market, it was found that this was a unique property among antipsychotics that was not shared by other classes of pharmacological agents, and that the selective suppression of conditioned avoidance response (CAR) produced by the antipsychotic drugs correlated with their main therapeutic mechanism of action namely brain dopamine D2 receptor blockade (Arnt 1982).

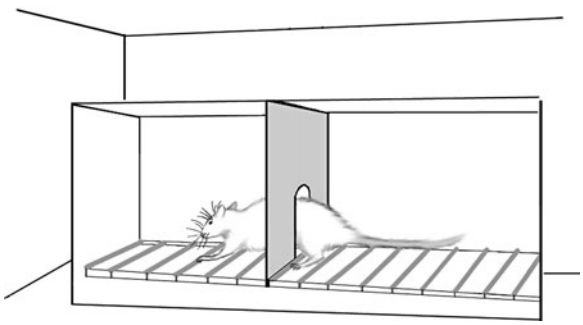
History and Procedures

The active avoidance procedure has connections back to classical conditioning (as first presented by I.P. Pavlov in 1927) (► Classical (Pavlovian) conditioning). The concept was further developed by the experimental psychologist B.F. Skinner. Skinner showed that a certain behavior could be maintained by the consequences it produced, and called this type of behavior operant behavior (► Operant behavior in animals). Thus, operant behavior (such as active avoidance response) can be defined as behavior that is maintained by its consequences.

The basic principle of active avoidance is that an animal (usually rodent) is trained (conditioned) to make a specific response within a fixed time interval when presented with an auditory, or visual, stimulus (CS). During training, incorrect responses (i.e., late responses) will trigger a negative reinforcer (unconditioned stimulus; UCS), usually a weak electric footshock presented in a grid floor, that will be active together with the CS until a correct response occurs. Thus, the animal terminates the negative reinforcer (together with the CS) by making the appropriate response. If the response, expected to be performed by the animal, is to move from one place to another upon presentation of the CS, the procedure is said to be using the active avoidance paradigm. Active avoidance procedures using a negative reinforcer typically record three dependent variables: avoidance (correct move within stipulated time frame), escape (correct, but late, move following onset of negative reinforcer), and escape failure (failure to perform a correct move despite the onset of negative reinforcer within a certain cut-off time) (see e.g., Wadenberg et al. 2007).

The active avoidance paradigm can be carried out mainly in two different ways: (1) one-way active avoidance; (2) two-way active avoidance. The one-way active avoidance procedure has the experimenter placing the animal in a chamber with a metal grid floor (for the electric shock, UCS), and upon presentation of the CS, the animal is required to move from the starting chamber into another (safe) compartment of the experimental box or jump onto a wooden pole hanging down from the ceiling of the box. The experimenter then has to move the animal back into the starting chamber for the next trial. In the two-way active avoidance procedure on the other hand, the animal moves back and forth (shuttles) between two compartments of equal size and appearance in the box via an opening in the partition dividing the box into the two compartments (shuttle-box) (Fig. 1). Here, the animal has to learn that upon presentation of the CS, it is always supposed to cross over to the other empty compartment in the box. Training and experimental sessions typically consist of a fixed number of trials over a certain time interval. The two-way active avoidance procedure has over time become the most commonly used procedure, most likely in part because this procedure can be set up as a computer-assisted apparatus with several boxes run simultaneously by one computer, thus saving time and money.

The training phase (typically needing three to four consecutive training days) in the active avoidance paradigm can be considered an acquisition phase (i.e., acquisition of avoidance performance), while, following training, animals that perform well show retention (over time) of the acquired avoidance performing ability. Screening for novel, potentially antipsychotic drugs uses well-trained, high avoidance performing animals. The marker for potential antipsychotic activity thus is the ability of an acutely administered drug to selectively, and temporarily, suppress the retention of avoidance performance in the animals.



Active Avoidance. Fig. 1. The figure shows a conventional two-way active avoidance apparatus (schematic drawing by Sofia I Wadenberg).

Evaluation and Use of the Active Avoidance Test

Animal behavioral tests (so-called animal models), used in the development of novel drugs for pharmacological treatment of diseases, are typically evaluated and rated for their fulfillment of validity criteria such as (1) predictive, construct and face validity; (2) their reliability; and (3) how they fare in terms of producing false positives or negatives. The active avoidance test is commonly considered to have high predictive validity, since all clinically effective antipsychotics, but not other classes of drugs, show the ability to selectively suppress avoidance behavior with a positive correlation between doses needed for the selective suppression of avoidance and their clinical potency for the effective treatment of schizophrenia (Seeman et al. 1976). More recently it was also found that antipsychotics produce selective suppression of avoidance in doses that result in a brain striatal dopamine D2 receptor occupancy around 65–75% in the rat (Wadenberg et al. 2001), which is also the percentage of dopamine D2 receptor occupancy usually needed for therapeutic response to occur in schizophrenic individuals following antipsychotic treatment. In other words, the active avoidance test identifies potential antipsychotic activity of new drugs tested with high predictive certainty. The active avoidance test has also been shown to have some construct validity (i.e., selective suppression of avoidance may mimic a blockade of some pathophysiological mechanisms in schizophrenia). Thus, the local application of an antipsychotic-related dopamine D2 receptor blocking agent, (-)sulpiride, into various brain areas in the rat, produced selective suppression of avoidance only when injected into the nucleus accumbens/ventral striatum (Wadenberg et al. 1990), a brain area that has a prominent role in the dopamine mesolimbic pathway that is commonly thought to be involved in the psychotic symptoms in schizophrenia (Laruelle et al. 1996) (► Aminergic hypotheses for schizophrenia). The active avoidance test has, however, no face validity, as it does not mimic any behavioral core symptoms of schizophrenia. The active avoidance test also shows high reliability, as there is a high degree of agreement between laboratories as to which compounds produce antipsychotic-like effects and in what dose range that occurs. Finally, to the best of the Author's knowledge, the active avoidance test produces few, if any, false positives or negatives. Thus, there is no antipsychotic, known to be clinically effective, that does not produce a selective suppression of active avoidance within a clinically relevant dose range. In addition, drugs

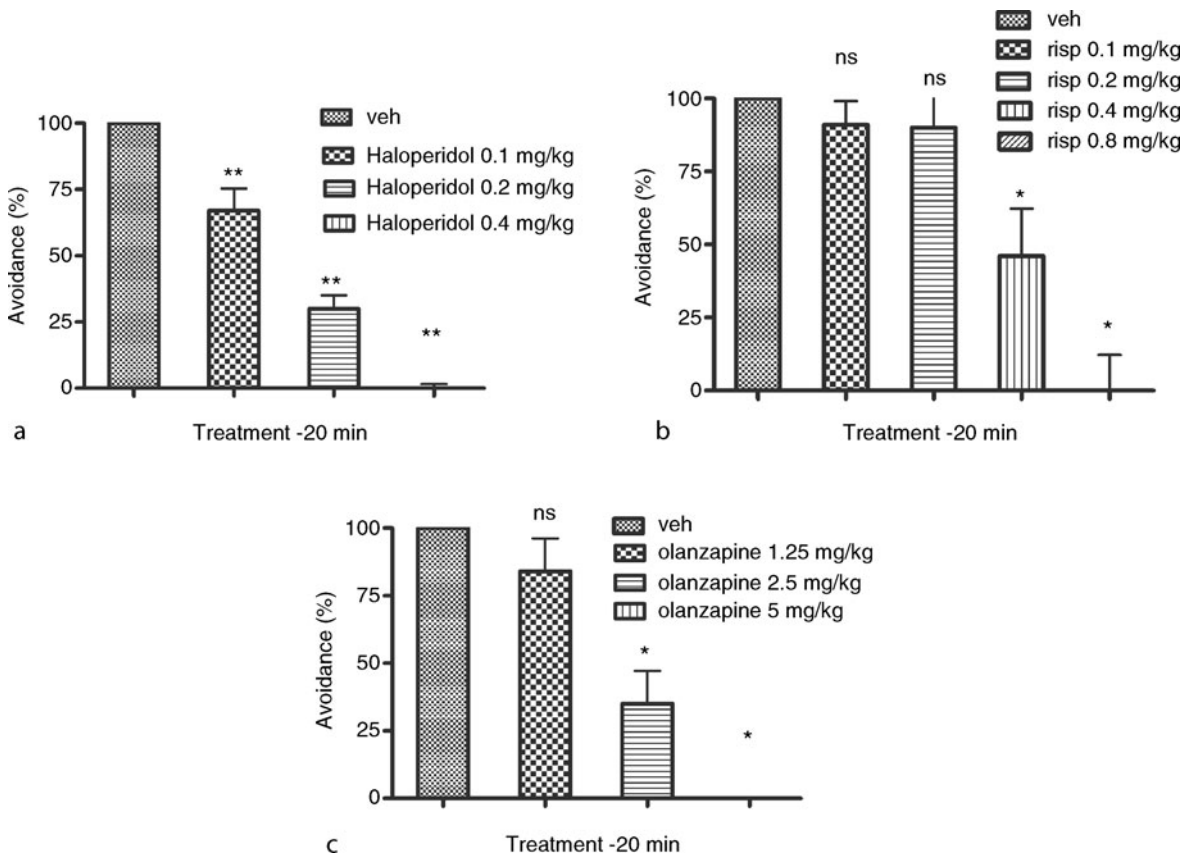
that have failed in clinical trials, or studies, for antipsychotic activity (such as for example, selective serotonin2A antagonists, selective dopamine D1 or D4 receptor antagonists) also, either showed no effect on active avoidance, or failed to produce a dose dependent suppression of avoidance without concomitant inhibition also of the escape variable (i.e., producing failures).

Based on the properties listed above, the active avoidance test falls into the category of so-called screening tests. A screening test is used by drug companies to evaluate synthesized molecules for a specific therapeutic property. When the screening test is an animal behavioral test, drug companies usually label the procedure in vivo pharmacology. Effects in these tests should occur following an acute administration of test drug, and only molecules that are effective against a particular disease should produce the specific effect that constitutes the marker for clinical activity – in this case selective suppression of avoidance within a clinically relevant dose range is produced.

The Active Avoidance Test and Identification of Drug Pharmacological Properties

There is no doubt that active avoidance behavior is strongly associated with brain dopamine neural transmission, and that the suppression of avoidance performance correlates significantly with the degree of striatal dopamine D2 receptor occupancy produced by D2 receptor blocking antipsychotic drugs. However, the active avoidance test not only identifies traditional, mainly dopamine D2 blocking antipsychotics such as haloperidol (Fig. 2a), but is also equally sensitive in detecting the antipsychotic activity of the newer, so-called atypical, antipsychotics with a different mechanism of action such as combined lower dopamine D2/high serotonin2 receptor blockade (e.g., olanzapine, risperidone) (Fig. 2b,c), or being partial agonists at dopamine D2 receptors rather than pure D2 antagonists (i.e., aripiprazole).

In addition, data from clinical studies (Litman et al. 1996; Schubert et al. 2006) are in line with, and support,



Active Avoidance. Fig. 2. Shown are typical dose-response effects on active avoidance response (selective suppression of avoidance) by the typical antipsychotic haloperidol (**a**), and the atypical antipsychotics risperidone (**b**), and olanzapine (**c**) in rats. Data are presented as medians ± semi-interquartile range (n=6–9).

experimental data showing that the active avoidance test also reliably detects sufficient antipsychotic activity obtained by adjunct treatment with some non-D2 blocking agents (such as alpha2 adrenoceptor antagonists or acetylcholinesterase inhibitors) to a low dose of an antipsychotic not giving sufficient dopamine D2 occupancy alone to produce antipsychotic activity (Wadenberg and Karlsson 2007; Wadenberg et al. 2007). Thus, the ability of the active avoidance test to detect antipsychotic activity does not seem to be solely limited to the detection of drugs with direct dopamine D2 receptor blocking properties. This certainly increases the value of this test as a screening tool in further development of new antipsychotic drugs, since many current development strategies, in order to minimize side effects and improve therapeutic efficacy, aim at moving away from molecules with mainly strong dopamine D2 receptor blocking properties.

Alternative Use of the Active Avoidance Test

The active avoidance test is primarily a test for detecting antipsychotic activity, that is, the ability of tested compounds to counteract psychotic symptoms in patients. However, since there is an element of training and learning (acquisition) associated with this test, there have been attempts to investigate if the test may be used also as a model for the detection of compounds that will enhance learning (effects on acquisition) or memory (effects on retention). Such attempts have overall not produced any consistent data. In fact, drugs that normally would impair memory (such as for example, drugs blocking brain neural transmission of acetylcholine) do not suppress avoidance behavior. Furthermore, the administration of a dopamine D2 receptor blocking antipsychotic to the animals during the training/acquisition phase does not impair the final outcome of avoidance performance in the absence of drug. This would suggest that suppressive effects on avoidance performance are not related to the impairment of memory, but rather to a temporary attenuation of the conditioned reflex, or urge, to hurry over to the other side in order to avoid getting a footshock. Indeed, gross observations of the behavior in animals given an antipsychotic drug strongly indicate that upon presentation of the CS, these animals still remember exactly what they are supposed to do; they just do not care enough to move within the time frame. Another way of explaining this phenomenon, although somewhat speculative, could be that the reason why active avoidance does not seem to work as a memory test, is because the acquisition and retention performance of active avoidance seem to primarily involve the brain subcortical mesolimbic system in general considered to be mediating behavior associated with basic reward and survival factors (i.e., survival reflexes), rather than recruiting higher order brain structures, such as for example, the prefrontal cortex, that are involved in memory processes of higher order events (Wadenberg et al. 1990).

Advantages and Limitations of the Active Avoidance Test

The active avoidance test has proven to be a unique and very useful screening test for the detection of drugs with antipsychotic activity with high predictive validity as well as excellent reliability. However, individuals suffering from schizophrenia do not only present with psychotic symptoms, but also have features of social withdrawal and cognitive impairment. These symptoms have a crucial impact on the quality of life for these individuals, and unfortunately, many of the currently used antipsychotics do not adequately improve these symptoms. Therefore, novel compounds showing antipsychotic-like effects in the active avoidance test, need to be tested also in an animal model of cognition as a complementary investigation of their potential cognitive enhancing activity compared with currently used antipsychotics. A major improvement in the field would be the development of an animal behavioral screening test that identifies both antipsychotic and cognitive enhancing activity of tested drugs.

Activities of Daily Living

Definition

The activities of daily living (ADLs) are a defined set of activities necessary for normal self-care. The activities are movement in bed, transfers, locomotion, dressing, personal hygiene, and feeding. These six activities are defined as follows:

1. Movement in bed (sitting in, rising from, and moving around in bed)
2. Transfers (moving from one seat to another, changing position from sitting to standing, and transferring to and from the toilet and bed)
3. Locomotion (walking on the level, on gentle slopes, and downstairs)
4. Dressing (putting on socks, stockings, and shoes, as well as clothing the upper and lower trunk)
5. Personal hygiene (grooming, and washing of face, trunk, extremities and perineum)
6. Feeding (eating and drinking, but not the preparation of food)

Acute Disappointment Reaction

Definition

A syndrome involving lowered or dysphoric mood, which occurs in response to a perceived unpleasant experience such as a loss, rejection, or insult to one's self-concept or self-esteem. The person having the acute disappointment reaction may or may not be fully aware of, or fully able to explain, the issue to which the reaction is in response. Acute disappointment reactions are usually relatively brief – generally lasting at most a week or two – unless the insult to which the response is attached is of a repetitive or continuing nature.

Addiction

Definition

The condition of a human or an animal where a drug is sought after and taken in spite of negative consequences to the individual. It is a state of obsession and compulsion in which the body depends on a substance for normal functioning, characterized by a loss of control over its consumption. The use of the term is usually restricted to the most serious and severe forms of drug abuse.

Definition

The Addiction Research Center (ARC) began as the research component of the U.S. Narcotics Prison Farm located in Lexington, Kentucky. It was a very important site for early clinical pharmacology studies of opioids and other drugs of abuse. Methods for assessing the physiological and subjective effects of drugs of abuse were refined here, and include such instruments as the Addiction Research Center Inventory and the Single Dose Questionnaire. The ARC eventually became the intramural research unit of the National Institute on Drug Abuse and moved to Baltimore, Maryland.

ARCI

Definition

A true/false questionnaire developed at the Addiction Research Center used to assess the subjective effects of various drugs of abuse. Items include such statements as:

I have a pleasant feeling in my stomach.
I am sweating more than usual.
I have a floating feeling.
My movements seem slower than normal.

The original version had 550 such statements, but newer and shorter versions have been developed and validated as well. The most widely used version today includes only 49 items. Responses on the ARCI yield scores on various scales (five for the short form) that were empirically derived by administering known drugs of abuse and establishing the pattern of responses. For example, the Morphine-Benzedrine Group scale (MBG) is used as a proxy for the euphoric effects produced by opioids and amphetamines.

Definition

Animal model: Experimental preparation developed for studying a given phenomenon found in humans. It is at the basis of experimental medicine, with its two sides: physiology and pathology.

Individual differences: Refer to the concept of differential psychology, personality, and temperament. Each individual is unique in terms of genetic and environmental backgrounds, and of life events and history.

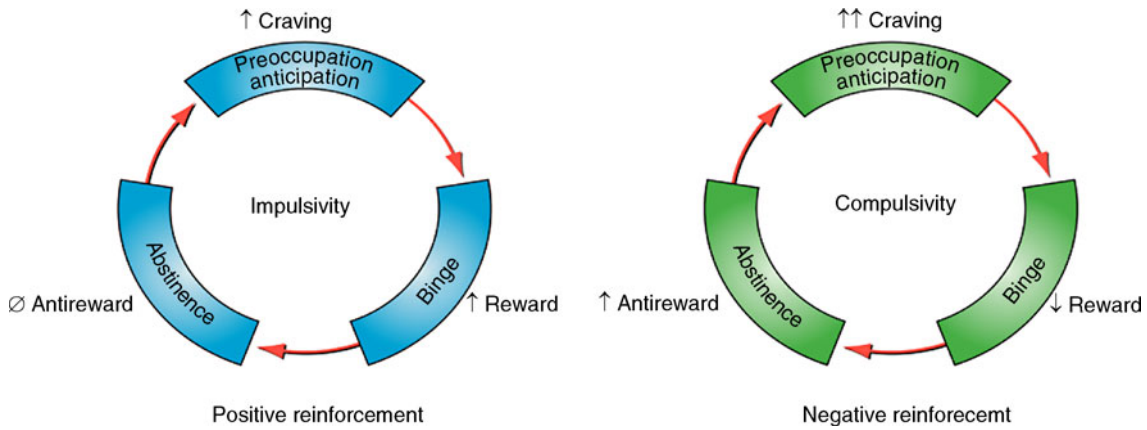
Vulnerability or frailty: A construct inherent to medical practice, for genetic or environmental reasons. It represents a biological state at the limits of homeostasis.

Current Concepts and State of Knowledge

Introduction: A Model of What?

In behavioral pathology and comparative psychiatry a precondition for an animal model is to be informed about what will be modeled. The poor awareness of the complexity of such human conditions is the origin of misunderstanding between clinicians and neurobiologists. This is particularly true in the field of drug abuse. Drug ► addiction, also known as substance dependence, is characterized by (1) compulsion to seek and take the drug, (2) loss of control in limiting intake, and (3) emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) when access to the drug is prevented (Koob and Le Moal 1997). The terms addiction and substance dependence (as currently defined by the American Psychiatric Association (1994)) are used interchangeably and refer to a final stage of a misusage process that moves from drug use to a chronic relapsing disorder. This point is critical. It is referred here to a brain pathology from which a recovery is questionable. In other words, the occasional but limited or controlled use of a drug with a potential for abuse or dependence is distinct from the emergence of a chronic drug-dependent state. An important goal of current neurobiological research is to understand the molecular and neuropharmacological neuroadaptations within specific neurocircuits that mediate the transition from occasional, controlled drug use to the loss of behavioral control over drug seeking and drug taking. A key element of the addiction process is the underactivation of natural motivational systems such that the reward system becomes compromised and that an antireward system becomes recruited to provide the powerful motivation for drug seeking associated with compulsive use (Koob and Le Moal 2008).

The process of drug addiction involves elements of both ► impulsivity and compulsivity (Fig. 1), where impulsivity can be defined by an increasing sense of tension or arousal before committing an impulsive act and by a sense of pleasure, gratification, or relief at the time of



Addictive Disorder: Animal Models. Fig. 1. "The addiction cycle." Diagram describing the addiction cycle that is conceptualized as having three major components: preoccupation/anticipation ("craving"), binge/intoxication, and withdrawal/negative affect. Note that as the individual moves from the impulsivity stage to the compulsivity stage, there is a shift from positive reinforcement associated with the binge/intoxication component to negative reinforcement associated with the withdrawal/negative affect component. Craving is hypothesized to increase in the compulsivity stage because of an increase in the need state for the drug that is driven not only by loss of the positive reinforcing effects of the drugs (tolerance), but also by generation of an antireward state that supports negative reinforcement. (Reproduced with permission from Koob and Le Moal 2008.)

committing the act. Compulsivity can be defined by anxiety and stress before committing a compulsive repetitive behavior and relief from the stress by performing the compulsive behavior. Collapsing the cycles of impulsivity and compulsivity yields a composite addiction cycle comprised of three stages: preoccupation/anticipation, binge/intoxication, and withdrawal/negative effect, where impulsivity often dominates at the early stages and compulsivity dominates at terminal stages. As an individual moves from impulsivity to compulsivity, a shift occurs from positive reinforcement driving the motivated behavior to negative reinforcement driving the motivated behavior. These three stages interact with each other, becoming more intense, and ultimately leading to the *final pathological state*: addiction. Here it is important to realize that the main symptoms correspond to different structural–functional entities including large systems in the brain.

Classic Validation of Animal Models of Drug Addiction

- General typology of animal models

Animal models are critical for understanding the neuropharmacological mechanisms involved in the development of addiction. While there are no complete animal models of addiction, animal models may exist for elements of the syndrome. An animal model can be viewed as an experimental preparation developed for studying a given phenomenon found in humans (McKinney 1988; Geyer and Markou 2002). The most relevant conceptualization of validity for animal models of addiction is the concept of *construct validity*. Construct validity refers to the interpretability, "meaningfulness," or explanatory power of each animal model and incorporates most other measures of validity where multiple measures or dimensions are associated with conditions known to affect the construct. An alternative conceptualization of construct validity is the requirement that models meet the construct of functional equivalence, defined as assessing how controlling variables influence outcome in the model and the target disorders and the most efficient process for evaluating functional equivalence has been argued to be through common experimental manipulations, which should have similar effects in the animal model and the target disorder (Katz and Higgins 2003). This process is very similar to the broad use of the construct of *predictive validity*. *Face validity* often is the starting point in animal models where animal syndromes are produced, which resemble those found in humans in order to study selected parts of the human syndrome but is limited by necessity. *Reliability* refers to the stability and consistency with which the variable of interest can be measured and is achieved when, following objective repeated measurement of the variable, small within- and between-subject variability is noted, and the phenomenon is readily reproduced under similar circumstances. The construct of *predictive validity* refers to the model's ability to lead to accurate predictions about the human phenomenon based on the response of the model system. Predictive validity is used most often in the narrow sense in animal models of psychiatric disorders to refer to the ability of the model to identify pharmacological agents with potential therapeutic value in humans. However, when predictive validity is more broadly extended to understanding the physiological mechanism of action of psychiatric disorders, it incorporates other types of validity (i.e., etiological, convergent or concurrent, discriminant) considered important for animal models, and approaches the concept of construct validity. Some animal models have been shown to be reliable and to have construct validity for various stages of the addictive process will be described.

- Animal models and the stages of the addiction cycle

Table 1 summarizes the models used in most laboratories according to the stages of the addiction cycle.

1. Animals models for the Binge/Intoxication Stage

According to the evolution of the process defined above (Fig. 1), the individual moves from impulsivity to compulsivity with the development of preoccupation-anticipation and when he or she is in abstinence, negative effect and withdrawal symptoms progressively appear as signature of addiction. The procedures used have proven reliability and to have predictive validity in their ability to understand the neurobiological basis of the acute reinforcing effects of drugs. If one could reasonably argue that drug addiction mainly involves counteradaptive mechanisms that go far beyond the acute reinforcing actions of drugs, understanding the neurobiological mechanisms for positive reinforcing actions of drugs of abuse also provides a framework for understanding the motivational effects of counteradaptive mechanisms. Many of the operant measures used as models for the reinforcing effects of drugs of abuse lend themselves to within-subjects designs, limiting the number of subjects required. Indeed, once an animal is trained, full dose-effect functions can be generated for different drugs, and the animal can be tested for weeks and months. Pharmacological manipulations can be conducted with standard reference compounds to validate any effect. In addition, a rich literature on the experimental analysis of behavior is available for exploring the

hypothetical constructs of drug action as well as for modifying drug reinforcement by changing the history and contingencies of reinforcement. The advantage of the intracranial self-stimulation (ICSS) paradigm as a model of drug effects on motivation and reward is that the behavioral threshold measure provided by ICSS is easily quantifiable. ICSS threshold estimates are very stable over periods of several months. Another considerable advantage of the ICSS technique is the high reliability with which it predicts the abuse liability of drugs. For example, there has never been a false positive with the classic discrete trials threshold technique. The advantages of place conditioning as a model for evaluating drugs of abuse include its high sensitivity to low doses of drugs, its potential utility in studying both positive and negative reinforcing events, the fact that testing for drug reward is done under drug-free conditions, and its allowance for precise control over the interaction of environmental cues with drug administration.

2. Animal Models for the Preoccupation/Anticipation Stage

Each of the models outlined above has face validity to the human condition and ideally heuristic value for understanding the neurobiological bases for different aspects of the craving stage of the addiction cycle. The DSM-IV criteria that apply to the craving stage and loss of control over drug intake include any unsuccessful effort or persistent desire to cut down or control substance use. The extinction paradigm has predictive validity, and with the reinstatement procedure, it can be a reliable indicator of the ability of conditioned stimuli to reinitiate drug-seeking behavior. The conditioned-reinforcement paradigm has the advantage of assessing the motivational value of a drug infusion in the absence of acute effects of the self-administered drug that could influence performance or other processes that interfere with motivational functions. For example, nonspecific effects of manipulations administered before the stimulus drug pairings, do not directly affect the assessment of the motivational value of the stimuli because the critical test can be conducted several days after the stimulus drug pairings. Also, the paradigm contains a built-in control for nonspecific motor effects of a manipulation by its assessment of the number of responses on an inactive lever.

The animal models for the conditioned negative reinforcing effects of drugs are reliable measures and have good face validity. Work in this area, however, has largely been restricted to the opiate field where competitive antagonists precipitate a withdrawal syndrome. There is consensus that the animal reinstatement models have face validity. However, predictive validity remains to be established. To date, there is some predictive validity for the stimuli that elicit reinstatement in the animal models, but little evidence of predictive validity from studies of the pharmacological treatments for drug relapse. Very few clinical trials have tested medications that are effective in the reinstatement model, and very few anti-relapse medications have been tested in the animal models of reinstatement. From the perspective of functional equivalence or construct validity there is some evidence of functional commonalities. For example, drug re-exposure or priming, stressors, and cues paired with drugs all produce reinstatement in animal models and promote relapse in humans.

3. Animal Models for the Withdrawal/Negative Affect Stage

It has been proposed by some authors that the motivational measures of drug withdrawal have much the

same value for the study of the neurobiological mechanisms of addiction as procedures used to study the positive reinforcing effects of drugs. ICSS threshold procedures have high predictive validity for changes in reward valence. The disruption of operant responding during drug abstinence is very sensitive. Place aversion is hypothesized to reflect an aversive unconditioned stimulus. Drug discrimination allows a powerful and sensitive comparison to other drug states. The use of multiple dependent variables for the study of the motivational effects of withdrawal may provide a powerful means of assessing overlapping neurobiological substrates and to lay a heuristic framework for the counteradaptive mechanisms hypothesized to drive addiction.

Individual differences, the concept of vulnerabilities and animal models

(a) Individual differences: a central problem in addiction medicine

For all the paradigms presented above and in consequence for these animal models used, all the subjects (rodents) are equal. The data are presented by means with their standard errors. In clinical practice, huge individual differences exist for the proneness to take drugs, for their perceived reinforcing effects and above all for the propensity to continue to misuse them and enter in a spiral of addiction. In other words, one of the most important problems in drug addiction today is to understand why an enormous amount of people take drugs according to the various circumstances of social life whereas only a small percentage of them will become addicted. Some individuals can stop their misusage without noticeable withdrawal syndrome. It is also reported that some get hooked with the first usage. Some individuals are vulnerable, other not. Vulnerability refers to a construct that covers all the fields of medicine. After a period devoted to the description of symptoms and diagnostic, then to identify the pathophysiological bases of the disease, then to find the causes, then to cure, predictive medicine will be the next step, i.e., to discover markers and prodromic states of vulnerabilities. Some vulnerabilities are specific for a given class of diseases, other are, in the state of knowledge, nonspecific. It is a strange phenomenon that while the problem of vulnerability in addiction medicine is abundantly discussed in clinical literature, it is almost completely absent in experimental and animal research.

Needless to say, drugs also have their own pharmacological effects that depend on intrinsic and differential dangerousness of the products. However, a drug is addictive because a specific individual in a given social environment uses it. Moreover, a vulnerable phenotype and vulnerability are revealed a-posteriori.

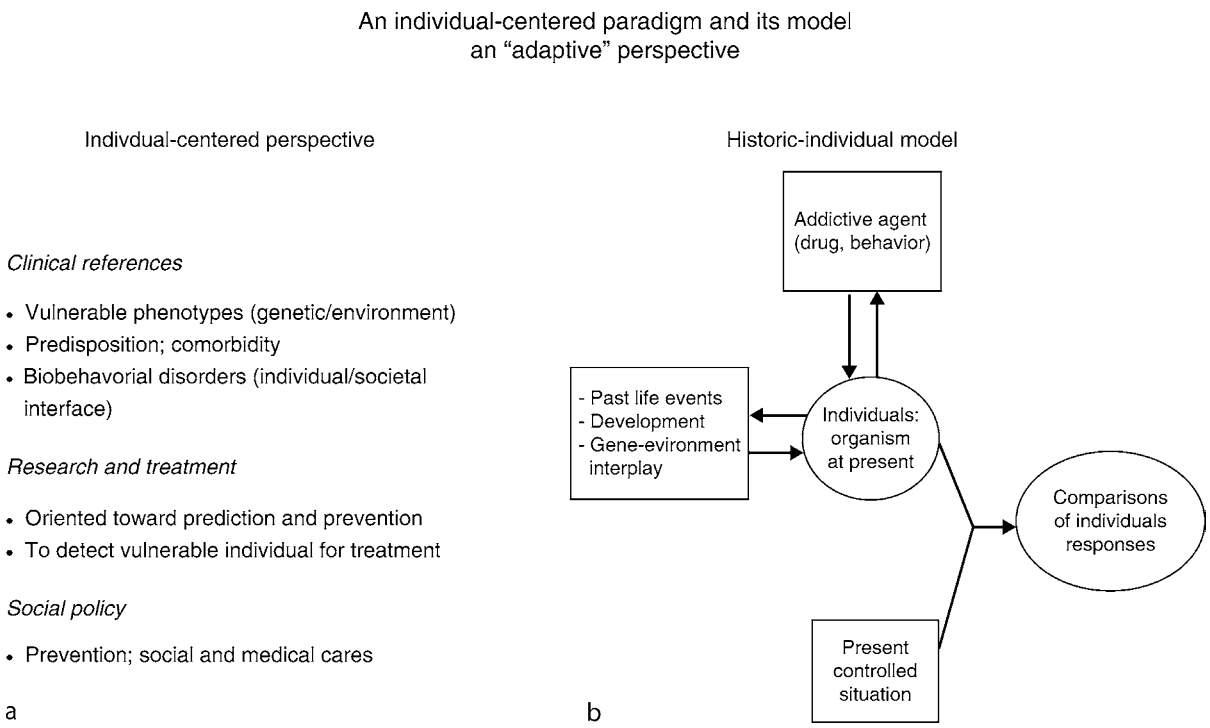
The origins of vulnerability are numerous and interacting: genetic, environmental, aversive life events and stress, age and gender. All these factors have left traces in the organism. Vulnerability participates to psychopathological syndromes and to comorbid factors diagnosed in most of the psychiatric disorders. Each individual has his own history that participates in a unique way to the entrance in addiction process. These factors, each or associated, contribute to psychobiological traits. However, such a view, based on clinical observations and studies is at variance with most of the experimental investigations and raised methodological considerations about animal and biological models and the neuroscience of addiction in general.

(b) Vulnerability and transition to addiction: two opposite views

The first one, adaptive or individual-centered, places the subject with his own characteristics at the center of research and interest. The adaptive perspective (Fig. 2) is based on a predisposition, on the fact that explains why subjects are at risk and why their intrinsic predisposed state determines the neuroplasticity induced by drugs.

To detect the sources of vulnerability would lead to predictive medicine and toward psychosocial interventions. A translation from the real world and from clinical psychiatry to the laboratory must discover and develop models that will present (1) gradual individual differences from the resilient to the most vulnerable phenotypes, (2) a transition from use to misuse for some animals prone to enter in the disease spiral and, (3) the main symptoms of the disease as defined by the DSM IV at the end of the process. An individual-centered approach is basically a historic approach. Patients and animals are considered different and more or less vulnerable because of their past, of developmental characteristics or genetic background. The sequences of the process are represented in Fig. 3.

This paradigm opposes classic pharmacological approaches, i.e., drug-centered, or exposure model, based on drug-induced neuroplasticity and on acquired vulnerability. Here, drug abuse is a iatrogenic disorder and both research and therapeutics are oriented toward understanding drug pharmacological properties and toxicological actions on brain substrates, and toward counteracting these effects by other pharmacological means. This paradigm is largely dominant in laboratory research; animals are considered not in relation with their past (a-historic models) but with the amount of drug taken (Fig. 4).



Addictive Disorder: Animal Models. Fig. 2. "An individual-centered research paradigm (**a**) for an historic-individual animal model (**b**)." Individuals are considered as different from the point of view of their past life events, developmental characteristics, and genetic background. Individual comparisons require nonparametric statistics. (Reproduced with permission from Le Moal (2009) Drug abuse: vulnerability and transition to addiction. Pharmacopsychiatry 42:S42–S55, © Georg Thieme Verlag Stuttgart, New York.)

Individual differences are hidden under statistical standard errors or considered as protocol artifacts.

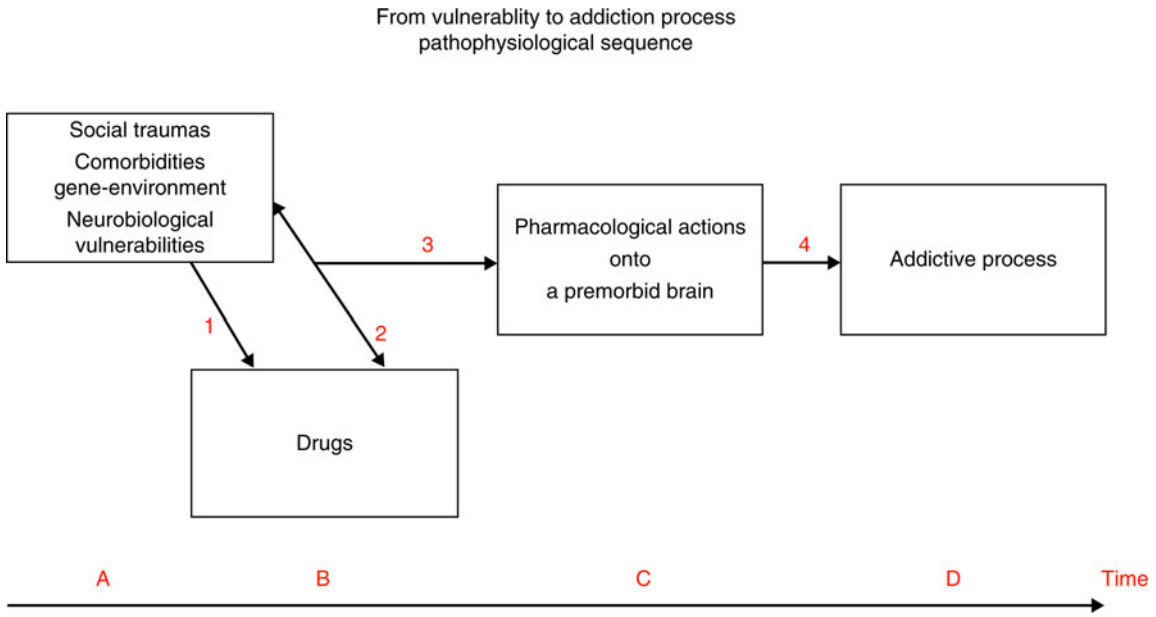
These two different research interests and practices have their own logic and necessities and are sometimes complementary. It is important to discover the neurotoxic damages and neuroplasticities induced by drugs. These neurobiological changes explain the transition from impulsive to compulsive behaviors and loss of control. Drugs of abuse have different addictive properties. It is a trivial observation that frequent usage of a drug, or the repetition of specific behaviors, combined with the intrinsic dangerous state of each drug (gambling, eating, sex...) are dangerous by themselves and lead progressively to loss of control.

(c) Two recent models: drug-centered versus individual centered

A conceptual framework upon which animal models can be directly related to the compulsive behavior and loss of control over intake, that is the hallmark of addiction, is to specifically relate a given animal model to a specific symptom of the DSM-IV criteria for addiction. Recent studies have emphasized animal models that contribute to specific elements of the DSM-IV criteria with strong face validity, and at the same time may represent specific endophenotypes of the compulsive nature of the addiction process.

1. Ahistoric model: escalation in drug self-administration with prolonged access

A progressive increase in the frequency and intensity of drug use is a behavioral phenomena often characterizing the development of addiction and has face validity with the DSM-IV criteria. A framework with which to model the transition from drug use to drug addiction is found in a recent animal model of prolonged access to intravenous cocaine self-administration. Historically, animal models of cocaine self-administration involved the establishment of stable behavior from day to day to allow the reliable interpretation of data provided by within-subject designs aimed at exploring the neuropharmacological and neurobiological bases of the reinforcing effects



Addictive Disorder: Animal Models. Fig. 3. "Vulnerability to addiction process." A given drug or behavior (e.g., eating, gambling, sex) is "addictive" because of its exposure to a vulnerable individual (1) who will be prone to repeat the drug use (2). Drug use then will induce neuropharmacological and neurotoxicological effects and profound neuronal changes (3) and then addiction (4). A, B, C, D: Process sequence. of acute cocaine. Typically, after the acquisition of self-administration, rats allowed access to cocaine for 3 h or less per day establish highly stable levels of intake and patterns of responding between daily sessions. These models do not fit with the concept of addiction.

To explore the possibility that differential access to intravenous cocaine self-administration in rats may produce different patterns of drug intake, rats were allowed access to the intravenous self-administration of cocaine for 1 or 6 h per day. One hour access (short access or ShA) to intravenous cocaine per session produced low and stable intake as observed previously. In contrast, with 6 h access (long access or LgA) to cocaine, drug intake gradually escalated over days (Ahmed and Koob 1998). It is observed in the escalation group, there was increased intake during the first hour of the session as well as sustained intake over the entire session and an upward shift in the dose-effect function, suggesting an increase in hedonic set point. When animals were allowed access to different doses of cocaine, both the LgA and ShA animals titrated their cocaine intake, but the LgA rats consistently self-administered almost twice as much cocaine at any dose tested, further suggesting an upward shift in the set point for cocaine reward in the escalated animals. Escalation also is associated with an increase in break point for cocaine in a progressive-ratio schedule, suggesting an enhanced motivation to seek cocaine or an enhanced efficacy of cocaine reward.

This model fits with the drug-centered paradigm. It is a-historic: the subjects are not considered from their individual characteristics but considered at the beginning of the experiment equal or similar. Only the drug parameters (amount taken) change.

2. Historic model: differential vulnerability for a transition to addiction

A second model considers that each individual has different characteristics and vulnerabilities to the pharmacological aspects of drugs. Such differential vulnerabilities had been demonstrated for the propensity to like drugs. A first paper published demonstrated that it was possible to evidence in rats (1) marked individual differences in the development of psychostimulant self administration; (2) that a differential propensity to drug taking was predicted by individual reactivity to novelty, a robust permanent trait; (3) a significant positive correlation between the magnitude of the reactivity and the amount of the drug self-administered during an acquisition session (Piazza et al. 1989). In a recent study explored further the behavioral effects of drug-taking in animals with access to cocaine for 3 months and a number of behavioral tests were administered that were hypothesized to capture DSM-IV criteria of addiction (Deroche-Gamonet et al. 2004). Unsuccessful effort or a persistent desire to cut down or control substance use was linked to the persistence of cocaine seeking during a period of signaled non-availability. A great deal of time spent in activities necessary to obtain the substance was linked to performance on a progressive-ratio schedule, and continued substance use despite knowledge of having a persistent physical or psychological problem was linked to the persistence in responding for drug by animals when drug delivery was associated with punishment. Rats were trained to self-administer cocaine intravenously and then separated by groups based on a test for reinstatement to small doses of cocaine administered after 5 days of extinction. The animals with the high tendency to show reinstatement showed progressively increased responding during signaled nondrug periods, higher break points on the progressive-ratio test, and higher responding after punishment (Deroche-Gamonet et al. 2004). Further study of rats subjected to all three tests above revealed that the animals that met all three positive criteria represented 17% of the entire population, a percentage noted by the authors to be similar to the number of human cocaine users meeting the DSM-IV criteria for addiction while 41% of the rats were resilient (0 criterion). This model highlights the importance of differential vulnerability to addiction. It demonstrates huge individual differences for the propensity to enter in the addiction cycle. It is typically anindividual-centered model and corresponds to what is met in addiction medicine.

Conclusion

Animal models for addiction have progressed from simple drug reinforcement models to sophisticated models with solid face validity. Escalation in drug intake with extended access has been observed in numerous laboratories with all the drugs of abuse. This drug-centered model do not discriminate animals according to potential previous vulnerabilities; here the transition to addiction is linked to compulsivity. More recently, animal models for criteria of addiction that reflect the channeling toward drug seeking at the expense of other environmental contingencies (Deroche-Gamonet et al. 2004; Vanderschuren and Everitt 2004) have been developed and linked to the compulsive loss of control over intake. The model described above may prove particularly sensitive to the transition to addiction in otherwise vulnerable individuals.

Definition

Endogenous nucleoside made up of the purinic base adenine and the pentose carbohydrate ribose linked through an N-9 bound. Adenosine is present in all mammalian tissues at both the intra- and extracellular level, and takes part in important physiopathological phenomena (e.g., modulation of inflammation, regulation of heart rhythm). At the level of the central nervous system, adenosine promotes a generalized inhibition of neuronal functionality, a reason why it is often referred to as "endogenous neurodepressant."

Adenosine A_1 Receptors

Definition

Protein G-coupled receptors whose stimulation inhibits the signal cascade mediated by adenylyl cyclase. A_1 receptors have a widespread distribution in the brain, being enriched at significant levels in almost every cerebral area. A_1 receptors are mostly located at the presynaptic level, where they inhibit the release of ► neurotransmitters. Postsynaptic A_1 receptors have also been described on medium-sized spiny neurons projecting from the caudate nucleus to the substantia nigra. These receptors may co-localize with D_1 receptors at the neuronal level, and opposite functional interactions between these receptors

exist (e.g., stimulation of A_1 receptors depresses D_1 receptors-mediated effects).

Adenosine A_{2A} Receptors

Definition
Protein G-coupled receptors whose stimulation activates adenylyl cyclase-mediated signal cascade. The large majority of A_{2A} receptors (about the 95%) are enriched in the caudate-putamen, where they are located at the postsynaptic level on medium-sized spiny neurons projecting to the globus pallidus. Presynaptic A_{2A} receptors have been detected, in the cortex, basal ganglia, and hippocampus, which participate in the regulation of neurotransmitter release. A_{2A} receptors usually co-localize at the neuronal level with D_2 receptors and opposite functional interactions between these receptors have been described (e.g., stimulation of A_{2A} receptors attenuates D_2 receptors-induced effects). A_{2A} receptors also display a similar modulatory activity on the function of D_1 receptors that is exerted through cross-talk mechanisms involving the basal ganglia network.

Adjustment Disorders

James J. Strain
Department of Psychiatry, Mount Sinai School of Medicine, New York, NY, USA

Synonyms
Anxiety or mixed states; Reactive depressions; Stress-related mood disorders; Subthreshold diagnoses

Definition
In DSM-IV, the adjustment disorders comprise a distinct group of subthreshold states that emanate from a known stressor that is not of an unusual or catastrophic type, and that can result in maladaptation at work, at school, or at the social level (e.g., interpersonal functioning), all within 3 months of the stressor (in the ICD-10, onset must occur within 1 month of exposure to an identifiable stressor). They can be further defined by the accompanying mood state, e.g., depressed, anxious, or mixed; by the presence of a disturbance of conduct; or by the absence of these predominating features, in which case they are considered unspecified. They can be acute (less than 6 months) or chronic (lasting 6 months or more). The criteria for diagnosing adjustment disorders are compromised in that there is no *specification of*, or *symptom checklist for*, (1) the stressor(s), (2) the maladaptation, or (3) the

accompanying behavior, mood state, or symptoms – the three components in the algorithm for this diagnosis. This characteristic of the adjustment disorder diagnosis means that its classification is more subjective than that of most of the other psychiatric disorders, thereby raising issues of validity and reliability. In addition, adjustment disorders need to be differentiated from normal dysphoric states, acute stress disorders, bereavement, and other problems that may be the focus of the mental health worker's attention. They are not solely the result of a psychosocial problem requiring medical attention, e.g., noncompliance, phase of life problem, etc. Although the upper threshold for diagnosing adjustment disorders is established by the specific criteria for the minor and major psychiatric disorders, the entry threshold between the adjustment disorders and psychosocial problems or normality is not sufficiently demarcated by operational criteria. This lack of specificity and questionable reliability and validity are the hallmarks of interface disorders and subthreshold phenomena, whether they are in diabetes mellitus, hypertension, or depression. Maercker et al conceptualize adjustment disorders as a stress response syndrome in which intrusions, avoidance of reminders, and failure to adapt are the central processes and symptoms. Empirical investigations have shown that the symptom profiles of adjustment disorders are very different in children and adolescents when compared with adults. The future evolution of this and other psychiatric diagnoses will need to consider the effect of developmental epochs, gender, and medical comorbidity on symptom profiles.

The subthreshold disorders present major taxonomical and diagnostic dilemmas, since they are poorly defined, overlap with other diagnostic groupings, and have indefinite symptomatology. However, the advantage of the "indefiniteness" of these subthreshold disorders is that they permit the classification of early or prodromal states when the clinical picture is vague and indistinct, and yet the morbid state is in excess of that expected in a normal reaction, and treatment at this stage is indicated.

Role of Pharmacotherapy

Clinical Features, Etiology, and Pathogenesis

Adjustment disorder with depressed mood: Predominant symptoms are depressed mood, tearfulness, or feelings of hopelessness.

Adjustment disorder with anxious mood: Predominant symptoms are nervousness, worry, or jitteriness or, in children, fears of separation from major attachment figures.

Adjustment disorder with mixed anxiety and depressed mood: Manifestations of depression and anxiety.

Adjustment disorder with disturbance of conduct: Predominant manifestation is a disturbance in conduct, in which there is violation of the rights of others or of major age-appropriate societal norms and rules (e.g., truancy, vandalism, reckless driving, fighting, and defaulting on legal responsibilities).

Adjustment disorder with mixed disturbance of emotions and conduct: When the predominant manifestations are both emotional symptoms (e.g., depression, anxiety) and a disturbance of conduct (see earlier subtype).

Adjustment disorder unspecified: Maladaptive reactions (e.g., physical complaints, social withdrawal, or work or academic inhibition) to psychosocial stressors that are not classifiable as one of the specific subtypes of adjustment disorder.

Etiology

As stated earlier, the adjustment disorders are a product of stressor(s) in a person's life, that is, the precipitating event for this psychiatric disorder is one or more exogenous stressor. It is one of those psychiatric disorders for which an etiology is known. It is assumed that once the stressor is terminated or the patient adjusts to the stressor, the adjustment disorder symptoms, e.g., disturbance of mood or conduct, will also terminate. However, some stressors do not abate, e.g., chronic medical illness, joblessness, financial distress, etc., and the patient may continue to have an adjustment disorder in excess of 6 months. Thus, adjustment disorders join that group of disorders that also have exogenous stressors as the key etiological agent, e.g., acute stress disorder and posttraumatic stress disorder. These stress-related disorders, the organic mental disorders and the substance abuse disorders, for all of which an etiology can be identified, are thus differentiated from the majority of psychiatric disorders in the primary psychiatric taxonomy, the DSM-IV, for which definitive etiologies are not known. Furthermore, since the stressor and symptom profiles in adjustment disorders have not been specified and therefore cannot be measured in a reliable and valid way, these disorders remain a subjective diagnosis.

This also means the adjustment disorders are difficult to study to ascertain their actual frequency in various populations. For similar reasons, it is difficult to study cohorts receiving various interventions in randomized controlled trials: it is uncertain whether one has comparable patient groups when attempts are made to observe outcomes. Adjustment disorders have been diagnosed in over 60% of burn patients, greater than 20% of patients with multiple sclerosis, and over 40% of poststroke

patients. This is the most common psychiatric diagnosis in medically ill inpatients in acute care general hospitals referred for consultation, with rates ranging from 11.5% to 21.5%. Fabrega et al, at the University of Pittsburgh, observed that 2.3% of patients in a walk-in clinic had adjustment disorder only, while in those with other psychiatric or personality disorder comorbidity, the rate was 20%. Mezzich et al, from the same institution, observed that 29% of the patients in the adjustment disorder group had a positive response on indicators for suicide risk, whereas such indicators were seen in 9% of the normal (no illness) group. This emphasizes that a subthreshold diagnosis may be associated with serious symptomatology and mortality as an outcome. Obviously, suicidality is not subthreshold. Adjustment disorder patients with suicidality had lower platelet monoamine oxidase (MAO) activity, higher activity of the norepinephrine metabolite 3-methoxy-4-hydroxyphenylethylene glycol (MHPG), and higher cortisol levels than controls. Although these findings differ from the lower MHPG and cortisol levels found in some studies of patients with major depressive disorder and suicidality, they are similar to findings in other major stress-related conditions.

One must always be on the alert for the symptom profile seen in a patient with an adjustment disorder evolving over time to that of a minor or major depressive disorder, or to a generalized anxiety disorder; the maturation of symptoms over time can easily reach the criteria for these major psychiatric entities.

Treatment

The use of psychopharmacological interventions for adjustment disorders has not been agreed upon, and guidelines usually recommend that talking therapies be applied initially – psychotherapy or counseling. The Cochrane Database reveals only two randomized controlled trials of psychotherapeutic treatment for this condition. Gonzales-Jaimes and Turnbull-Plaza demonstrated that "mirror psychotherapy" for adjustment disorders with depressed mood secondary to a myocardial infarction was both an efficient and effective treatment. Mirror therapy is described as a type of therapy with psychocorporal, cognitive, and neurolinguistic components, with a holistic focus. Mirror therapy was compared to Gestalt psychotherapy or medical conversation in addition to a control group. An "activating intervention" (emphasizing the acquisition of coping skills and the regaining of control) was employed specifically for patients with adjustment disorder associated with occupational dysfunction. In comparison with the control group, the activating intervention decreased sick leave and shortened absenteeism. In a mixed study group of minor depression and adjustment disorders, brief psychodynamic therapy demonstrated greater improvement than brief supportive therapy in a 6-month follow-up. In an unpublished study of eye movement desensitization and reprocessing (EMDR), patients with adjustment disorder and anxious or mixed features, but not those with depressed mood, had significant improvement.

If talking therapy has not been successful in relieving symptoms, then a trial with a selective serotonin reuptake inhibitor (SSRI) (for adjustment disorder, depressed type) or benzodiazepine (for adjustment disorder, anxious type) is warranted. In a retrospective chart review, it appeared that adjustment disorder patients were twice as likely to respond to typical antidepressant therapy in contrast to depressive patients. In another study, the efficacy of etifoxine, a non-benzodiazepine anxiolytic drug, and lorazepam were compared in a primary care setting. Those on etifoxine had less rebound after stopping the medication.

Research is not conclusive on the use of psychopharmacological agents in patients with adjustment disorder. It would be preferred that cautious psychotropic drug administration is employed to avoid subjecting the patient to the risk of unfavorable medical drug-psychotropic drug adverse interactions. Psychotropic medication will not be necessary if the adjustment disorder resolves. If it evolves into a minor or major psychiatric disorder, then appropriate psychopharmacological agents should be employed. If the adjustment disorder does not respond to psychotherapy or the symptoms are significantly uncomfortable or disabling, then small doses of antidepressants and/or anxiolytics may be appropriate. This is especially true for patients with severe life stress(es) and an unrelenting depressed or anxious mood. Tricyclic antidepressants or buspirone are recommended in place of benzodiazepines for adjustment disorder patients with current or past excessive alcohol use, because of the greater risk in these patients of abuse of, or dependence on, the prescribed medications. The use of antidepressants is important for those patients with debilitating maladaptation and in whom the mood is pervasive, especially if a trial of psychotherapy has been shown to be ineffective. Psychopharmacological interventions can be started concurrently with psychotherapies in severe cases of adjustment disorders.

Adolescence and Responses to Drugs

Adolescent neurodevelopmental vulnerability; Peri-adolescent psychopharmacology

Definition

Adolescence is a major developmental phase in which the body, brain, mind, and behavior of the child progress to those of an adult. Although it has long been known that mental functioning and behavior differ significantly between children and adults, an emerging body of evidence indicates that these changes are driven by changes in brain architecture and function. To the extent that these changes are the most robust in, or exclusive to, adolescence, this phase may also represent a context in which drugs impacting the central nervous system produce especially potent and long-lasting alterations.

Current Concepts and State of Knowledge

Adolescent Neurodevelopment

Adolescence encompasses the growth and alteration of many neural and somatic systems and spheres of function that evolve with differing developmental timelines both within and between individuals (Cicchetti and Cohen 2006). Given this complexity, precise definitions of its start and end are elusive. Adolescence is a phase of continuous change within a lifespan of continuous change, while cultural–legal demarcations of the onset of adulthood vary widely. Behavioral neuroscience assumes a general concept of peri-adolescence as the passage of the individual from characteristics of mind, brain, and behavior specific to, and shared among, children of different ages (i.e., from birth to ages 10–15), to characteristics shared among healthy adults (i.e., from age 18–25 and older) (Erickson and Chambers 2006; Romer and Walker 2007). Fundamentally, children are the recipients of teaching and caretaking; their role is to learn about their environment through instruction and play while inviting and acquiescing to caretaking. Adults are the providers of teaching and caretaking; their role is to manipulate, and work within, the environment in the service of caretaking. Between these age ranges (from approximately 13–23 years), adolescent neurodevelopment revises the brain from a design best adapted to play, learning, experimentation, and receiving care, to one best adapted to acting on what has been learned and delivering care.

Changes in Mind and Behavior

Adolescent neurodevelopment involves changes spanning multiple spheres of higher order central nervous system function and anatomy, including those that subserve cognition, emotion, and motivation (Romer and Walker 2007). Cognition in childhood, initially dependent on concrete interpretations of the physical world, and yet prone to fantasy and make-believe, becomes increasingly efficient and accurate with respect to classifying and predicting complex contingencies. Emotions are used less unidimensionally for engendering caretaking or exploring relationships with specific caregivers. They become more complex,

and at times volatile, both for asserting independence from caregivers, and for experimenting with and learning effective emotional conduct across a potentially large variety of peer and other social relationships spanning diverse personal and occupational domains (Nelson et al. 2004). Motivation becomes extremely sensitive to novelty and social competition, especially with respect to stimuli or situations that characterize adult social, sexual or occupational roles, and skill sets (Chambers et al. 2003). Reflecting a desire to achieve adult abilities, and even adult levels of power, the adolescent is motivated to act as an adult, even though prior experience has been largely limited to imaginative play and verbal or role-modeled instruction. Instead of playing with toy cars, the adolescent is suddenly motivated to drive real ones.

Changes in Brain Form and Function

Profound changes involving multiple brain regions underlie the adolescent transformation. Those changes occurring in the ► prefrontal cortex (PFC) are currently the best characterized (Erickson and Chambers 2006; Romer and Walker 2007). The PFC functions as the brain's closest analogue to the central processing unit of a computer; it governs decision making and regulates cognitive working memory, attention, and emotional awareness. Its central functional role and high degree of connectivity with a diversity of cortical and subcortical brain regions, which are more directly specialized in memory formation, emotion, and motivation, probably relate to its keystone position as the last cortical structure to undergo significant micro- and macrostructural revision prior to adulthood. Within the PFC, both excitatory and inhibitory neurons undergo shifts in patterns of connectivity, in which many short-range connections are eliminated (e.g., ► synaptic pruning), and long-range (e.g., transcortical) connections undergo final stages of ► myelination, rendering them more efficient for transferring information. Macrostructurally, these changes correspond to overall declines in PFC energy demands and PFC gray matter thickness. In totality, these changes correspond to the development of greater computational efficiency, adult cognitive styles, and the ability of PFC cognitive processes to intervene in or regulate complex emotional and motivational processes.

While research on developmental changes within subcortical regions primarily involved in memory formation (e.g., ► hippocampus), emotion (e.g., ► amygdala), and motivation (e.g., ► nucleus accumbens/mesolimbic ► dopamine system) is itself in an early developmental stage, growing evidence indicates that, like the PFC, all of these regions undergo peri-adolescent developmental revision (Cicchetti and Cohen 2006; Nelson et al. 2004). Changes spanning these areas include alterations in intrinsic and extrinsic neural connectivities involving multiple neurotransmitter, neuropeptide and neurohormonal systems that collectively change the way these regions process information and communicate with each other and the PFC. For example, parameters of dopamine neurotransmission into the PFC and nucleus accumbens undergo peri-adolescent maturational changes implicated in the particularly robust aspects of adolescent motivation, such as behavioral sensitivity to novel stimuli (Romer and Walker 2007). While both the hippocampus and the amygdala are richly endowed with neurohormonal receptors related to stress responsivity (e.g., corticosteroids) and sexuality (e.g., estrogens and androgens), peri-adolescent changes in the levels and regulation of these hormones can have profound effects on cellular and local circuit functions (Chambers et al. 2003; Nelson et al. 2004). These changes in turn contribute to adolescent-age alterations in emotional, social, and sexual behavior and related motivational programming, as mediated in part via the connectivity of the hippocampus and the amygdala with the nucleus accumbens and prefrontal cortex.

An important aspect shared among these modulatory neurotransmitters and neurohormonal factors is that they are powerful inducers and facilitators of ► neuroplasticity. While the information-processing and learning and memory functions of neurons and local neural connections throughout the central nervous system are most directly carried by changes in the way excitatory and inhibitory transmitters (e.g., ► glutamate and ► GABA) send signals between individual neurons, these modulatory factors (e.g., dopamine and corticosteroids) can produce more broadly distributed influences on the manner, scope, quality, and depth of local neuroplastic changes. These effects are observable on the molecular, cellular, and physiological as changes in cellular mechanisms that govern glutamatergic/GABA transmission, neural firing properties, dendritic arborizations of individual neurons, birth of new neurons, and stimuli-induced activation patterns spanning whole neural networks. Thus, by hierarchically influencing mechanisms of local plasticity in a way that is broadly distributed throughout multiple brain regions in a coordinated fashion, these modulatory systems likely play a key role in the global theme of structural revision in adolescent neurodevelopment. Understanding how these neuromodulatory factors are themselves changed during adolescence, as a result of developmentally timed and environmentally triggered changes in gene expression, will increasingly form the focus of future research on adolescent neurodevelopment.

Impact of Drugs During Peri-Adolescent Neurodevelopment

Peri-adolescent changes in neural systems function, architecture, and plasticity, unparalleled by neural events in middle childhood or adulthood, may reflect a transition that relates to the flexibility–stability dilemma, a fundamental concept of theoretical neuroscience. In this concept, neural systems are thought to operate optimally in the service of one of two goals: learning new information (flexibility) vs. acting on what has been learned (stability) (Liljenstrom 2003). Importantly, while the brain is capable of serving both of these goals to some extent, it cannot serve them both to the highest degree possible simultaneously. The vast yet limited biological resources of the brain, and physical rules of ▶ neuroinformatics, would require that the brain operate in a way that optimizes one goal at the expense of the other. By developmental design, flexibility is favored in childhood, while stability is most adaptive in adulthood. In adolescent neurodevelopment, the brain must undergo a considerable revision of architecture and function to shift the brain toward the stability goal. During this phase, the artificial (e.g., pharmacological) perturbation of neural processes and systems, particularly those that impact the neuroplasticity of cognitive, motivational, and emotional substrates, could produce effects that are thereafter "locked-in," in a semipermanent way, as the brain shifts its design toward the stability goal.

Impact of Drug Exposure on Motivation and Addiction Vulnerability

The most clear and broad-based evidence for such a pharmacological effect is the heightened capacity of addictive drug exposure during adolescence for determining future motivational programming with respect to the acquisition of addictive disorders (Chambers et al. 2003). The vast majority of adult-age addictions begin in adolescence (ages 15–25). Greater accumulated dose of drug exposure, earlier exposure, and the extent of multidrug experimentation during adolescence are all risk factors for adult addictions.

The advancement in our understanding of this developmental age vulnerability to addictions has been informed in part by research on ▶ dual diagnosis in mental illnesses such as ▶ schizophrenia, which involve both peri-adolescent developmental onset and high rates of addiction comorbidity. Adolescence is a normative period of heightened novelty seeking, behavioral disinhibition, and risk taking, all serving as component manifestations of the more general construct of impulsivity (Erickson and Chambers 2006). ▶ Impulsivity, whether occurring in normative adolescence or as an abnormal feature of adult mental illness, is a general trait-marker of addiction vulnerability (Erickson and Chambers 2006; Redish et al. 2008). Moreover, it is often a manifestation of those immature or dysfunctional PFC substrates that are responsible for decision making and response inhibition. As reviewed earlier, during adolescence the PFC is normally immature and thus incapable of adult levels of decision making and behavioral control. At the same time, subcortical motivational systems (e.g., the nucleus accumbens/dopamine system) are operating in a particularly robust manner. This not only allows motivational programming to be relatively sensitive to novel or other reinforcing stimuli that promote dopamine transmission. By virtue of the capability of dopamine itself to regulate neuroplastic events in the PFC and nucleus accumbens, this robustness of function may also facilitate changes governing maturational plasticity underlying the installment of stable, long-lasting, motivational repertoires (Chambers et al. 2003, 2007). In adolescence, this scenario may be viewed simplistically as a car acquiring an accelerator before it acquires adequate brakes. Of course, only the accelerator can make the car go, and give the driver cause for needing, and learning how and when, to apply the brakes. In normative adolescent neurodevelopment, this developmental plan, in which the PFC matures under conditions of robust motivational function, is thought to be a necessary aspect of initiating experiential-action learning, with all of its hazards (Chambers et al. 2003). With addictive drug exposure, and by virtue of the shared pharmacological effect of addictive drugs to further augment dopamine transmission and exert neuroplastic effects, motivational–behavioral repertoires (and underlying neural systems) are potently and more semipermanently sculpted to include drug-seeking and – taking as frequent behavioral options (Chambers et al. 2007).

Impact of Drug Exposure on Cognition and Emotion

The centrality of dopamine in both natural motivation and in the reinforcing properties of drugs with diverse psychoactive and pharmacological profiles (e.g., nicotine, alcohol, cocaine, amphetamine, cannabinoids, and opiates) has rendered progress in our understanding of the responsiveness of adolescents to the motivational properties of drugs a relatively straightforward process. Expanding outward from this core of knowledge, research is beginning to explore the more complex task of understanding how adolescent neurodevelopmental change involving spheres of function other than motivation, and encompassing other neurotransmitter systems and brain regions, may make adolescents particularly vulnerable to long-lasting cognitive and emotional effects of drug

exposure. In essence, this exploration is a contemporary variant of the long-pursued notion that drug use can cause or predispose to permanent acquisition of psychiatric illness or illness features. For many recreational drugs frequently used in the general population, this thesis has not proven easy to support with firm clinical and epidemiological data. However, new evidence detailing the unique and profound neurodevelopmental revision of the brain during adolescence, along with the recognition of the capacity of drugs to modulate cognitive and emotional functions during this developmental period, has renewed interest in this area. For instance, new findings indicate that peri-adolescent ► nicotine exposure can have an enduring impact on acetylcholine neurotransmission in the brain, while producing long-lasting cognitive and emotional dysfunction potentially consistent with features of mental illness (Slotkin 2008). Similarly, ► alcohol as a drug active at glutamatergic and GABAergic synapses, and in a host of other neurotransmitter systems, may produce semipermanent cognitive and emotional changes (Clark et al. 2008). Since endogenous ► cannabinoids are robustly active in PFC and hippocampal networks as modulators of glutamatergic and GABAergic transmission and plasticity, marijuana smoking in adolescence could have particularly profound and long-lasting effects toward changing thresholds for developing mental disorders that involve these regions, including ► schizophrenia and ► depression.

Conclusion

As research on adolescent drug effects continues to evolve, it is expected that animal modeling, involving developmentally timed drug exposures in peri-adolescence, will play an especially crucial role in advancing understanding in this field, given the ethical boundaries, time and cost expenses, and lack of environmental control inherent to longitudinal prospective human studies. Examining adolescent developmental effects of recreational drugs is also expected to inform and inspire investigations that may reveal properties of therapeutic agents that may semipermanently ameliorate or abort illness trajectories for varieties of mental disorders of peri-adolescent onset or worsening.

Impact of Psychoactive Drugs

Types of Aggression

Aggressive acts are shaped by social experiences via action on molecular events in discrete ascending aminergic pathways from the mesencephalon to the limbic and cortical targets, and the cascade of these intracellular events is increasingly understood. Aggressive behavior is an important behavioral adaptation in all phyla of living creatures, mainly serving reproductive purposes. In addition, maladaptive types of aggressive behavior are the focus of human and veterinary medicine and also of the criminal justice system. Types of aggression differ in terms of their ontogenetic and phylogenetic origins, motivations, and functions, and all indications are in their neurobiological mechanisms. Clinicians distinguish between those types of aggression that include hostile, affective, impulsive, and reactive features from those that are characterized by proactive, premeditated, instrumental, controlled, and also predatory elements. Behavioral researchers, by contrast, focus on adaptive types of aggressive behavior, mostly as part of reproductive strategies such as aggression during the formation and maintenance of dominance hierarchies or territories. Animal species that disperse during the reproductively active lifespan as well as those that live cohesively, engage in aggressive behavior in order to secure the resources for reproduction or to protect the offspring.

The classic ethological thesis that ritualized displays are the major means to maintain a dominance hierarchy has been challenged by rare, but repeatedly documented episodes of intensely injurious aggression in chimpanzees that pursue neighboring groups in order to kill them. The significance of lethal raiding parties in hominids constitutes problems, not the least of which for the typology of aggressive behavior, since it focuses on rare events that are carefully planned and coordinated and, at the same time, involve intense autonomic and behavioral excitement. The adaptive purpose of these lethal raids eludes the traditional theoretical framework. Conventionally, once the frequency, duration, and intensity of aggressive behavior escalate beyond the species-typical levels, it is considered maladaptive and may constitute a behavioral pathology in need of intervention.

Much pharmacological, neurochemical, and molecular biology research on aggressive behavior uses laboratory mice, often recombinant inbred strains and transgenic lines. These animals are housed in same-sex groups, preventing the species-typical formation of demes ("breeding units"), and only a small proportion of these mice actually engage in territorial aggressive behavior that is characteristic of this pugnacious species. Under captive laboratory conditions, group-housed animals may develop a despotic social organization, with one male dominating all other group members.

Neurotransmitters

More than any other neurochemical system, brain ▶ serotonin remains the focus for neurobiological studies of mechanisms mediating impulsive, hostile, and intensely violent outbursts as well as predatory-like aggression. Only detectable in trace amounts in mammalian brain, this phylogenetically old transmitter, arising from cells along the center of the neuroaxis and acting in mammals on at least 14 different receptor subtypes, has a significant role in aggression ranging from invertebrates to humans. Several neurotransmitters comprising amines, acids, ▶ neuropeptides, and ▶ neurosteroids interact with serotonin (5-hydroxytryptamine, 5-HT).

Glutamate

▶ Glutamate and ▶ GABA are the extensively distributed excitatory and inhibitory transmitters, and they modulate the cellular and behavioral effects of serotonin at several levels of the ascending mesocorticolimbic pathways. Early research has established an excitatory role of glutamate in violent outbursts during seizures, although the precise role of glutamate activity during ictal and inter-ictal events remains to be defined. Sparse evidence shows how pharmacological manipulations of glutamate receptor subtypes affect aggressive behavior and also suggests a potential role of ▶ NMDA receptors in escalated aggressive behavior. Low-affinity channel blockers such as ▶ memantine or partial agonists to the glycine-binding site on the NMDA receptor may offer potential options in the pharmacotherapeutic management of escalated aggressive behavior due to their favorable side-effect profile. Regulatory changes in NMDA receptor systems occur also in individuals who are repeatedly victimized by aggressors as revealed by prevention of their sensitized response to psychomotor stimulants with protective administration of NMDA receptor antagonists. It will be of considerable interest to learn how glutamate modulates the ascending monoaminergic, especially dopaminergic and serotonergic projections to limbic and cortical target areas. Several

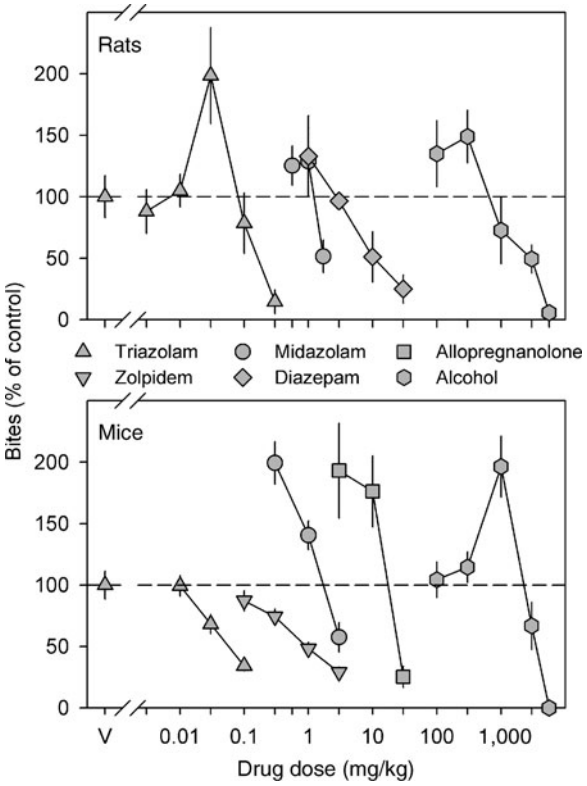
metabotropic glutamate receptors appear to be promising pharmacotherapeutic targets in the management of escalated aggressive behavior.

GABA

By distinction from glutamate, GABA and particularly, the $GABA_A$ receptor complex have been consistently implicated in the neural control of several types of aggressive behavior. Especially positive ► allosteric modulators of the $GABA_A$ receptors such as benzodiazepines, barbiturates, ethanol, and progestin-derived neurosteroids can increase aggressive behavior after low acute doses or after tolerance to the sedative doses has developed (Fig. 1). At moderate and higher doses, the antiaggressive effects of these substances are accompanied by sedation and motor impairment. The bidirectional effects of allosteric positive modulators of the $GABA_A$ receptors depend not only on the dose, but also on the context and the prior experience with aggressive behavior. When social consequences lower the rate of aggressive behavior, benzodiazepines and ethanol are more likely to increase its occurrence. In spite of the consistent epidemiological evidence linking alcohol to two thirds of all violent crimes, the neurobiological mechanism of action for these alcohol effects remains elusive. The current challenge is to understand how an individual's prior experiences with aggressive behavior modify the $GABA_A$ receptor complex so that proaggressive effects of $GABA_A$ positive modulators emerge. The prevalent current hypothesis attributes the divergent effects of $GABA_A$ positive modulators on aggressive behavior to differential expression of genes encoding the subunits that form the pentameric $GABA_A$ receptor complexes. Emerging data from gene deletion and pharmacological antagonism studies suggest a structural dissociation between the anxiety-attenuating, sedative, and aggression-heightening effects of $GABA_A$ receptor positive modulation, primarily due to the differential role of alpha subunits. In addition to the $GABA_A$ receptor, the $GABA_B$ receptors are widely distributed throughout the neuroaxis. The population of $GABA_B$ receptors in the dorsal raphé nucleus modulates serotonin cells, and this may be the mechanism via which $GABA_B$ receptor agonists can increase aggressive behavior in mice.

Norepinephrine

Catecholaminergic and serotonergic pathways contain reciprocal anatomical links which provide the basis for extensive functional interactions. Particularly, intense arousal that is associated with salient life events, among them certain types of aggressive behavior on just observing a fight, is based on elevated activity in noradrenergic cell bodies in locus coeruleus and cortical noradrenergic terminals. Pharmacological blockade of beta receptors may achieve its calming effects in patients with intensely aggressive, hostile outbursts by reducing noradrenergic hyperactivity, although alternatively, beta blockers also act as antagonists at $5\text{-}HT_{1A}$ receptors. Molecular manipulations of the genes encoding for the noradrenergic transporters, or metabolic enzymes such as COMT have so far resulted in inconsistent results with regard to aggressive behavior and traits.



Aggression. Fig. 1. $GABA_A$ positive allosteric modulators and aggression. Biphasic effects of $GABA_A$ receptor positive modulators on aggression in rats (*top*) and mice (*bottom*). Low doses of alcohol (filled hexagon), the benzodiazepines diazepam (filled diamonds, rats only) and midazolam (filled circles), and the neurosteroid allopregnanolone (filled triangles, mice only) increase the mean (±SEM, vertical lines) number of attack bites, expressed as a percentage of vehicle control, while higher doses decrease this measure of aggression. Triazolam (filled upward triangles) increases attack bites in rats but not mice. No increase in aggression was seen after treatment with zolpidem, the alpha1-preferring agonist (filled downward triangles, mice only). The dotted horizontal line represents the baseline at 100%. (From Miczek et al. 2007.)

Dopamine

Specific dopamine (DA) pathways and DA receptor subtypes critically contribute to the neurobiological mechanisms of species-typical and escalated, pathological types of aggressive behavior. Anatomical and pharmacological data provide evidence for serotonergic receptors on soma of DA neurons in the VTA and substantia nigra suggesting modulation of ascending DA pathways by 5-HT.

The most widespread option for pharmacotherapeutic management of aggressive individuals relies on antipsychotic medication that acts via blockade of dopamine (DA) D_2 receptors, although the antiaggressive effects of ► first-generation antipsychotics such as ► haloperidol or ► chlorpromazine are embedded in sedative and motor-incapacitating side effects. At present, the so-called ► atypical antipsychotic drugs with more complex mechanisms appear to be preferred as antiaggressive medication on account of a more favorable side-effect profile. Clearly, there continues to be a need for more satisfactory medication development.

Case studies point to ► amphetamine intoxication as a potentially triggering event for lethal violence. At intermediate doses, amphetamine disrupts many types of social behavior and at lower doses, it may increase aggressive behavior, probably due to its antifatigue and arousing effects. Increased corticolimbic DA can be detected via in vivo measurement and imaging techniques in individuals who react defensively to an aggressive confrontation and who prepare for such an event. Anatomical and temporal analysis with higher resolution may enable a more precise delineation of DA activity in different phases and types of aggressive behavior.

Genetic disruption of the genes that are critically involved in the inactivation of ► catecholamines, COMT, and MAO-A can promote aggressive behavior in male mice. It is tempting to relate these preclinical data to the specific polymorphism in the gene for COMT which is associated with increased aggressive behavior in schizophrenic men.

MAO

Considerable evidence links monoamine oxidase (MAO)-A to traits of violent behavior. It remains to be determined which of the monoamines is primarily responsible for the effects of mutations or deletions of the gene for this enzyme or for the effects of its pharmacological inhibition. An early influential study illustrated how acts of violence by the male members of a Dutch family who were also mentally retarded, appears to be linked to a missense mutation in the gene for this enzyme on the X chromosome. In preclinical research, mice lacking this gene were found to initiate injurious aggressive behavior faster. Probably, the most significant findings link the allelic variant with low activity of MAO-A to the antisocial and violent behavior only in those adult males who were severely maltreated in childhood, whereas the allelic variant with high MAO-A activity or the absence of maltreatment had no such influence in adults. A variable-number tandem repeat polymorphisms of MAO-A may also be associated with the increased probability of a life history of aggressive behavior, particularly aggression involving dysregulated affect. However, there is also evidence that links lower MAO-A activity to aggressive tendencies independent from polymorphisms in MAO-A. While MAO-A is one of the leading candidates, a number of inconsistent findings obscure the causal relationship between the expression of the MAO-A gene, its interaction with early life experiences, and traits of hostile, antisocial, aggressive outbursts.

The differential expression of specific genes for MAO-A in aggressive and nonaggressive individuals is often associated with alterations in the brain serotonin system, based on additional pharmacological studies. A wide array of methodological approaches has implicated the serotonin system in aggressive traits, impulsivity, and also in the initiation and termination of certain types of aggressive behavior. A venerable hypothesis postulated a serotonin deficiency as the characteristic of the trait of ► impulsive aggression, receiving early support from the 5-HT assay data obtained from the hindbrain of isolated aggressive mice and CSF 5-HIAA samples of patients. The significance of CSF 5-HIAA measures is compromised by the uncertainty as to their precise anatomical origin. Direct challenges of brain 5-HT functions with either an agonist or a tryptophan-depleted diet demonstrated a blunted prolactin response in violent patients with various diagnoses, possibly due to actions on 5-HT_{1A} and 5-HT_{2A} receptors. Instead of relying on a single sample of CSF, a peripheral marker, or an endocrine response to a single pharmacochallenge, in vivo microdialysis reveals no changes in cortical 5-HT during the phase of initiating an attack, but then 5-HT begins to decline once the fight is progressing and terminating. The termination of an anticipated aggressive confrontation is accompanied by a decrease in accumbal 5-HT suggesting a potentially significant role for 5-HT in the inhibition of aggressive behavior. Thus, the tonic levels of 5-HT activity have been linked to aggressive traits, and phasic changes in 5-HT may be relevant to the termination of an aggressive burst.

SERT

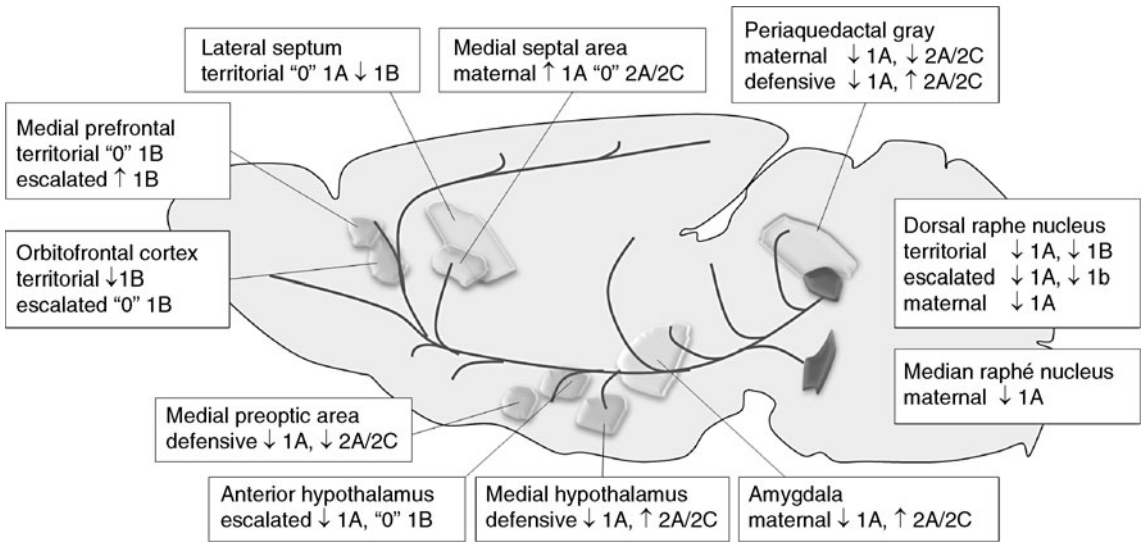
Several receptor families and the 5-HT transporter (SERT) have been characterized in terms of their genetic

basis and molecular features. Pharmacological and molecular genetics studies have begun to implicate the 5-HT_1 and 5-HT_2 receptor families and SERT in different types of aggressive behavior. Agonists of the 5-HT_{1A} and 5-HT_{1B} receptors reduce aggressive behavior; and the antiaggressive effects of the 1B receptor subtype are behaviorally specific and especially, effective in situations that engender escalated levels of aggressive behavior, although these effects remain to be translated to the clinic. Microinjection studies provide evidence that 5-HT_{1A} and 5-HT_{1B} receptor agonists can achieve their antiaggressive effects via action at either somatodendritic autoreceptors in the dorsal raphé nuclei or the presynaptic terminal autoreceptors or the postsynaptic heteroreceptors (Fig. 2). If, in fact, the decrease in extracellular levels of corticolimbic 5-HT after 5-HT_{1A} and 5-HT_{1B} receptor stimulation constitutes a critical mechanism of action for the antiaggressive effects, a significant revision of the serotonin deficiency hypothesis is required. Genetic deletion studies of 5-HT_{1A} and 5-HT_{1B} receptors generate a more complex pattern of results that appears to be influenced by the genetic background of the mouse or by developmental compensations in mutant mice. Similarly, associations between ▶ polymorphisms of 5-HT_{1A} and 5-HT_{1B} receptors and aggressive traits in humans remain inconsistent.

5-HT Receptors

Antagonism of 5-HT_{2A} receptors represents the mechanism via which some atypical antipsychotic compounds achieve their calming effects in patients with diagnoses that range from schizophrenia, dementia, depression, and posttraumatic stress disorders (PTSD). Yet, the side-effect profile of these agents highlights the problematic nature of this new class of antipsychotic agents. Preclinical studies of the 5-HT_{2A} and 5-HT_{2C} receptors have to await the development of more selectively acting molecular tools, since at present it is not possible to differentiate between the antiaggressive effects of agonists and antagonists at these receptor subtypes. Similarly, linkage studies between polymorphisms in the 5-HT_{2A} receptor and impulsive-aggressive or antisocial traits require replication.

Blockade of the reuptake mechanism for 5-HT via the SERT reduces aggressive episodes in most patients, especially when given over extended periods. Large meta-analyses have identified the exceptional nature of the occasional reports of increased aggressivity and suicidal tendencies among those treated with selective serotonin reuptake inhibitors (SSRI). Preclinical studies have shown that acute and chronic treatment with SSRIs reduces aggressive behavior in species ranging from invertebrates to primates. Chronic SSRI administration can also restore competent agonistic



Aggression. Fig. 2. Modulation of aggressive behaviors in rodents by microinjections of 5-HT_{1A}, 5-HT_{1B}, and 5-$HT_{2A/2C}$ receptor agonists. Text boxes show that local injections of 5-HT_{1A} receptor (1A), 5-HT_{1B} receptor (1B), or 5-$HT_{2A/2C}$ receptor (2A/2C) agonist increases (↑), decreases (↓), or has no effect ("0") on territorial, escalated, maternal, and defensive aggressive behaviors. Serotonergic neurons originate from the raphé nuclei and project to several brain areas.

interactions in placid laboratory strains of rats that do not show intact species-typical aggressive behavior.

The short-length allele in the serotonin-transporter gene-linked polymorphic region (5-HTTLPR) leads to lower SERT expression and lower serotonergic activity relative to those with the long-length allele. Some evidence supports the association of the short allele with increased hostility, impulsivity, and aggressiveness, primarily in males. The contribution of the 5-HTTLPR to the variation in aggressive personality traits is relatively small and appears to depend on epistatic influences and on environmental triggers. Early stressful life experiences in monkeys and humans may increase the probability of escalated aggression toward others and themselves, particularly in those individuals who carry the short-length allele. A more adequate understanding of SERT expression in corticolimbic regions promises to be relevant for the display of aggressive personality traits.

Brain serotonin modulates and is modulated by other amines, amino acids, and also neuropeptides and neurosteroids. For example, serotonergic projections in specific hypothalamic nuclei may regulate the release and action of vasopressin (VP), a neuropeptide that is associated with high rates of aggressive behavior in several animal species via action at 5-HT_{1A} and 5-HT_{1B} receptors. Similarly, the modulation of serotonergic neurons by corticotrophic releasing factor (CRF) and opioid peptides provides the anatomical basis for functional interactions that appear relevant to aggressive behavior. The promising information on CRF, GABA, and glutamate in amygdaloid connections with hypothalamic and brainstem structures during displays of intense emotion should prompt a detailed examination of these mechanisms in escalated types of aggressive behavior.

Definition

Behavior by an individual directed at another person or object in which either verbal force or physical force is used to injure, coerce, or express anger.

Role of Pharmacotherapy

Types of Clinical Aggression

Human aggression constitutes a multidetermined act that results in physical or verbal injury to self, others, or objects. It appears in several forms and may be defensive, premeditated (e.g., predatory), or impulsive (e.g., nonpremeditated)

in nature. Defensive aggression is generally seen as dictated by particular external realities and within the normal range of human behavior. Premeditated and impulsive aggressive behaviors are commonly viewed as pathological. Specific acts of aggression may be situational, but the tendency to behave aggressively represents a behavioral trait. While the frequency of aggressive acts tends to decrease with advancing age, numerous studies document that the trait of aggressiveness begins early in life and continues through adulthood. Both impulsive and premeditated aggression represents the potential for significant physical and psychological harm to the individual, to those subjected to the effects and to society in general. However, a converging pattern of empirical data from a variety of studies consistently links *impulsive*, but not premeditated, aggression to biological, environmental, and pharmacological or psychological treatment response factors.

One guiding principle to the consideration of human aggression is that biological and psychological factors contribute significantly to this behavior. Biological factors contribute to aggressive behavior through reduced inhibitory, and/or increased facilitatory, neuronal inputs to behavior. Research in this area has found utmost support for the role of inhibitory behavioral inputs modulated by brain serotonin (5-HT) function. The role of various neurotransmitter systems in increasing facilitatory input for aggressive behavior has received less attention and, in contrast to 5-HT, the results have been somewhat inconsistent. On the other hand, psychotherapy outcome research has successfully focused attention in this general area, vis-a-vis the relationship between the impulsive aggressive individual and his/her external/internal environment as facilitatory in generating impulsive aggressive behavior. Here, the focus is on the hypothesis that vulnerable individuals manifest impulsive aggressive behavior in response to external/internal stimuli perceived as "provocative" or "aversive" in nature which lead to variable states of anger that drive susceptible individuals (e.g., individuals with reduced central 5-HT function) to exceed their "threshold" for effective behavioral inhibition so that an impulsive aggressive outburst is initiated. If so, treatment aimed at increasing central (5-HT mediated) behavioral inhibitory tone and reducing states of high anger (i.e., negative emotionality) should be an effective strategy in treating impulsive aggressive behavior in human subjects. To date, research has shown the potential efficacy of (1) pharmacological approaches to reducing impulsive aggressive outbursts and, (2) psychological approaches to reducing states of acute (and chronic) anger. To date, however, neither approach has been combined or compared in the same study.

Impulsive Aggression Expressed as a Dimension

Behavioral Genetics of Impulsive Aggression

Data from twin, adoption, and family studies suggest genetic influence on aggression. Heritability estimates for measures of aggression are moderately substantial in adults ranging from 44% to 72% and a recent meta-analysis confirmed the presence of a substantial genetic influence for aggression. Heritability estimates were most pronounced for aggression measures reflecting anger and hostility, or anger, impulsiveness, and irritability. It is noteworthy that these same phenomena are associated with the clinical profile of intermittent explosive disorder (IED).

Psychosocial/Environmental Correlates of Impulsive Aggression

The most important psychosocial factors involved in the development of aggression appear to be low socioeconomic status, ineffective parenting style, as well as physical punishment in childhood and exposure to aggression within and outside of the family. Notably, harsh discipline and child abuse (regardless of SES status) have been found to predict the development of *impulsive*, but not nonimpulsive, aggressive behavior in children. In one study, 41% of children abused in the first 5 years of their life became *impulsively* aggressive later in life, compared with 15% of nonabused children; in contrast, none of the nonimpulsively aggressive subjects had a history of child abuse.

Neurochemical Correlates of Impulsive Aggression

Among all of the biological factors potentially involved in aggression, the most studied factors relate to brain neurochemistry, specifically monoamines such as serotonin (5-HT) and other centrally acting neurotransmitters (Brown et al. 1979; Coccaro and Siever 2005; Coccaro et al. 1989). Evidence of a role of brain 5-HT in human aggression is especially strong and points to an inverse relationship between brain 5-HT activity and aggression in animal models, nonhuman primates, and humans. In human studies, various measures reflecting central (as well as peripheral) 5-HT function have been shown to correlate inversely with life history, questionnaire, and laboratory measures of aggression. Most importantly, the type of aggression associated with reduced central 5-HT function appears to be *impulsive*, rather than nonimpulsive aggression (Linnoila et al. 1983). In human studies, there are selective cases where the relationship between 5-HT and aggression is positive in direction or does not exist at all. This may be due to the presence of other factors (e.g., diagnostic group; drug dependence; developmental stage) which may involve differential

contributions from other neurotransmitter systems that also influence the tendency to react aggressively in social contexts. Limited evidence also supports a role for Non-5-HT brain systems and modulators in impulsive aggression. These findings suggest a permissive role for ► dopamine, ► norepinephrine, vasopressin, testosterone, and an inhibitory interaction between neuronal nitric oxide synthase and testosterone in rodents.

Functional Neuroanatomy of Aggression-Related Disorders in Humans

While IED is the only DSM-IV disorder (see later) for which aggression is the cardinal symptom, both borderline personality disorder (BPD) and antisocial personality disorder (AsPD) share a number of attributes associated with aggression as a dimension. At their most basic level, all three disorders are associated with increased anger and irritability as well as self- and other-directed aggression. All three diagnostic groups demonstrate a number of the deficits associated with the orbital ► medial prefrontal cortex (OMPFC)-amygdala tract including deficiencies of executive functions and socioemotional information processing. For IED, a series of PET studies on "impulsive aggressive" patients with both IED and BPD fail to parallel the increase in OMPFC metabolism by normal controls in response to acute administration of serotonin agonists, suggesting an important reduction in OMPFC function in impulsive aggressive individuals (New et al. 2002). Notably, however, chronic administration of a serotonin agonist over 12 weeks can both increase OMPFC metabolism and reduce impulsive aggressive behaviors. A study of temporal lobe epilepsy patients with and without IED, found that a subgroup of 20% of the IED patients (BPD status not assessed) had "severe" amygdala atrophy. In contrast to these studies, the only available imaging data from subjects with IED, demonstrate that IED subjects (even those without BPD or AsPD) have augmented Amygdala (AMYG), and reduced OMPFC, fMRI blood oxygenated level dependent (BOLD) signal activation to angery faces (Coccaro et al. 2007). In contrast to IED, there is a larger imaging literature among patients with BPD and AsPD. Structural MRI studies show only weak support for the existence of reduced frontal volumes for either disorder with equally equivocal support for morphological changes in the amygdala. In contrast, PET and fMRI studies have produced a fairly consistent pattern of altered corticolimbic activation for both disorders. Three PET studies have reported reduced metabolism in the frontal (e.g., OMPFC) cortex in BPD subjects. Both BPD and AsPD populations show decreased OMPFC activation during emotional information processing (e.g., trauma scripts, a conditioned aversive stimulus) compared to control populations. Psychopaths also evidence less activation to abstract words in the right lateral frontal cortex. Both groups show increased amygdala activation to emotional stimuli; BPD subjects display enhanced amygdala activation to unpleasant pictures, as well as fearful and neutral words (viewed as negative by BPD subjects). While psychopaths showed increased amygdala activation when passively viewing negatively valenced pictures, amygdala activation for psychopaths may be attenuated/eliminated during emotional learning/conditioning tasks.

Recurrent, Problematic, Impulsive Aggressive Behavior as a Target for Study and Intervention: Intermittent Explosive Disorder

Although the term IED has only been in the DSM since the third edition (1980), the "construct" of a "disorder of impulsive aggression" has been in the DSM since its inception in 1956. Currently, it describes individuals with recurrent, problematic episodes of aggression not accounted for by other medical or psychiatric factors (Coccaro et al. 2005). While DSM-IV does not specifically refer to the aggression in IED as impulsive in nature, premeditated aggression is typically a characteristic seen in antisocial personality disorder.

Clinical Description

Aggressive outbursts in IED have a rapid onset, often without a recognizable prodromal period. Episodes are typically short-lived (less than 30 min) and involve verbal assault, destructive and nondestructive property assault, or physical assault. Aggressive outbursts most commonly occur in response to a minor provocation by a close intimate or associate, and IED subjects may have less severe episodes of verbal and nondestructive property assault in between more severe assaultive/destructive episodes. The episodes are associated with substantial distress, impairment in social functioning, occupational difficulty, and legal or financial problems.

Epidemiology

In the largest epidemiological study to date, the lifetime prevalence of IED by "Narrow" DSM-IV criteria is estimated at 5.4% with 1-year prevalence estimated at 2.7% (Kessler et al. 2006).

Age of Onset and Demographics

IED appears as early as childhood and peaks in mid-adolescence, with a mean age of onset in three separate studies ranging from 13.5 to 18.3 years. The average

duration of symptomatic IED ranges from 12 to 20 years to the whole lifetime. While initially thought to be more common in males, recent data suggest the gender difference in prevalence of IED may be closer to 1:1. Sociodemographic variables (e.g., sex, age, race, education, marital and occupational status, family income) do not appear to differ meaningfully as a function of IED status.

Laboratory Studies

To date, published data have reported IED subjects as having altered ▶ serotonin function compared with non-IED subjects or healthy controls. Other studies demonstrate a reduction in prolactin responses to ▶ fenfluramine challenge, in the numbers of platelet 5-HT transporters in IED subjects compared with non-IED subjects. Two FDG PET studies report low FDG utilization after D,L-fenfluramine challenge in frontal areas of the brain and low FDG utilization after m-CPP challenge in the anterior cingulate in IED subjects compared with healthy controls. A ligand binding study of the 5-HT transporter also reports reduced low 5-HT transporter availability in the anterior cingulate in IED subjects versus healthy controls. Finally, fMRI study demonstrates increased activation of AMYG, and reduced activation of OMPFC, to angry faces, in IED subjects compared with healthy controls.

Family Study

Family history study of IED subjects demonstrates a significantly elevated morbid risk for IED in relatives of IED, compared with healthy controls, probands (0.26 vs. 0.08, $p < 0.01$). Elevation in morbid risk for IED was not due to the presence of comorbid conditions among IED probands (e.g., history of suicide attempt, major depression, alcoholism, drug use disorder, etc.) and not due to elevations in morbid risk of other non-IED disorders in relatives (e.g., major depression, alcoholism, drug use disorders, anxiety disorder, and any other disorder).

Treatment of Impulsive Aggression and IED

Impulsive Aggression

Several psychopharmacologic agents appear to have effects on impulsive aggression. Classes of agents shown to have "antiaggressive" effects in ▶ double-blind, ▶ placebo-controlled trials of individuals with "primary" aggression (i.e., not secondary to psychosis, severe mood disorder, or organic brain syndromes) include mood stabilizers (e.g., ▶ lithium), 5-HT uptake inhibitors (e.g., fluoxetine) and, anticonvulsants (e.g., diphenylhydantoin, ▶ carbamazepine). While norepinephrine beta-blockers (e.g., ▶ propranolol, nadolol) have also been shown to reduce aggression, these agents have exclusively been tested in patient populations with "secondary" aggression (e.g., mental retardation, organic brain syndromes, etc.). Classes of agents which may have also "pro-aggressive" effects under some conditions include ▶ tricyclic antidepressants (e.g., ▶ amitriptyline), ▶ benzodiazepines, and stimulant and hallucinatory drugs of abuse (e.g., amphetamines, ▶ cocaine, ▶ phencyclidine). Emerging evidence of differential psychopharmacology is of critical importance, and findings from the literature of double-blind, placebo-controlled, clinical trials suggest that antiaggressive efficacy is specific to *impulsive*, rather than nonimpulsive, aggression.

Intermittent Explosive Disorder: Effect of Psychopharmacologic Intervention

▶ Fluoxetine demonstrates clear antiaggressive efficacy for reducing impulsive aggressive behavior in IED subjects compared with placebo (Coccaro et al. 2009). Fluoxetine's antiaggressive effect is most clearly seen on verbal aggression and aggression against objects. Despite this effect, somewhat less than 50% of IED subjects treated with fluoxetine achieve remission. Gains made with fluoxetine typically dissipate within 1 month after discontinuation but can be achieved again when the drug is reinstituted. Notably, fluoxetine has not been shown to increase aggression in IED subjects in placebo-controlled trials. Another placebo-controlled study of IED involving divalporex reported a favorable effect of this agent on overt aggression but only in IED subjects with comorbid cluster B personality disorder.

Intermittent Explosive Disorder: Effect of Psychosocial Intervention

While there are very few studies on the psychosocial treatment of impulsive aggression in adults, the efficacy of treatments that address the related constructs of anger dyscontrol and/or interpersonal aggression have been evaluated and suggest that relaxation training, interpersonal skill training, cognitive therapy, and multicomponent treatments all have moderate to large effects in the treatment of anger, and that the anger-reducing effects of anger treatment remain at follow-up. Of the different approaches for treating individuals with anger and aggression problems, cognitive restructuring, interpersonal skills training, multicomponent treatments, and relaxation skills had the strongest influence on aggression with effect sizes (Cohen's d) for the four types of treatment ranging from 1.06 to 1.87. Recently, a well-controlled study of cognitive behavior therapy in IED focusing on cognitive restructuring, relaxation and coping skills

training has been published, demonstrating significant reduction in impulsive aggressive behavior and in hostile automatic thoughts (McCloskey et al. 2008). The antiaggressive response in this study was similar to that seen with fluoxetine, suggesting the possibility that the two interventions, together, may be very effective in treating the impulsive aggression seen in individuals with IED.

Definition

A melatonin MT1 and MT2 receptor agonist and 5-HT_{2C} antagonist, known to be effective in acute treatment and relapse prevention in major depressive disorder, it also has proven efficacy in Generalized Anxiety Disorder. It seems better tolerated than some SSRIs and ► venlafaxine, with fewer treatment-emergent side effects and a reduced burden of discontinuation symptoms.

Agonist

Synonyms

Receptor activator

Definition

A substance that binds to a receptor and alters the receptor state, resulting in a biological response. The response mimics the effect of the endogenous activator of the receptor. A compound can be a full agonist, which leads to the maximum possible response of the system under study, or a partial agonist, an agonist that under specified conditions does not elicit as large an effect as a full agonist. This is in contrast to antagonists that have affinity but no efficacy at a receptor, and hence have no observable effects except to modify the actions of an agonist at that receptor. Inverse agonists are compounds that produce a pharmacological response that is opposite in direction to that of an agonist.

Definition

Agoraphobia is an anxiety syndrome in which patients experience severe anxiety or distress in certain places or situations. This can lead to the avoidance of these situations. The places often represent those from which escape might be difficult or embarrassing e.g., public transport, supermarkets, crowds, or lifts. However, symptoms can also occur when the patient is alone in any place where they anticipate that they will be unable to obtain help should "the worst" happen. It often starts after unexplained spontaneous symptoms of anxiety or ► panic attacks, and the fear of anxiety symptoms rather than the actual attacks becomes predominant leading to a heightened state of anticipation.

Role of Pharmacotherapy

Diagnostic Categories

Currently, ► Panic attacks and agoraphobic avoidance are seen as independent yet closely related anxiety factors. Therefore, two main types of disorder involving agoraphobia are defined according to the major classification systems (APA 2000):

(a) Agoraphobia
(b) Panic Disorder with Agoraphobia

► Panic Disorder in combination with agoraphobia is more common as many patients with Panic Disorder go on to develop agoraphobia eventually. Agoraphobia develops when avoidance behavior intensifies and it results in impairment of personal work and social functioning. Some patients cannot leave the house alone and can become fearful when left alone at home. Agoraphobia without a history of panic disorder is rare in clinical studies (Kessler et al. 2006), but this may be because of the nature of the disorder e.g., strong fear of travel and widespread avoidance, would make clinic visits extremely difficult. In confirmation of this, it is more commonly found when researchers visit the home of the patient, as in community studies (Perugi et al. 2007). Agoraphobia also occurs as a ► comorbid condition with other Anxiety Disorders e.g., ► Social Anxiety Disorder, Generalized Anxiety Disorder, or with ► Depressive Disorders and it is also associated with Axis II personality disorders such as Avoidant or Dependent Personality Disorder. The risk of ► substance abuse, usually of alcohol or benzodiazepines, is increased in these patients when they need to travel or face situations they fear. The onset of agoraphobia is usually gradual and can easily become chronic if not recognized. Severe agoraphobic avoidance can be hidden for years and the disorder is therefore often inadequately treated.

A range of drugs is available to treat agoraphobia with and without panic disorder. However, after establishing the diagnosis, it is important to explain the nature and symptoms of anxiety to the patient clearly so that they do not present to numerous medical facilities searching for a physical rather than a psychological explanation for their somatic symptoms. Patients fear that panic symptoms signal imminent danger in terms of a heart attack, collapse, going mad, or death. Their understanding of bodily functions can be overestimated and simple explanations about ► hyperventilation and palpitations are extremely valuable. The value of regular exercise in understanding bodily symptoms and reducing tension and the frequency of panic attacks should also be explained. In addition, it is helpful to outline the negative impact of using both stimulant and sedative substances on symptoms. For example, large amounts of coffee (► caffeine) are likely to increase shakiness and heart rate and although ► Alcohol may lead to some temporary reduction in anxiety, its consumption is likely to lead to ► dependence, if used for this purpose.

Drugs used to Treat Agoraphobia With and Without Panic Disorder

Drug treatment and ► cognitive-behavioral therapy (CBT) have been shown to be equally effective in the acute treatment of agoraphobia with and without panic disorder (Mitte, 2005). However, it is essential to consider severity of agoraphobic avoidance, local service availability, and patient preference when selecting or combining treatments as some studies indicate that CBT is more acceptable to patients (Otto et al. 2001). The drug treatments which have been shown to be effective in the acute treatment of agoraphobia are shown in Table 1. Slightly higher doses than those recommended for depression may be necessary to control symptoms enough to promote behavior change.

Behavior therapy – exposure	16–20

Although Tricyclic ► antidepressants (TCAs) and ► Selective Serotonin Reuptake Inhibitors (SSRIs) have been found to be equally effective in reducing both the severity and the number of panic attacks (Bakker et al. 2002), SSRIs are currently recommended as the first line of drug treatment. Initial side effects, to which anxious patients are especially sensitive, can be minimised by slowly increasing the dose. When first prescribing drug treatment, it is important to explain certain principles to the patient (Table 2).

If the patient has responded to the drug therapy by 12 weeks, treatment should be continued for a further 6 months. When stopping treatment, the dose should be reduced gradually over several weeks to avoid discontinuation and rebound symptoms. If longer term treatment is required, both ► paroxetine and ► sertraline have shown efficacy for long-term maintenance or for prophylactic use to prevent relapse (Perugi et al. 2007). However, CBT with exposure should be considered as there is evidence that this approach reduces relapse rates (Nathan and Gorman, 2002). If the patient has not responded to

treatment after 12 weeks, the prescriber should consider switching to a different treatment or combining drug and psychological approaches.

1. *Efficacy.* All the drug treatments shown in Table 1 have been shown to be more effective than placebo. SSRIs have been shown to be effective treatments for agoraphobia. They reduce panic severity, eliminate attacks, diminish agoraphobic avoidance, and improve overall quality of life. They are recommended as the first line of drug treatment. TCAs are also effective in reducing panic attack severity and the number of attacks and benzodiazepines have shown similar efficacy to antidepressants.
2. *Side effects and toxicity.* SSRIs can cause nausea and gastric side effects and decrease ► libido whereas ► benzodiazepines can cause sedation and impair some motor and memory functions. However, both SSRIs and benzodiazepines have relatively benign side effect profiles. TCAs can cause unpleasant ► anticholinergic side effects and weight gain and are dangerous in overdose.
3. Advantages and disadvantages of different agents. SSRIs are considered the first choice of treatment for agoraphobia because they combine therapeutic efficacy with safety and tolerability. However, they can increase activation levels leading to agitation and anxiety at the start of treatment and patients should therefore be started at low doses which are gradually increased. Tricyclic antidepressants (TCAs) are the second choice of treatment but their side effects can also lead to drop-outs or reduced ► adherence at the beginning of treatment. ► Benzodiazepines have been shown to be effective in the treatment of agoraphobia. They are also quicker acting and better tolerated than antidepressants. However, benzodiazepines

can cause tolerance, dependence, and withdrawal effects (► Sedative, Hypnotic, and Anxiolytic Dependence) and because of their palatability, they are also prone to misuse and ► diversion. These factors limit their usefulness and they should only be prescribed either when other drugs have not been effective or for short periods at the beginning of treatment, i.e., to counteract increased anxiety which can be caused by the antidepressant or until it takes effect. Some studies have examined the combination and found that patients who received combined treatment showed faster improvement than those receiving either drug alone but that the benefit was only apparent up to 6 weeks of treatment (Perugi et al. 2007). Benzodiazepines used as combined therapy in this way should therefore be tapered off after 6 weeks.

Other Medications

When no response occurs to the evidence-based drug treatments in Table 1, then, ► monoamine oxidase inhibitors (MAOIs) provide an alternative treatment. ► Phenelzine has been shown to help some patients but the dose has to be titrated on an individual patient basis as it can vary between 15 and 90 mg/day. ► Tranylcypromine has been used at doses of 10–60 mg/day. However, these drugs need careful supervision as they can cause toxicity if patients do not adhere to strict dietary and concomitant drug restrictions. The evidence for the efficacy of the reversible inhibitor of MAO, ► moclobemide, is mixed but it has proved effective at a dose of 450 mg/day in at least two studies.

Psychological Treatment

Behavior therapy comprises graded exposure in vivo to a personally constructed hierarchy of feared situations to target agoraphobic avoidance. ► Cognitive behavior therapy aims not only to change behavior but to challenge and modify beliefs focussed on the catastrophic misinterpretation of bodily symptoms. Both approaches have been shown to be effective but because CBT combines behavioral and cognitive approaches, it is more robust.

Combined Treatment

Several narrative or unsystematic reviews of combined psychological and drug treatment have been done but provided mixed results. However, a recent systematic review completed a ► meta-analysis of 23 studies which examined the effects of combining psychotherapy and antidepressant drug treatment for panic disorder with agoraphobia (Furukawa et al. 2006). The authors found that combined treatment was superior to antidepressant treatment alone. The combination decreased the global severity of the disorder and social dysfunction. The superiority was still evident at follow-up. In addition, combined treatment was more effective than psychotherapy alone at the end of acute phase treatment but this diminished at follow-up. A separate meta-analysis of 13 studies using patients with agoraphobia alone showed similar results. A systematic review of the combination of psychotherapy and benzodiazepines has been carried out (Watanabe et al. 2009). However only three trials were found and this was insufficient to show any advantage for combined therapy over either therapy alone.

Conclusion

Agoraphobia is often overlooked and undertreated. Early intervention is important as it can develop into a chronic, relapsing condition. Effective drug treatment is now widely available and access to psychological therapy has improved. The combination of antidepressant drug treatment and psychotherapy is especially effective in acute treatment and produces more improvement than drug treatment alone at follow up.

Akathisia

Definition
A syndrome of increased motor activity and/or subjective sense of desire for motor activity believed to be due to functional irregularities in the extrapyramidal motor system in the brain. Most blatantly, akathisia may involve fidgeting, inability to remain seated, shuffling gait, shortened stride, cogwheel rigidity, reduced accessory movements such as arm-swing while walking or gesturing, and pacing. It may include more subtle phenomena such as wandering (with attendant boundary issues) and excessive talking (which the patient may be aware of, but unable properly to control). Akinesia can also affect small muscle groups, such as those of the face and/or larynx, leading to a reduced amount and range of facial expression and/or monotonous voice tone. Subjectively, akathisia is frequently experienced as an unpleasant, dysphoric state.

Definition
Alcohol (chemical formula C_2H_5OH or $CH_3–CH_2–OH$) is a volatile, flammable, and colorless liquid. Due to its psychoactive properties, it is the most widely used recreational drug, and the term "alcohol" generally refers to alcohol-containing beverages that vary in alcohol concentration, usually between 3 and 60%.

Pharmacological Properties

History
Alcohol is thought to be the earliest drug in common use, probably dating back to the paleolithic age (around 8,000 BC). Initially, alcoholic drinks were obtained through yeast-induced conversion of sugars (fermentation) from a variety of carbohydrate-based liquids, such as honey and grains steeped in water or fruit/vegetable juices. Fermentation-obtained beverages have a maximum alcohol content of about 12%, since alcohol concentration above that level causes the yeast to die, thus preventing further fermentation. Around 800 AD, Arabs discovered a process of distillation of fermented liquids, which produces beverages of much higher alcohol content, sometimes as high as 80%. The use of both types of alcoholic beverages – fermented

drinks such as beer, wine, or mead and distilled drinks ("spirits"), such as whiskey, vodka, or gin – is widely spread throughout the history as well as in modern times, and it plays a significant role in social and religious customs of many cultures.

Acute Effects

Alcohol exerts a number of effects, ranging from stimulant and pleasurable to sedative, anxiolytic, attention reduction, amnestic, anticonvulsant, muscle relaxant, hypnotic anesthetic, and can lead to death. The effects of alcohol are biphasic: at low blood alcohol concentrations (BAC) it is disinhibitory, thereby facilitating spontaneous behavior and having stimulant properties, while its effects at high BAC are sedative–hypnotic (Table 1). Acute alcohol poisoning (BAC $\geq$ 40%) may result in death due to the formation of edema (swelling) in the base of the brain (medulla), where centers of respiratory and cardiovascular regulation are located. Behavioral reaction to alcohol intake depends upon several factors, including the rate of alcohol absorption, alcohol metabolism, and ► tolerance.

Pharmacokinetics

Alcohol is a molecule soluble in water, which has low lipid solubility and which, like water, is easily absorbed into the bloodstream from the stomach and the duodenum (the top part of the small intestine). Since the majority of absorption occurs in the duodenum, the absorption rate tends to be slower for the stronger spirits than for the beverages of medium alcohol content, such as wine, because the high alcohol content of spirits inhibits the opening of the pyloric valve that allows for the stomach contents to pass into the duodenum.

The mode of alcohol transport in and out of the cells is passive diffusion, which is determined by the concentration gradient across the cell membranes. Thus, the absorption of alcohol into the body tissues depends on the level of vascularization (blood supply) of those tissues as well as the alcohol concentration of the beverage. In healthy adults, 80–90% of absorption occurs in the first 30–60 min following ingestion, although this is delayed and reduced if food is present in the stomach. Table 2 presents the number of standard drinks required to obtain a given BAC. The gender difference in the achieved BAC and, consequently, in the behavioral effects of the same dose of alcohol is thought to be due to the difference in the distribution of the body mass between men and women (Graham et al. 1998). Men have higher ratio of muscles to fat than women and thus proportionally more blood in the body (fat tissue lacks blood supply). Consequently, the same amount of alcohol is more diluted in the blood of men than women and less will be absorbed into the tissues due to the lower concentration gradient. Additionally, women have been suggested to metabolize alcohol more slowly, due to reduced levels of the metabolizing enzyme, ► alcohol dehydrogenase (► ADH),

although this has not been demonstrated unequivocally (Graham et al. 1998).

The effects of alcohol consumption are determined not only by the rate of absorption but also by the rate of its metabolism and elimination. Less than 10% of alcohol is eliminated unchanged via lungs, urine, and perspiration. Most of the ingested alcohol (approximately 90%) is metabolized in the liver via several metabolic pathways. The main pathway of alcohol metabolism in the liver is the oxidative process involving the enzyme ADH. ADH is located in the cytoplasm of liver cells and utilizes the coenzyme ► nicotinamide adenine dinucleotide (NAD) to convert alcohol into ► acetaldehyde. Another metabolic mechanism in the liver which contributes to the conversion of alcohol into acetaldehyde is the ► microsomal ethanol-oxidizing system (MEOS) involving the enzyme CYP2E1. This process, however, only accounts for 10–15% of the total hepatic metabolism of alcohol, and its activity plays a more pronounced role only during heavy and sustained drinking (see below).

The first by-product of alcohol, acetaldehyde, is a highly toxic substance but its levels are usually very low as it is rapidly converted into acetic acid by the second oxidative process mediated by another cytoplasmic liver enzyme, aldehyde dehydrogenase (ALDH). Acetic acid is then released into the hepatic venous blood where it binds to coenzyme A forming acetyl CoA which is subsequently oxidized into carbon dioxide and water.

Some of the ingested alcohol is also metabolized in the stomach and the duodenum, prior to absorption into the bloodstream. However, since the gastric and intestinal levels of ADH are comparatively low, this "first-pass" metabolism is less efficient than the hepatic metabolism and may only exert a more significant effect on the BAC

when alcohol is ingested together with food, which tends to slow down the absorption of alcohol due to food-induced closure of the pyloric valve.

The average rate of alcohol metabolism is approximately 7–10 ml (6–8 g) of alcohol per hour and the rate-limiting factor is the ADH and the NAD availability. However, significant genetic differences exist in the efficiency of alcohol metabolism. Individuals with the allelic variations of the ADH genes-1B and -1C (ADH1B and ADH1C) show a reduced rate of conversion of alcohol into acetaldehyde, which results in an increased level of intoxication. Similarly, individuals with the allelic variation of the ALDH2 gene, which results in inactivity of the ALDH, experience accumulation of the toxic acetaldehyde in the blood and thus experience the "flush reaction" to alcohol. Flush reaction includes more intense feelings of intoxication, facial flushing, nausea, tachycardia, hypotension, and increased body sway. One of the drugs for the treatment of ► alcohol abuse and dependence, ► disulfiram ("Antabuse") is based on the same principle. Disulfiram pharmacologically blocks ALDH resulting in aversive reaction to alcohol which promotes abstinence.

Due to increased propensity of adverse reactions to alcohol, individuals with the ADH1B, ADH1C, and ALDH2 genotypes usually completely abstain from alcohol consumption. These genotypes are more common among the Asian population, where up to 80% of individuals in some subgroups posses at least one copy of one of these genes (Eng et al. 2007).

Tolerance

Tolerance to alcohol can be acute or chronic. ► Acute tolerance is observed during a single drinking session when some effects of alcohol are more pronounced during the ascending, compared to the descending, phase of the BAC curve. This so-called Mellanby effect has been suggested to occur due to the acute behavioral or cellular adaptations to the effects of alcohol (see below). It is also evident during the descending phase of the BAC curve, when subjective feelings of intoxication decline faster than the rate of decline of the BAC. Indeed, the subjective intoxication may entirely disappear during the descending phase of the BAC curve, even with BAC as high as 0.03–0.05% (Martin and Moss 1993). Chronic tolerance occurs as a result of repeated exposure to alcohol and is manifested by the reduced effectiveness of the same doses of alcohol, which were effective previously. This type of tolerance occurs as a result of metabolic (pharmacokinetic) or pharmacodynamic (cellular, molecular, functional) adaptations.

Metabolic tolerance is characterized by a diminished peak BAC obtained by a given dose of alcohol, resulting from increased absorption or clearance of alcohol from the bloodstream, which in turn result in a diminished alcohol effect. While repeated alcohol exposure may result in an increase in the ADH activity, this is unlikely to be the main mechanism underlying metabolic tolerance. This is because the degree of ADH activity is limited by the rate of the regeneration of the coenzyme NAD, which is insufficient to keep pace with the increased ADH production. Instead, it seems that the main mechanism underlying metabolic tolerance is the upregulation of the second major hepatic metabolic pathway involving the enzyme CYP2E1. This metabolic pathway is upregulated following chronic alcohol use, leading to as much as double the rate of alcohol breakdown in alcoholics when compared with moderate drinkers (Koob and Le Moal 2006). As a result of metabolic tolerance, peak BAC for the tolerant individual is much lower than for the nontolerant individual at the same dose of alcohol. Metabolic tolerance effect, however, is transient and is usually lost after as little as 3 weeks of abstinence.

► Pharmacodynamic tolerance occurs independently of the metabolic tolerance and is expressed as the shift to the right of the BAC dose-response curve. That is, a higher BAC is needed to produce the same degree of intoxication as previously obtained with a lower BAC, suggesting that the target central nervous system (CNS) tissues have become less responsive to alcohol. This is thought to be due to counteradaptive neuronal and molecular changes involving neurotransmitter release, receptors and secondary messenger systems including cAMP and G-proteins (Feldman et al. 1997; Pandey 1998). One proposed mechanism of pharmacodynamic tolerance involves latent hyperexcitability, resulting from alcohol-induced depression of neuronal activity. This depression of neuronal activity may result from desensitization or reduction of the number of existing receptors, making the postsynaptic targets less responsive to alcohol-induced neurotransmitter release. Another proposed mechanism involves reduction in neurotransmitter release, which may result from neurotransmitter depletion (e.g., not enough neurotransmitter synthesized to keep pace with the release) or end-product inhibition (stimulation of presynaptic autoreceptors inhibiting further release). Both these opponent mechanisms of pharmacodynamic tolerance are thought to contribute to the rebound phenomenon of acute alcohol ► withdrawal when effects opposite to those of alcohol are observed (e.g., sedation/anxiolysis during intoxication, ► hyperactivity/anxiety during withdrawal).

Pharmacodynamic tolerance and, to a lesser extent, metabolic (pharmacokinetic) tolerance are also revealed through the phenomenon of ► cross-tolerance, whereby heavy drinkers and alcoholics who display tolerance to alcohol are also tolerant to other drugs, particularly to pharmacologically related compounds. This has important clinical implications because the level of alcohol use needs to be taken into account when determining a therapeutic dose of a prescription drug.

Tolerance to alcohol as well as the rebound withdrawal symptoms are mediated not only by the adaptive processes occurring in response to the presence of the drug in the body but may also be ► conditioned drug effects, whereby environmental cues associated with alcohol use trigger the adaptive opponent process in anticipation of alcohol consumption. For an extensive review of different types of tolerance, see Fadda and Rossetti (1998).

Individual differences in sensitivity to the effects of alcohol are thought to be partly heritable and underlie differential susceptibility to ► alcohol abuse and dependence, with social drinkers who initially have low level of response to alcohol being more vulnerable (Schuckit et al. 2004).

Withdrawal

Withdrawal symptoms occur after abrupt cessation of prolonged heavy alcohol use, and in milder form withdrawal-like symptoms may also occur in social drinkers following alcohol binges ("hangover" effect). ► Alcohol withdrawal syndrome consists of two or more of the following symptoms and signs: autonomic hyperactivity (increased sweating and pulse rate), increased hand tremor, insomnia, nausea and vomiting, psychomotor agitation, anxiety, and irritability (Stage I). Following a longer history of alcohol dependence, Stage I symptoms become more severe and the following additional symptoms can be observed: transient visual, tactile or auditory hallucinations, grand mal seizures or even full-blown epileptic seizures (Stage II). A few days after the initial stage I and II withdrawal symptoms have diminished, between 1 and 15% of patients experience ► delirium tremens (Stage III). This is characterized by confusion, disorientation, and agitation, as well as terrifyingly vivid persecutory hallucinations, which are usually perceived as real by patients, even after the recovery. Between 1 and 15% of the patients who experience delirium tremens die due to cardiovascular collapse (Feldman et al. 1997).

Withdrawal symptoms result from acute and chronic neuroadaptive changes which also underlie tolerance to alcohol (Fadda and Rossetti 1998). Acute alcohol withdrawal produces long-lasting neurodegenerative changes, and there is evidence that previous repeated withdrawal episodes exacerbate these neurodegenerative processes, not only producing a worsening in withdrawal-associated hyperexcitability (the so-called "kindling of withdrawal") but also leading to neurotoxicity associated with cognitive impairment and emotional incompetence (Duka et al. 2004). Withdrawal-induced neurodegeneration may be one of the main factors contributing to brain damage observed in individuals suffering from alcoholism.

Chronic Effects

Chronic alcohol abuse and dependence lead to a number of morphological, neurophysiological, and biochemical changes in the CNS and the associated cognitive deficits (Fadda and Rossetti 1998). While some of these changes are due to direct effects of alcohol and alcohol withdrawal, others are more indirect, resulting from nutritional deficiencies common in this population. Postmortem studies of the brains of heavy drinkers and alcoholics as well as in vivo brain imaging studies reveal a number of morphological changes, including brain shrinkage, increased ventricle size, reduction in the volume of white matter in the cerebral hemispheres, and thinning of the corpus callosum (Fadda and Rossetti 1998; Feldman et al. 1997).

Approximately 10% of alcoholics develop alcohol amnestic disorder (► Korsakoff's syndrome) or alcoholic dementia. While the former is characterized by anterograde memory impairment with relative preservation of intelligence and other cognitive functions, the latter is characterized by global severe dementia and intellectual impairment. Some of the cognitive impairments and morphological changes observed after chronic alcohol use may be reversible by abstinence, while others, such as cerebellar atrophy seen after prolonged excessive alcohol use, appear to be irreversible (Feldman et al. 1997).

Mechanisms of Action

Alcohol has multiple mechanisms of action on the CNS.

Alcohol acutely facilitates γ-aminobutyric acid (GABA) transmission by potentiating GABA-stimulated Cl^- flux at the $GABA_A$-benzodiazepine (BDZ) receptor complex, inhibits glutamatergic transmission via its interaction with the *N*-methyl-D-aspartic acid (NMDA) receptors, increases serotonin (5-hydroxytryptamine; 5-HT) transmission by slowing its reuptake, and enhances 5-HT action at $5\text{-}HT_3$ receptors. Alcohol acutely increases the release of opioid β-endorphin and indirectly activates

mesolimbic dopamine (DA) system, via its actions on opioid system as well as the 5-HT_3 serotonin receptors. In addition to this, alcohol exerts a number of other effects, including enhancement of cholinergic function and increase on the levels of the corticosteroid hormones released from the adrenal glands. More recently, attention has been drawn to the effects of alcohol on ► neurosteroids which seem to contribute to neurophysiological and behavioral effects of alcohol. The most important of these actions are briefly discussed as follows:

$GABA_A$

The acute alcohol effects on ► GABAergic transmission contribute not only to the anxiolytic and sedative–hypnotic properties but also to its intoxication including motor incoordination. Alcohol induces allosteric changes in several ► $GABA_A$ Receptor subtypes, which is associated with increased function of these receptor subtypes. However, it is not clear yet which $GABA_A$ receptor subtypes are involved in the effects of alcohol. Alcohol is also found to increase the release of GABA in several brain areas, although the mechanism associated with the GABA presynaptic release is not yet clear.

Chronic effects of alcohol on $GABA_A$ receptor function and GABA release leads to functional adaptations of GABAergic system in several brain areas. Such neuronal adaptations contribute to the hyperexcitability like anxiety or even seizures seen during alcohol withdrawal (Pandey 1998). BZDs, which bind to $GABA_A$ receptors and facilitate GABAergic function are the treatment of choice for alcohol withdrawal symptoms.

Glutamate

Alcohol interacts with ► glutamate, the major excitatory neurotransmitter in the mammalian brain. Alcohol acutely inhibits glutamatergic synaptic transmission mediated by NMDA receptor that contributes to alcohol's anxiolytic effects. Neuronal plasticity mediated by ► NMDA receptors is also inhibited by alcohol; this alcohol effect on neural plasticity may contribute to its strong amnestic effects. NMDA receptor antagonists such as the drug ► ketamine have been reported to produce subjective effects resembling ethanol intoxication in healthy subjects as well as in detoxified alcoholics (Krystal et al. 2003).

Chronic alcohol exposure induces changes in NMDA receptor number and function as a result of compensatory mechanisms to counteract the inhibitory effects of acute alcohol. At withdrawal glutamatergic systems are disinhibited, leading to neuronal hyperexcitability and to neuronal damage induced by alcohol. ► Acamprosate, a drug that is thought to act by inhibiting neuronal activation probably due to an interaction with the glutamatergic neurotransmission is currently used as a treatment for alcohol addiction. Furthermore, a number of drugs that target glutamatergic transmission are currently being developed or tested for their efficacy in the prevention of relapse in alcoholism.

Dopamine

DA release in the mesolimbic system, from ventral tegmental area (VTA) into nucleus accumbens (NAcc), underlies motor stimulant and positive reinforcing effects of alcohol and other drugs of abuse. However, dopaminergic action of alcohol does not appear to be critical for maintaining alcohol reinforcement, since depletion of the mesolimbic DA did not significantly alter alcohol self-administration in animal studies.

Serotonin

Enhancement of 5-HT activity at the 5-HT_3 receptors contributes to alcohol's positive reinforcing and stimulant effects, since the densely distributed 5-HT_3 receptors in the mesolimbic DA-containing neuronal terminals enhance DA release. Consequently, 5-HT_3 receptor blockade was found to reduce alcohol-induced enhancement of DA release as well as alcohol consumption in humans. However, although the effects of alcohol on 5-HT and DA have been studied in the hope of developing new drugs for the treatment of alcoholism, the effectiveness of these drugs has been equivocal.

β-endorphin

The opioid system, particularly the β-endorphin, is thought to mediate positive hedonic effects of alcohol and to contribute to its reinforcing properties via indirect stimulation of DA release into NAcc (part of the reward pathway). Opioid receptor antagonists reduce alcohol-induced DA release, as well as alcohol consumption in animals and in humans. ► Naltrexone, an opioid antagonist, is commonly used as a treatment for alcoholism. Reduced consumption during naltrexone treatment may result either from reduction of the positive hedonic effects of alcohol ("liking") or by reduction of the positively reinforcing properties of alcohol ("wanting").

Due to its variety of actions in the CNS, alcohol produces a ► discriminative stimulus complex, or compound cue, composed of distinct components that are mediated by different receptor systems and which are not uniformly amplified as the ethanol dose is increased. This would account for the biphasic effects of alcohol described above. For instance, DA release into NAcc

underlies the stimulant effects of alcohol at lower doses, while at higher alcohol doses, despite further increase in DA release, the stimulant effects disappear due to increased sedative effects of ethanol, mediated by the GABAergic system; finally intoxication with even higher doses of alcohol may occur due to its interaction with the NMDA receptors.

Definition

Pharmacological treatment of alcohol dependent subjects includes both treatment of the acute physical withdrawal syndrome and relapse prevention treatment (Anti-► craving).

Whereas today withdrawal treatment is highly standardized, on the basis of randomized controlled trials and clinical experience from several decades, relapse prevention treatment represents a fairly new intervention. The available compounds are not widely prescribed and proved evidence for differential pharmacotherapeutic strategies is lacking.

Role of Pharmacotherapy

Physical Withdrawal Treatment: General Pharmacological Withdrawal Strategies

In the majority of cases, treatment of patients suffering from alcoholism starts with the termination of alcohol use and treatment of withdrawal symptoms. The general consensus is that the complicated ► alcohol withdrawal syndrome (severe physical withdrawal or withdrawal with seizures, ► alcohol hallucinosis or ► delirium tremens) requires pharmacological treatment. It is also agreed that adequate hydration, electrolyte compensation, thiamine substitution and monitoring of the cardiovascular parameters are required during all phases of the withdrawal syndrome. In addition to curative therapy, avoidance of seizures and reduction of the risk for delirium tremens should be considered.

For the treatment of a moderate to severe withdrawal syndrome, administration of ► benzodiazepines such as ► chlordiazepoxide or ► clomethiazol, a sedative hypnotic, is preferred. Comparative studies did not show a difference in efficacy between benzodiazepines and clomethiazol. In cases of delirious and hallucinatory syndromes, additional medication with neuroleptics is often applied; ► butyrophenones are preferred due to a somewhat lower risk of seizure during withdrawal. In outpatient treatment, substances such as tiaprid, ► carbamazepine, and clonidine, which have no dependence potential, achieved good results.

Specific Pharmacologic Withdrawal Strategies

Benzodiazepines

Benzodiazepines are the first choice in the treatment of alcohol withdrawal syndrome, delirium tremens, and

seizures during withdrawal. This is based on a broad cross tolerance with alcohol, the large therapeutic window and the fast onset of effect. Benzodiazepines are sedative, hypnotic, anti-convulsive, anxiolytic, and muscle relaxing and thus appropriate for the reduction of withdrawal symptoms as well as the prevention of delirium, hallucinations and withdrawal seizures. Allergic reactions and pulmonary complications are rare. Different benzodiazepines in equivalent doses have a similar effect in the treatment of uncomplicated alcohol withdrawal syndrome. Substances such as ▶ diazepam and clordiazepoxide, which have a long half-life, are most frequently used in the treatment. Shorter acting benzodiazepines (▶ oxazepam, ▶ lorazepam), however, include benefits due to a lower accumulation (especially in terms of liver cell damage), a reduction of aversive effects, and better controllability.

Treatment with diazepam is presented as an example. Diazepam is nearly totally reabsorbed; the oral bioavailability amounts to 95%. The half-life period adds up to 20–40 h and is extended in cases of liver cirrhosis and at higher age. It is mainly eliminated through the liver by forming active metabolites (half-life period up to 100 h). Diazepam is not known to have hepatotoxicity.

A dose based on the clinical symptoms should be favored rather than a schematized administration, as the effect on the alcohol withdrawal syndrome cannot be predicted.

Sellers et al. (1983) recommend an oral diazepam "loading" with 20 mg initially and consecutive administrations after gaps of 1–2 h, until the withdrawal syndrome is significantly reduced or the patient is slightly sedated. The maximum dose per day is 150 mg. During the next couple of days, the dose should be reduced to 25–50% to avoid accumulation of active metabolites (e.g., N-desmethyldiazepam). The benefits of this therapy are fast saturation, rapid onset of effect and the "shielding" of patients during the course of the withdrawal syndrome due to the long half-life period of diazepam (20–40 h) and its metabolite (30–40 h).

Side Effects and Contra-Indications

During treatment with benzodiazepines, reduction of blood pressure, which increased during alcohol withdrawal syndrome, and sedation occur. Undesired side effects can be respiratory paralysis, tachycardia, intestinal atony and muscle relaxation. Myasthenia gravis and a known oversensitivity are absolute contra-indications. Special care should be taken in cases of sleep apnoea syndrome. Benzodiazepines initially improve sleep quality but after cessation, a rebound can occur, which can trigger a relapse.

In cases of overdosing of benzodiazepines, a benzodiazepine antagonist (anexate) can be administered. Dosage: initially 0.2 mg slowly i.v., later, medication of 0.1 mg up to a maximum of 1 mg at an interval of at least 1 min. An outpatient withdrawal treatment with benzodiazepines can be considered under continuous monitoring over a maximum period of 1 week, considering the dependence potential of the substance.

Clomethiazol

This medication is not used in Anglo-Saxon countries. However, it is widely prescribed in other parts of the world, such as central Europe. ▶ Clomethiazol is a synthetic derivate of the thiazole portion of vitamine B1 (thiamine). The exact mechanism of action is still unknown, but includes the potentiation of GABAergic inhibition, possibly via a direct effect on the chloride channel. Clinically, clomethiazole acts sedatively, hypnotically, anticonvulsively and anxiolytically. The risk of developing a delirium tremens is reduced.

Clomethiazol is metabolized via the liver by forming inactive metabolites with a half-life period of approximately 4–6 h and is excreted renally. In cases of impaired liver function, the half-life period is extended and increases the risk for accumulation, while the half-life period is abbreviated in alcohol-dependent individuals without liver damage. Clomethiazole is not hepatotoxic.

The dose titration should be adjusted according to clinical symptomatology rather than a merely schematized administration. A too careful up-dosing can often lead to the development of a delirium, whereas a too slow dose reduction does not consider the dependence potential of the substance.

In case of severe physical withdrawal syndromes and during pre-delirium, 2–4 capsules should be administered. If sedation is insufficient, 6–8 capsules can be administered additionally after approximately 30 minutes during the first 2 h. Later on, a maximum of 2 capsules/2 h, depending on the symptoms and the state of the cardiovascular system, should be administered.

The average dose in the clinical routine is about 10–15 capsules/day. A careful dose reduction of approximately 2–4 capsules/day can be considered the second day. In case of pronounced symptoms, a plateau phase of 3–5 days is recommended. Because of its addictive effect, clomethiazole should be tapered within 8–10 days.

Side Effects and Contra-Indications

Oral administration can cause a decrease in blood pressure, which increased during alcohol withdrawal and a reduction of tachycardia. However, cardiovascular

insufficiency requiring treatment is rare. The risk of a hypoventilation and unconsciousness is also very low when administration is done orally. Further undesirable side effects are rashes, irritations of the throat and sneezing, tears and stomach problems. Bronchial secretion is increased. If taken for a long period, medication carries the risk of developing a dependence.

Sleep apnoea syndrome and central respiratory problems are absolute contra-indications. Clomethiazole should not be administered in case of bronchial asthma or acute lung or bronchial diseases. A concomitant administration of other hypnotics, tranquilizers, neuroleptics or alcohol can have life-threatening effects due to effect intensification, which is difficult to assess.

Outpatient treatment with clomethiazole should not be considered because of a dependency potential, as well as possible serious side effects, especially in cases of overdosing and alcohol consumption.

Tiapride, Carbamazepine, Oxcarbazepine and Clonidine

A combination treatment with tiapride and carbamazepine, especially oxcarbazepine, offers a good alternative, especially for outpatient treatment and leads to good results in treating vegetative symptoms within the withdrawal syndrome and offers concomitant seizure prevention.

Tiapride is a selective D2-receptor antagonist and belongs to the group of benzamide derivates. The special field of application of the substance is the treatment of extrapyramidal motor diseases. However, long-term experiences in pharmacotherapy for alcohol withdrawal syndrome exist as well. Tiapride has psychomotor effects and is sedative and anxiolytic, but does not have an effect on the seizure threshold during alcohol withdrawal. The low rate of undesired effects, the lower sedative effect, and especially the non-dependence potential seem to be advantages, compared to clomethiazole or benzodiazepines. Undesired side effects are tiredness, vertigo, orthostatic dysregulation and, sometimes, extrapyramidal motor symptoms. As tiapride lacks anti-convulsive efficacy, a combination therapy with carbamazepine has been suggested. A major advantage of carbamazepine, besides its anti-convulsive effect and lack of interaction with alcohol, is the reduction of the kindling effect. The half-life period is 15 h, but is reduced by enzyme induction after prolonged intake. It is eliminated via hepatic oxidation and renal elimination. The active metabolite carbamazepine epoxy has a half-life of approximately 8 h. Because of this fact and the delayed onset, no retarded release preparation of carbamazepine should be administered during withdrawal treatment.

Patients with liver dysfunction can be treated with oxcarbazepine, a derivative of carbamazepine that does not have liver toxicity. It showed good effects, as its elimination requires no hepatic metabolisation.

Patients receiving outpatient treatment should be monitored daily; after 1 week, detoxification is usually concluded. A dose increase of tiapride up to 1,800 mg per day in cases of severe withdrawal symptoms has been suggested; for inpatients, the recommendation is upto 2,400 mg per day.

If arterial blood pressure increases, the administration of the imidazole derivate clonidine can be helpful. Clonidine acts sympathicolytically via stimulation of presynaptic inhibitory alpha-two receptors located in the locus coeruleus. It reduces cardiovascular stress during alcohol withdrawal and decreases agitation, anxiety, tremor, and tensions in the muscular system. The substance does not have anti-delirious or anti-convulsive effects. The oral bioavailability amounts to 75% and the half-life period is 20 h. When administered parenterally, the effect appears after 10 min. Elimination happens 60% renally and 40% via hepatic metabolisation.

In cases of slight to moderate alcohol withdrawal syndrome, clonidine should initially be administered at a dose of 75 µg orally; the max. daily dose is 600 µg. Typical side effects are drop in blood pressure (initially also rise in blood pressure!), bradycardia, tiredness, xerostomia, and muscle relaxation. Contra-indications are AV-block II and III grades, sick sinus syndrome, phaechromocytoma, pronounced hypotonia, and depression.

Therapy for Delirium Tremens

Only about 5% of alcohol-dependent individuals with a vegetative withdrawal syndrome develop delirium tremens. While hallucinations (mainly optical, rarely acoustic) can also be observed during severe vegetative withdrawal syndromes, the presence of disorientation is the critical differential-diagnostic criterion, recommending the diagnoses of delirium tremens. Additionally, visual, tactile and acoustic hallucinations can occur, and, rarely, grand mal seizures, as well as disorders of consciousness and cognitive abilities. Psychomotor hyperactivity is also a typical symptom.

The presence of delirium tremens is a life-threatening situation that always requires immediate referral to an intensive care unit. Pharmacotherapeutic treatment prefers ► benzodiazepines, usually in combination with neuroleptics (e.g., ► haloperidol 5 mg/4 h) which are injected i.v. for electrolyte and liquid compensation. Under this medication, a delirium tremens usually subsides in 2–4 days. In this case, a tapering dose of the medication is

important. The administration of thiamine (50 mg slowly i.v., 50 mg i.m.) is usually necessary for the prophylaxis of Wernicke's encephalopathy.

Pharmacological Relapse Prevention

About 40–60% of patients relapse within 1 or 2 years after treatment. This proves the necessity for additional medication to prevent a relapse. Recent studies show that "anti-craving" compounds, especially during the first months after discharge from an inpatient withdrawal treatment, reduce the relapse risk (O'Brien 2005). So far, substances with an effect on the cholinergic, glutamatergic, serotonergic, dopaminergic, gabaergic and opioidergic systems have been examined (Spanagel and Kiefer 2008).

Acamprosate

Acamprosate, a calcium-bis-acetyle-homotaurinate, has been approved for preventing relapse of alcohol dependence. In cases of chronic alcohol consumption, a higher activity of the glutamatergic system can be seen, caused by a counter regulation of the acute inhibiting effect of alcohol on the excitatory glutamatergic neurotransmission. ▶ Acamprosate binds on the NMDA receptor and thus inhibits the increased excitability. After confirmation of experimental results in animal models, the effect of acamprosate on alcohol dependence was also examined in numerous controlled clinical studies. Evidence-based reviews have confirmed the efficacy of acamprosate on abstinence rate and number of drinking days and recommend clinical application (Mann et al. 2009).

Acamprosate has an effect on alcohol dependence especially when given concomitantly with psycho-therapeutic or psychosocial measures. The COMBINE Study included 1,383 recently alcohol-abstinent patients (Anton et al. 2006) and showed no effect of acamprosate on abstinence proportion, in contrast to the majority of European studies on this topic. Patient characteristics suggest that subjects who had no physical withdrawal syndrome requiring withdrawal treatment were mainly included in the Combine study. As acamprosate's efficacy is associated with its ability to modulate withdrawal-induced hyperglutamatergic states inducing craving, the specific pharmacological target for acamprosate might have been missing in the patients included in this study.

Acamprosate does not cause any interaction to other medications, does not increase alcohol toxicity, and does not have any dependence potential or other psychotropic effects. Frequent but usually transient side effects are diarrhea, other gastrointestinal conditions, headaches, and pruritus. Contra-indications are pregnancy and lactation periods, serum creatinine $>120\,\mu$molg/L in patients with renal insufficiency and the presence of severe liver insufficiency. The medication should be administered after detoxification in patients motivated for abstinence. A treatment period of 12 months is recommended. Treatment should be maintained even after short term relapses. The combination with alcohol bears no safety risks.

The daily dose of acamprosate is 3×2 tablets (à 333 mg). According to the manufacturer, the medication should be started after achieving abstinence and continued for approximately 1 year. It has been suggested that acamprosate has also an anti-withdrawal and a neuroprotective effect. With respect to the kindling phenomenon, administration of acamprosate should be considered one week prior to withdrawal. This would include a period of 7 days until the brain is in a steady state.

Naltrexone

▶ Naltrexone acts antagonistically mainly at mu-opiate receptors, counteracting alcohol craving. It is assumed that the endorphin-mediated, subjectively pleasant and positive reinforcing effects of alcohol are inhibited (O'Brien 2005). In animal models, the alcohol-antagonistic effect of naltrexone was demonstrated. Various placebo-controlled studies verified this effect in humans as well. Naltrexone has proved especially effective in combination with psychotherapeutic treatments. Yet several large trials did not show a superiority of naltrexone over the placebo. A Cochrane meta-analysis, however, confirmed a reduction in alcohol consumption, even if the time to first alcohol consumption was not always extended (Johansson et al. 2007).

Nausea, gastrointestinal disorders, and headaches are the main side effects of the otherwise well- tolerated substance. Contra-indications are acute hepatitis or severe liver dysfunction. Prior to treatment it should be ensured that at least some days of abstinence were observed, to avoid a concurrence of possible gastrointestinal side effects and withdrawal syndrome. The opiate-antagonistic effect should be considered for the indication of the further course of treatment. An actual or recent opiate consumption, taken as addictive drug or as pain relief, is an exclusion criterion for the administration of naltrexone. An opiate analgesia, necessary under administration of naltrexone, requires special precautions, especially if discontinuation of the medication cannot be done in time. Treatment with naltrexone should be continued for more than 3 months and not interrupted or discontinued after a timely, limited relapse. Naltrexone does not increase the toxicity of alcohol and does not possess any

dependence potential. The recommended daily dose of nemexine® is 50 mg.

Disulfiram

► Disulfiram has caused more controversies than any other medical treatment for alcoholism . While in Scandinavia and Great Britain up to 50% of alcohol-dependent individuals have been treated with this substance during the last decades, no considerable prescriptions were given in Germany after an initial success during the last two decades of the twentieth century. Only the increasing discussion on the prescription of anti-craving substances for relapse prevention led to a reconsideration of the administration of disulfiram. A special treatment concept for severely alcohol-dependent individuals was also performed (Ehrenreich et al. 1997). It showed the efficacy of the substance under daily supervised intake. A prescription, however, implies detailed knowledge of the mode of action and especially of the possible life-threatening side effects. It should only be prescribed under strict supervision.

Disulfiram affects the metabolisation of alcohol. The acetaldehyde dehydrogenase is blocked, so that a further decomposition to acetic acid is interrupted, resulting in an accumulation of ► acetaldehyde. This leads to unpleasant symptoms such as flushes, headaches, nausea, vomiting, diarrhea, drop in blood pressure and potentially to syncopes. These symptoms can be ascribed to the toxicity of acetaldehyde. A genetically conditioned lack of an isoenzyme of the aldehyde-dehydrogenase can be found in 50% of the Asian population, though in only around 5% of Caucasians. Alcohol consumption leads to the clinical symptoms described above, especially in homozygous carriers of this variation.

According to specialty information the following dose is recommended: First day: 1.5 g disulfiram, equivalent to 3 antabus, 0.5 dispergettes. Second day: 2 dispergettes. Third day: 1 antabus, 0.5 dispergette, which should also be the maintenance dose.

Contra-indications are: Coronary heart disease, severe cardiac arrhythmia, clinically manifest cardiomyopathy, impaired cerebral blood flow, advanced arteriosclerosis, oesophageal varices, hypothyroidism. Disulfiram should not be administered in cases of non alcohol-related depressions and schizophrenic psychosis. The same holds true in cases of severe hypotonia, decompensated liver cirrhosis and asthma bronchiale.

A treatment with disulfiram and concomitant alcohol consumption leads to aversive symptoms as mentioned above. Some rare cases of death were reported when administration was not supervised. This means that today treatment with disulfiram should be regarded as the "therapy of last choice." On the other hand direct and indirect comparisons with other anti-craving substances suggest a possible superiority.

Two open randomized studies compared disulfiram with naltrexone and with acamprosate (de Sousa and de Sousa 2005). In both cases disulfiram showed a significant superiority. A further study with a concomitant comparison with naltrexone, acamprosate and disulfiram has been published. The superiority of disulfiram over naltrexone and acamprosate was also confirmed in some international meta-analyses (e.g., Berglund et al. 2003). These results confirm earlier indications, concluding that disulfiram requires a re-evaluation. Recent reviews agree with this view.

Differential and Combined Treatment

Pharmacological relapse prevention in alcoholics is currently based on three extensively tested medications: acamprosate, naltrexone, and disulfiram.

It is being discussed whether individuals respond differently to different drugs. Individualized treatment with the "right drug" could thus increase the effects of pharmacotherapy significantly. At least the effects of acamprosate and naltrexone appear to relate to different aspects of drinking behavior, with the former primarily stabilizing abstinence and the latter primarily decreasing alcohol consumption. However, due to large differences in baseline characteristics, it is unreliable to compare studies retrospectively.

A prospective study performed in Germany that compared and combined both drugs under RCT conditions showed that both prolonged the time to first drink and the time to first relapse into heavy drinking compared to the placebo. The combination of both drugs was more effective than both placebo and monotherapy with acamprosate (Kiefer et al. 2003). Feeney's open cohort study replicated these results (Feeney and Connor 2005). A larger comparative study addressing this issue and involving 1,383 recently alcohol-abstinent patients (Anton et al. 2006) showed no treatment effects of acamprosate on abstinence proportion and no additive effect of combining naltrexone with acamprosate. Only naltrexone showed a significant but modest treatment effect on one out of two predetermined endpoints (return to heavy drinking vs. percent days abstinent). Patient characteristics suggest that patients without a physical withdrawal syndrome requiring withdrawal treatment were mainly included in the Combine study.

Since acamprosate and naltrexone have an effect on different neurotransmitters, neurobiologically-based a

priori examinations could provide indications on specific predictors concerning the response to each of these medications. A prospective study targeting biologically based endophenotyes including fMRI, PET, and psychophysiology is currently under way (Mann et al. 2009).

Biological matching of patients with their specific treatment holds the potential of moving the field of pharmacotherapy of alcoholism forward.

Alcohol Dehydrogenase

Synonyms

ADH; ALDH

Definition

Alcohol dehydrogenase is an enzyme that is responsible for catalyzing the formation of alcohols into aldehydes or ketones. There are five classes of alcohol dehydrogenases in humans, and the hepatic form, which is used primarily, is alcohol dehydrogenase class 1. Class 1 dehydrogenase catalyzes the oxidation of ethanol to produce acetaldehyde.

Alcohol Dependence

Synonyms

Alcoholism

Definition

Alcohol dependence is characterized as a maladaptive pattern of drinking, leading to clinically significant impairment, as manifested by a compulsion to drink, a lack of control over the amount of alcohol consumed and continued drinking, despite a knowledge of the problems associated with it. DSM-IV defines alcohol dependence as current if any three or more of the following seven criteria are present in the past 12 months:

1. Tolerance – as defined by either of the following – a need for markedly increased amounts of alcohol to achieve intoxication or desired effect, or markedly diminished effect with continued use of the same amount of alcohol.
2. Withdrawal.
3. Alcohol is often taken in larger amounts or over a longer period than was intended.
4. A persistent desire or unsuccessful efforts to cut down or control alcohol use.
5. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.

7. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the alcohol (e.g., continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Alcohol Hallucinosis

Definition

Alcoholic hallucinosis represents a rare complication of the alcohol withdrawal syndrome. It includes mainly auditory hallucinations, often accusatory or threatening voices. Alcoholic hallucinosis develops and resolves rapidly, involves no disorientation nor physical symptoms.

Definition

Alcohol preference tests generally include a set of experimental procedures that allow assessment of the intake of alcohol-containing solutions by laboratory animals when there is also an availability of one or more solutions at the same time that do not contain any alcohol. Alcohol preference is measured as the amounts of the alcohol solution(s) consumed, relative to those of the nonalcoholic solution(s). Although this is the most commonly used procedure for studying alcohol preference, several related behavioral procedures have also been used to draw inferences about preference for alcohol. These other procedures are briefly described in the next section.

Impact of Psychoactive Drugs

Description of Procedures

Many behavioral procedures have been used to assess the effect of psychoactive drugs on ethanol preference in nonhumans (Egli 2005). The most common approach is to assess ethanol intake relative to the intake of an alternative fluid (e.g., water) in a procedure that allows the animal to orally self-administer both fluids at the same time. For example, many studies have offered rats and mice a choice between drinking tubes containing 10% ethanol versus water in the home cage. Other studies have used operant self-administration procedures that require the animal to make a specific response to obtain each fluid, e.g., press lever A to obtain ethanol or press lever B to obtain water (Gonzales et al. 2004; Samson and Czachowski 2003). Regardless of the procedure used, the most informative data on treatment drug effects come from studies in which the pattern of self-administration is monitored continuously over time, or from studies in which the treatment drug is assessed during short sessions (e.g., 30–60 min) that normally yield high ethanol intakes (or high blood alcohol concentrations) in vehicle-treated control animals.

As the most commonly studied species (rats, mice) do not voluntarily consume sufficient alcohol to become dependent, most studies of psychoactive drugs have been conducted in nondependent animals. However, several recent studies have examined treatment drug effects on ethanol self-administration in animals that have been made dependent by chronic ethanol exposure (e.g., intragastric infusion or gavage, liquid diet or vapor inhalation

chamber). Importantly, these studies have shown that sensitivity to the effects of some psychoactive drugs is altered by a history of chronic ethanol exposure and dependence. Several examples of such findings are noted in later sections.

The development of stable ethanol self-administration in animals generally requires a prolonged period of training that may last several days, weeks, or months. In operant procedures, this training phase might also require a special "initiation" procedure (e.g., gradual reduction in the concentration of an added sweetener as ethanol concentration is increased). Thus, most studies of psychoactive drugs have examined treatment effects on a well-established baseline of ethanol self-administration. Over the last 10–15 years, however, there has been increasing interest in procedures that mimic relapse to ethanol self-administration after a period of abstinence (e.g., Alcohol Deprivation Effect, ADE), as well as procedures that produce reinstatement of responding after extinction of operant self-administration of ethanol (e.g., exposure to priming doses of ethanol, ethanol-associated cues or stressors). The primary purpose of such studies has often been to study the effects of treatment drugs on ethanol-seeking responses (i.e., responses that were previously paired with ethanol reinforcement), rather than direct effects on ethanol self-administration. Of interest, these studies have sometimes shown divergence in the effects of treatment drugs on ethanol seeking and ethanol self-administration.

The conditioned place preference (CPP) procedure offers another approach to evaluate treatment drug effects. In this procedure, the effect of a treatment drug on ethanol reward can be measured indirectly by drug-free testing of the animal's preference for contextual stimuli that have been previously associated with ethanol given alone (vehicle control group) or in combination with the treatment drug (experimental group). CPP can also be used to test the effect of a treatment drug on ethanol's conditioned rewarding effect by giving the drug just before a post-conditioning preference test in the absence of ethanol. Performance during a CPP test can be viewed as a form of ethanol seeking that is conceptually analogous to responding during the extinction or reinstatement of operant self-administration. One limitation on the use of CPP for studying treatment drug effects on ethanol reward is that although the phenomenon is robustly observed in mice, it has been much more difficult to demonstrate reliably across laboratories in rats.

Psychoactive Drug Testing

Ethanol is known to interact directly or indirectly with a wide range of neurochemical systems in brain (Koob and LeMoal 2006; Vengeliene et al. 2008). Effects of manipulating most of those systems have been studied using one or more types of alcohol preference test. Primary emphasis has been on systems implicated in ethanol's rewarding or conditioned rewarding effects and on systems thought to underlie the negative motivational effects of withdrawal (Koob and LeMoal 2008). Because space limitations preclude a detailed review of this literature, this essay focuses on psychoactive drugs currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of alcohol dependence, as well as several drugs that have been evaluated for their therapeutic potential or that are considered to be promising candidates (Heilig and Egli 2006; Tambour and Quertemont 2007; Vengeliene et al. 2008).

FDA-approved drugs: Currently, only four treatment drugs are approved for the treatment of alcoholism: oral or extended-release ► naltrexone, ► acamprosate, and ► disulfiram (Swift 2007). Disulfiram (Antabuse), which produces an aversive reaction when alcohol is ingested due to interference with ethanol metabolism, has rarely been studied in alcohol preference models and there is a mixed evidence for its efficacy in clinical trials (Heilig and Egli 2006; Swift 2007). In contrast, the more recently approved drugs (naltrexone, acamprosate), which yield more consistently positive results in clinical trials (Swift 2007), have also been effective in reducing ethanol intake and reinstatement in animals (Egli 2005; Vengeliene et al. 2008). In fact, the original naltrexone clinical trials were encouraged by animal studies that had shown a reduction in alcohol intake after injection of non-selective opioid antagonists. The mechanisms underlying the efficacy of naltrexone and acamprosate are not fully understood. Naltrexone is thought to modulate mesolimbic dopamine neurotransmission that may be involved in the direct and conditioned rewarding effects of ethanol, whereas acamprosate is hypothesized to act through its effects on ► glutamate neurotransmission (Tambour and Quertemont 2007).

Dopaminergic drugs: The mesolimbic dopamine system has long been implicated in the reinforcing and rewarding effects of most abused drugs, including ethanol. Animal studies have shown that both dopamine agonists and dopamine antagonists inhibit oral ethanol self-administration, a pattern of findings that has been difficult to reconcile (Gonzales et al. 2004). Some studies have suggested that dopamine antagonists have a greater impact on ethanol-seeking responses than on ethanol intake (Samson and Czachowski 2003). However, clinical studies with dopaminergic drugs have yielded mixed results, discouraging their use for alcoholism treatment in humans (Tambour and Quertemont 2007).

GABAergic drugs: Many of ethanol's physiological and behavioral effects have been linked to its interaction with the gamma-aminobutyric acid (► GABA) receptor system. Alcohol preference studies in animals have focused on drugs that target the ► $GABA_A$ receptor. These studies have generally shown an inhibitory effect of $GABA_A$ antagonists and benzodiazepine receptor ► inverse agonists and antagonists on ethanol self-administration. In contrast, results with $GABA_A$ agonists have been mixed, with reports of both increases and decreases in self-administration (Chester and Cunningham 2002). A few recent studies have indicated that the $GABA_B$ receptor agonist baclofen reduces ethanol self-administration, relapse after deprivation (ADE) and responding during extinction of self-administration (Heilig and Egli 2006), effects that may be mediated by suppression of mesolimbic dopamine signaling (Tambour and Quertemont 2007). Preliminary clinical studies have suggested that baclofen might also be effective in the treatment of alcoholism (Heilig and Egli 2006; Tambour and Quertemont 2007).

Recent clinical trials have also suggested that the antiepileptic ► topiramate has efficacy in the treatment of alcohol dependence (Heilig and Egli 2006; Tambour and Quertemont 2007). While topiramate is thought to alter GABA signaling, effects on glutamategic transmission and voltage dependent sodium channels have also been proposed. Topiramate's clinical efficacy has been attributed to putative indirect effects that alter mesolimbic dopamine transmission (Tambour and Quertemont 2007). The preclinical literature using alcohol preference tests is quite limited and it does not provide strong support for an inhibitory effect of topiramate on ethanol drinking (Heilig and Egli 2006).

Serotonergic drugs: Preclinical studies have shown that ► selective serotonin reuptake inhibitors (SSRIs) as well as agonists and antagonists at various ► serotonin receptors ($5\text{-}HT_1$, $5\text{-}HT_2$, $5\text{-}HT_3$) can reduce alcohol consumption (Vengeliene et al. 2008), although some of these findings may reflect non-specific effects on consummatory behaviors (Heilig and Egli 2006; Tambour and Quertemont 2007). Despite their efficacy in ethanol self-administration studies in animals, SSRIs and the partial $5\text{-}HT_{1A}$ agonist ► buspirone have not been effective in clinical trials (Egli 2005; Tambour and Quertemont 2007). However, the $5\text{-}HT_3$-receptor antagonist ondansetron appears to have relatively selective effects on ethanol self-administration in animals, an effect that some investigators attribute to a reduction in ethanol-induced dopamine release (Tambour and Quertemont 2007). Moreover, human trials have shown promising results for ondansetron in the treatment of early onset alcoholism (Heilig and Egli 2006; Tambour and Quertemont 2007).

Glutamatergic drugs: The observation that ethanol dose-dependently inhibits NMDA receptor activation has encouraged examination of glutamatergic drug effects on ethanol self-administration. However, animal studies have found few consistent effects of ► NMDA receptor antagonists on ethanol self-administration (Vengeliene et al. 2008). Thus far, the most promising preclinical studies have suggested that selective antagonists targeting the metabotropic mGluR5 glutamate receptor (e.g., 2-methyl-6-(phenylethynyl)-pyridine, MPEP) can reduce high levels of ethanol self-administration in selectively-bred alcohol preferring rats (Heilig and Egli 2006). MPEP also reduces cue-induced reinstatement of operant self-administration after extinction as well as relapse to self-administration after a period of abstinence (ADE) (Vengeliene et al. 2008). Although there have been no clinical trials with mGluR5 receptor antagonists, the preclinical and clinical efficacy of acamprosate might be related, at least in part, to antagonism of this receptor subtype (Tambour and Quertemont 2007).

Cannabinoid drugs: A potential role for the endocannabinoid system has been supported by studies showing that pharmacological blockade of the CB_1 receptor subtype reduces ethanol intake and cue-induced reinstatement of an extinguished operant self-administration response in animals (Tambour and Quertemont 2007; Vengeliene et al. 2008). The CB_1 receptor antagonist ► rimonabant is currently under investigation in a human study that is designed to test its effects on ethanol consumption in heavy drinkers (Heilig and Egli 2006).

Neuropeptides: Animal studies have suggested that ► neuropeptides implicated in stress and anxiety influence ethanol self-administration, especially those targeting the corticotropin-releasing factor (CRF) and neuropeptide-Y (NPY) systems. For example, non-selective CRF antagonists and selective CRF1 antagonists have been found to reduce ethanol self-administration, but only in alcohol-dependent animals (Heilig and Egli 2006; Vengeliene et al. 2008). CRF1 receptor antagonists have also been shown to interfere with cue- and stress-induced ► reinstatement of operant responding after extinction of ethanol self-administration (Vengeliene et al. 2008). NPY decreases ethanol self-administration in high-drinking animals, an effect that was enhanced by a period of alcohol deprivation. Blockade of NPY Y1, Y2 and Y5 receptors has also been reported to suppress ethanol drinking or operant responding for ethanol in non-dependent animals, though the effect of Y2 blockade is greater in ethanol dependent animals (Heilig and Egli 2006). Clinical

trials targeting the role of the CRF or NPY systems in alcohol dependence have not yet been reported.

Other Uses of Alcohol Preference Tests

Although this essay has focused on the use of alcohol preference tests to study effects of psychoactive drugs, it is important to note that these tests are widely used by basic scientists for many other purposes. For example, these procedures are used to study the basic behavioral processes involved in the learning, extinction, and recovery (e.g., reinstatement) of ethanol-related memories. These procedures are also commonly used to characterize the neurochemical systems, brain circuitry, and genes that underlie ethanol self-administration and excessive drinking. Finally, these procedures have been used to study the impact of addiction-related neuroadaptations on ethanol-reinforced behavior (e.g., tolerance, dependence, and withdrawal).

Alcohol Withdrawal

Definition

Alcohol withdrawal can occur after stopping alcohol use or following a reduction in use in individuals with a history of chronic use. Symptoms of alcohol withdrawal can include: autonomic hyperactivity, hand tremor, insomnia, nausea or vomiting, hallucinations, psychomotor agitation, anxiety, and seizures.

Alcohol Withdrawal Delirium

Definition

Alcohol withdrawal delirium, also known as delirium tremens, is the type of delirium that occurs during withdrawal from alcohol. It is commonly associated with tactile or visual hallucinations in addition to autonomic hyperactivity, disorientation, and agitation. It occurs in approximately 5–15% of patients in alcohol withdrawal typically within the first 72–96 h of withdrawal. Severe alcohol withdrawal delirium is a medical emergency and requires prompt treatment.

Alcohol Withdrawal Syndrome

Definition

A constellation of signs and symptoms that appears when a physically alcohol-dependent person stops drinking alcohol. The physiological basis is the alcohol tolerance: chronic alcohol intake causes reversible adaptations within the body that tend to compensate for the original alcohol effects over time. When alcohol intake is suddenly stopped or decreased, the adaptations do not immediately disappear. Unopposed by alcohol, the adaptations appear as withdrawal signs and symptoms that include tension, anxiety, sleep disturbance, increased blood-pressure and heart rate, tremor, sometimes seizures.

Allosteric Modulators

Definition

In contrast to orthosteric molecules, which bind to the same receptor domain as the endogenous agonist, allosteric modulators bind to a site that is topographically different from the orthosteric binding site. Allosteric modulators produce an effect through a change in protein confirmation and can increase (positive allosteric modulator or PAM) or decrease (negative allosteric modulator or NAM) the affinity and/or efficacy of an orthosteric agonist.

Allosteric Potentiating Ligand

Definition

Allosteric antagonists or agonists produce unique effects by binding to a site on the receptor to produce a bias in

the receptor conformation. Allosteric modulators of nicotinergic receptors are compounds that interact with the receptor via binding sites that are distinct from those for acetylcholine and ► nicotinic agonists and antagonists. Consequently, modulators are not directly involved in the neurotransmission process they affect and hence usually do not induce compensatory processes, as direct agonists and antagonists may do (e.g., receptor ► desensitization, ► downregulation of expression).

Definition

Alprazolam is a high-potency, short-acting anxiolytic benzodiazepine medication used in the treatment of anxiety, panic, and phobic disorders. It has some antispasmodic and anticonvulsant effects. It is not antidepressant. It is sometimes used in conjunction with antipsychotic medication in acute psychotic episodes. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Long-term use may induce dependence with withdrawal reactions. Recreational use and abuse can occur: alprazolam is a scheduled substance.

Alternative Splicing

Synonyms

mRNA splice variants

Definition

Antisense technology has also been used to manipulate alternative splicing patterns altering the ratio of different splice variants of a gene and its function. Several diseases are linked to mutated alternative splicing of specific genes such as thalassemia, Duchenne muscular dystrophy, cystic fibrosis, and parkinsonism linked to chromosome 17. The therapeutic potential of this antisense approach, for example, to silence gene mutations responsible for defect pre-mRNA splicing is enormous.

► Antisense oligonucleotides that alter splicing should be different from those designed to downregulate gene expression and should be chemically modified such as to prevent activation of RNase H as this would destroy pre-mRNA before splicing, to have a higher nuclease resistance and affinity for the target sequence. According to ex vivo intracellular localization studies, the antisense oligonucleotides need to enter the nucleus for successful modulation of splicing. Aberrant splicing of pre-mRNA is

prevented or correct splicing is restored. In vivo confirmation of these mechanisms of action is missing.

Amine Depletors

Philip J. Cowen
Department of Psychiatry, University of Oxford, Neurosciences Building Warneford Hospital, Oxford, Oxfordshire, UK

Synonyms
Catecholamine depletion; Monoamine depletion; Tryptophan depletion

Definition
Amine depletion refers to a pharmacological or dietary manipulation that lowers levels of monoamine neurotransmitters in the brain for therapeutic or investigational purposes. An amine depletor is therefore an agent that diminishes levels of one or more monoamines in the brain.

Pharmacological Properties

Available Methodologies
The monoamines targeted by amine depletion are typically the catecholamine neurotransmitters, dopamine and

noradrenaline, and the indoleamine neurotransmitter, serotonin. Amine depletion in humans can be carried out in three principal ways:

1. Through pharmacological inhibition of vesicular storage of amines in the nerve terminal
2. Through pharmacological inhibition of neurotransmitter synthesis
3. Through dietary-induced brain depletion of amino acids required for neurotransmitter synthesis

Monoamine depletion may also occur as an adverse consequence of drug use, both licit and illicit; for example the substituted amphetamine, methylenedioxymethamphetamine (► MDMA), lowers brain serotonin levels. However, amine depletion occurring as an adverse effect will not be considered further in this article.

Inhibition of Vesicular Storage

A number of drugs including ► reserpine, ► tetrabenazine, and oxypertine bind to the vesicular monoamine transporter and thereby inhibit transport of synthesized monoamine from the cytoplasm to the vesicular storage granule. The monoamines in the cytoplasm are therefore exposed to metabolism by monoamine oxidase and monoamine levels at nerve terminals decline, lowering neurotransmission.

Reserpine has a long history in psychopharmacology and reserpine-induced depression formed the cornerstone of the monoamine theory of depression. Tetrabenazine and oxypertine have been used to treat ► tardive dyskinesia, presumably through their ability to deplete presynaptic ► dopamine levels. Tetrabenazine is still used for the treatment of abnormal movements, particularly those associated with Huntington's Chorea.

Pharmacological Inhibition of Neurotransmitter Synthesis

Under this heading, we can consider two pharmacological agents, para-chlorophenylanine (PCPA) and alpha-methyl-para-tyrosine (AMPT). PCPA irreversibly inhibits the enzyme tryptophan hydroxylase, which converts the amino acid ► tryptophan to 5-hydroxytryptophan and is the rate-limiting step in the synthesis of ► serotonin. PCPA administration therefore leads to depletion of brain serotonin. PCPA was previously used to treat carcinoid syndrome and has been employed in a limited way as an investigational tool in human psychopharmacology. For example, PCPA treatment of depressed patients who had responded to the monoamine oxidase inhibitor tranylcypromine resulted in clinical relapse showing the importance of intact serotonin function for the therapeutic action of this antidepressant. PCPA is still used extensively in animal experimental investigations as a pharmacological means of lesioning brain serotonin pathways.

AMPT is a competitive antagonist of the enzyme tyrosine hydroxylase, which converts the amino acid tyrosine to L-dopa. Administration of AMPT therefore decreases brain levels of ► noradrenaline and ► dopamine. In healthy volunteers, AMPT treatment results in sedation and can sometimes cause movement disorders such as Parkinsonism. Plasma prolactin is elevated and nocturnal melatonin secretion reduced, consistent with the known roles of dopamine and noradrenaline in the regulation of these two hormones. AMPT has been used clinically as an antihypertensive agent and in the treatment of pheochromocytoma.

AMPT has also been employed as an investigational tool in studies of the role of catecholamine pathways in depression and the mode of action of ► antidepressants. In healthy volunteers, AMPT does not reliably cause depression but in recovered depressed patients who have been withdrawn from antidepressant medication, AMPT causes a temporary clinical relapse. This suggests that in people vulnerable to depression, lowering catecholamine function is sufficient to produce clinical symptomatology. AMPT also reverses the therapeutic effect of antidepressant drugs such as desipramine which act primarily through noradrenergic mechanisms. This has been taken as evidence that intact noradrenaline neurotransmission is essential for the continued action of catecholamine-potentiating antidepressants in patients who have responded to this form of treatment (Booij et al. 2003; Ruhé et al. 2007).

Dietary-induced Brain Depletion of Amino Acids

As has been mentioned earlier, the synthesis of monoamine neurotransmitters depends on the availability of precursor amino acids to the brain. Dietary manipulations can take advantage of this fact to limit the availability of specific amino acids and thereby lower the synthesis in the brain of the corresponding neurotransmitter. The most studied manipulation is "tryptophan depletion" (TRD). In this procedure, participants are asked to ingest a balanced mixture of amino acids (traditionally about 80–100 g) from which tryptophan has been removed. This amino acid load drives protein synthesis in the liver and because tryptophan is an essential amino acid, the body has to use its own tryptophan supplies to manufacture protein. This leads to a sharp decline in plasma

tryptophan levels, which decreases the amount available for brain serotonin synthesis. In addition, amino acids compete with each other for active transport across the blood–brain barrier. The excess of other amino acids in plasma means that the small amount of tryptophan which remains available in plasma after TRD is inhibited by competition from transport into the brain. Thus, lowering levels of plasma tryptophan and decreasing its brain entry produces a substantial depletion of brain tryptophan and of serotonin synthesis. Because of the effects of the amino acid mixture on protein synthesis as well as subjective adverse effects (principally nausea), in investigational studies it is important to use a control mixture of amino acids containing a balanced amount of tryptophan.

Because of the interest in the role of serotonin pathways in psychiatric disorder and the effects of psychotropic drugs, TRD has been widely used as an investigational tool. The greatest volume of research has taken place in the field of mood disorders (Bell et al. 2005a,b). It seems fairly well established that TRD in healthy individuals with no risk factors for depression does not cause reliable effects on mood. Therefore, lowering serotonin function is not sufficient to cause depression in nonvulnerable individuals. However, TRD can cause acute depressive clinical symptomatology in some circumstances. For example, depressed patients who have responded successfully to serotonin-potentiating drugs such as ▶ selective serotonin reuptake inhibitors (SSRIs) may show a transient but striking relapse a few hours after TRD even though SSRI treatment is continued. This has been taken as evidence that the maintenance of the therapeutic response to SSRI treatment requires a sustained increase in the availability of serotonin. Interestingly, depressed patients successfully maintained on catecholamine-potentiating drugs such as desipramine do not relapse when administered TRD. This suggests that antidepressant drugs can produce therapeutic effects in depressed patients through distinct pharmacological mechanisms (Booij et al. 2003; Ruhé et al. 2007).

It is also noteworthy that patients with a history of depression, not currently on medication, can show transient clinical relapse following TRD (Smith et al. 1997). A mega-analysis revealed that female patients with a history of recurrent depression and suicide attempts were most likely to show this reaction (Booij et al. 2002). This finding suggests that in some vulnerable individuals, lowering serotonin function can be sufficient to cause clinical symptomatology. Theoretically, such individuals may have pre-existing deficits in serotonin pathways or perhaps abnormalities in the brain regions involved in mood regulation which are "revealed" in the low serotonin environment.

TRD is not particularly well tolerated since the amino acids load can cause nausea and retching. Attempts have therefore been made to use better-tolerated low-dose procedures with decreased total dose of amino acids (20–30 g). These mixtures reliably lower plasma tryptophan but their effect on mood is somewhat variable even in vulnerable individuals. However, changes in emotional processing that are congruent with depressed mood have been revealed (Hayward et al. 2005).

The success of TRD also led to dietary attempts to lower catecholamine neurotransmission by depleting plasma and brain tyrosine levels. In the body, tyrosine can be synthesized from phenylalanine, so dietary manipulations provide a mixture of amino acids lacking both phenylalanine and tyrosine. Ingestion of such a mixture produces a substantial lowering of plasma tyrosine. It also increases plasma prolactin indicative of a diminution in dopamine neurotransmission; however, nocturnal ▶ melatonin secretion is unaffected suggesting that noradrenaline function is not attenuated. This pattern of effect is consistent with experimental animal studies indicating that tyrosine depletion preferentially limits dopamine function, while apparently sparing noradrenaline neurotransmission. The reason for this is not clear but presumably relates to a greater dependency of dopamine neurons on tyrosine availability, perhaps because they have generally faster firing rate than noradrenaline neurons.

Tyrosine depletion has been less studied in experimental paradigms than TRD. Tyrosine depletion does not lower mood in healthy subjects and, in contrast to AMPT, fails to cause relapse in unmedicated recovered depressed patients. This suggests that the relapse seen in such subjects following AMPT is probably due to interruption of noradrenaline function or perhaps to a simultaneous decrease in noradrenaline and dopamine activity. Consistent with its ability to lower dopamine function, tyrosine depletion has been shown to attenuate the psychostimulant effects of ▶ methamphetamine in healthy volunteers and to diminish clinical ratings of mania in patients with ▶ bipolar disorder (McTavish et al. 2001). Tyrosine depletion does not attenuate the antidepressant effects of SSRIs arguing against theories that posit a key role for dopamine facilitation in antidepressant action.

Definition

The aminergic hypotheses of ► depression refer to theories of the role of abnormalities of aminergic neurotransmitters, or of physiologic perturbations in the functioning of neurons that contain aminergic neurotransmitters, in the cause and/or symptoms of a major depressive disorder.

Role of Pharmacotherapy

The aminergic hypotheses of ► depression were logical extensions of four landmark discoveries: that neurons communicate via the release of chemical substances called neurotransmitters; that aminergic neurotransmitters are found in high concentration in specific brain regions; that antidepressant drugs increase brain levels of aminergic neurotransmitters; and that drugs or procedures that reduce monoamine neurotransmitters induce depressive symptoms in some people. These discoveries provided the necessary scientific knowledge on which the aminergic hypotheses were based.

The theory that communication between neurons is mediated by chemical substances (neurotransmitters) rather than electrical impulses did not gain widespread acceptance until the mid-1900s. Prior to 1900, it was generally thought that neurons communicated with one another by electrical signals. The chemical theory of neurotransmission was initially based on the observation by J. N. Langley in 1901 that extracts from the adrenal gland had similar effects on end-organ targets as did stimulation of sympathetic nerves. He proposed that there could be "receptive substances" between a nerve cell ending and the target end organ that is activated when the nerve impulse reaches the nerve terminal. Elliot subsequently hypothesized in 1904 that an adrenalin-like substance might be secreted by sympathetic nerve terminals to chemically stimulate the target end organ. Many still doubted that this was relevant to communication between nerve cells, but the theory of chemical neurotransmission gained significant ground in 1921 when Otto Loewi conducted his now classic experiment showing that the liquid surrounding a heart that had had its nerves electrically stimulated to slow its rate could be transferred to a second un-stimulated heart to cause an identical slowing of the second heart's rate. Loewi proposed that the electrical stimulation of the nerves innervating the heart caused the release of a chemical substance that mediated the nerve's ability to reduce heart rate. In 1936, Loewi shared the Nobel Prize in medicine with Sir Henry Dale for their work on the discovery of chemical neurotransmission (see Tansey 1991 for a review). Subsequent research showed that other monoamine chemicals, such as ► dopamine (DA) and ► serotonin (5-HT), also served as neurotransmitters in the peripheral nervous system.

By the late 1950s, research had shown that the brain contained large amounts of several ► monoamines, including the ► catecholamine neurotransmitters ► norepinephrine (NE) and DA and the ► indoleamine 5-HT. These monoamines were localized to, and synthesized by, neurons within discrete brain nuclei. Two landmark observations,(1) that patients with Parkinson's disease showed a marked reduction in basal ganglia DA and (2) that oral administration of the metabolic precursor of DA, L-dihydroxy-phenylalanine (► L-DOPA), led to rapid improvements in the motor symptoms of

► Parkinson's disease Birkmayer and Hornykiewicz (1964), added considerable momentum to the investigation of the role of brain monoamines in behavior, and established a compelling theoretical model that greatly influenced the first aminergic hypotheses of depression (see Carlsson, 2001 for a review of the work of this time period).

The late 1950s and early 1960s saw the rapid clinical development of several drugs with potent effects on increasing or decreasing brain monoamines. This included drugs that were subsequently found to block reuptake, synthesis, metabolism, or receptors of one or more monoamines, as well as drugs and/or nutrients that served as synthetic precursors to monoamines. The drug ► reserpine (rauwolfia) had been shown in the 1950s to cause a long-lasting depletion of brain monoamines in laboratory animals, and this was associated with a profound depression-like state in laboratory animals and clinical depression in up to 18% of people receiving the drug for the treatment of hypertension. The catecholamine synthesis inhibitor alpha-methyl-para-tyrosine (AMPT) was also tested as a potential antihypertensive and a similar subset of patients developed clinical depression during the initial trials. Because reserpine caused profound sedation in humans, it was also used extensively as a sedative in agitated psychiatric patients, often in combination with other sedatives or the newly discovered antipsychotic drugs. Many other new drugs with central nervous system effects were introduced into clinical trials during the mid-late 1950s. ► Imipramine, a tricyclic compound, was being studied as a potential sedative, while isoniazid, a ► monoamine oxidase inhibitor (MAOI), was being used to potentiate antituberculosis treatments. Both drugs were noted by chance observation to cause resolution of depressive symptoms, stimulating an explosion of controlled clinical trials of these agents as potential treatments for depression. As evidence of the therapeutic effects in the depression of imipramine and its metabolites (such as desipramine) and MAOIs (such as iproniazid and tranylcypromine) accumulated, it became clear that understanding the pharmacology of these drugs might be relevant to the neurobiological underpinnings of major depression. Given that MAOIs were well known to increase brain levels of monoamines, this pharmacological property was suggested to underlie the therapeutic effects of such drugs in depression by the late 1950s (Carlsson 2001; Pare 1959).

The first fully developed aminergic hypotheses of depression finally emerged in the mid-1960s as investigators began to realize that these new antidepressant drugs potently increased brain levels of monoamines, while drugs that reduced monoamines could cause depression-like symptoms in some people. The catecholamine deficiency hypothesis of depression was based on the observation that many antidepressant drugs increased synaptic concentrations of NE, while the catecholamine-depleting drug reserpine seemed to cause depression-like symptoms (Schildkraut 1965). This hypothesis postulated that depression was due to a deficiency and mania, an excess of brain NE. The indoleamine hypothesis postulated that a deficit of brain 5-HT was responsible for depression, while drugs which increased synaptic 5-HT, such as MAOIs or 5-HT precursors such as 5-hydroxytryptophan (5-HTP) and ► L-tryptophan (TRP), relieved depression (Coppen 1967). These competing aminergic hypotheses led to an extensive body of research in the next few decades aiming to determine which of these two monoamine systems was most responsible for depression and the therapeutic effects of antidepressant drugs.

During the 1970s and 1980s, converging data made it seem as though mood disorders would turn out to be simple "chemical imbalances" of aminergic neurotransmitters. First, as the anatomy and physiology of monoamine systems began to emerge, it became clear that these systems play an important role in regulating the brain areas that are involved in core symptoms of depression, including mood, attention, sleep, sexual function, appetite, and pain perception. Monoamine systems are almost exclusively organized as large *systems* of single source divergent neurons, thereby able to simultaneously coordinate neural activity across many parts of the brain. Second, based on the theory that the antidepressants work by increasing NE and/or 5-HT, several new antidepressants that selectively inhibited the reuptake of one or two monoamines were developed. The ► selective serotonin reuptake inhibitors (SSRIs; e.g., ► fluoxetine), norepinephrine reuptake inhibitors (NARIs; e.g., ► reboxetine), and serotonin and norepinephrine reuptake inhibitors (SNRIs; e.g., ► venlafaxine) proved to be landmark drugs with comparable efficacy but greater tolerability and safety than the earlier line of drugs such as imipramine. Finally, human studies employing monoamine depletion showed that the depletion of catecholamines or 5-HT could induce a rapid return of depressive symptoms in some patients taking antidepressants. Depletion studies suggest that the 5-HT and NE effects of antidepressants may be independent of each other. For example, depleting 5-HT causes a rapid return of depression in depressed patients who have responded to fluoxetine, ► fluvoxamine, MAOIs, and imipramine, but not in those who have responded to desipramine, ► nortriptyline, or ► bupropion. Depleting NE and DA causes a rapid return of depression in those depressed patients who have

improved on desipramine, but not on fluoxetine. These results confirm that monoamines are necessary for maintaining antidepressant therapeutic response in most patients. This convergence of data on the anatomy and physiology of monoamine systems in the brain, pharmacological effects of antidepressants, and the depression-inducing effects of lowering monoamines generated considerable optimism in the field that the pathophysiology of these disorders was now close to being understood (Delgado et al. 1999; Delgado 2004).

However, there are inconsistencies and gaps in the aminergic theories. First, while antidepressants increase brain monoamine levels severalfold within minutes of their administration, the antidepressant response takes weeks to emerge. Attempts to speed up antidepressant responses by more rapidly increasing monoamine levels or using postsynaptic monoamine receptor agonists have largely failed. Further, deficiencies of NE or 5-HT or their metabolites in cerebrospinal fluid (CSF), blood, or urine have not been consistently demonstrated in depressed patients, despite extensive efforts to do so (Charney et al. 1981). When abnormalities have been found, they have tended to be nonspecific. Also, while a small subset of people with a history of prior psychiatric illness report depressive symptoms when exposed to monoamine depleting drugs or monoamine synthesis inhibitors, the majority of people exposed to these drugs or procedures do not experience clinical depression. For example, in an open treatment trial of AMPT in patients with essential hypertension, six of 20 hypertensive patients had a history of a previous depressive episode. Three of these six became agitated on AMPT, requiring drug discontinuation. In a trial of the 5-HT synthesis inhibitor para-chloro-phenylalanine (PCPA) in patients with carcinoid tumors, a subset of the patients experienced a variety of acute symptoms ranging from lethargy, irritability, anxiety, and depression to psychosis, although most subjects demonstrated little behavioral change. Neither 5-HT nor NE depletion has resulted in depressive symptoms in studies of volunteers without a personal or family history of depression (Delgado 2004).

Recent attempts to understand the slow onset of antidepressant action have focused on the "downstream" adaptive changes that temporally follow increases in synaptic levels of monoamines. This includes research on receptor adaptations, changes in second-messenger molecules, changes in ► gene expression, release of ► neurotrophic factors, and ► neurogenesis. This work has led some investigators to focus on the integrity and functioning of limbic brain areas modulated by monoamine systems as an alternative explanation for the pathophysiology of depression. Brain imaging and autopsy studies have noted marked differences in the structure and/or function of several limbic areas such as the ► prefrontal cortex, anterior cingulate gyrus, ► hippocampus, and ► amygdala that are believed to be involved in core brain functions that become abnormal in depression (Duman et al. 2004).

Current research suggests that depression is what geneticists define as a "complex" disorder, where illness results from the summation of numerous genetic and environmental factors, each of which have small effects and result in illness only when their combined effects surpass a certain threshold. If true, then the biochemical and genetic causes of major depression may differ markedly from one patient to another. This may explain the sometimes inconsistent results in research studies investigating specific biochemical abnormalities associated with depression. The results of monoamine depletion studies suggest that a simple deficiency of 5-HT or NE is not likely to be the sole cause of depression. Research pursuing causal pathways that directly cause injury to brain areas such as the frontal cortex, hippocampus/amygdala, and basal ganglia known to be modulated by monoamine systems is warranted.

Therefore, the available data suggests that the initial aminergic hypotheses were partially correct. While research supporting a causal role of monoamine dysfunction as the primary cause of depression is not sufficiently supported, the data supporting a primary role for an increase in monoamines in the initial step of antidepressant drug action is quite strong. Most or all drugs currently approved by the US Food and Drug Administration (FDA) for the treatment of depression directly or indirectly increase the synaptic availability of 5-HT and/or NE. Increasing brain NE and/or 5-HT appears to be the initial pharmacological step responsible for antidepressant efficacy in depression. This most likely includes a temporal sequence with increased monoamine levels causing alterations in presynaptic autoreceptor density and sensitivity that allow further increases in synaptic levels of the monoamines, culminating in postsynaptic receptor adaptations, and changes in neuronal plasticity and neurogenesis. The postsynaptic areas affected by the increased monoamine levels notably include most of the brain areas involved in emotion regulation, cognition, and sensory and pain perception. Increased monoamines observed as a result of treatment with 5-HT and NE reuptake inhibitors may serve to partially restore neuronal function in dysfunctional limbic circuits. The acute reappearance of depressive symptoms upon monoamine depletion in depressed patients in remission but not in

healthy people may underscore the possibility that depressed patients have greater fragility than healthy controls of the limbic networks modulated by monoamines.

Definition

An explanation for the pathophysiology of schizophrenia and mechanism of action of antipsychotic drugs with a special focus on aminergic (dopamine, serotonin, and noradrenaline) neural systems.

Role of Pharmacotherapy

Schizophrenia is characterized by a variety of symptoms, including hallucination, delusion, and psychomotor excitement. A dopamine receptor antagonist, ▶ chlorpromazine, was introduced in the treatment of this illness in 1952 and has shown its effectiveness, which has made the dopaminergic system a primary target of research on the pathogenesis of schizophrenia as well as potential mechanisms of antipsychotic action of this type of drugs. This has led to the prototype of the dopaminergic hypothesis for schizophrenia where the increase and decrease in the dopaminergic neural transmission is attributed to its symptoms and treatment effects of ▶ antipsychotic drugs, respectively. Although this hypothesis has been revisited and further developed, the dopaminergic system cannot fully account for the mechanisms underlying this illness. Recently, other neural systems such as glutamatergic and cholinergic systems have also come to the front line of this line of research.

▶ Dopamine was the first target of research on schizophrenia, and is still considered to play a primary role in the pathogenesis of this illness and mechanisms of actions of antipsychotic drugs. The hypothesis that explains the involvement of the dopaminergic system in this illness (the dopamine hypothesis) has been supported by a vast amount of both animal and human studies and further occasionally updated with the accumulation of relevant new clinical and basic data. The first version of the dopamine hypothesis focused on the dopaminergic receptors where psychosis was considered to be due to excessive transmission at dopaminergic receptors and diminished by blocking these receptors. The most widely accepted support for this hypothesis is the fact that dopamine antagonist antipsychotic drugs can relieve psychotic symptoms. The first antipsychotic drug, chlorpromazine, was introduced in the treatment of schizophrenia in 1952. As this type of medication had been found to have a dopamine receptor blocking property, the dopaminergic system came to the forefront of scientific inquiry. While blockade of dopamine receptors had already been thought to be associated with therapeutic effects of antipsychotic medications in the 1960s and 1970s, Seeman et al. first systematically demonstrated that the degree of dopamine receptor antagonism by antipsychotics was closely associated with their antipsychotic efficacy in 1976 (Seeman

et al. 1976). This relationship is still valid after ► second-generation antipsychotics have become available, although ► clozapine seems exceptional, as we discuss next. Another frequently referred support for this hypothesis is the presence of psychotic symptoms associated with the administration of amphetamine. Both animal and human studies have demonstrated the increase of endogenous dopamine levels, following ► amphetamine administration, and shown that amphetamine-induced psychotic symptoms resemble schizophrenic symptoms. Furthermore, these amphetamine-induced psychotic symptoms are reversible with the use of dopamine antagonist antipsychotic drugs. In addition, psychotic symptoms caused by amphetamine administration in drug-free schizophrenia patients were found to be associated with exaggerated stimulation of dopaminergic transmission, compared to those who did not present those symptoms following its administration (Laruelle et al. 1996) – lending further support to this model.

In 1980, Crow proposed a hypothesis where schizophrenia could be grouped into two separate conditions: the type I syndrome characterized by positive symptoms, including delusion, hallucinations, and thought disorder, and type II syndrome characterized by negative symptoms, including affective flattering and poverty of speech (Crow 1980). In this theory, the type I syndrome was considered to be associated with high dopaminergic activity and reversible with antipsychotic treatment while negative schizophrenic symptoms were thought to be caused by deficiency in the dopaminergic function and involve a component of irreversibility. This hypothesis tried to comprehensively link potential pathogenesis and symptomatology of schizophrenia to the dopaminergic system. Although this proposal has often been criticized later due to its simple dichotomization and a lack of sufficient convincing biological support, its impacts on further investigations have still been tremendous. In 1991, Davis et al. published a landmark review and proposed the co-occurrence of high and low dopamine activities in schizophrenia to the concurrent presence of positive and negative symptoms (referred to as the dopamine hypothesis, Version II) (Davis et al. 1991). Evidence, particularly from intracellular recording studies in animals and plasma homovanillic acid (HVA) measurements, suggests that antipsychotics exert their effects by reducing dopamine activity in mesolimbic dopamine neurons. Postmortem studies have shown high dopamine and HVA concentrations in various subcortical brain regions and greater dopamine receptor densities in patients with schizophrenia, compared to healthy people. On the other hand, they attributed the negative/deficit symptom complex of schizophrenia to low dopamine activity in the prefrontal cortex, which is now known as "hypofrontality." Davis et al. hypothesized that abnormally low prefrontal dopamine activity caused deficit symptoms in schizophrenia, while excessive dopamine activity in mesolimbic dopamine neurons resulted in positive symptoms.

With further accumulation of basic and clinical data on the function of the dopaminergic system, psychopathology of schizophrenia, and potential mechanisms underlying treatment effects of antipsychotics, Kapur reviewed those findings (Kapur 2003) and linked the neurobiology (brain), the phenomenological experience (mind), and pharmacological aspects of psychosis in schizophrenia into a unitary framework. A central role of dopamine is to mediate the "salience" of environmental events and internal representations. It is proposed that a dysregulated, hyperdopaminergic state at a "brain" level of description and analysis leads to an aberrant assignment of salience to the elements of one's experience at a "mind" level. This would result in delusions as a clinical manifestation as patients make a cognitive effort to make sense of these aberrantly salient experiences. On the other hand, ► hallucinations reflect a direct experience of the aberrant salience of internal representations. Antipsychotic drugs are expected to dampen the salience of these abnormal experiences and by doing so permit the resolution of symptoms, where the antipsychotics are thought not to erase the symptoms but to provide the platform for a process of psychological resolution. Therefore, if antipsychotic treatment is stopped, the dysregulated neurochemistry returns, the dormant ideas and experiences become reinvested with aberrant salience, resulting in a relapse. Although this hypothesis does not explain the mechanisms of negative symptoms of schizophrenia, current ideas regarding the neurobiology and phenomenology of psychosis and schizophrenia, the role of dopamine, and the mechanism of action of antipsychotic medication are integrated.

In its latest iteration, Howes et al. proposed the updated version of the dopamine hypothesis (Version III), where multiple factors, including stress and trauma, drug use, pregnancy and obstetric complications, and genes, interact to result in the increased presynaptic striatal dopaminergic function in schizophrenia (Howes and Kapur 2009). This striatal dopaminergic dysregulation is considered the final common pathway of the pathogenesis of this illness, in this theory. This hypothesis suggests that current treatments act downstream of the critical neurotransmitter abnormality and emphasized the need of future drug development with a focus on the upstream factors that converge on the dopaminergic funnel point.

However, pathogenesis of schizophrenia and the resolution of its symptoms with antipsychotics are not expected to be solely related to the effects in the dopaminergic system. Superior clinical effects of clozapine despite its low dopamine D_2 receptor blocking propensity are one example of the limitations of the dopamine hypothesis. There are several others: many patients do not respond despite adequate dopamine blockade, some respond with rather low D_2 blockade, and many relapse despite adequate D_2 blockade. So, clearly the genesis of psychosis and its response depends on more than just dopamine. But, precisely what is beyond dopamine – has been harder to confirm. The involvement of other neural systems such as the glutamatergic, cholinergic, and serotonergic systems has been proposed.

Several lines of evidence suggest that the glutamatergic neural system is also involved in the pathogenesis of schizophrenia (Bubenikova-Valesova et al. 2008). ▶ Glutamate acts through several types of receptors, of which the ionotropic glutamate N-methyl-D-aspartate (▶ NMDA) receptor has been considered to be closely associated with schizophrenia (i.e. the glutamate hypothesis of schizophrenia). The most prominent support for this hypothesis is the acute psychomimetic effects of noncompetitive antagonists of glutamate NMDA receptors, such as ▶ phencyclidine and ▶ ketamine. These drugs have been shown to change both human and animal behavior and induce schizophrenia-like manifestations. For example, ketamine has been demonstrated to cause a variety of schizophrenia-like symptoms in healthy people, including positive symptoms (e.g., illusions, thought disorder, and ▶ delusions), negative symptoms (e.g., blunted emotional responses, emotional detachment, and psychomotor retardation), and cognitive symptoms, in particular impairments on tests of frontal cortical function (e.g., increased distractibility and reduced verbal fluency). In patients with schizophrenia, ketamine causes auditory or visual hallucinations while antipsychotics significantly reduce the ketamine-induced increase in positive symptoms. This hypothesis is also in line with the neurodevelopmental model of schizophrenia. Susceptibility to the psychotomimetic effects of ketamine is minimal or absent in children and becomes maximal in early adulthood, which is consistent with the fact that many schizophrenia patients experience their first episode until their 20s. Increased cellular destruction by ▶ apoptosis or changes in the function of NMDA receptors in the early development of the central nervous system are expected to be decisive for the subsequent development of ▶ psychosis, which in turn would be expected to finally manifest in their early adulthood. However, although pharmacological intervention to the NMDA receptors, using their antagonists, may lead to the development of novel therapeutic agents for schizophrenia in theory, no agent has been available until now.

The available evidence also suggests an important role for the muscarinic cholinergic system in the pathophysiology of schizophrenia (Raedler et al. 2007; Scarr and Dean 2008). ▶ Acetylcholine is synthesized in neurons from acetyl-CoA and choline in a reaction catalyzed by the enzyme ▶ choline acetyltransferase. There are two families of acetylcholine receptors: muscarinic receptors and nicotinic receptors. Muscarinic cholinergic neurotransmission has been shown to play a significant role in various cognitive functions, including learning and memory, which has lead to a hypothesis that these receptors are involved in cognitive impairment in schizophrenia (the cholinergic hypothesis of schizophrenia). Postmortem and in vivo brain imaging studies have consistently shown a significant decrease of muscarinic M1 receptor density, and this decrease is seen in patients with schizophrenia but not those with bipolar disorder or major depression. Thus, these changes are expected to be disease-specific and considered to be associated with deficits in the cognitive function in schizophrenia. Pharmacological studies of the muscarinic system in schizophrenia have indicated that targeting muscarinic M1 receptor might be an effective strategy to ameliorate the cognitive impairment in schizophrenia. Although stimulating cholinergic neurotransmission, using ▶ cholinesterase inhibitors, has not yielded promising therapeutic effects on cognitive function in schizophrenia, muscarinic M1 agonists have been shown to improve cognitive function. For example, N-desmethylclozapine, an active metabolite of ▶ clozapine, is a potent M1 agonist and has gathered attention as a new pharmacological agent for the treatment of schizophrenia although the data are still preliminary. Thus, the currently available evidence suggests that deficits in muscarinic M1 neurotransmission in brain are associated with cognitive impairments in schizophrenia. Although there is no clinically available muscarinic M1 agonist as a cognitive enhancer for the treatment of schizophrenia, the preliminary data indicate the potential benefits of targeting these receptors to improve cognitive function in patients with this illness.

The potential involvement of the serotonergic system in the pathogenesis of schizophrenia was first proposed earlier than the dopamine hypothesis. Based on a phenomenological similarity between psychosis-like effects of lysergic acid diethylamide (LSD) and symptoms of schizophrenia, it was proposed in the mid 1950s that the abnormal neural transmission in the serotonergic system

may be responsible for psychotic symptoms in schizophrenia (referred to as the serotonergic hypothesis of schizophrenia). A subsequent series of human and animal studies have confirmed that 5-HT_{2A}-receptor agonists such as LSD and psilocybin have effects that mimic schizophrenia-like symptoms (Geyer and Vollenweider 2008). These findings seem to support that psychopharmacological intervention in the serotonergic neural system may be promising for drug development, which is not the case in reality. Antipsychotic drugs such as clozapine and chlorpromazine had significantly higher affinity for 5-HT_2 than for D_2 receptors. However, as described earlier, the degree of dopamine receptor antagonism (rather than their 5-HT_2 antagonism) by these antipsychotics has been shown to be more closely associated with their antipsychotic efficacy, suggesting that 5-HT_2 blockade is not the principal mechanism of their antipsychotic action. Consistent with this contention, clinical trials have failed to provide robust antipsychotic effects of selective antagonists at 5-HT_{2A} receptors until now. Some atypical antipsychotics, including ► risperidone, have been suggested to have a safer side effect profile in motor function, which may be due to their 5-HT_{2A} antagonistic property. Although antagonism at 5-HT_{2A} when added to D_2 antagonism may contribute to the safe profile of those newer drugs, targeting solely serotonergic neural transmission is unlikely to provide antipsychotic effects for the treatment of schizophrenia.

In summary, while the current data suggest the involvement of several aminergic neural systems in the pathophysiology of schizophrenia and mechanisms of actions of antipsychotics drugs, the dopaminergic system is still considered to play a principal role. In fact, there is no effective antipsychotic that does not have an effect on the dopamine system. On the other hand, nonpsychotic symptoms, especially negative symptoms and cognitive impairment, may be reversed with the use of drugs working on nondopaminergic neural systems such as the glutamatergic and cholinergic system. Given that manipulating the dopaminergic system is effective, but not always perfect for the treatment of schizophrenia, further psychopharmacological research on other neural systems would also be needed.

Amisulpride

Definition

Amisulpride is a benzamide derivative and is a second-generation antipsychotic with high affinity for D2 and D3 receptors. Its pharmacology is unusual in that at low doses, amisulpride preferentially blocks presynaptic D2 receptors, while at high dose it acts as an antagonist at postsynaptic D2 receptors. Amisulpride is used for the treatment of positive and negative symptoms of ► schizophrenia, as well as the management of dysthymia. Its therapeutic and safety profile is similar to that of the atypical antipsychotic ► risperidone, but amisulpride is associated with less weight gain and endocrine disturbance.

Amitriptyline

Definition

Amitriptyline is a ► tricyclic antidepressant with a tertiary amine chemical structure. One of the earlier tricyclics to be developed, it acts by inhibiting the reuptake of ► serotonin and ► norepinephrine, with roughly equal effects on each of these neurotransmitters. While its primary use is in the treatment of depression, it is also used in lower doses to treat migraine headache. It is metabolized to ► nortriptyline, which is itself marketed as an antidepressant. Usage of amitriptyline has declined in recent years due to its unfavorable side effect profile, including marked sedation, cardiovascular effects, and anticholinergic effects (e.g., constipation, dry mouth, blurred vision, urinary retention), and its high potential for lethality in overdose.

Amobarbital

Synonyms

Amylobarbitone

Definition

Amobarbital is a medium- to long-acting sedative ► barbiturate medication used in the treatment of severe and refractory anxiety and insomnia. It is sometimes used in conjunction with ► antipsychotic medication in acute psychotic episodes. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Interaction with ► alcohol can be hazardous. It depresses respiration and is highly toxic in overdose. It can induce liver microsomal enzymes. Long-term use induces dependence with severe withdrawal reactions. Recreational use and abuse can occur: amobarbital is a scheduled substance.

AMPA Receptor

Synonyms

AMPAR

Definition

The alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (or AMPA receptor) is a glutamate-activated ionotropic receptor (a ligand-gated cation channel) that mediates fast excitatory synaptic transmission and that has been linked to processes of synaptic plasticity that underlie learning and memory.

Ampakines

Definition

Ampakines are a new class of compounds that modulate ► glutamate in the brain. They work by allosterically binding to the AMPA subtype of ► glutamate receptors, which play a key role in memory formation and learning. Ampakines rapidly cross the ► blood–brain barrier and enhance the functioning of AMPA receptors to produce fast excitatory synaptic responses in the ► hippocampus. Thus, ampakines may produce cognitive benefits when

used as drugs. There is research interest in memory enhancement, stroke therapy, dementia treatment, sleep deprivation aid, and other therapeutic uses of ampakines.

Amphetamine

Synonyms
Benzedrine

Definition
Amphetamine is a stimulant drug structurally related to the more potent and toxic stimulant ► methamphetamine. Amphetamine has two forms or isomers: (+)-amphetamine and (−)-amphetamine (otherwise called dextroamphetamine and levoamphetamine, respectively). The (−)-isomer has greater sympathomimetic properties; accordingly, the pure (+)-isomer is preferred for therapeutic use, although a mixture of 75% (+)-amphetamine salts and 25% (−)-amphetamine has become widely used for treating ADHD. Amphetamines were used to treat obesity due to their anorexic properties, but the tendency for tolerance reduced their effectiveness and increased the risk of dose escalation and abuse. Amphetamines are used for ► narcolepsy and chronic fatigue. Although they are also used as recreational drugs, with important neurotoxic consequences when abused, addiction is not a high risk when therapeutic doses are used as directed.

Analgesics are drugs that are used to reduce pain.

Pharmacological Properties

Opioid Drugs

Opioid drugs have been the mainstay for the relief of mild to severe pain for centuries. It is worth noting that the first recorded use of ► morphine was in the third century BCE, and that it remains the first line analgesic in medical practice today. This reflects on both morphine's effectiveness in relieving pain and the inability of medical science to develop better drugs for the treatment of pain.

Opioid analgesics are defined as drugs that reduce pain by an action on opioid receptors. Before it was possible to define the protein structure of receptors, opioids were drugs whose effects could be prevented or reduced by administration of an ► opioid antagonist such as ► naloxone. Three opioid receptors, mu (named for the prototype drug that acts at this receptor, morphine), kappa, and delta receptors were defined by this method. Once the amino acid structure of receptor proteins could be determined, the definition of opioid receptor became a membrane protein with a structure that had considerable amino acid homology with the mu opioid receptor. Kappa and delta receptors continued to qualify, and a new receptor termed the Nociceptin/Orphanin FQ Peptide (NOP) receptor was discovered that met this definition as well.

Because of the effectiveness of ► mu opioid agonists in reducing pain, the capacity of agonists at each of the other opioid receptors to reduce pain has been thoroughly studied. Drugs that act on the kappa and delta receptors have analgesic effects, but have no clinical use for this indication because of adverse side effects (dysphoria in the case of kappa agonists and convulsions in the case of delta agonists) and because their pain-relieving potential seems not to be superior to that of morphine-like drugs. Drugs that act on these sites remain interesting and useful in experimental studies in animals and in vitro, and drugs with primarily kappa and delta activity have considerable promise in the treatment of itch and depression, respectively. The possibility that drugs that act on the NOP receptor may present a favorable profile of analgesic action is still under consideration in animal studies; this is described in more detail in the section Novel Approaches.

A great many analgesic drugs with mu opioid receptor ► affinity and ► efficacy have been developed over the past 50 years. Prior to that time, morphine and ► codeine, both naturally occurring opioids derived from the opium poppy, were almost the only strong analgesics that were available. Heroin, easily synthesized from morphine, was also in use as was ► methadone, the first totally synthetic opioid, which was identified in Germany in 1937. Between this time and 1977, when the most recent opioid analgesic (► tramadol) was introduced in Germany, the pharmaceutical industry expended gradually decreasing efforts to synthesize new opioid drugs in the hope that a drug could be identified that had morphine's ability to reduce pain but with fewer unwanted side effects.

The side effects of morphine that are most problematic include constipation, respiratory depression, sedation, and with some routes of administration, pruritus. In addition, when used daily for the treatment of chronic pain, morphine can produce physiological dependence and a resulting uncomfortable ► withdrawal syndrome if and when the drug is discontinued. The ► abuse liability of morphine is also of considerable concern, and has biased markedly some physicians against using opioid analgesics in cases of chronic, non-cancer pain. Over the years, drugs such as ► hydrocodone and hydromorphine, etorphine, ► fentanyl, and its derivatives (sufentanil, alfentanil, remifentanil), ► buprenorphine, ► pentazocine, nalbuphine, and tramadol were synthesized and marketed for analgesic use. Although these drugs differed widely in their pharmacokinetics, efficacies, and potencies, they all produced the majority of their analgesic actions through the mu opioid receptor. Pentazocine, with a confusing profile of action that may include some kappa receptor efficacy, and tramadol, which may act on serotonin as well as mu opioid receptors to reduce pain, are two opioid analgesics with additional sites of action. Unfortunately, the side effects that morphine produced were all found to be mediated through the mu receptor, and each of the newer opioid analgesics retained this same side-effect profile to a degree commensurate with their efficacies at the mu opioid receptor. These drugs are all currently available as analgesics in many countries, and are used because of their various pharmacokinetic advantages, but none has replaced morphine as the drug of choice in most situations that require relief of moderate to severe pain (Corbett et al. 2006). Most likely because of this determination, few pharmaceutical companies are currently attempting to develop improved opioid analgesics.

Two opioid analgesics, methadone and buprenorphine, because of their long-acting ► pharmacokinetic profile of action and because they can be taken by mouth, are currently used more frequently for the treatment of heroin abuse than they are used for the treatment of pain. The mechanism of methadone's ability to reduce heroin use is unknown, but variously attributed to methadone-induced cross-tolerance to heroin and to methadone-induced reduction in opioid cravings. The same mechanisms have been applied to buprenorphine, with the additional advantage that this partial mu opioid receptor agonist has some opioid antagonist effects as well. The pure opioid antagonist, ► naltrexone, is also effective in reducing heroin abuse by blocking the reinforcing effects of heroin. Compliance with opioid antagonist therapy for heroin abuse is a serious drawback, but may be soon overcome by the development of depot forms of antagonist administration (Comer et al. 2007).

When given frequently for the treatment of chronic pain, ► tolerance can develop to the analgesic effects of morphine. This means that the dose needs to be increased in order for the pain relief to be maintained. This has been demonstrated most readily in animal models of pain relief; there remains considerable debate about whether the requirement of increasing doses of morphine to treat chronic cancer pain, for example, is due to a reduced response to morphine or to an increase in the disease-related pain over time (Ballantyne and Shin 2008).

The mechanism of tolerance to morphine's analgesic effect is also a source of debate. There is no increased metabolic degradation of morphine with chronic administration, and no change in the number of mu opioid receptors or affinity of morphine for these receptors as a consequence of frequent administration. One of the more intriguing theories to account for opioid tolerance invokes a ► dual-process mechanism whereby the original actions of the drug (analgesia) are followed in time by the opposite action (► hyperalgesia). According to this theory, with chronic administration the hyperalgesic actions occur more rapidly and to a larger extent following each drug administration and attenuate the analgesic actions, resulting in a tolerance-like effect.

Morphine and most mu opioid analgesics are effective by oral or parenteral routes of administration, although variable gastric absorption of morphine makes intravenous or intramuscular administration more common in dealing with acute pain. Codeine is more consistently absorbed when given by mouth. Allowing patients to control their analgesic administration has become increasingly popular (► patient controlled analgesia or PCA). It has been found that providing patients in pain with a button to press that causes a brief intravenous injection of morphine produces better pain relief with less drug than the previous procedure of nurse-administered analgesia on a regular, every 4-h basis (Polomano et al. 2008). Certain limits are placed on the amount of morphine than can be infused over time, but there is rarely any tendency of patients to attempt to exceed these limits, and the amount of morphine infused typically decreases as the pain subsides.

Morphine and more lipophilic opioids such as remifentanil or sufentanil are also used frequently by the ► intrathecal or epidural route of administration for childbirth pain and postsurgical pain, and for patients who are resistant to or have unacceptable side effects from morphine given by other routes. For those in the latter group, it is possible to implant an intrathecal catheter and maintain

morphine analgesia by this route for dealing with chronic pain. Pain relief can be accomplished by much smaller doses of opioids when they are delivered around the spinal cord, which decreases the risk of adverse side effects. Nevertheless, respiratory depression remains the side effect of most concern with this route of administration, nausea and vomiting continue to occur, and pruritus may be more profound following intrathecal as compared with other routes of morphine administration (Schug et al. 2006).

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

NSAIDs are effective analgesics for mild to moderate acute pain such as minor trauma, dysmenorrhea, or headache, and for more chronic pain that is related to inflammatory responses, such as osteo- and rheumatoid arthritis. There are currently more than 25 members of this class, including the salicylic acid derivative, aspirin, the arylpropionic acids such as ibuprofen and naproxen, the COX-2 inhibitors such as celecoxib, rofecoxib, and parecoxib, and the heteroaryl acetic acids such as diclofenac and ketorolac. All but ketorolac and parecoxib are available only for oral administration. The mechanism of action of each of these drugs is inhibition of an enzyme (cyclo-oxygenase; COX) that normally produces prostaglandins and thromboxanes, some of which sensitize spinal neurons to pain, but others of which inhibit gastric acid secretion and protect gastric mucosa (Rang et al. 2007).

There are two primary cyclo-oxygenase isoforms, known as COX-1 and COX-2. COX-1 is a constitutive enzyme, active in most tissues, including red blood cells. The prostaglandins it catalyzes have a role in the protection of gastric tissues, and platelet aggregation. COX-2, on the other hand, is active when stimulated by inflammatory reactions, and the ► prostanoids that it catalyzes often mediate inflammation. Drugs such as aspirin, ibuprofen, and naproxen block both cyclo-oxygenase isoforms. It is generally thought that the ability of these drugs to reduce inflammatory pain is related to their block of COX-2, whereas the side effects of gastric irritation, and decreased clotting time were due to block of COX-1 enzyme. A concerted effort to develop drugs that blocked only the COX-2 enzyme and thereby yield NSAIDs that reduced pain but had fewer side effects resulted in the synthesis of the coxib drugs such as celecoxib and rofecoxib. In fact, these drugs do have a reduced ability to produce gastric irritation and bleeding while retaining considerable pain relieving effectiveness. Unfortunately, it appears as though some selective COX-2 inhibitors also increase the risk of adverse cardiovascular events, apparently because of the loss of a protective effect of COX-1 inhibition. A recent meta analysis of a series of NSAIDS and the risk they pose for adverse cardiovascular effects indicates that although the COX-2 selective inhibitors are more likely to produce dose-related myocardial infarction than NSAIDS that are less COX-2 selective, there is no close correspondence between the degree of COX-2 selectivity and risk of cardiovascular damage (Farkouh and Greenberg 2009).

The side effects of use of the nonselective COX-inhibitors are primarily gastric irritation and bleeding, which can be serious and life threatening, and decreases in platelet aggregation, which is a positive effect in individuals with coronary artery disease.

Other Drugs for Pain Relief

Acetaminophen is used to reduce mild to moderate pain, in much the same manner as aspirin. Acetoaminphen has less anti-inflammatory effects than NSAIDS, but it is very effective in reducing fever, which is done by blocking prostaglandin biosynthesis under conditions of fever. This analgesic is much less irritating to the GI tract than are NSAIDS, and does not alter blood coagulation as significantly as NSAIDS do. The primary risk factor of acetoaminophen is liver damage, which can occur if large doses are taken, or if an individual has a genetic polymorphism of liver enzymes that results in increased levels of a toxic acetoaminophen metabolite.

Calcium channel blockers. Although opioid drugs are recommended for moderate to severe pain, they are thought to be relatively ineffective in the treatment of neuropathic pain, or pain due to nerve damage or neuropathies. These conditions are usually chronic, making use of the large doses of opioids that are required to reduce this pain problematic. In 1994, a novel drug, gabapentin, was approved as an adjunct to the treatment of some types of seizures. It was fairly quickly discovered that ► gabapentin is also effective in reducing neuropathic pain, and it is currently widely prescribed for this purpose, although this is an off-label use. ► Pregabalin is a drug with a similar mechanism of action and spectrum of analgesic effects as gabapentin, and it is marketed for this use.

Both these drugs are structurally based on the inhibitory neurotransmitter ► GABA, but their effects are not related to the activity of this neurotransmitter. Rather, they may produce their analgesic effects through a blockade of a subunit of voltage-sensitive calcium channels in the brain and spinal cord. This blockade results in reduction in stimulated release of many neurotransmitters, including glutamate, GABA, ► substance P, and glycine, and this effect is currently thought to participate in the analgesic actions of these drugs (Taylor 2009). There are few side effects noted for these analgesic drugs.

Ketamine. This drug acts on the subtype of the ► glutamate receptor that is sensitive to *N*-methyl-D-aspartate (NMDA) application and produces both analgesia and anesthesia. ► Ketamine, the most widely used NMDA antagonist, is classified as a dissociative anesthetic because of the profound psychotomimetic effects of this drug that are apparent upon emergence. These effects are dysphoric in most individuals, limiting the use of ketamine as an anesthetic–analgesic primarily to patients with burn injuries, particularly children, who are less disturbed by the ► hallucinations produced by ketamine. Nevertheless, ketamine has a number of distinct advantages. It is rapidly effective by all routes of administration (intravenous, intramuscular, epidural, oral, rectal, and transnasal) and has analgesic, anesthetic, and amnestic effects. It does not depress respiration, and it stimulates the cardiovascular system in most patients (Aroni et al. 2009). The use of ketamine and other NMDA antagonists for the treatment of pain usually involves the use of relatively small doses in conjunction with opioid administration, frequently by means of PCA (Rang et al. 2007).

Antidepressants. The tricyclic ► antidepressants (► amitriptyline is the gold standard for analgesia) are recognized for their ability to reduce neuropathic pain. Other antidepressants, particularly the newer norepinephrine–serotonin reuptake inhibitors such as ► venlafaxine and ► duloxetine and the nonspecific reuptake inhibitors such as ► trazodone and nefazodone are inconsistently effective in this regard. The mechanism of action is likely complicated, but appears to be different from that mechanism involved in the antidepressant actions; not all antidepressants are effective analgesics. The side effects that accompany the treatment for depression remain when these drugs are used to treat pain, although the smaller doses used for analgesia tend to reduce these side effects. As with the calcium channel blockers, antidepressants have some efficacy in the treatment of neuropathic pain, and may be most useful when combined with opioid analgesics.

Novel Approaches

Although there is limited interest in opioid analgesic development currently by the pharmaceutical industry, basic science continues to search for drugs that reduce acute and chronic pain, with greater efficacy and/or fewer side effects than those currently available. Three such classes of compounds are sufficiently interesting to warrant mention. These drugs are not currently available for human use. Nevertheless, the promising profiles of these three agents, particularly given their divergent mechanisms, suggest that continued research on this topic may eventually yield more helpful pharmacotherapies for pain.

NOP receptor agonists. The Nociceptin/Orphanin FQ Peptide (NOP) receptor is the fourth type of opioid receptor (defined as a non-opioid branch of the opioid family), identified in a search for protein structures that were homologous with the mu opioid receptor. Drugs that bound to the NOP receptor were evaluated for their ability to produce analgesia. The vast majority of these tests were carried out in rats and mice, and it was found that agonists at the NOP receptor produced rather than reduced various types of experimental pain in rodents, especially when they were given centrally/supra-spinally (Lambert 2008). More recently, however, the analgesic properties of NOP agonists were evaluated in rhesus monkeys where they were found to be as effective as morphine by several routes of administration (e.g., Ko et al. 2009). More important, NOP agonists did not appear to have abuse liability in rhesus monkeys, and they did not produce pruritus, an important side effect of spinally administered morphine. Further testing in human and nonhuman primates may demonstrate the potential usefulness of these compounds as powerful analgesics devoid of the side effects associated with morphine.

Serotonin receptor agonists. Two aspects of mu opioid agonist-induced analgesia noted above, viz, the development of tolerance through a putative dual-action effect, and the relative ineffectiveness of these drugs in neuropathic pain, have prompted research into identifying a drug that produces pain initially as a "first-order" effect, but follows this with a longer lasting analgesia as a "second-order" effect. Because the dual process is likely to be neuronally mediated, this drug would be considered as potentially useful in treating chronic pain resulting from nerve damage.

Agonist actions at the serotonin 5-HT_{1A} receptor have recently been suggested as having this ability (Colpaert 2006). In contrast to morphine, which produces analgesia followed by hyperalgesia in rat models of mechanically induced pain, the 5-HT_{1A} agonist F-13640 produces hyperalgesia initially, but with further multiple injections, analgesia is obtained. Notably, following chronic administration of morphine, tolerance to its analgesic effects were observed, whereas, following chronic administration of F-13640, tolerance to its hyperalgesic effects and a resulting augmented analgesia was observed. Of particular interest was the finding that in rat models of tonic neuropathic pain, F-13640 was analgesic on initial administration, prompting the notion that the "first-order" effect of hyperalgesia may have been induced by the pain induced

by the intraplantar formalin injection, leaving the 5-HT_{1A} agonist to induce only the "second order" effect of reducing the pain sensation.

Transient receptor potential, vanilloid subfamily member 1 (TRPV1) is one of a family of cation channel receptors, and is activated by changes in temperature, acid pH, capsaicin, and some animal venoms. The receptor is located in the dorsal root gangion neurons and the trigeminal ganglion neurons as well as on a subset of primary sensory neurons (Aδ fibers) in the presence of inflammation.

Activity at TRPV1 receptors appears to sensitize the channel to other stimuli. Antagonists of TRPV1 have been targeted as analgesic agents because they seem to block the ability of the neurons to release a number of pro-inflammatory neuropeptides. Interestingly, TRPV1 agonists such as capsaicin, although they produce pain initially, also have considerable subsequent analgesic actions, probably by desensitizing sensory fibers. There is considerable ongoing experimental work targeting TRPV1 and other members of this family, searching for a profile of specificity and agonists/antagonist actions that result in the treatment of inflammatory, thermal, and other pain (Cortright and Szallasi 2009).

Animal Models for Psychiatric States

Paul Willner
Department of Psychology, School of Human Sciences, Swansea University, Swansea, UK

Synonyms

Animal models of psychopathology; Behavioral models of psychopathology; Simulations of psychopathology

Definition

Animal models of psychiatric states are procedures applied to laboratory animals that engender behavioral changes which are intended to be homologous to aspects of psychiatric disorders, and can therefore be used as experimental tools to further the understanding of human psychopathology.

Principles and Role in Psychopharmacology

Basic Concepts

The concept of modeling psychopathology in animals is as old as the use of animals in psychological investigations: its roots may be found in the work of Pavlov, Watson, and even earlier. However, for many years, practical attempts to devise animal models were sporadic, ad hoc, and unconvincing. As a result, animal models of psychiatric states were until recently viewed with justified suspicion. Over the last 20–30 years, this situation has changed, with the recognition that animal models can provide a means of investigating the neurobiological mechanisms underlying psychopathology. Indeed, given the limitations of the investigational techniques currently available for use in human subjects, animal models represent the only means of asking many important questions. Animal models can also be of great value in the process of psychotropic drug development, and again, frequently represent the only viable method of predicting novel therapeutic actions. The recent development and acceptance of animal models may thus be seen as an adjunct to the concurrent growth and maturation of psychopharmacology and biological psychiatry, where they serve as indispensable tools for ► translational research.

The definition of animal models of psychiatric states presented above includes a number of features:

1. The *procedures* used to generate models are many and varied. Broadly, they involve environmental manipulations (e.g., exposure to social or physical stressors, or training regimes), and/or alteration of the internal environment (e.g., by brain lesions or administration of psychotropic drugs), and/or identification of vulnerable individuals (by selective breeding or genomic methods). Some examples of each of these procedures are shown in Table 1.
2. While in principle any animal species could be used, in practice the scope of modeling is restricted to *laboratory animals*. The most extensively used species has traditionally been the rat, but mouse models are being increasingly developed in order to capitalize on the availability of genetically modified strains. (► Genetically modified animals) Other species used occasionally include guinea pigs, marmosets, and chicks.
3. Some earlier definitions of animal models described them as analogous to psychiatric disorders. The present definition emphasizes that models aim to be *homologous*: that is, to simulate essentially the same process across species. This issue is discussed further below.

4. An animal model of a psychiatric disorder includes a behavioral end point, which represents a model of a process that is thought to be important in the disorder. The scope of models is typically limited: they aim to simulate specific *aspects* rather than the entirety of the disorder, though it may be found subsequently that further aspects of the disorder are also present. Table 1 lists the primary behavioral end points that

were the focus of the original publications on each model, but in almost every case, a variety of other behavioral changes have also been described.

5. The definition also emphasizes the purpose of animal models of psychopathology: to provide a means of studying aspects of mental disorders. Animal models are *experimental tools*, and they are developed for specific investigational purposes. Initially, the primary aim was to elucidate psychological processes, but models are now used largely to address neurobiological issues. The specific issues most commonly addressed include: mechanisms of action of psychotherapeutic drugs, the neurotransmitter, neuroreceptor, and intracellular changes underlying psychiatric states, the neuroanatomical basis of psychiatric states, and increasingly, questions about the role of specific genes.

This article discusses some general issues concerning animal models of psychiatric states; models of specific psychiatric states are discussed elsewhere. ► Animal models; ► Anxiety: Animal Models; ► Autism: Animal Models; ► Dementias: Animal Models; ► Depression: Animal Models; ► Eating Disorder: Animal Models; ► Primate Models of Cognition; ► Rodent Models of Cognition; ► Schizophrenia: Animal Models. Fitness for Purpose

Because models are built to be used, they have to be viewed in relation to the broader objectives of a research program. Behavioral models are used in psychopharmacology for two distinct purposes: as simulations within which to study aspects of psychiatric states, and as screening tests for the development of new treatments. Screening tests are subject to logistical considerations: for example, the test should be completed in the shortest possible time, and ideally will respond to acute drug treatment. However, in a model of a psychiatric state, these same features may be counter-indicated. For example, antidepressant drugs are clinically ineffective if administered acutely and largely inert if administered to nondepressed people: therefore, a model of clinical antidepressant action should involve chronic drug treatment, administered within a context of abnormal behavior rather than to "normal" animals. (► Antidepressants) Thus, a particular time course of antidepressant action and a particular level of behavioral sophistication may be desirable or undesirable features, depending upon the purpose for which a procedure is being used.

Conclusions arising from the use of a model are essentially hypotheses, which must eventually be tested against the clinical condition being modeled. The more valid a model, the more likely it is that insights derived from it will hold true for the clinical condition. Therefore, an assessment of the validity of a model provides an indication of the degree of confidence that we can place in the hypotheses arising from its use. Assessment of validity is not a yes/no judgment, but rather an evaluation of strengths and weaknesses and areas of uncertainty.

The systematic validation of an animal model is no different in principle from that of any other psychological device, such as a psychometric test or a psychiatric diagnosis, and the same general approaches to validation are applicable. Several systems of evaluation have been proposed, which have the common feature that models are assessed on two or more independent dimensions. One widely used method, described below in more detail, employs the three dimensions of predictive, face, and construct validity: ► predictive validity means that performance in the test predicts performance in the condition being modeled (and vice versa); ► face validity means that there are phenomenological similarities between the two; and ► construct validity means that the model has a sound theoretical rationale.

Some reviewers have advocated the primacy of one of these three dimensions, and each has its advocates. In principle, construct validity should be considered as the most fundamental dimension. In practice, however, the construct validity of animal models of psychopathology is difficult to determine, and therefore a balanced approach is needed, in which a view of the validity of a model is formed only after considering all three sources of evidence. In all three areas, discriminant validity is a further consideration: that is, the extent to which the evidence points to a particular disorder, as distinct from a different or a nonspecific psychiatric disorder. The three sets of validation criteria provide a convenient framework for organizing large volumes of data and ensuring that when different models are compared, like is compared with like. The major issues described below are summarized in Table 2.

Assessment of Predictive Validity

The concept of predictive validity implies that manipulations known to influence the pathological state should have similar effects in the model: thus, manipulations known to precipitate or exacerbate the disorder should precipitate or exacerbate the abnormalities displayed in the model, while manipulations known to relieve the disorder should normalize behavior in the model. In

Animal Models for Psychiatric States. Table 2. Issues to consider in assessing the validity of animal models.

Predictive validity	Specificity: No false positives
	Sensitivity: No false negatives
	Relative potencies and appropriate dose ranges
	How firmly established are the clinical data on effective and ineffective treatments?
Face validity	Extent of correspondence vis-à-vis symptoms and neurobiological features
	Specificity of symptoms/features modeled
	Centrality of symptoms/features modeled
	Coherence of symptoms/features modeled: Do they co-occur clinically?
	How robust is the psychiatric diagnosis?
Construct validity	How well do we understand the model: Does it measure what it claims to measure?
	How well do we understand the disorder: Would clinicians agree with how it is being characterized?
	If there is a parallel human experimental model, how well has that model been validated?
	Do similar theoretical structures apply: Can homology be demonstrated in relation to psychological processes, anatomical localization, neurochemical mechanisms, or gene expression?

practice, the predictive validity of the animal models used in psychopharmacology is determined largely by their response to therapeutic drugs.

In this context, the primary requirements for predictive validity are that a valid test should be sensitive and specific: sensitivity means that the test should respond to effective therapeutic agents and specificity means that it should fail to respond to ineffective agents. Positive responses should occur at sensible doses, and should be demonstrable with a range of structurally diverse compounds, and where applicable, to nonpharmacological treatment modalities. Negative responses should be demonstrable with agents that cause behavioral changes similar to the therapeutic effect but achieve these effects by nonspecific actions (e.g., by changing locomotor activity). However, while sensitivity and specificity are crucial to an assessment of predictive validity, results may sometimes be distorted by species differences in drug kinetics or metabolism, which can lead to apparent discrepancies of drug action in animal models versus human patients.

In some circumstances, it may be possible to demonstrate that the relative potencies of different agents in a model correlate positively with their potencies in clinical use. This is potentially a powerful test, provided that there is sufficient variation among the chosen drugs in their clinical potencies. However, it can generate trivial data if the analysis fails to sample a range of chemically distinct compounds. For example, the positive correlation between the clinical potency of ▶ benzodiazepines and their performance in several animal models of anxiety (▶ Anxiety, animal models) serves only to confirm that these drugs act at the same receptor.

There will always be a group of drugs for which, through a shortage of research, there is uncertainty over their status as clinically effective or ineffective. Moreover, the clinical classification of drugs as active or inactive may sometimes be incorrect. Drugs thought to be active on the basis of early open trials are frequently found to be inactive in later well-controlled tests; conversely, a drug may appear to be inactive because the emergence of side effects prevents its administration at adequate dosages, a problem that is less likely to arise in an animal model. It follows that the failure of an animal model to predict accurately will tend to weigh against the model, but may sometimes call instead for a reevaluation of the clinical wisdom. This illustrates an important principle: that the validity of a model is absolutely limited by the quality of the clinical information available to describe the condition modeled.

Assessment of Face Validity

Face validity refers to a phenomenological similarity between the model and the disorder modeled. On the one hand, the model should resemble the disorder; on the other, there should be no major dissimilarities. The checklist approach to psychiatric diagnosis adopted by the Diagnostic and Statistical Manuals of the American Psychiatric Association (▶ DSM) provides a useful starting point for enumerating areas of potential comparison. In DSM, psychiatric diagnoses are established by reference to a checklist of core symptoms and a further checklist of subsidiary symptoms, with a requirement to demonstrate the appropriate number of symptoms from each list. If several points of similarity are demonstrable between a model and the disorder, then it is necessary to ask whether the cluster of symptoms identified forms a coherent grouping that might realistically be seen in a single patient, or whether they are drawn from a variety of diagnostic subgroups. Frequently, animal models focus on a single behavioral endpoint. In that case, it is important to

assess whether this models a core symptom or a subsidiary symptom. For example, if the behavior in the model consists simply of a change in locomotor activity, this is likely to be of peripheral relevance to most psychiatric disorders. Similarly, the face validity of the model is less strongly supported if the symptom modeled is common to a several different psychiatric disorders (discriminant validity).

While a comparison with DSM provides an extremely useful starting point for assessment of face validity, other relevant comparisons should also be considered. For example, if the clinical condition only responds to chronic drug treatment (e.g., depression), then the model should also respond only to chronic drug treatment. Any neurobiological parallels between the model and the disorder also contribute to face validity.

Similarity between behavior in the model and the clinical symptom modeled should be demonstrated, rather than assumed. The demonstration of similarity requires a thorough experimental analysis, which, sadly, is often lacking. This can result in specious claims for face validity being advanced on the basis of unsupportable interpretations of behaviorally unsophisticated models. For example, many animal models of depression are based on a decrease in locomotor activity. (► Depression: animal models) It is certainly possible that a decrease in locomotor activity might simulate symptoms of depression such as psychomotor retardation or loss of motivation, but without further behavioral analysis, these remain unsupported analogies. As a general rule, the less sophisticated the behavior (in the sense that its interpretation is less open to experimental investigation and analysis), the lower is the possibility of making a judgment of face validity.

A fundamental consideration in assessing face validity is that the comparison of symptoms between a model and the clinical condition can only proceed in respect of symptoms that are expressed behaviorally. Many symptoms of psychiatric disorders are only known from patients' verbal reports, and these symptoms, in principle, cannot be modeled. An example is suicidal ideation in depression. However hard we worked, we could never know if a rat was feeling suicidal (or to take an actual research example, if it was feeling a state of "despair"), (► Behavioral despair) and therefore, this question falls outside the realm of scientific discourse: we simply cannot ask it. Nevertheless, it may sometimes be possible to express subjective symptomatology in behavioral terms. ► Hallucinations are subjective phenomena that should be out of bounds for modeling in animals, but from careful observation of patients who are hallucinating, a set of operational criteria was developed to define associated behavioral phenomena (such as staring intently at an invisible object), thus enabling the inclusion of hallucinations as symptoms that in principle could be simulated in animal models of schizophrenia. (► Schizophrenia: animal models) The rule, then, is that if a symptom can be expressed behaviorally and defined operationally, we can attempt to model it, but if it can only be expressed verbally, we cannot.

It is also important to remember that most DSM diagnoses are poorly established hypothetical constructs that can change radically between successive revisions of the manual. Again, the assessment of the validity of animal models is limited by the quality of the clinical data.

Assessment of Construct Validity

In order to evaluate the theoretical rationale of an animal model (construct validity), we require a theoretical account of the disordered behavior in the model, a theoretical account of the disorder itself, and a means of bringing the two theories into alignment. This can only be done if the clinical theory occupies an appropriate framework, which uses terms and concepts applicable also to subhuman species. Clearly, the subjective dimension of psychopathology cannot be central to such a theory, since subjective phenomena in animals are for most practical purposes outside the realm of scientific discourse. However, at the level of the cognitive processes underlying psychopathology, and the neurobiological mechanisms that underlie those cognitive processes, the possibility exists of constructing parallel theories. It follows from this analysis that the assessment of construct validity involves a number of relatively independent steps.

First, the theoretical account of behavior in the animal model requires evaluation. Just how well do we understand the model? Does it measure what it claims to measure? For example, if an animal model of depression is conceptualized as a decreased ability to respond to rewards, then at the very least, it must be convincingly demonstrated that the decrease in rewarded behavior cannot be explained by, for example, sedative effects or a nonspecific decrease in consummatory behavior (► Depression: animal models). Similarly, an animal model of dementia must demonstrate that performance failures result from a disorder of learning or memory, rather than from nonspecific causes, and further work should seek to characterize the specific memory processes involved. (► Rodent models of cognition; ► Primate models of cognition)

In some areas, human experimental procedures have been developed that are based on procedures used in animal studies. However, demonstrating that a similar

psychological process occurs in humans and animals is of limited value, since its role in the disorder also needs to be demonstrated. For example, some groups of schizophrenic patients show sensorimotor gating deficits that are very similar to those seen in animal models of schizophrenia: however, the contribution of sensorimotor gating deficits to schizophrenia remains uncertain (► Prepulse inhibition, ► Latent inhibition). It will be clear that a detailed consideration of the human disorder forms an essential step in the evaluation of animal models, and that the relatively poor state of theoretical understanding of most psychopathologies places an upper limit on construct validity.

Recent developments in neuroimaging and psychiatric genetics may help to decrease the difficulty of establishing homology between animal models and psychiatric states. A major focus of work with animal models has been to establish the brain areas responsible for the behavioral changes, and neuroimaging methods can now provide similar information for psychiatric states, making it possible to evaluate in a much more precise manner whether common mechanisms are involved. (► Magnetic resonance imaging: functional) Similarly, the identification of susceptibility genes and ► endophenotypes can now be translated directly into genetically modified animal models. (► Genetically modified animals) This is a rapidly developing area of research, and it is likely that it will be used increasingly to develop animal models of psychopathology that by definition will have a degree of construct validity.

Animal Models of Acute Stroke

Definition

A model of acute stroke produced in a laboratory animal, generally a rodent but sometimes a higher species such as

a primate. A cerebral blood vessel (commonly the middle cerebral artery, since this is the vessel most often affected in human stroke) is occluded by clipping, electrocoagulation, or a thread. If the occlusion is not removed, this is referred to as permanent focal ischemia; if the occlusion is removed, it is called transient focal ischemia. Injection of small clots into the cerebral arteries is called a thromboembolic stroke model.

Anorexia Nervosa

Synonyms

Eating disorders: animal models

Definition

Eating disorder that primarily affects women and that is characterized by an obsession with losing weight, and distorted body image. Patients suffering from anorexia nervosa will restrict their diet to levels that lead to severe malnutrition, and if left untreated, could lead to death.

Anorexigenic

Definition

Systems or endogenous factors that prevent or foreshorten eating events.

Antagonist

Synonyms

Receptor inhibitor

Definition

An antagonist binds to a receptor but causes no change in receptor activity itself. Rather, an antagonist maintains the receptor in the same state as exists when it is not bound by a stimulatory (agonist) or inhibitory (inverse agonist) substance. Thus, an antagonist has no impact on receptor activity in the absence of an agonist or inverse agonist, but prevents or reverses the effects of such substances when they are present by blocking their binding to the receptors. An antagonist may be competitive (or surmountable), that is, it binds to a region of the receptor common with the endogenous agonist. The effects of a competitive antagonist may be overcome by increasing the concentration of agonist. Alternatively, antagonists may be insurmountable, where no amount of agonist is capable of completely overcoming the inhibition. Insurmountable antagonists may bind covalently to the agonist binding site, or act allosterically at a different site on the receptor.

Anticonvulsants

Antiepileptics; Mood stabilizers

Definition

Anticonvulsants are drugs defined by their efficacy in the treatment of epilepsy. They are also widely used to treat nonepileptic conditions such as neuropathic pain, migraine, and ► bipolar disorder.

Pharmacological Properties

History

Anticonvulsants were first studied and approved for the treatment of epilepsy, while their therapeutic activity in other disorders was identified later. Anticonvulsants are traditionally divided into two groups, according to the year of marketing (before and after 1990) (Beghi 2004): ► first-generation anticonvulsants (or "older"), including ► phenobarbital, ► phenytoin, primidone, ► carbamazepine, ► valproic acid, and ethosuximide, and ► second-generation anticonvulsants (or "newer"), such as ► lamotrigine, ► gabapentin, ► topiramate, ► oxcarbazepine, levetiracetam, ► pregabalin, ► tiagabine, and ► zonisamide.

In addition to their use for the management of epilepsy, anticonvulsants are also commonly used to treat a variety of nonepileptic neurological conditions, such as neuropathic pain, migraine, and essential tremor, and psychiatric disorders, such as bipolar disorder and anxiety. This presumably reflects their complex mechanisms of action involving a wide range of pharmacological effects on different neurotransmitter systems and ion channels.

Concerning their use as ► mood stabilizers, anticonvulsants began to be studied in the late 1970s, when a logical parallel was drawn between affective and seizure disorders, based on the theory that mania may "kindle" further episodes of mania (Post et al. 2007). Since the first compounds tested, namely carbamazepine and valproate, proved effective in treating the manic phase of bipolar disorder, this has led to the idea that many anticonvulsants could be mood stabilizers, especially for mania. In recent years, a number of anticonvulsants have been more rigorously investigated for their potential mood-stabilizing properties. Anticonvulsants are heterogeneous in their mechanisms of action, ► pharmacokinetics, and ► efficacy in the various mood states in bipolar illness, as well as in their safety/tolerability profiles.

Mechanisms of Action

The exact mechanism of action of anticonvulsants remains largely unknown. However, anticonvulsants have various

targets of action in the synapse and may affect pathophysiological processes regulating neuronal excitability. The main pharmacological mechanisms responsible for the clinical efficacy of anticonvulsants in epilepsy and in the various nonepileptic neurological and psychiatric disorders are likely to include increased GABAergic inhibitory neurotransmission, decreased glutamatergic excitatory neurotransmission, blockade, or inhibition of voltage-dependent sodium or calcium channels, and interference with intracellular signaling pathways (Johannessen Landmark 2008). In addition, indirect mechanisms may be involved, such as the modulation of other neurotransmitters, including the ► monoamines. Current knowledge indicates that most anticonvulsants have more than one mechanism of action, each of which may contribute to its therapeutic efficacy to a variable extent.

Anticonvulsants differ in their effects on neurotransmission and on ion channels, both of which may be related to the pathophysiology of epilepsy and nonepileptic disorders. Valproate inhibits voltage-gated sodium channels and potentiates the inhibitory action of gamma-aminobutyric acid (► GABA), by either increasing its release, decreasing its reuptake, or slowing its metabolic inactivation. Valproate may also interact with other ion channels, such as voltage-gated calcium channels, and also indirectly block ► glutamate action. Carbamazepine and structurally related oxcarbazepine may act by blocking the alpha subunit of voltage-gated sodium channels, and may also interfere with calcium and potassium channels. As with carbamazepine, the mood-stabilizing effect of lamotrigine is probably related to the inhibition of sodium and calcium channels in presynaptic neurons and the subsequent stabilization of neuronal membranes. In addition, lamotrigine may reduce the release of the excitatory neurotransmitter glutamate. Topiramate has been demonstrated to possess many molecular effects, including enhanced GABAergic activity, reduced glutamatergic neurotransmission, and inhibition of voltage-gated calcium channels. Gabapentin and pregabalin possess a selective inhibitory effect on the $\alpha_2\delta$ subunit of the voltage-gated calcium channels and may also facilitate GABAergic function. Levetiracetam binds to the synaptic vesicle protein 2A (SV2A), thereby reducing glutamate release. Tiagabine inhibits GABA reuptake, thereby increasing its postsynaptic availability.

Interference with intracellular mediators and signaling pathways is an important postulated mechanism in the pathophysiology of bipolar disorder (Rogawski and Loscher 2004). In addition, recent evidence from brain imaging and postmortem histopathology indicates that atrophy and glial death in specific brain regions, especially prefrontal cortex and hippocampus, are involved in mood disorders (Zarate et al. 2006). It has been hypothesized that mood-stabilizing agents may exert long-term beneficial effects by activating intracellular signaling pathways that promote neuroplasticity, ► neurogenesis or cell survival. Common actions on cell signaling of anticonvulsants and ► lithium, the gold standard in the treatment and prophylaxis of bipolar disorder, have been identified in recent years. As with lithium, the mood-stabilizing action of valproate and, possibly, carbamazepine has been linked to inositol depletion. Lithium and valproate block inositol monophosphatase (IMPase), preventing the conversion of inositol-1-phosphate (IP_1) to *myo*-inositol. This effect is considered to result in the stabilization of the structural integrity of neurons and the enhancement of synaptic plasticity. Valproate shares with lithium other effects on downstream signal transduction cascades, such as the inhibition of protein kinase C (PKC) and myristolated alanine rich C kinase substrate (MARKCS). The mood-stabilizing properties of lithium have also been attributed to the inhibition of glycogen synthase kinase 3β (GSK3β), an enzyme that contributes to many cellular functions, including apoptosis. Valproate and lamotrigine have similar effects on GSK3β, whereas carbamazepine does not. Other common effects of lithium and valproate are to increase the activity of the extracellular signal-regulated kinase (ERK) pathway, resulting in the enhanced transcription of neurogenesis and cell survival factors, such as antiapoptotic protein Bcl-2 and ► brain-derived neurotrophic factor (BDNF). Valproate may also regulate ► gene expression and transcription by acting as a ► histone deacetylase inhibitor.

In summary, anticonvulsants may be effective in many non-epileptic disorders. With regard to their use as mood stabilizers, anticonvulsants such as valproate, carbamazepine, and lamotrigine appear to have a clear role based on their effect on intracellular pathways. Anticonvulsants with effects on voltage-gated sodium or calcium channels, such as gabapentin, pregabalin, carbamazepine, lamotrigine, and valproate, may be particularly useful in neuropathic pain. Some agents, namely valproate and topiramate, have demonstrated efficacy in the prevention of migraine, possibly by increasing GABAergic and decreasing glutamatergic neurotransmission, thereby reducing neuronal hyperexcitability. The enhancement of GABAergic function may explain the beneficial effect of gabapentin, pregabalin, valproate, and tiagabine in anxiety disorders and essential tremor.

Animal Models

There is a limited number of fully validated and appropriate animal models of bipolar disorder for in-depth

behavioral, biochemical, histological, and pharmacological analysis (Gould and Einat 2007). The paucity of suitable animal models and difficulty in assessing the prophylactic effects of mood stabilizers is a rate-limiting step in the process of understanding the neurobiology of the disorder, as well as in the development of novel medications. Modeling bipolar disorder in animals is problematic for a number of reasons, including limited knowledge about underlying pathophysiology, susceptibility genes, and mode of action of the available mood stabilizers. In addition, in humans, the disease is cyclical and clinically heterogeneous, and there are no established biomarkers for the disease state or the effects of treatment.

The existing animal behavioral tests and models may be classified into a number of general areas, such as whether they focus on particular symptoms, bipolar endophenotypes, and pathophysiology, or response to existing medications (Gould and Einat 2007). Symptom-based models of bipolar disorder are attempts to represent aspects of either the manic or the depressive phase of the illness. Symptoms of mania that can be modeled in mania include increased activity, irritability, aggressive behavior, sexual drive, and reduced need for sleep. Models of the depressive phase are based on models previously validated in the context of depression research, and are available for symptoms such as anhedonia, fatigue, changes in sleep patterns, and changes in appetite or weight. Models based upon ► endophenotypes and pathophysiology can be neurophysiological, biochemical, endocrine, neuroanatomical, genetic, cognitive, or neuropsychological. In particular, the identification of susceptibility genes for bipolar disorder might help to define specific neurobiological processes and associated behaviors. Consequently, animal models studying the relevance of changes in the levels of proteins, circuits and synapses, and brain function, without regard to modeling of symptoms, may be particularly useful. A number of models have been developed based upon response to existing medications. They have considerable value both in understanding the mechanism of action of available drugs and in developing new treatments for bipolar disorder. In this respect, given the evidence for some overlapping signal transduction properties of lithium and valproate, it is reasonable for newly developed drugs that have effects on neuronal intracellular signaling and ion channel-mediated actions to be considered in preclinical and clinical testing for their potential effects on bipolar disorder, irrespective of whether such drugs are called anticonvulsants.

A model based on the phenomenon of "kindling," which is an animal model of epileptogenesis, was proposed as relevant to bipolar disorder pathophysiology and the mechanism of action of anticonvulsants used for treatment (Post 2007). The kindling model predicts temporal variation in the function of neural circuits and associated episodes, evolution of the illness and episode cyclicity, and might explain how events trigger affective episodes. Many anticonvulsants have demonstrated antikindling effects in vitro and this may account for their efficacy in both epilepsy and bipolar disorder.

► Pharmacokinetics

Anticonvulsants are generally well absorbed. They are lipophilic compounds that easily cross the ► blood–brain barrier and accumulate in fatty tissues. All commonly used anticonvulsants, except gabapentin, pregabalin, and levetiracetam are metabolized in the liver by cytochrome P450 isoenzymes (CYPs) or uridine diphosphate glucuronosyltransferases (UGTs). The elimination half-lives of anticonvulsants differ among the various agents, ranging between a few hours (valproate) and days (phenobarbital). Time to reach steady-state levels differs accordingly, but once- or twice-daily dosing is possible for all compounds. In this respect, extended-release formulations of valproate and carbamazepine have recently become available. As most anticonvulsants are extensively metabolized via hepatic enzymes, they may be involved in ► drug interactions. Their biotransformation can be affected by the concomitant administration of other drugs, including other anticonvulsants with inhibiting or inducing properties toward these enzymes. In addition, some anticonvulsants have prominent inhibitory or inducing effects on the activity of the hepatic enzymes that metabolize the majority of existing medications. In this respect, valproic acid is considered a broad-spectrum inhibitor of various drug-metabolizing enzymes. The first-generation anticonvulsants carbamazepine, phenytoin, and phenobarbital are broad-spectrum inducers of a variety of CYP enzymes, including CYP1A2, CYP2C9, CYP2C19, and CYP3A4, as well as UGTs and microsomal epoxide hydrolase. Compared with older agents, new anticonvulsants appear to have clear advantages in terms of a lower potential for such interactions. As the mode of action of anticonvulsants involves different effects on various neurotransmitter systems and ion channels, these compounds may be involved in potentially adverse pharmacodynamic interactions with other drugs, in particular other central nervous system (CNS) agents.

Efficacy

Although traditionally used to treat epilepsy, anticonvulsants have proven to be effective in a variety of disease

states (Spina and Perugi 2004). With regard to their ► efficacy in psychiatric conditions, three anticonvulsants, namely valproate, carbamazepine, and lamotrigine, are currently approved for the treatment of various aspects of bipolar disorder in most countries (Weisler et al. 2006). Large-scale, randomized, double-blind, well-controlled studies have documented that valproate and carbamazepine are highly effective in the treatment of acute mania. On the other hand, neither valproate nor carbamazepine has robust evidence supporting their efficacy in the treatment of acute bipolar depression. Valproate and, to a lesser extent, carbamazepine appear to be effective in the prophylactic treatment of many bipolar patients, including those refractory to or intolerant of lithium, but they are not approved for long-term maintenance therapy. While some studies have suggested that lamotrigine may be effective for the acute treatment of bipolar depression, there is strong evidence of its efficacy in preventing the recurrence of depressive episodes without the associated risks of cycle acceleration or manic/hypomanic switches (Weisler et al. 2008). Lamotrigine is currently approved only for the prophylaxis of bipolar I disorder. Concerning other newer anticonvulsants, oxcarbazepine has limited data suggesting efficacy in acute mania, while gabapentin and topiramate are ineffective as primary antimanic treatments, although they may be useful adjuncts for the treatment of comorbid conditions such as anxiety, pain, migraine, or weight problems. No controlled trial data are available for levetiracetam, tiagabine, or zonisamide.

Some anticonvulsant medications are widely used in the treatment of a number of chronic pain syndromes. Carbamazepine is commonly prescribed as first-line therapy for patients with trigeminal neuralgia. Gabapentin and pregabalin have been approved for the treatment of neuropathic pain associated with diabetic polyneuropathy and postherpetic neuralgia. Topiramate and valproate, in the form of divalproex sodium, are indicated for the prophylactic treatment of migraine.

Safety/Tolerability

Treatment with valproate is commonly associated with CNS side effects (tremor, somnolence, dizziness, ataxia, and asthenia) and gastrointestinal distress (nausea, vomiting, abdominal pain, and dyspepsia). Other important adverse events include weight gain, hair loss, and hyperammonemic encephalopathy in patients with urea cycle disorders. Hepatotoxicity and pancreatitis are rare but serious adverse effects associated with valproate therapy. The most common side effects reported during carbamazepine treatment include dizziness, somnolence, ataxia, nausea, and diplopia. Other important events less frequently observed include benign skin rashes, mild leucopenia, and thrombocytopenia, and hyponatremia, which is more common in the elderly population. Rare, but serious adverse events associated with carbamazepine therapy include severe dermatologic reactions, namely, Lyell syndrome (toxic epidermal necrolysis) and Stevens–Johnson syndrome (erythema multiforme major). The use of both valproic acid and carbamazepine during the first trimester of pregnancy is associated with an increased risk of congenital malformations, in particular spina bifida.

Lamotrigine is generally well tolerated, except for its propensity to cause rashes, including rarely the life-threatening Stevens–Johnson syndrome. Rashes by lamotrigine are in most cases reversible and can be minimized by very slow titration of the drug during the initiation of therapy and by avoiding or managing drug interactions, such as those with valproate, that raise lamotrigine levels. Further and rare side effects are vertigo, somnolence, diplopia, and gastrointestinal symptoms.

Other newer anticonvulsants occasionally used to treat bipolar disorders, such as oxcarbazepine, topiramate, gabapentin, or levetiracetam, have a relatively favorable tolerability profile. Oxcarbazepine is less sedating and has less bone marrow toxicity than its congener carbamazepine. Moreover, differently from carbamazepine, oxcarbazepine seems to possess only a modest inducing effect on hepatic drug-metabolizing enzymes and, therefore, has a lower potential for pharmacokinetic drug interactions. Topiramate is associated with weight loss and is sometimes given as an adjunct to mood stabilizers that cause weight gain.

Conclusion

In summary, anticonvulsants represent a heterogeneous group of drugs that, in addition to having proven efficacy for the management of epilepsy, are increasingly used to treat a variety of other neurological and psychiatric conditions. In particular, some anticonvulsants, namely valproate, carbamazepine, and lamotrigine, have become an integral part of the pharmacological treatment of bipolar disorder. Other newer anticonvulsants appear to have more favorable tolerability and drug interaction profiles as compared to older compounds, thus improving compliance with treatment. However, evidence for their efficacy in treating the various phases of bipolar disorder is still inadequate. Therefore, there is an ongoing need for controlled studies with a large number of patients and greater homogeneity of diagnosis in order to establish the efficacy of individual anticonvulsants in the management of psychiatric disorders.

Definition

Antidepressants are compounds used to treat depression. Specifically, they reduce symptoms of depression. They do not elevate mood. The agents approved for the treatment of depression, however, are also useful in an array of other disorders, including anxiety disorders, pain syndromes, attention deficit hyperactivity disorder (ADHD), smoking cessation, and premenstrual dysphonic disorder. In most cases, the term "antidepressant" is still retained to refer to the class of drugs.

Pharmacological Properties

History

The first agents approved for use in depression by the US Food and Drug Administration (FDA) were discovered in the late 1950s. Roland Kuhn, a Swiss psychiatrist, was exploring compounds that might have value in depression. He observed that G 22355, a J. R. Geigy company compound, appeared to be of value in patients with endogenous depression. This compound, also known as ▶ imipramine (*Tofranil*), possessed a three-ring structure somewhat similar to ▶ chlorpromazine, an antipsychotic. This finding had enormous consequences not only for the treatment of depression, but also in providing a conceptual basis for a psychopharmacologic theory of depression (Schildkraut 1965). In subsequent years, several other tricyclic (TCA) and related heterocyclic compounds were introduced for treating depression (Nelson 2009). These agents would be the first-line agents for the treatment of depression for the next 3 decades.

Also during the late 1950s, a drug used in treating tuberculosis, iproniazid (a ▶ monoamine oxidase inhibitor [MAOI]) was observed to improve symptoms of depression. Further testing confirmed antidepressant effects and it was widely used for a short period of time. Because of concerns that iproniazid caused jaundice, its successors, isoniazid (*Marplan*), ▶ tranylcypromine (*Parnate*), and ▶ phenelzine (*Nardil*) became the MAOI agents used for the treatment of depression. Because of safety issues involving interactions with tyramine in the diet, and

interactions with sympathomimetic and other medications, the MAOI drugs were not widely used.

During the 1980s, several new antidepressants were developed. Unlike the tricyclics, which had similar chemical structures, the newer agents differed in structure but were grouped according to their function. The first of these to be marketed was ▶ trazodone (*Desyrel*). Trazodone is an antagonist at the postsynaptic serotonin 2 (5-HT_2) receptor and has antihistaminic properties. It was widely used in the 1980s but its use in depression declined with the introduction of the selective serotonin reuptake inhibitors (SSRIs). ▶ Bupropion was also introduced in the 1980s. As it was coming to market, a few patients in a bulimia study experienced seizures and its marketing was delayed while this safety issue was explored. It was reintroduced with the recommendation not to exceed 450 mg/day.

In the late 1980s, ▶ fluoxetine (*Prozac*) was approved for use in depression. It was followed later by ▶ paroxetine (*Paxil*), ▶ sertraline (*Zoloft*), and ▶ citalopram (*Celexa*). The greater tolerability of these agents led to rapid acceptance; by 1994, this class of antidepressants surpassed the tricyclics as the most widely used antidepressants. The active marketing of the SSRIs in depression coupled with new indications for ▶ panic disorder, ▶ obsessive–compulsive disorder, ▶ social anxiety disorder, ▶ posttraumatic stress disorder, ▶ premenstrual dysphoric disorder, bulimia, and ▶ generalized anxiety disorder, led to a substantial growth, in the 1990s, of the market for antidepressants in general and the SSRIs in particular. ▶ Fluvoxamine (*Luvox*), another SSRI, was approved by the FDA for use in OCD, but not in depression. ▶ Escitalopram (*Lexapro*), the s-isomer of citalopram, was the last SSRI developed for use in depression.

For a period of time in the 1980s and into the 1990s, drug development focused on these "selective" agents. While their improved tolerability and safety offered advantages, their efficacy was no better than the tricyclics, and some questioned if they were less effective. In an attempt to improve efficacy, new agents were introduced that had actions on both ▶ serotonin (5-HT) and ▶ norepinephrine (NE). These dual action agents were known as the SNRIs and included ▶ venlafaxine (*Effexor*) and ▶ duloxetine (*Cymbalta*). Recently, the desmethyl metabolite of venlafaxine (▶ desvenlafaxine [*Pristiq*]) was introduced. Each of these compounds is relatively more potent in blocking 5-HT uptake than NE uptake, but as the dose increases, NE uptake blockade increases. These compounds are relatively free of the antihistaminic, anticholinergic, and sodium channel effects of the TCAs that contributed to side effects. Venlafaxine and duloxetine were also approved for use in generalized anxiety disorder, and additionally appeared to have the beneficial effects in chronic pain syndromes shown by amitriptyline and other tricyclics. Duloxetine is now approved for use in diabetic neuropathic pain and fibromyalgia.

Two other second-generation antidepressants were marketed in the USA – nefazodone (*Serzone*) and ▶ mirtazapine (*Remeron*). Nefazodone is somewhat similar to trazodone but less antihistaminic. Its principle effect is postsynaptic at the 5-HT_2 receptor and in theory, this should have reduced side effects. While it had little effect on weight or sexual function, cases of fatal hepatic failure led to decreased use of the drug. Mirtazapine has a different mechanism of action. As the result of antagonism of $alpha_2$ adrenergic receptors, levels of serotonin and norepinephrine increase. The agent also antagonizes 5-HT_2 receptors and 5-HT_3 receptors, and is antihistaminic.

Mechanism of Action

The principal mechanism of action of most antidepressants involves the blockade of serotonin and norepinephrine at the presynaptic neuron in the brain (Charney et al. 1991). This increases the availability of these neurotransmitters at the synapse, the junction at which one neuron communicates with another. In response to the increase in these neurotransmitters, autoreceptors on the presynaptic neuron turn down the firing rate of those cells and less neurotransmitter is released. During a few weeks of treatment, these autoreceptors are desensitized and the firing rate returns to its tonic rate. At this point, neurotransmission is increased. While the feedback mechanisms in the norepinephrine system are less well understood, the net effects are similar. These delayed effects that occur over time are thought to be more consistent with the timing of symptomatic change during the treatment of depression. The confirmation of a central role for serotonin and norepinephrine in the mechanism of action of several agents came from studies depleting serotonin or norepinephrine (Delgado et al. 1993). In depressed patients who had responded to a serotonin antidepressant, the blockade of serotonin synthesis with ▶ tryptophan depletion resulted in relapse. Similar effects were noted in patients taking a norepinephrine antidepressant if NE was blocked with AMPT (alpha-methyl-para-tyrosine). ▶ Clomipramine, amitriptyline, imipramine, doxepin, venlafaxine, desmethylvenlafaxine, and duloxetine all block the uptake of serotonin and norepinephrine with varying potency. In some cases (clomipramine, amitriptyline, imipramine), the parent compound has a greater effect on serotonin uptake and the metabolite on norepinephrine. Mirtazapine also increases 5-HT and NE

concentrations, but through a different mechanism – the blockade of alpha$_2$ adrenergic receptors. Trazodone, nefazodone, mirtazapine, and some tricyclic antidepressants (amitriptyline and nortriptyline) are also 5-HT$_2$ receptor antagonists. This receptor acts in opposition to the primary serotonin receptor (5-HT$_1$), so that antagonism at the 5-HT$_2$ receptor enhances the effects of serotonin. Clinically this appears to benefit sleep and may help reduce anxiety. Bupropion appears to have a different mechanism, blocking the uptake of dopamine and norepinephrine. Both the parent drug and its metabolite, hydroxybupropion, participate in these effects.

The antidepressants also have other effects that have been thought to contribute to side effects. The tricyclics have ► anticholinergic side effects, which can contribute to dry mouth, blurred vision, constipation, and urinary hesitancy. These effects can also impair cognition and in older patients can cause delirium. Amitriptyline is the most anticholinergic of the antidepressants. The tricyclics, trazodone, and mirtazapine are antihistaminic. These effects can contribute to sedation and weight gain. Mirtazapine is the most antihistaminic antidepressant followed, by doxepin. Alpha$_1$ adrenergic effects contribute to orthostatic hypotension, the most common side effect of the tricyclic antidepressants that limits treatment. The tricyclic antidepressants also have effects on sodium channels, which prolong cardiac conduction. In most patients, this is not a problem. However, in patients who already have delayed conduction, this effect can result in heart block. This effect increases at the high plasma concentrations that are frequently achieved with overdose and is the primary reason for death with overdose.

Recently, interest in the neuroprotective effects of antidepressants has emerged (Schmidt and Duman 2007). A number of converging lines of evidence suggest this mechanism may be involved in the treatment of depression. It has been demonstrated in animals that repeated or chronic exposure to cortisol damages the hippocampus. Cortisol levels are elevated in some depressed patients. Brain imaging studies in depressed human subjects show evidence of smaller hippocampal volumes, and one study found the duration of untreated depression was correlated with smaller hippocampal volumes. A particularly intriguing finding is that antidepressants increase neuroprotective factors, such as ► brain derived neurotrophic factor (BDNF), and that antidepressant treatment regenerates nerve cell growth in the dentate gryus of the ► hippocampus. These findings suggest a role for ► neuroprotection in the action of antidepressants. It is unclear currently if these effects are involved in acute treatment response or if these effects become more important during chronic treatment. All antidepressants share this effect, so it would not explain differences among them. Some agents that are not antidepressants have these effects. This theoretical model does not appear as useful for predicting some of the synergistic effects of medication combinations as have the older synaptic transmission models.

Animal Models

There are no adequate animal models for depression. None of the animal models adequately account for all of the symptoms seen in human subjects, especially the psychological symptoms. As a result, it is not possible to use animal models to develop a comprehensive understanding of the neurobiology of depression. There are animal assay models that test certain properties of antidepressant drugs. There are also "homologous" models in which animals display behaviors that are somewhat similar to those observed in depressed subjects. These models include the reduction in motor activity induced by ► reserpine, the swim test immobility model, the syndrome in monkeys induced by isolation and separation, and the uncontrolled foot shock model (also known as the ► learned helplessness model). The chronic stress models may come closest to mimicking the physiology of depression. Recently gene "knock-out" models, usually in mice, have been used to explore the effects of specific genes on behaviors seen in depression and then test the effects of drugs on these behaviors. Selective breeding has been used to develop strains of animals with specific behaviors. While these models have aided drug development, insofar as they provide a model of what existing antidepressants do, ironically they may lead to development of drugs with profiles similar to older agents rather than to truly novel agents.

► Pharmacokinetics

All of the antidepressants described here are cleared from the body by hepatic metabolism. Various enzymes in the cytochrome P450 system in the liver participate in this process. Polymorphisms (genetic variants) of certain genes that control these enzymes can result in widely variable plasma concentrations of drugs given at the same dose. Individuals deficient in certain enzymes can develop dangerously high plasma concentrations of the drug. Alternatively, a few individuals may be "ultra fast" metabolizers and have very low, ineffective plasma levels at usual doses. Because side effects were common and limited dosing of the tricyclics, blood level monitoring was sometimes employed to achieve adequate levels without exceeding safe concentrations. With the second-generation agents, improved tolerability allowed these agents to be given at

doses high enough to be effective in most individuals and blood level monitoring is seldom employed.

► Cytochrome P450 enzymes are important for understanding drug interactions (Nemeroff et al. 1996). Drug that block the enzymes are known as inhibitors. Drugs that speed up the enzymes are inducers. Enzyme induction results from the production of more enzymes and takes 2–3 weeks. The 1A2 pathway is induced by nicotine. The 3A4 pathway is induced by ► carbamazepine, ► barbiturates, ► phenytoin, and St. John's Wort. Enzyme inhibition occurs within days and is more common. Some antidepressants are potent enzyme inhibitors. Fluvoxamine inhibits the 1A2 pathway as well as 2C9 and 2C19, fluoxetine inhibits 2D6 and the 2C family, and paroxetine inhibits 2D6, as does bupropion and duloxetine. Nefazodone inhibits the 3A4 pathway.

During metabolism, active metabolites may be produced. Their effects may differ from the parent compound. The tertiary tricyclic agents are metabolized to secondary amines (e.g., desipramine, nortriptyline, and desmethylclomipramine). The secondary amines tend to be more potent NE uptake blockers, while their parent compounds have greater effects on 5-HT. The hydroxy-metabolite of bupropion is selective for NE uptake blockade, while bupropion itself has greater effects on dopamine. The net effect of the drug, then, depends on the relative concentrations of the parent and metabolites. Among the SSRIs, fluoxetine is noteworthy for its active metabolite norfluoxetine. This metabolite has activity similar to the parent but a much longer half-life of 5–7 days. The metabolite of venlafaxine has a longer half-life than the parent and extends the action of the compound. Nefazodone has perhaps the most complicated array of three active metabolites with different effects and different half-lives.

The antidepressants are widely distributed in the body. In order to cross the ► blood–brain barrier, they are lipophilic (fat soluble). This property makes them less soluble in plasma and they are carried in the blood stream attached to plasma proteins. In most cases, they are highly bound to these proteins. Venlafaxine is an exception and protein binding is lower. As the result of hepatic metabolism, most of these compounds are conjugated to inactive substances and excreted by the kidney.

The hepatic clearance of the antidepressants is variable. Ideally, drugs with a half-life of about 24 h can easily be given once a day. Some agents such as bupropion, which has a half-life of 16 h, were initially given several times a day. Extended-release preparations allowed for less frequent dosing. As mentioned earlier, the half-lives of fluoxetine and its metabolite were considerably longer than those of the other SSRIs. This helped to reduce the effect of occasional missed doses, and at one point, the manufacturer marketed a once weekly formulation of the drug. The long half-life also resulted in a gradual decline in the plasma level, which helped to minimize discontinuation symptoms. On the other hand, the long half-life required a longer washout period – about 5 weeks – before most of the drug was out of the body.

The MAOI agents have a different pharmacology. The older compounds had irreversible effects, inactivating monoamine oxidase enzymes. As a result, the duration of their effects was unrelated to the duration of their plasma concentrations; instead, effects persisted until new MAO enzyme was produced. Usually it would take 2 weeks after stopping an MAOI for enzyme levels to return to normal. ► Moclobemide, an MAOI not marketed in the USA, is a reversible MAOI. The advantage of this compound is that foods containing tyramine do not need to be restricted in the diet. The recent ► selegiline transdermal system allows for cutaneous absorption. As a result, the drug has less effect on MAO enzymes in the gut, so at lower doses dietary restrictions are not required.

Efficacy

Antidepressants are effective in the treatment of depression, several pain syndromes, anxiety disorders, ADHD, and smoking cessation. One of the largest recent reviews of antidepressants in major depressive disorder found 182 controlled trials conducted in over 36,000 individuals (Papakostas and Fava 2009). The mean pooled response rate was 54% with drug treatment and 37% with placebo, and the difference was highly significant. This translates into an estimated number need to treat of about six, which is considered clinically meaningful. Recently it has been suggested that the published literature may overestimate efficacy because negative studies are less likely to be published; however, there is little question that these drugs are effective, and analyses of all trials reported to the FDA, published or not, have been preformed. The difference between drug and placebo is greater in more severely depressed individuals and greater if the likelihood of receiving placebo is higher. There also appears to be recent a trend toward higher placebo response rates and smaller drug-placebo differences.

Antidepressants are also effective in chronic major depressive disorder and dysthymia. Their efficacy as monotherapy in psychotic depression appears to be reduced, but they are often given with ► antipsychotics. In bipolar I disorder, antidepressants can induce mania and may aggravate rapid cycling; most guidelines recommend avoiding their use or giving them only with mood stabilizers.

In addition to being effective for the acute treatment of depression, antidepressants reduce relapse and recurrence in depression. This is particularly important because depression is usually a recurrent illness. A meta-analysis of 31 randomized controlled trials in major depressive disorder found that drug treatment reduced relapse and recurrence rates by 70% (Geddes et al. 2003). In fact, this appears to be the most potent and well replicated effect of antidepressant agents, although it is noted that this effect is demonstrated in individuals who have had an acute response to the same agent.

An area of considerable interest is whether one antidepressant or a class of antidepressants is more effective than another. A specific question raised by the widespread use of SSRI agents is whether they were as effective as the tricyclics. A review of over 100 comparison trials found comparable efficacy except for a small number of studies in inpatients (Anderson 2000). Two studies by the Danish University Group found the tricyclic clomipramine more effective than the SSRIs citalopram and paroxetine. Clomipramine has effects on both NE and 5-HT. Recently, it has been suggested that other dual action ► SNRIs (serotonin-norepinephrine reuptake inhibitors) might also be more effective. Reviews of venlafaxine and duloxetine studies found some evidence to support this; however, the largest meta-analysis of 93 trials of dual action drugs found that while the difference was statistically significant, it was sufficiently small to be of doubtful clinical importance. Another question of great interest is whether there are predictors of response to one agent or another. In the pre-SSRI era, the MAOIs were found to be superior to tricyclics in ► atypical depression, a syndrome in which mood is reactive to current events and sleep and appetite are increased. However, the second-generation antidepressants do not appear to differ in efficacy in this syndrome. Few prospective trials of symptom predictors have been performed and there is no well-established pattern of symptoms that predicts response to a particular drug class. Investigators have also examined if there are biological differences that might predict response in depression to a particular drug class. Recently, this exploration has shifted to looking for genetic predictors. To date, no reliable biologic predictor has been identified.

Uses in Other Disorders

Antidepressants, tricyclics in particular, have been extensively studied in chronic pain syndromes. Evidence suggests the magnitude of the effect (effect size) may be larger in pain than depression. It appears that dual action NE – 5-HT drugs are most effective, followed by NE uptake inhibitors, with SSRIs least effective for chronic pain. Duloxetine is the first antidepressant approved by the FDA for use in diabetic neuropathic pain and fibromyalgia.

Although imipramine was the first antidepressant shown to be effective for panic disorder and generalized anxiety disorder, it was never approved for use in these conditions. Clomipramine was shown to be effective in OCD and has that indication in the USA. The SSRIs are the first class with FDA approval in a variety of anxiety disorders including panic disorder, OCD, PTSD, social anxiety disorder, and generalized anxiety disorder. Not all SSRIs are approved for use in each disorder but it appears likely this is a class effect. Sertraline and paroxetine are approved for panic disorder, PTSD, and SAD. Paroxetine and escitalopram are approved for generalized anxiety disorder. Four of the SSRIs are approved for use in OCD and this is the only indication for use in the USA for fluvoxamine. Fluoxetine is approved for use in bulimia. Fluoxetine and sertraline are approved for use in premenstrual dysphoric disorder. Venlafaxine and duloxetine are both approved for use in generalized anxiety disorder. It appears that agents that block 5-HT uptake, whether they are SSRIs or SNRIs, have efficacy across a spectrum of anxiety disorders. Among these serotonergic agents, differences in the indications that are approved appear to reflect marketing decisions more than real differences in efficacy; however, without controlled trials this supposition is unconfirmed.

Bupropion is approved for use in smoking cessation under the brand name Zyban. The tricyclic norepinephrine reuptake inhibitor desipramine was previously commonly used in treating childhood ADHD but cases of sudden death in children under 12 years led to a rapid decline in use. ► Atomoxetine, a more selective NE uptake inhibitor, is approved for use in ADHD. Bupropion in controlled studies appeared to be effective in adult ADHD but does not have FDA approval for that indication.

Safety and Tolerability

The tricyclic antidepressants have a variety of tolerability issues related to their anticholinergic, antihistaminic, and alpha-1 blocking properties (Richelson and Nelson 1984). Patients often experienced dry mouth, increased heart rate, and light-headedness on standing, and sometimes sedation, urinary hesitancy, and constipation. It was uncommon for a patient on a tricyclic not to notice at least one side effect. The tricyclics delayed ventricular conduction (Glassman et al. 1993). In vulnerable individuals, at high plasma levels or after overdose, this could cause heart block. Seizures also occurred with the tricyclics, and risk was higher in vulnerable individuals, at high plasma levels, or after overdose. The tricyclics could be fatal in

overdose with as little as a 10-day supply of the drug. For many years, amitriptyline was the second leading cause of death by overdose with a single agent in the USA, after acetaminophen.

The MAOIs could also cause hypotension at therapeutic doses. The main concern with this class was the possibility of a hypertensive crisis or ▶ serotonin syndrome. A hypertensive crisis could occur when a patient on an MAOI ingested foods rich in tyramine or other drugs with sympathomimetic properties. The hypertensive crisis could result in a stroke. As a result, patients taking a MAOI needed to follow a diet low in tyramine and avoid certain drugs. These risks appeared reduced with the reversible MAOI meclobemide. The selegiline transdermal system (patch), because it is absorbed through the skin, has less effect on MAO enzyme in the gut, and at a dose of 6 mg/24 h does not require a tyramine restricted diet. Serotonin syndrome can occur in patients on an MAOI who ingest an SSRI or meperidine. Serotonin syndrome is characterized by confusion, fever, restlessness, myoclonus, hyperreflexia, diaphoresis, hypomania, shivering, and tremor, and can be fatal. It is thought to be caused by the excessive activation of 5-HT_{1A} receptors. The severity of these risks and the need to restrict diet and other drugs limited the use of the MAOIs.

The second-generation agents are substantially safer than the TCAs and MAOIs. They are less likely to be fatal in overdose. They do not prolong the electrocardiographic QTc interval. With the exception of bupropion, the risk of seizures is low. Perhaps the biggest difference, however, is tolerability. While few studies have assessed overall side effect burden, relatively more patients on a second-generation agent can take the drug without experiencing disruptive side effects during chronic dosing. When starting an SSRI, patients can experience nausea and some patients experience restlessness. Both are dose-related and usually transient. With long-term treatment, some patients experience sexual dysfunction or weight gain. The acute and long-term side effects of the SSRIs were shared by venlafaxine and duloxetine. Venlafaxine is associated with hypertension at high doses, e.g., 300 mg/day. This had also been observed in younger patients on desipramine and may be related to norepinephrine effects. Other uncommon events can occur. SSRIs block the uptake of serotonin into the platelet and affect platelet function. This can increase the risk of bleeding, with a risk similar to that of taking one aspirin a day. SSRIs have also recently been reported to increase bone demineralization and increase the risk of nontraumatic fractures. Although not well studied, the SNRIs, having similar effects on 5-HT uptake, would be expected to have similar risks.

Bupropion has a different side-effect profile. The most common side effects are agitation, insomnia, sweating, dry mouth, constipation, and tremor. Of the antidepressants, it is least likely to cause sedation or sexual dysfunction and is either weight-neutral or associated with weight loss. The most serious safety issue is seizures. The risk is dose related and similar to the tricyclics. This risk led to the recommendation not to exceed 450 mg/day. Seizure risk is reduced with delayed-release formulations that are associated with lower peak levels.

Mirtazapine, because of its antihistaminic properties, is the antidepressant most likely to cause sedation during initial treatment. Tolerance usually develops. Because the antihistaminic effect occurs at low doses and the alpha-2 adrenergic antagonism (which may be alerting or activating) occurs at higher doses, it was suggested that paradoxically the drug might become less sedating at higher doses. The antihistaminic effect also contributes to increased appetite and weight gain in some patients. This tends to limit the use of the agent in younger patients, but can be an advantage in older depressed patients.

Definition

Antidepressants are drugs used to treat depression, although many have been studied in and are used to treat a wide variety of conditions, including anxiety disorders, pain disorders, and others.

Pharmacological Properties

History

Since the serendipitous discovery of the ▶ antidepressant effects of tricyclics in the 1950s, depression has generally been treated by agents that boost the synaptic actions of one or more of the three ▶ monoamines (serotonin (5HT), ▶ norepinephrine (NE), and ▶ dopamine (DA)). Acutely enhanced synaptic levels of monoamines could lead to adaptive downregulation and desensitization of postsynaptic receptors over time, a pharmacological action consistent with current ▶ aminergic hypotheses of depression, which posit that the disorder may be due to the pathological upregulation of neurotransmitter receptors (Stahl 2008a). Thus, antidepressants theoretically reverse this pathological upregulation of receptors over time. Adaptive changes in receptor number or sensitivity are likely the result of alterations in ▶ gene expression and transcription. This may include not only turning off the synthesis of neurotransmitter receptors but also increasing the synthesis of various ▶ neurotrophic factors such as ▶ brain-derived neurotrophic factor (BDNF). In fact, preclinical studies demonstrate that antidepressants increase BDNF expression (Duman et al. 2001). Such prototrophic actions may apply broadly to all effective antidepressants and may provide a final common pathway for the action of antidepressants.

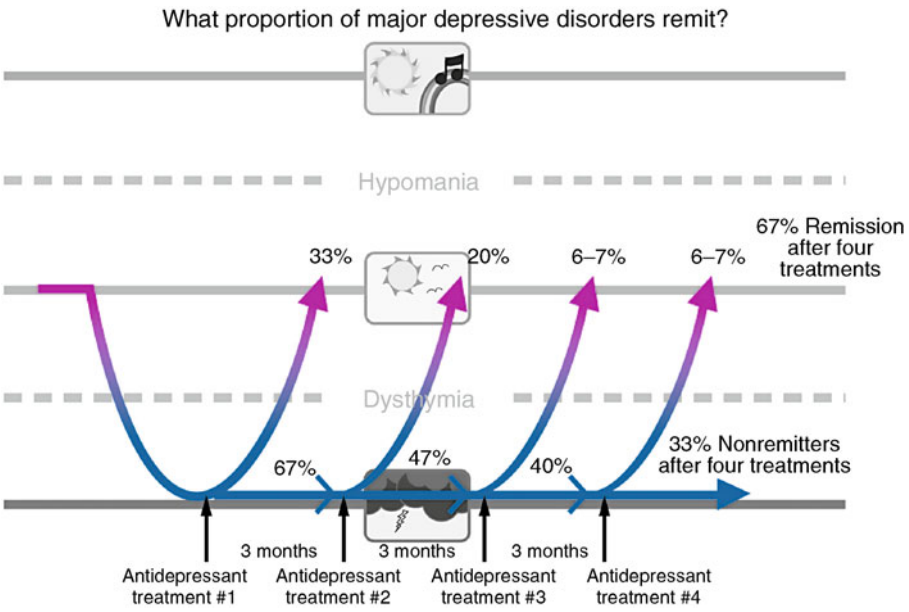
Although treatment with currently available antidepressants is effective for many patients, a large proportion experience residual symptoms, treatment resistance, and relapse. In the recent STAR*D (Sequenced Treatment Alternatives to Relieve Depression) study (Warden et al. 2007), only one-third of the patients on monotherapy with ▶ citalopram remitted initially. For those who failed to remit, the likelihood of ▶ remission with another antidepressant monotherapy decreased with each successive trial. Thus, after a year of treatment with four sequential antidepressants taken for 12 weeks each, only two-thirds of patients achieved remission (Fig. 1). Of additional concern is the fact that the likelihood of relapse increased with the number of treatments it took to get the patient to remit.

These results highlight the need for the continued exploration of more effective methods to treat major depression. A plethora of treatments are either under investigation or newly available for major depressive disorder, including new formulations of current antidepressants, new and existing agents that exploit the monoaminergic link to depression, and experimental agents with novel mechanisms of action.

New Twists on Old Drugs

One developmental focus for antidepressants is to improve the tolerability of existing agents. A recently approved hydrobromide salt formulation of ▶ bupropion allows the administration of single-pill doses up to 450 mg equivalency to bupropion hydrochloride salt, unlike bupropion hydrochloride controlled release formulations for which the biggest dose in a single pill is 300 mg. This could facilitate dosing for difficult-to-treat patients.

In addition, approval is pending for a once-daily controlled release formulation of ▶ trazodone that allows



Antidepressants: Recent Developments. Fig. 1. Remission rates in major depressive disorder with sequential monotherapies.

much more tolerable administration of high antidepressant doses (e.g., 300–450 mg). This may increase the utility of trazodone in depression, as the immediate release formulation is often not tolerated at high antidepressant doses due to its propensity to cause severe next-day sedation, and is used instead at low doses as a hypnotic.

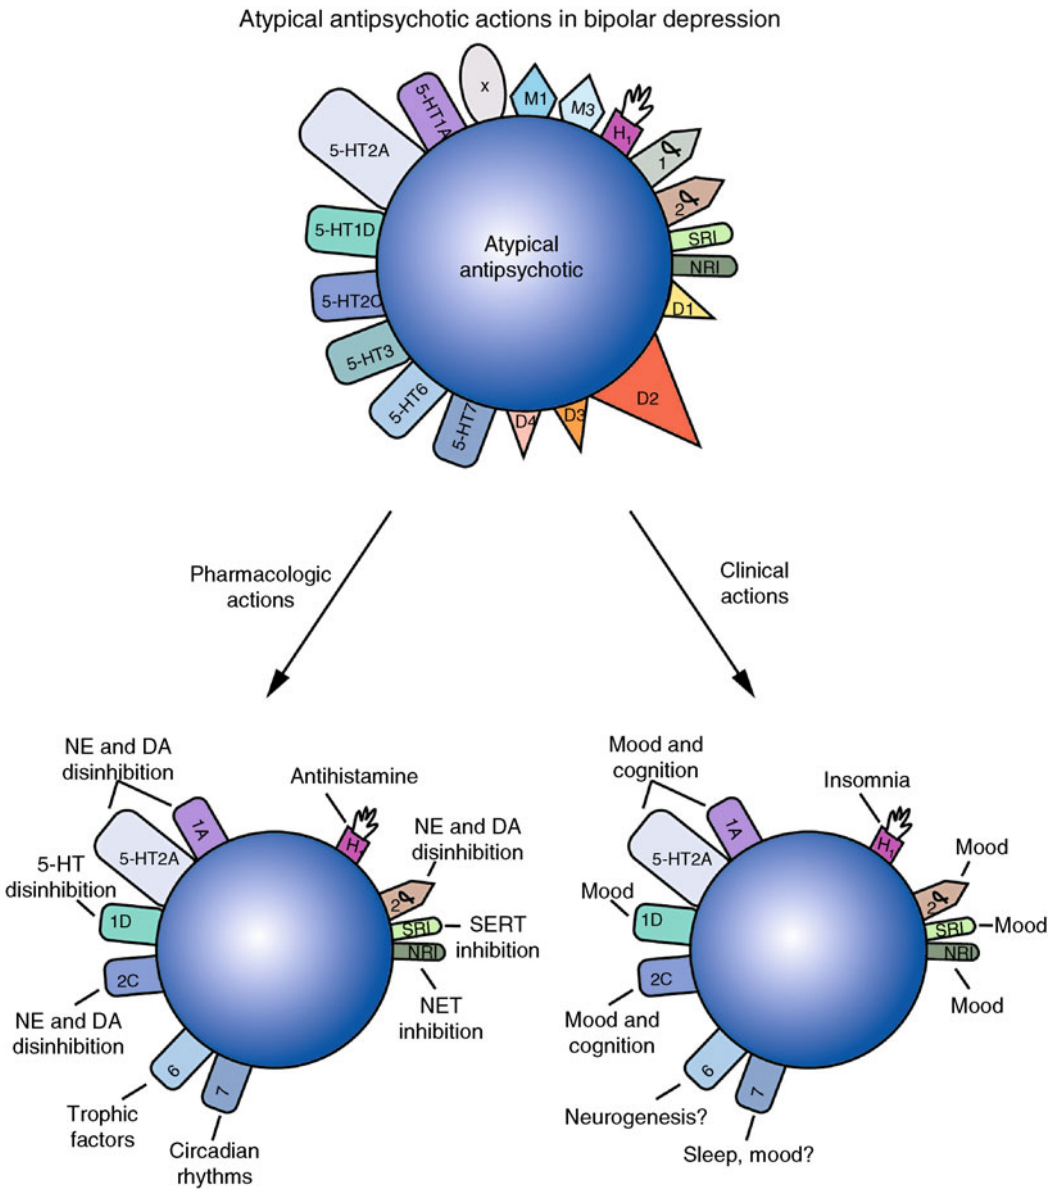
Another twist on an old drug is the availability of ► desvenlafaxine, the active metabolite of ► venlafaxine, as a unique antidepressant agent. Desvenlafaxine is formed as the result of CYP450 2D6 and thus itself bypasses this metabolic step, potentially giving it more consistent plasma levels than venlafaxine (Stahl 2009). In addition, although desvenlafaxine, like venlafaxine, is more potent at the 5HT ► transporter (SERT) than the NE transporter (NET), it has relatively greater actions on NET versus SERT than venlafaxine does at comparable doses. This greater potency for NET may make it a preferable agent for symptoms theoretically associated with NE actions, such as pain symptoms and vasomotor symptoms. In fact, desvenlafaxine was shown to be efficacious for hot flushes in perimenopausal women (Stahl 2008a; Wise et al. 2008), although it was not approved for this use due to cardiovascular safety concerns.

New Means of Monoaminergic Modulation

Atypical Antipsychotic Drugs

Currently, atypical ► antipsychotic drugs are used to treat ► bipolar disorder, with similar efficacy to each other in the manic phase but varying efficacy in treating the depressed phase. Several mechanisms are feasible explanations for how certain atypical antipsychotic drugs may work to improve symptoms in the depressed phase of bipolar disorder (Stahl 2008a). Actions at numerous receptors by different atypical antipsychotic drugs can increase the availability of 5HT, DA, and NE, which, as discussed earlier, are critical in the action of current antidepressants in unipolar depression (Fig. 2). Specifically, actions at $5HT_{2A}$, $5HT_{2C}$, and $5HT_{1A}$ receptors indirectly lead to NE and DA disinhibition, which may improve mood and cognition. Mood may also be improved by increasing NE and 5HT via actions at alpha 2 adrenergic receptors, by increasing NE via the blockade of the NE transporter, and by increasing 5HT via actions at $5HT_{1D}$ receptors and the blockade of the 5HT transporter. Antihistamine actions could improve insomnia associated with depression. Actions at other 5HT receptors may also play a role in treating depression.

Each atypical antipsychotic has a unique portfolio of pharmacological actions that may contribute to its antidepressant actions (Fig. 3). This may explain why these agents differ in their ability to treat the depressed phase of ► bipolar disorder and also why some patients respond to one of these drugs and not to another. The agent with the most evidence of efficacy as a monotherapy for bipolar depression is ► quetiapine, which was recently approved for this indication. The effective dose of quetiapine in bipolar depression is 300–600 mg/day, lower than



Antidepressants: Recent Developments. Fig. 2. Pharmacologic properties of atypical ► antipsychotic drugs and their links to symptoms of depression.

that needed for the saturation of the D2 receptor but sufficient to cause $5HT_{2C}$ antagonism, $5HT_{1A}$ agonism, and norepinephrine reuptake inhibition, especially through the newly discovered pharmacologic actions of its active metabolite norquetiapine (Stahl, 2008a, 2009). This lends further weight to the speculative mechanisms described earlier for antidepressant action of atypical antipsychotic drugs.

Whether atypical antipsychotic drugs will be proven effective with a sufficiently favorable side effect and cost profile for unipolar depression is still under intense investigation (Papakostas et al. 2007). ► Aripiprazole was recently approved as an adjunct treatment for resistant depression (defined as failing one SSRI/SNRI trial). At its effective dose in depression – 2–10 mg/day, lower than that used for ► schizophrenia – aripiprazole is

primarily a D2 and D3 ► partial agonist with only weak $5HT_{2A}$ ► antagonist and $5HT_{1A}$ partial agonist properties (Stahl 2008b).

Triple Reuptake Inhibitors (TRIs)

These drugs are testing the idea that if one mechanism is good (i.e., selective serotonin reuptake inhibitors or SSRIs [► SSRIs and related compounds]) and two mechanisms are better (i.e., serotonin and norepinephrine reuptake inhibitors or ► SNRI antidepressants), then maybe targeting all three mechanisms of the trimonoamine neurotransmitter system would be the best in terms of efficacy. Several different triple reuptake inhibitors (or serotonin–norepinephrine–dopamine reuptake inhibitors) are listed in Table 1 (Stahl 2008a). Some of these agents have additional pharmacological properties as well. In particular, LuAA 24530, currently in clinical trials, is not only a TRI but also binds 5HT2C, 5HT2A, 5HT3, and alpha 1A adrenergic receptors. The question regarding TRIs is how much blockade of each monoamine transporter is desired, especially for the dopamine transporter or DAT. Too much dopamine activity can lead to a drug

of abuse, while not enough means that the agent is essentially an SNRI. Perhaps the desirable profile is the robust inhibition of SERT and the substantial inhibition of NET, like the known SNRIs, plus the addition of 10–25% inhibition of DAT. Some testing suggests that dopamine reuptake inhibition also increases acetylcholine release, so TRIs may modulate a fourth neurotransmitter system and act as multitransmitter modulators (Stahl 2008a). Further testing will determine whether TRIs will represent an advance over SSRIs or SNRIs in the treatment of depression.

Novel Serotonin Targets (Serotonin Agonists and Antagonists)

A large number of novel serotonin targets are in testing and are listed in Table 2 (Stahl 2008a). One particularly interesting novel serotonin target is the $5HT_{2C}$ receptor. Blockade of $5HT_{2C}$ receptors causes the release of both norepinephrine and dopamine, which is why these agents can be called norepinephrine dopamine disinhibitors (NDDIs). The novel antidepressant ► agomelatine combines this property of $5HT_{2C}$ antagonism with additional agonist actions at ► melatonin receptors (MT1 and

MT2). Agomelatine also has $5HT_{2B}$ antagonist properties. This portfolio of pharmacological actions predicts not only antidepressant actions due to the NDDI mechanism of 5HT2C antagonism but also sleep-enhancing properties due to MT1 and MT2 agonist actions. Positive trials of agomelatine have been completed in the USA, and it is now approved in Europe with liver function monitoring required.

Another novel serotonergic agent is LuAA21004, currently in clinical trials. This agent is a serotonin reuptake inhibitor and also an antagonist at $5HT_3$ receptors, with additional actions at $5HT_{1A}$ receptors.

Novel Targets and Mechanisms

An interesting development is the potential utility of L-5-methyl-tetrahydrofolate (MTHF) as an adjunct treatment for depression. MTHF is a key derivative of ▶ folate and plays a critical role in monoamine synthesis; thus, the administration of MTHF could theoretically boost trimonoamines (Stahl 2008a). Current research specifically suggests that MTHF may be indicated for depressed patients with low folate levels and who have not responded adequately to antidepressants (Fava 2007). Available as a "medical food," MTHF appears to be safe with few side effects, but further research is necessary to determine its ultimate role in depression treatment.

Nonpharmacological developments in the treatment of depression include the approval of ▶ transcranial magnetic stimulation, in which a rapidly alternating current passes through a small coil placed over the scalp to generate a magnetic field that induces an electrical current in the underlying areas of the brain (Avery et al. 2006), and research into ▶ deep brain stimulation, in which a battery-powered pulse generator is implanted in the chest wall with one or two leads tunneled directly into the brain, especially within the subgenual area of the ventromedial prefrontal cortex, to send brief repeated pulses there (Mayberg et al. 2005).

Finally, a large number of agents that act at several other novel targets are in preclinical or early clinical development, and are listed in Table 3 (Stahl 2008a). Many of these agents are low-molecular-weight drugs that target stress hormone release from the hypothalamic–pituitary–adrenal (HPA) axis, while many others are antagonists at neurokinin receptors.

Conclusion

In summary, there are many avenues of pursuit for increasing the effectiveness of antidepressant treatment, including not only building on existing agents and/or existing mechanisms but also exploring new and unique mechanisms and techniques. It remains to be seen which of these will ultimately represent major advances in the treatment of depression.

Antimuscarinic/Anticholinergic Agent

Definition

An anticholinergic drug is one that blocks the physiological action of the neurotransmitter ► acetylcholine in the central and the peripheral nervous system. These drugs are classified according to the receptors that are affected. Most anticholinergics are muscarinic receptor antagonists, that is, agents that reduce the activity of the muscarinic acetylcholine receptor. Others are antinicotinic agents operating on the ► nicotinic receptors. The antimuscarinic drugs are used in the treatment of a variety of medical conditions including Parkinson's disease and antipsychotic-induced parkinsonism.

Antinociception

Definition

Antinociception refers to the reversal or alteration of the sensory aspects of pain intensity. Most models for examining antinociception were developed for use in animals in order to explore alterations in sensitivity to a painful stimulus following the administration of a drug with potential analgesic (pain-relieving) properties. The term is usually used to avoid the anthropomorphic connotation of the term analgesia, which strictly means reversal of the subjective sensation of pain, the presence of which can only be inferred in animals.

Analgesia tests

Definition

Antinociceptive tests encompass a large group of experimental procedures specifically developed for examining sensitivity to painful stimuli and the alteration of pain sensitivity following drug administration. Since most antinociceptive tests have been designed for examining pain sensitivity in animals, they provide limited

information about the affective aspects of pain perception such as discomfort or unpleasantness. These characteristics are more likely to be examined in studies with human subjects.

Principles and Role in Psychopharmacology

A number of procedures have been developed for examining the pain-relieving (i.e., ► analgesic) properties of drugs in laboratory animals. Each of these procedures involves the presentation of a potentially painful (or ► nociceptive) stimulus, followed by the measurement of a clearly observable response. Typically, data are based on the time it takes the organism to respond to or withdraw from a nociceptive stimulus. Once baseline levels of responding in response to the nocicepetive stimulus are determined and considered reliable, a drug is administered, and response latencies are then redetermined in the presence of the drug. If the time it takes the organism to respond to the stimulus is longer following drug administration, and importantly, if this change is not because the animal is unable to make the response due to the sedative or motor effects of the drug, then the drug is said to produce antinociceptive effects.

Although this experimental paradigm appears relatively simple and straightforward, it becomes far more complex when one considers the multiple variables that influence the data that can be obtained with these procedures. For example, the type of nociceptive stimulus (e.g., thermal, mechanical, electrical, or chemical), its intensity, and the duration and outcome of its effect determine the drug-induced alterations in response latency, and therefore, these must be quantified very precisely. Similarly, the nature of the response itself – whether it involves an elementary reflex response or a more integrated escape or ► avoidance response – can influence the interpretation of a drug's effect. Antinociceptive tests also attempt to differentiate nonspecific response alterations from those that are specific to the nociceptive stimulus. This is particularly important in the assessment of drug-induced alterations in response to the nociceptive stimulus since a drug may produce motor effects that interfere with the ability of the organism to execute a particular response. A more extensive discussion of these issues can be found in a classic review by Beecher (1957) and a recent review by Le Bars et al. (2001). For the discussion of parallel issues related to pain assessment in humans, see Turk and Melzack (2001).

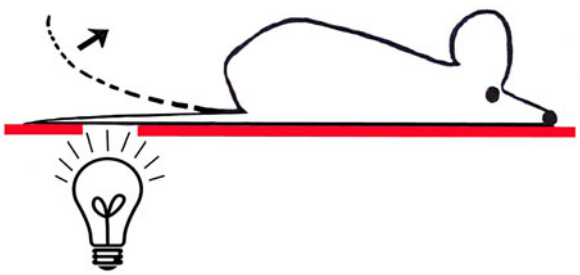
Although antinociceptive procedures vary in many ways, it is convenient to place them in one of two larger groups – those that involve acute pain and those that involve more persistent pain as might occur with tissue injury or nerve damage.

Models of Acute (or Phasic) Pain in Animals

In general, antinociceptive tests for examining acute pain involve the presentation of a brief thermal, mechanical, or electrical stimulus that is delivered to the skin, paws, or tail of an animal. One of the most common procedures in this category is the *tail-flick procedure,* originally developed by D'Amour and Smith (1941). In this procedure, a high intensity light is focused on an area close to the tip of the tail as shown for a mouse in Fig. 1, and the time (response latency) taken by the mouse to remove (i.e., flick) its tail from the light source is determined. The light intensity can be adjusted to yield baseline response latencies that are relatively short (i.e., between 3 and 5 s) or long (i.e., between 8 and 10 s).

Typically, the time taken by the mouse to remove its tail from the heat source is measured prior to the drug administration to determine baselines response latencies. After baseline latencies have been determined, drug administration takes place, and tail flick latencies are determined either once or multiple times over a set time period. However, caution has to be taken with repeated measurements, as the tail-flick response is prone to ► habituation. The tail flick response is easy to observe, and it is considered to involve simple spinal reflexes. It can be measured either with a stopwatch or through a system that uses photocells to determine when the tail has been removed from the light source. ► Opioid analgesics such as ► morphine are very active in this procedure, though their effects depend on the intensity of the thermal stimulus. For example, if the light intensity is very high and elicits short tail flick latencies, a higher dose of morphine is usually required to alter the tail flick latency than when the light is set at a lower intensity.

One very important characteristic of the tail flick procedure, and almost all other acute antinociceptive procedures, is the use of a cutoff time to prevent tissue damage. The *cutoff time* is defined as the maximal time



Antinociception Test Methods. Fig. 1. This figure provides a simple schematic of the tail-flick procedure, showing the position of the mouse's tail over a light source.

that an animal is exposed to the nociceptive stimulus. For example, if a high intensity light is used in the tail flick procedure and the animal (e.g., a mouse) does not remove its tail from the light source within 10 s (cutoff time), the mouse is removed from the apparatus by the experimenter. The cutoff time also influences certain aspects of the data analysis since it is one of the variables in the formula commonly used to quantify antinociceptive drug effects.

A drug's effect in the tail flick procedure is usually quantified by determining the difference between the response latency obtained under baseline conditions and response latency obtained after drug administration. This difference is then divided by the difference between the cutoff time and the baseline latency and a *percent maximal effect (%MPE)* is derived from these measures.

$$\%\text{MPE} = \frac{\text{latency (s) following drug administration} - \text{latency (s) under baseline conditions}}{\text{cutoff time(s)} - \text{latency (s) under baseline conditions}}$$

Since baseline latencies vary between animals, this formula accommodates individual differences in response to the nociceptive stimulus.

The *tail-withdrawal test* (Janssen et al. 1963) is a modification of the tail-flick test. In this procedure, mice or rats are gently restrained, and their tail is placed into a water bath maintained at temperatures between 48° and 56°C. Some investigators have also used cold water as the painful stimulus, although this is less common. Latency to remove the tail from the water is measured, much in the same way as in the tail flick procedure, and data are usually described with the percent maximal effect formula described for the tail flick procedure.

The *tail-withdrawal test* has also been used in primates and the procedure parallels those used in rodents. In this procedure, a monkey is placed in a restraint chair and the lower portion of their tail is immersed in water maintained at a specific temperature (40, 50, or 55°C). The latency to remove the tail from the water is then determined. Typically, monkeys do not remove their tails from 40°C water; however, response latencies might average 10 s when the water is 50°C and 5 s or less when the water is 54°C (Dykstra and Woods 1986). If the monkey does not remove its tail from the water within the predetermined cutoff time (e.g., 20 s), the tail is removed by the experimenter and the latency assigned a value of 20 s (cutoff time). Investigators have shown that reliable data can be obtained with this procedure and tail withdrawal responses can be measured every 15–30 min for periods as long as 3 h.

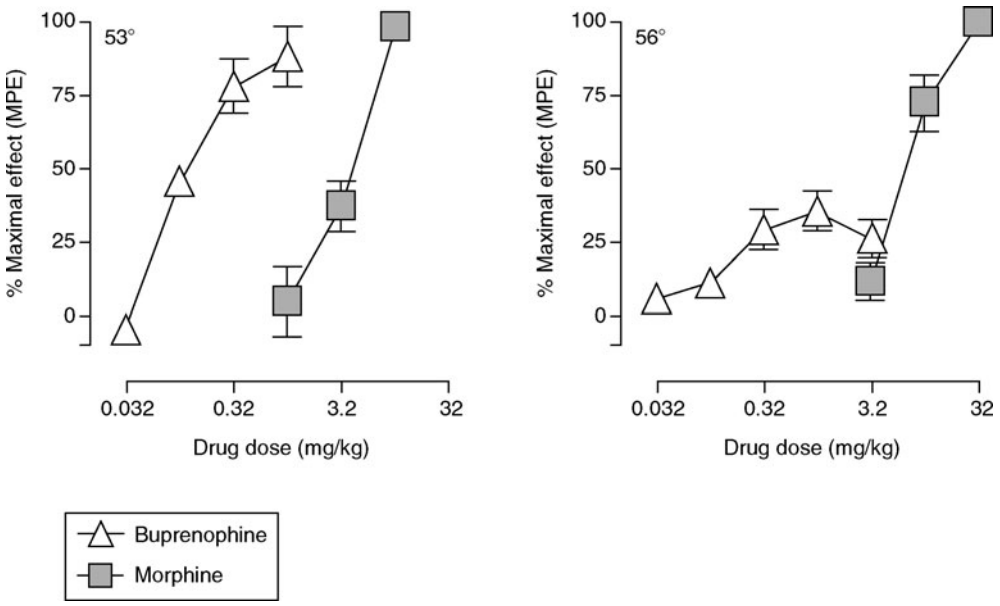
The *hot plate procedure* is another acute antinociceptive test that is commonly used to assess drug effects. In this procedure, an animal (usually a rodent) is placed on a flat surface maintained at a set temperature (e.g., 52–56°C). The baseline nociceptive response to the hot plate is evaluated by recording the latency to lick or shuffle the hind paw(s), or jump from the hotplate surface. Following the determination of baseline response latencies, drug administration is initiated. Figure 2 illustrates data obtained with this procedure. Responses are measured using a stopwatch and a predetermined cutoff time is established to prevent tissue damage. If an animal does not exhibit a nociceptive response after this cutoff period, they are manually removed from the hot plate and assigned a response value equal to the cutoff time.

Figure 2 shows data obtained at two different hot plate temperatures following the administration of two different opioid analgesics, a high efficacy opioid, morphine, and a lower efficacy opioid, ▶ buprenorphine. The left portion of Fig. 2 shows data obtained when the hot plate temperature was 53°C. Under these conditions, both morphine and buprenorphine produced dose-dependent increases in the percent maximal possible effect (%MPE), with morphine producing 100% maximal effect at 10 mg/kg. The right portion of Fig. 2 shows data obtained when the hot plate temperature was 56°C. Under these conditions, a higher dose of morphine was required to produce 100% maximal effect (32 mg/kg), and buprenorphine's effects were markedly attenuated at the higher temperature. (Adapted from Fischer et al. 2008.)

In contrast to the procedures described above, which usually involve assessment of an unlearned response following presentation of an acute stimulus, a few procedures, especially those conducted in primates, involve a period of training. In the titration procedure, monkeys are trained on an avoidance task in which a stimulus such as an electric shock is presented to the monkey's tail (or foot) in increasing intensities. If the monkey makes one or more responses on a lever, the shock is turned off (avoided) for a period of time and the intensity is reduced when the shock resumes again. The intensity at which each monkey maintains the shock is then used as a measure of sensitivity to the potentially painful stimulus. One advantage of this procedure is that the animal, rather than the experimenter determines the level at which the stimulus is maintained. Moreover, responding can be maintained for relatively long periods of time with this procedure, which provides a convenient way to examine onset and termination of a drug effect (Allen and Dykstra 2001).

Models of Persistent (Tonic) or Neuropathic Pain

Antinociceptive test methods that involve persistent or long duration pain typically administer an irritant, which



Antinociception Test Methods. Fig. 2. Antinociceptive effects of several doses of morphine or buprenorphine on a hot plate set either at 53°C (left) or 56°C (right).

produces inflammation, or they induce injury, often by ligation of a nerve such as the sciatic nerve. These procedures often examine multiple aspects of pain sensitivity, including heightened sensitivity to pain (► hyperalgesia) or ► allodynia, a condition in which stimuli that are not normally painful are perceived as painful.

The *abdominal constriction (or writhing)* test is one example of a persistent pain model. In the abdominal constriction test, an irritant is injected directly into the peritoneal cavity of a mouse, resulting in a characteristic writhing response. Although a number of compounds have been used in this assay (acetic acid, acetylcholine, bradykinin, hypertonic saline, phenylquinone, etc.), a solution of 0.6% acetic acid is one of the most commonly used. The onset of inflammation following acetic acid occurs about 5 min after the injection and lasts for approximately 30 min, but has been reported to last for longer periods, depending on the concentration of acetic acid. In order for this assay to produce consistent data, the writhing response must be clearly defined. For example, writhes are often defined as "lengthwise stretches of the torso with a concomitant concave arching of the back" often in combination with a reduction in motor activity and some loss of coordination. Scoring is done by experimenter observations, usually of videotaped experimental sessions. One of the advantages of this procedure is the fact that it is sensitive to weak analgesics such as aspirin and other ► nonsteroidal anti-inflammatory drugs (NSAIDs); however, the lack of specificity in response to drugs without analgesic activity (false positives) sometimes makes interpretation more difficult.

The Formalin test (Dubuisson and Dennis 1977) is one of the most commonly used tests for examining persistent pain. With this test, responses are measured following a subcutaneous injection of a formalin solution into the hind paw. Two spontaneous responses are typically measured with the formalin test, an acute, early phase response and a tonic, inflammatory phase response that occurs somewhat later. These responses are usually scored on a four-level scale, from normal posture to licking, nibbling, and/or shaking of the injected paw. Given the two types of responses elicited by the formalin injection, it is possible to examine both acute pain and tonic pain in the same animal, in response to a single injection of formalin.

Carrageenan, a substance derived from Irish sea moss, is another compound that has been used in persistent pain models as it produces inflammation and consequent hypersensitivity in rodents. In a typical procedure, a 2% suspension of carrageenan is injected subcutaneously into one of the hind paws of a mouse; the opposite hind paw is not injected. This two-paw protocol in which comparisons are made between an inflamed paw and healthy paw was first introduced by Randall and Selitto

(1957) and is now the standard protocol for tests of this nature. Several hours after the carrageenan injection, mice are tested for pain sensitivity and the *Hargreaves' test* is often used for this assessment. To conduct the Hargreaves' test, mice are placed in individual, transparent chambers with a glass floor. After adaptation to the chamber, a high-intensity beam such as a projector bulb is directed at the plantar surface of the mouse's hind paw. Time to withdraw the paw is then measured.

The *von Frey test* of mechanical sensitivity provides another way to examine pain sensitivity in animals that have been treated with irritants or have experienced nerve damage. In this procedure, animals are placed in a transparent box which rests on a metal mesh floor. Von Frey monofilaments (or hairs) are then applied to the foot with a single, steady application. Since each monofilament has a different bending force, experimenters can determine the monofilament that elicits foot withdrawal 50% of the time under baseline conditions, and then following drug administration.

Another procedure that has been used to examine pain sensitivity as well as hyperalgesia and/or allodynia is capsaicin, the pungent ingredient in hot chili peppers. Exposure to capsaicin produces inflammation and allodynia, which is defined as pain that is produced by a stimulus that is not normally painful. A modification of the primate tail withdrawal procedure, using warm water rather than hot water, has been used to examine allodynia following exposure to capsaicin. The monkey is restrained and the distal part of its tail is immersed in water maintained at a comfortable temperature such as 46°C. At this temperature, monkeys usually leave their tails in the water for at least 20 s, which is used as the cutoff time. After baseline latencies are determined, capsaicin is injected above the tip of the tail. Following administration of capsaicin, allodynia develops as revealed by a decrease in tail-withdrawal latencies from 20 s to approximately 2 s. Local administration of an opioid analgesic has been shown to inhibit the allodynia induced by capsaicin under these conditions (Ko et al. 1998).

Advantages and Limitations of Antinociceptive Tests

One clear advantage of most of the antinociceptive procedures described here is that they are relatively easy to perform in animals. As a group, they require very little training time and produce reliable, repeatable, and easily quantified measures of nociception across a range of stimuli. The acute antinociceptive procedures, such as the tail flick and hot plate, are predictive of the effects of morphine-like opioid analgesics, but do not reveal activity for a number of other drugs, including the nonsteroidal anti-inflammatory drugs (NSAIDS). In contract, persistent pain procedures such as the abdominal constriction test, and formalin test, are predictive of the antinociceptive effects of nonsteroidal anti-inflammatory drugs (NSAIDS) as well as morphine-like analgesics. The fact that these procedures can predict the analgesic activity of drugs in humans, certainly verifies their usefulness as animal models. Beyond being predictive of analgesia in humans, investigations using these procedures have also advanced understanding of the multiple variables that influence the processing of nociceptive stimuli as well as the alteration in nociception following administration of different classes of drugs.

Definition

► Parkinson's disease (PD): a syndrome defined in life by clinical criteria involving tremor at rest, rigidity, slowness and paucity of movement, altered posture, gait and balance with the absence of "atypical" features (Lang and Lozano 1998a,b). It is defined at autopsy by strict pathological criteria including the loss of neurons in the pars compacta of the substantia nigra, locus ceruleus and dorsal motor nucleus of the vagal nerve, and the presence of Lewy bodies.

Pharmacological Properties

Although Parkinson's disease (PD) is classified as a "movement disorder," it should also be considered as a "neurobehavioral" disorder. The diagnosis of PD is based on the presence of clinical criteria having to do purely with movements and the absence of exclusionary or atypical features, laboratory tests being of little or no value. Nevertheless, the most devastating aspects of PD are more often behavioral. Other nonmotor problems, such as sympathetic dysfunction and sleep disorders have only attracted clinical and research attention in the last few years. For perspective two studies, one a large retrospective review in Australia, and the other, a county wide prospective study with formal testing in Norway, both concluded that by the time of death, 80% of PD patients are demented. In addition, at any point in time, somewhere between 30 and 50% are depressed; 40% suffer from anxiety; 40% with apathy; 30% of drug treated patients with visual hallucinations; 5–10% of drug treated patients with delusions; and over 30% of newly diagnosed patients, untreated, suffer from fatigue unrelated to depression or the severity of their motor dysfunction.

PD in simplistic terms is often understood as a dopamine deficiency disease. While it is this, there are also abnormalities in multiple neurotransmitter systems. The dopamine motor system is the best understood and deficiencies here do cause many of the major motor problems in PD, including bradykinesia, rigidity, tremor, and gait dysfunction. Improving dopamine transmission has been the focus of modern drug therapy, starting with the introduction of the first rational designed treatment for a neurological disorder, L-Dopa.

► L-Dopa, combined with an aromatic amine decarboxylase inhibitor (AADI), ► carbidopa, has been the mainstay of the treatment of PD since it was introduced in the late 1960s (Cotzias et al. 1967). The AADI reduces the amount of L-Dopa converted in the bloodstream to ► dopamine, dramatically reducing the problem of nausea which was frequent when L-Dopa was used alone. L-Dopa is the precursor to dopamine, and in the chemical path that converts tyrosine to dopamine, L-Dopa occurs after tyrosine hydroxylase, the rate-limiting enzyme. L-Dopa is taken up by the remaining nigral cells and converted to dopamine. L-Dopa improves slowness, rigidity, akinesia, and gait, but does not usually improve speech, freezing, balance, and its effect on tremor are unpredictable. In addition to the existence of symptoms not responsive, and therefore presumably not of dopamine deficiency origin, the disease progresses and drug manipulations are unable to keep up. As more dopamine secreting cells die, the drug becomes less effective.

Long-term use of L-Dopa often leads to motor complications, which are not seen when other drugs are used in PD patients who have never been exposed to L-Dopa (Fox and Lang 2008). These include ► dyskinesias induced by the drug, as well as markedly variable responses to the drug with "on" periods, when patients have a good response to the drug, and either predictable or unpredictable "off" periods when the medicine stops producing benefit.

Other ways of enhancing dopamine transmission involve reducing dopamine breakdown or altering L-Dopa ► pharmacokinetics. The monoamine oxidase-b inhibitors (MAOb-I), ► selegiline and ► rasagaline, are both used as adjunctive agents to enhance the activity of dopamine. These drugs work both peripherally, in the bloodstream to block the degradation of L-Dopa and centrally, in the brain to reduce degradation of dopamine. In the brain, dopamine is primarily resorbed by the presynaptic neuron though the dopamine transporter, but about 10% is broken down in the synaptic cleft by monoamine oxidase b and catechol-o-methyltransferase. Blocking the degradation of dopamine in the synapse allows more dopamine to activate the dopamine receptors, thereby increasing the potency of the dopamine stimulation as well as its duration of action. Both drugs are therefore approved for the purpose of increasing "on" time in patients who suffer from clinical motor fluctuations in reponse to L-Dopa. Rasagaline is also used as a monotherapeutic drug, presumably acting in the same fashion, enhancing dopamine stimulation. Its benefits are less than those typically seen with dopamine agonist monotherapy, but its side effect profile in these patients is not much different than that of placebo.

The greatest interest in the MAO-b inhibitors lies in their possible disease "modifying" effect that is, slowing of

disease progression. There is suggestive data supporting this contention for rasagaline. The first large study to slow PD progression used selegiline, and while initially deemed a positive study, was reinterpreted in light of its mild, but statistically significant symptomatic effects. The rasagaline studies used a different research paradigm to avoid this confound (Olanow et al. 2009).

Although nonspecific MAO inhibitors hold the potential for a large number of drug and food interactions, all of these are due to MAO-a inhibition. At the doses approved for PD, the MAO-b inhibitors are free of MAO-a inhibition and are quite safe, free of tyramine interactions, and of interactions with selective serotonin reuptake inhibition (SSRI) antidepressants. However, there is a concern about an unexplained, potentially fatal interaction with meperidine.

In monotherapy, rasagaline has no significant behavioral effects. When used adjunctively with L-Dopa, all L-Dopa side effects are enhanced.

The catechol-o-methyltransferase inhibitors (► COMT-i) block the enzyme, catechol-o-methyltranserfase that, along with MAO-b, breaks down dopamine. There are two such drugs used in USA, ► tolcapone and ► entacapone, neither of which crosses the blood-brain barrier to an appreciable degree. These drugs therefore exert their effect on the pharmacokinetics of L-Dopa. By themselves, these drugs do not have any known effect on PD. Tolcapone may cause severe liver damage in a very small percentage of users. Entacopone is less effective, but is free of liver toxicity.

Since dopamine does not cross the blood-brain barrier, dopamine agonists have been used to compensate. These medications, ► bromocriptine, ► pramipexole, ropinerole, lisuride, ► rotigotine, ► cabergoline, and ► apomorphine, all directly stimulate D2 receptors (along with variable potencies at other dopamine receptors), and produce motor benefits comparable to L-Dopa at the early stages of the disease, but are less effective for the long-term. Unlike L-Dopa, these medications do not cause long-term motor side effects such as "wearing off," in which the benefit of L-Dopa declines before the next dose, unpredictable fluctuations, in which the L-Dopa doses last highly variable periods of time, or dyskinesias, which are involuntary movements, usually choreic in nature (Constantinescu et al. 2007; Jankovic and Stacy 2007). Unfortunately, these drugs produce more short-term side effects including hypotension, ► hallucinations, nausea, and generally need to be supplemented with L-Dopa within a few years. The ► dopamine agonists are often used as initial therapy to postpone the long-term side effects of L-Dopa, or may be added to L-Dopa as its benefits decline.

Anticholinergic drugs were the mainstay of drug therapy of PD until the development of L-Dopa. These drugs are helpful in reducing tremor and rigidity, but are thought to provide little benefit in slowness, or gait, two of the most functionally debilitating symptoms in PD. Additionally, these drugs have profound side effects that make them difficult to use, particularly in older people. These side effects are very common, and include dry mouth (which may be useful to reduce drooling), constipation, memory dysfunction, urinary retention, blurred vision, hallucinations. These drugs are primarily used in younger patients, who tolerate them better, particularly where tremors and drooling are problems.

► Amantadine was first reported in 1972 to ameliorate the motor symptoms of PD as a serendipitous observation when used to treat influenza in people with PD. The drug had been thought to work by increasing dopamine secretion or by blocking acetylcholine, but it is currently believed to work as an NMDA glutamate antagonist. It is helpful for all aspects of PD, including tremor, but is not as effective as dopamine agonists or L-Dopa. It has been increasingly used in recent years after it was shown to reduce L-Dopa induced dyskinesias in PD patients, without a reduction in the other drugs used to treat PD motor symptoms. Amantadine may induce psychotic symptoms, delirium, and mild anticholinergic side effects, as well as livedo reticularis (which has no negative consequences other than appearance) and pedal edema (Pahwa et al. 2006).

Although ► dementia is a common problem in PD, only one drug has been approved for its treatment (Burn et al. 2006). Most authorities believe that the three cholinesterase inhibitors probably work about equally well, but this is not based on clinical data. Since Parkinson's disease dementia (PDD) patients have a greater cholinergic deficit than Alzheimer's patients, it was assumed that the cholinesterase inhibitors might therefore work better than in Alzheimer's disease (AD). This has not been borne out by clinical observation. The mechanism of action of these drugs is presumed to be the same in PDD as in AD, blocking the degradation of acetylcholine. However, the benefits of ► rivastigmine in PDD are extremely limited, and most patients do not sustain sufficient benefits to justify the cost of the drug. ► Memantine, which is the only noncholinesterase inhibiting drug approved for treating dementia in AD, shares NMDA glutamate antagonism with amantadine, but it has not been shown to produce any motor benefit in PD. Rivastigmine is more helpful for concentration, apathy, and hallucinations than it for cognitive and memory problems (Burn et al. 2006).

No antipsychotic is approved for treating hallucinations and delusions in PD in USA, but ► clozapine, at extraordinarily low doses, is approved for this use in other countries based on two multi-center double blind placebo controlled trials (Parkinson study group 1999). In USA, ► quetiapine has been recommended as the drug of first choice by an American Academy of Neurology task force, despite the fact that no double blind trials, support its efficacy (Miyasaki et al. 2006). Clozapine is the task force's second line recommended drug.

No antidepressant has been approved for treatment of depression in PD, and none has been adequately tested to confirm benefit. Some high quality data published in 2009 indicates that depression in PD may be medication responsive, and that tricyclics may be more effective than ► selective serotonin reuptake inhibibitors (SSRI) (Menza et al. 2009). Although the SSRI's may produce tremor or parkinsonism, they have been well tolerated in PD.

Definition

Antipsychotic medication refers to the use of a group of psychoactive drugs that is mainly used to treat patients

suffering from psychoses, most often ► schizophrenia but also mania and other delusional disorders. A wide range of antipsychotics has been developed. The first generation of antipsychotics was discovered in the 1950s. Most of the drugs in the second generation (often called atypical antipsychotics) have been developed more recently, although the first atypical antipsychotic, ► clozapine, was discovered in the 1950s. Both classes of medication block dopamine receptors in the brain and in many cases, they also act at a much wider range of receptor targets. Side effects vary greatly between different antipsychotics and include weight gain, movement disorders, and agranulocytosis (a loss of the white blood cells that help a person fight infection). The development of new antipsychotic medication and the relative efficacy of different ones is an important ongoing field of research. The most appropriate drug for an individual patient requires careful consideration.

Definition

Antipsychotic medications are a group of psychoactive drugs used to treat psychosis, which is typified by ► schizophrenia. The currently available antipsychotic medications show some benefit to patients, but have considerable limitations in terms of efficacy and side effects. The development of new antipsychotic compounds with novel mechanisms of action is being pursued based on specific strategies and guided by various pathophysiologic hypotheses. This article focuses on novel goals and targets for therapeutic intervention and potential strategies for future development of antipsychotic medication.

Pharmacological Properties

Limitations of Currently Available Antipsychotic Medications

The introduction of newer ► second-generation antipsychotics (SGAs) represents an important advance in the pharmacologic treatment of schizophrenia since the advent of ► chlorpromazine, the prototypical ► first-generation antipsychotics (FGAs). However, current evidence suggests that the clinical benefits of SGAs in terms of efficacy are modest at best (Leucht et al. 2009), and the effect sizes on ► cognitive impairment are small. In the largest and longest effectiveness trial, the ► clinical antipsychotic trials of intervention effectiveness (► CATIE) study, no substantial advantage for the SGAs was demonstrated over the FGA for the treatment of negative and cognitive symptoms (Lieberman et al. 2005). Negative and cognitive symptom domains are recognized as a core feature of schizophrenia and play a greater role in poor functional outcome. Thus, it is obvious that there is a distinct need to identify and validate novel molecules that possess pharmacological profiles that better treat these symptom domains.

To date, the prototypical SGA ► clozapine remains the "gold standard" antipsychotic drug because of a lower liability for ► extrapyramidal motor side effects (EPS) and because it has proved superior to all other ► antipsychotic drugs in efficacy (Leucht et al. 2009), particularly in treatment-resistant schizophrenia. However, even with clozapine, a significant number of patients are unresponsive to treatment and it carries a risk of serious side effects such as agranulocytosis, weight gain, and metabolic abnormalities. Because individuals with schizophrenia have many risk factors that may predispose them to poor health and excess mortality, safety and tolerability of antipsychotic medications are an essential treatment concern. Furthermore, remission and recovery rates for schizophrenia by the treatment with current antipsychotic medications are discouragingly low. Thus, it is important to pursue the development of more tolerable and more effective antipsychotics than clozapine. To expedite the clinical development of such drugs, biological or surrogate markers of the illness and treatment effects using chemical technologies (e.g., ► PET imaging) must be identified and validated to enable more efficient and reliable proof of efficacy of novel compounds.

Challenges of Future Drug Discovery

A number of mechanisms of action of antipsychotics have been explored during the past 30 years. However, it is still unclear as to what pharmacological profile of

antipsychotic medication is necessary to show the highest efficacy and effectiveness without serious adverse effects in the treatment of schizophrenia and other psychosis. Moreover, there is still an ongoing debate as to whether drugs selective for single molecular target (i.e., "magic bullets") or drugs selectively nonselective for several molecular targets (i.e., "magic shotguns") will lead to new and more effective medications for psychosis (Agid et al. 2008; Roth et al. 2004).

All currently available antipsychotic medications target dopamine D_2 receptors, but one example of new multitarget strategies is the utility of combined dopamine D_2-like receptor antagonism and ▶ serotonin 5-HT_{1A} receptor agonism (Jones and McCreary 2008). It is suggested that the balance between D_2 antagonism and 5-HT_{1A} agonism may be critical in determining the efficacy of these compounds. In addition, further serotonergic strategies may be a key area of schizophrenia research such that combined activity at the D_2 receptor with ▶ selective serotonin reuptake inhibitor, and the use of 5-HT_{2C} receptor agonists, 5-HT_6 receptor antagonists, or 5-HT_7 receptor agonists may be of great interest in expanding treatment options (Jones and McCreary 2008).

Recent antipsychotic research has examined agents that have no direct effect on the dopamine system, although most of them have indirect effects on dopaminergic pathways. For example, with the emerging evidence for glutamatergic dysregulation in schizophrenia, a number of agents with direct or indirect activity on the ▶ glutamate system are being investigated, especially for their potential impact on cognitive and negative symptom domains (Miyamoto et al. 2005). Glutamate-based agents in various stages of development include agonists at the glycine allosteric site of the ▶ N-methyl-D-aspartate (NMDA) receptor, ▶ glycine transporter 1 inhibitors, ▶ Group II metabotropic glutamate receptor agonists, α-amino-3-hydroxy-5-methy-isoxazole-4-propionic acid (AMPA)/kainate receptor antagonists, and higher-potency ▶ ampakines. The putative antipsychotic action of these drugs has been studied as monotherapy and/or add-on treatment (Gray and Roth 2007).

It has also been suggested that the central cholinergic system is involved in the cognitive deficits observed in schizophrenia, and enhanced cholinergic activity may improve these deficits (Miyamoto et al. 2005). Currently available treatments which are potentially suitable for this purpose include ▶ acetylcholinesterase inhibitors (e.g., galantamine), partial ▶ muscarinic agonists (e.g., xanomeline), ▶ nicotinic agonists, and allosteric potentiators of nicotinic receptor function (Gray and Roth 2007). These potential ▶ cognitive enhancers may be better suited to particular stages of schizophrenia, perhaps showing efficacy in early or later stages.

In recent years, significant progress has been made on elucidating various susceptibility genes in schizophrenia, including ▶ dysbindin, neuregulin 1, catechol-O-methyltransferase (COMT), disrupted in schizophrenia 1 (DISC1), and others (Gray and Roth 2007). Many of these genes appear to be associated with the control of ▶ synaptic plasticity and glutamate transmission, especially NMDA receptor function. Research on these molecules will allow for rational drug development in which drugs are developed on the basis of targets derived from theories of pathogenesis of the disease. However, the conundrum of single-target versus multitarget agents will remain at the forefront of drug development until the etiology of the illness is fully elucidated. In the near future, optimal treatment will probably include different therapeutic agents, each uniquely targeting a specific dimension of schizophrenia (Agid et al. 2008). In other words, single-target agents will augment multitarget agents, and there is a possibility that novel biological agents will also be investigated (Nikam and Awasthi 2008).

Recently, a growing body of evidence has demonstrated that some SGAs may increase or preserve neurotrophic factor levels, ▶ neurogenesis, neuronal plasticity, mitochondrial biogenesis, cell energetic, and antioxidant defense enzymes (Lieberman et al. 2008). Moreover, specific SGAs can ameliorate the loss of gray matter in schizophrenic patients in the early stages. These neuroprotective properties of some SGAs have become more relevant in the light of the increasing acceptance by the field of a progressive pathophysiological process and possibly neurodegenerative process coincident with the onset of schizophrenia that may underlie the clinical deterioration. Ongoing research on the neuroprotective effects of antipsychotics may reflect another mechanism of action that antipsychotics can act through that is clinically relevant and should stimulate the search for new agents for psychosis with novel mechanisms beyond the monoaminergic systems (Lieberman et al. 2008).

New Preparations of Antipsychotic Medications

At present, antipsychotic medications are available as tablets, liquid concentrates, orally dissolving formulations, short-acting intramuscular (I.M.) preparations, or long-acting injection (LAI) preparations. Among them, several SGA LAI preparations have been and are being developed. By increasing the available treatment choices for clinicians and patients alike, new preparations such as drug-in adhesive transdermal patches and nasal spray are

a welcome development. Researchers must study these preparations beyond the usual registration package.

Moving Toward the Future Individualized Treatment

There is a great need for the development of novel methods to identify optimum individualized treatment plans. In particular, the efficacy and tolerability of antipsychotics could be directly influenced by genetic variations in ► cytochrome P450 (CYP) enzymes. Their activity may also be influenced by genetic alterations affecting the drug target molecule, such as monoaminergic receptors, neurotransmitter transporters, and enzymes. In the future, genetic tests for the pretreatment prediction of drug metabolic status, antipsychotic response, and drug-induced side effects such as EPS and weight gain are expected to bring enormous clinical benefits by helping to chose the medication, adjust therapeutic doses, and reduce adverse reactions (Arranz and de Leon 2007). Further development of genetic tests and ► pharmacogenetic research into genetically determined drug metabolic polymorphisms as well as ► pharmacogenomic strategies to the identification of novel factors influencing response would lead to a better understanding of the rational basis for the personalization of antipsychotic treatment. In addition, antipsychotic drugs may also be targeted to specific patient subgroups based on profiling and the identification of endophenotypes of schizophrenia. Clinical implementation of this practice may have a strong impact in reducing adverse effects and improving treatment adherence and efficacy (Arranz and de Leon 2007).

Conclusion

Future drug discovery approaches will have to be truly revolutionary, but there is a hope that we could obtain novel antipsychotic drugs with greater efficacy and improved safety profiles. These drugs, however, alone may not produce a complete cure. It is essential that all of the pharmacologic tools should always be used in combination with psychosocial and psychotherapeutic intervention to optimize overall ► quality of life and return patients to the best level of functioning.

Definition

Antipsychotics are drugs used to treat all kinds of psychoses, although the best evidence for their clinical effects stems from studies in the treatment of schizophrenia.

Pharmacological Properties

History

Antipsychotics, as we use the term now, were introduced into clinical psychiatry in the 1950s. They were originally

called neuroleptics, a term still broadly used in medical jargon which is derived from Greek and loosely translated as "grasping the nerve." This reflects the fact that originally the sedative effects of these drugs were in the foreground of clinical interest. This was also the origin of the American term "major tranquilizers."

Over the last two decades antipsychotics has become the preferred term for this class of drugs based on their main indications and clinical effect. While it was originally felt that antipsychotic efficacy was inextricably linked to ▶ extrapyramidal motor side-effects (EPS), the introduction of ▶ clozapine in the early 1970s demonstrated that this was not the case, as this drug proved to be an excellent antipsychotic with only a minimal risk to induce EPS. This also triggered a new classification of antipsychotics, which had so far been differentiated either by their chemical structure (e.g., ▶ phenothiazines, ▶ thioxanthenes, and ▶ butyrophenones) or their affinity to the dopamine D2 receptor (high and low potency neuroleptics). The fact that clozapine was found to be an effective antipsychotic without inducing motor side-effects was considered an "anomaly," and the term "atypical" was coined to describe clozapine and to differentiate it from the older "typical" drugs with their considerable potential for such adverse events. Consequently, antipsychotics which were developed following clozapine's introduction and which shared at least some of its characteristics were also subsumed under the category "▶ atypical antipsychotics." It soon became clear that "atypical antipsychotics" represent a rather inhomogeneous group, both from preclinical and clinical pharmacological perspectives. As the receptor pharmacology of these drugs is complex and provides no solid basis for differentiation, the field agreed upon classifying these drugs based upon a less contentious base, namely a more historical dimension. Thereby, all drugs developed until the advent of clozapine were called ▶ first-generation antipsychotics (or sometimes "classical" or "traditional") while the drugs that were introduced after clozapine and shared its low risk for EPS are now called ▶ second-generation antipsychotics. We are now on the threshold of a ▶ third-generation of antipsychotics, initiated with the registration of ▶ aripiprazole, the first licensed antipsychotic which is not a D2 antagonist.

Mechanisms of Action

It took about 10 years after the clinical efficacy of these drugs had been established until it was realized that antipsychotics block ▶ dopamine receptors. This finding can be seen as the cornerstone of the dopamine hypothesis of schizophrenia. More than adecade later, Seeman et al. (1976) published their classic paper on the correlation between D2 dopamine receptor affinity and clinically effective doses of antipsychotics, demonstrating that drugs with high receptor affinity required lower doses than drugs with lower affinities. All currently licensed antipsychotics with the exception of aripiprazole, a partial D2 agonist, block postsynaptic dopamine D2 receptors. The fact that most of these drugs also influence other receptor systems has given rise to a number of alternative attempts to achieve antipsychotic effects. The most prominent targets were various subtypes of the serotonin receptor (e.g., $5HT_{2A}$, $5HT_{1A}$) and lately the glutamatergic system, including both ionotropic and ▶ metabotropic receptors (Miyamoto et al. 2003).

Countless clinical and preclinical experiments link the effects of antipsychotics to the dopaminergic system. In very general terms, the acute administration of antipsychotics leads to an increased firing rate and neurotransmitter turnover in dopaminergic neurons while these effects are reversed after chronic administration (Grace 1992). In this respect older drugs, such as ▶ haloperidol, are different from newer ones such as clozapine insofar as haloperidol demonstrates these characteristics both in neurons originating in the substantia nigra (A9 dopaminergic neurons) as well as in those which project from the ventral tegmentum (A10 neurons) while clozapine only blocks A10 neurons. This has been replicated many times using different electrophysiological, neurochemical, and imaging techniques and is considered the reason why clozapine exerts antipsychotic effects without affecting the motor system (Miyamoto et al. 2003).

Clinically, the introduction of single photon emission tomography (▶ SPECT) and positron emission tomography (▶ PET) have provided the most relevant neurobiological leads into the effects of antipsychotics in humans. All available antipsychotics bind to striatal (and possibly extrastriatal) dopamine receptors in varying degrees. A dose–response relationship between human D2 receptor affinity and clinical profile is very likely, albeit it is challenged by the findings that the highly effective antipsychotic clozapine and also ▶ quetiapine only loosely bind to this receptor (Stone et al. 2009).

In summary, all evidence taken together clearly points to a disruption of dopaminergic function in schizophrenia patients and strongly suggests that a restoration of balance in this system contributes to the therapeutic efficacy of antipsychotics.

As outlined earlier, other receptor systems have also been investigated in this context. As clozapine has high affinity to a number of other neurotransmitter receptors (including ▶ serotonin, histamine, and ▶ noradrenaline),

these systems have been explored regarding their potential contribution to the drug's benefit–risk profile. The hypothesis most vigorously explored was the one that linked its serotonin ($5HT_2$) antagonist properties to the clinical profile. In conjunction with previous preclinical research which had found that serotonin antagonists can counteract extrapyramidal motor side-effects of neuroleptics, Meltzer et al. (1989) formulated the hypothesis that $5HT_2$ antagonism which is proportionally larger than D2 antagonism is responsible for the advantages that clozapine and all other drugs sharing this profile have over the older drugs in terms of lower EPS risk. In addition, they and other authors feel that these pharmacological characteristics also contribute to enhanced clinical efficacy, especially with regard to negative symptoms and cognitive impairment. Although an intriguing and well thought through hypothesis, it is somewhat challenged by the pure dopamine antagonist ► amisulpride which has no direct effects on the serotonergic systems, yet shares a lot of the clinical effects with $5HT_2$/D2 antagonists (McKeage and Plosker 2004).

The glutamate system is intricately linked with dopaminergic neurotransmission throughout the central nervous system (CNS), a topic reviewed by Carlsson et al. (2001). It functions as a modulator of dopaminergic neurotransmission. This has led to a number of clinical experiments aiming at investigating drugs that do not directly act via the dopaminergic systems. Both the glycine sites of ► NMDA receptors and ► metabotropic glutamatergic receptors have been the targets of such investigations. Clinical studies are encouraging but have not yet led to licensed medications (Miyamoto et al. 2005).

Other neurotransmitter systems have mostly been considered in the context of drug safety. Many antipsychotics which block noradrenergic α_1 receptors have been found to affect blood pressure. Antihistamine effects have been related to sedation and weight gain, just to provide a few examples.

Animal Models

There is no reliable and valid animal model for schizophrenia. All available models are either derived from the dopamine hypothesis of schizophrenia or from the actions that effective antipsychotics induce in laboratory animals. Many of them are related to non-therapeutic effects of antipsychotics such as those which affect the motor system. At the most, we may optimistically assume that these models are in some approximation to the clinical syndrome of the disorder. Nevertheless, animal models, imperfect as they may be, are still a cornerstone of antipsychotic drug development (Lipska and Weinberger 2003). Conditioned ► active avoidance is a classic among these models. All antipsychotics block conditioned avoidance and this test is therefore one of the early screening experiments in the development of potential antipsychotics.

Another set of experiments involve the various motor effects of this class of drugs. Spontaneous locomotor activity as well as pharmacologically enhanced psychomotor activity is usually decreased after the administration of antipsychotic drugs. First- and second-generation antipsychotics are nicely differentiated by the dose needed to induce catalepsy, which is a good indicator for clinical EPS risk.

More recent models which can also be performed in humans include various variants of sensory motor gating studies. One example for these is ► prepulse inhibition (PPI), which is based on the finding that a weak prepulse reduces the startle reflex to a given, usually acoustic, stimulus. It is seen as part of the information processing capabilities of the CNS. PPI can be disrupted by both dopamine agonists and NMDA antagonists, thereby providing a model within the dopamine/glutamate hypothesis of schizophrenia. As antipsychotics restore PPI in animals in which it has been disrupted, such sensory motor gating models are also seen as indicative of potential antipsychotic effects.

► Pharmacokinetics

Antipsychotics are generally well absorbed and most of them are metabolized by hepatic ► cytochrome P450 isoenzymes. They are generally highly lipophilic and therefore cross the ► blood-brain barrier well and accumulate in fatty tissues. The benzamides ► sulpiride and ► amisulpride are an exception to these rules.

The elimination half-lives of antipsychotics are distributed over a wide range between a few hours (► quetiapine) and days (aripiprazole). Steady-state levels differ accordingly, but as a rule of thumb once-daily dosing is possible. It is important to note that elimination from the brain and the drugs' target organs has been shown to be much slower than from plasma (Gruender 2007).

Given that all drugs with the exception of the benzamides are metabolized via cytochrome isoenzymes in the liver, the potential for interactions with other drugs which compete for these enzymes needs to be considered. Pharmacodynamic interactions are to be expected when antipsychotics are coadministered with drugs that target the same receptor systems, either centrally or peripherally. These include drugs with antihistamine and antiadrenergic effects which can lead to a potentiation of sedation, weight gain, or hypotensive adverse events.

Efficacy

Next to antipsychotic effects, i.e., reducing ▶ delusions and ▶ hallucinations, most antipsychotics also have sedative properties. Furthermore, they have been shown to reduce negative symptoms, enhance cognitive functions, ameliorate affective symptoms (both manic and depressive) in patients suffering from schizophrenia and, most likely as a secondary effect, improve the quality of life and psychosocial reintegration (Miyamoto et al. 2003). Although most research with antipsychotics has been performed in schizophrenia patients, the therapeutic actions of these drugs extend beyond this diagnosis. Indications include mania, psychotic depression, ▶ schizoaffective disorder, ▶ bipolar depression, psychotic symptoms in the context of organic disorders from delirium to ▶ dementia, personality disorders, and treatment-resistant obsessive compulsive disorder, just to list the better researched disorders. As most of these are be covered in other entries, only general treatment principles in schizophrenia patients are briefly reviewed.

Recent evidence indicates that the onset of antipsychotic action in schizophrenia can be seen within days of commencing treatment (Agid et al. 2006), although it may take up to 6 months to achieve full remission of symptoms. Close to two thirds of first-episode schizophrenia patients reach symptom remission within this time if the duration of previously untreated psychosis is not too long. Response patterns become less favorable with increasing chronicity of the disorder. Next to acute symptom control and stabilization, antipsychotics also have powerful relapse-preventing properties (Kane 2007). Regularly taking medication over long periods of time protects about 80% of patients from a psychotic relapse. Having said that, compliance is one of the major challenges of the long-term management of schizophrenia (Fleischhacker et al. 2003). To aid uninterrupted dosing, depot antipsychotics that are injected at regular, long intervals have been developed. So far ▶ risperidone and ▶ olanzapine are the only second-generation antipsychotics available for this method of administration (Fleischhacker 2009).

Clozapine plays a special role in the management of schizophrenia. On the one hand, it is the drug of choice in patients with a treatment-resistant course of the disorder; on the other hand, it has a 1% risk to induce agranulocytosis which makes it a third line drug despite its excellent efficacy (Tandon et al. 2008).

Safety/Tolerability

For first-generation antipsychotics, sedation as well as acute and tardive extrapyramidal motor side effects represented the biggest safety obstacles that also translated into tolerability and compliance problems. Next to that, these drugs, depending on their receptor profiles, induced a number of other adverse events including anticholinergic side effects, orthostatic hypotension, weight gain, hormonal aberrations including sexual disturbances, dermatologic problems including acne-like manifestations and photosensitivity, disturbances of gastrointestinal motility, hematological side effects, cardiac arrhythmias, seizures, and the ▶ neuroleptic malignant syndrome, just to name the clinically most relevant. Apart from potentially life-threatening adverse events such as clozapine-induced agranulocytosis, tachyarrhythmia, and the neuroleptic malignant syndrome, many of these side effects constitute problems affecting subjective tolerability rather than objective health risks. Prevalence rates differ considerably between drugs, and the incidence of these side effects is difficult to predict on an individual level. Therefore, patients treated with antipsychotics have to be well informed and monitored regularly.

Second-generation antipsychotics as a group have a considerably lesser risk to induce EPS than the older drugs. This applies to both frequency and severity of acute and chronic motor side effects. Some of these drugs, most notably clozapine and olanzapine, have a substantial propensity to induce weight gain and metabolic disturbances such as hyperlipidemia and reduced insulin sensitivity. Apart from these concerns the newer drugs appear to be tolerated appreciably better than traditional neuroleptics. Clearly, despite this, the same recommendations regarding patient information and monitoring must be followed (Miyamoto et al. 2003).

Conclusion

In summary, antipsychotics represent a crucial component of the pharmacotherapeutic options in psychiatry. A large array of effective drugs is available. Antipsychotics are employed over a broad range of indications with a very favorable benefit–risk profile. It is hoped that their main therapeutic limitations, namely efficacy beyond psychotic symptoms, will be overcome with the exploration of pharmacologic mechanisms which extend beyond the dopamine system.

Antisaccade Task

Definition

An important variant of the prosaccade task, in which participants are required to saccade to the mirror image location of a sudden onset target. Healthy participants typically make errors (prosaccades toward the target) on around 20% of trials. This figure is increased in patients with lesions to the dorsolateral prefrontal cortex and patients with schizophrenia. The task indexes cognitive processes associated with goal activation and inhibitory control.

Definition

Antisense oligodesoxynucleotides are relatively short, single-stranded synthetic DNA molecules (between 13 and 25 nucleotides) that are complementary to a chosen mRNA causing translational arrest. Chemical modifications improve their cellular uptake and intracellular stability. Functionally, they are antisense oligonucleotides.

Also, ribozymes and DNA enzymes have antisense properties (Fig. 1D). Ribozymes are RNA enzymes that are catalytically active oligonucleotides that bind to and cleave their target mRNA. These RNA processing capabilities are of potential interest for their use as antisense agents. A number of ribozymes have been characterized, including the most widely studied form called the hammerhead ribozyme.

► Antisense oligonucleotides are relatively short, single-stranded DNA (► antisense oligodesoxynucleotides) or single- (► antisense RNA) or double-stranded (► short interfering RNA, ► siRNA) RNA molecules (between 13 and 25 nucleotides or *mer* from Greek *meros*, "part") which are complementary to a chosen (coding or non-coding) mRNA. The potential of oligonucleotides to act as antisense agents that inhibit viral replication in vitro was discovered by Zamecnik and Stephenson (1978). Both in vitro and in vivo, their common mechanism of action is the complementary binding to a specific target mRNA via Watson–Crick base-pair hybridization; thus inhibiting translation of mRNA and blocking the transfer of the genetic information from DNA to protein; thereby reducing the availability of the gene product within a given tissue. Synthetic, antisense oligonucleotides can be potentially used as therapeutic agents for selective gene silencing, and are currently used as tools to study gene functions in preclinical research including psychopharmacology (antisense technology).

Principles and Role in Psychopharmacology

Modes of Action of Antisense Oligonucleotides

There are several main intracellular mechanisms of actions of antisense oligonucleotides to prevent the expression and translation of the target protein (Dias and Stein 2002, Fig. 1a–e). The first mechanism is based on the disruption of protein translation of target mRNA by base-pairing of single-stranded antisense oligodesoxynucleotides (► antisense DNA) to the respective complementary mRNA strand and physically/sterically obstructing the translation machinery, prevention of ribosomal complex formation, and translation of mRNA into the gene product (translational arrest) (Fig. 1b). The second main mechanism is also based on the complementary binding between the antisense oligodesoxynucleotides (antisense DNA) and the target mRNA. This DNA/RNA hybrid can then be degraded by the enzyme RNase H, a mechanism which significantly enhances the efficacy of antisense potency (Fig. 1c). The RNase endonuclease specifically cleaves RNA in DNA/RNA heteroduplexes. Short-term effects of antisense oligodesoxynucleotides inhibiting neuronal responsiveness without altering gene protein content and availability have been described in neuroendocrine cells (Fig. 1d) (Neumann and Pittman 1998).

Also, ► ribozymes have antisense-like properties (Fig. 1d); those RNA molecules bind to and cleave their target mRNA.

A revolutionary development in antisense research is the finding that 20–25 nucleotide double-stranded RNAs, called siRNA, can efficiently block gene expression (Figs. 1e and 2) via the ► RNA interference (► RNAi) pathways. Any gene of interest with known sequence can be targeted by siRNAs that match the mRNA sequence.

Cellular Uptake of Antisense Oligonucleotides

A main problem for antisense technologies is the limitation of cellular uptake of these nucleic acids due to their hydrophilic nature. This is true for negatively-charged siRNA, or chemically modified antisense oligodesoxynucleotides with uncharged backbones such as methylphosphonates, phosphorothioates, or morpholino-derivatives.

For improved efficacy of antisense uptake, agents that enhance transmembrane permeation, i.e., cell-penetrating peptides (CPP) and drugs that target specific receptors, i.e., cell-targeting ligands (CTL) are discussed (Juliano et al. 2008). Also, antisense oligonucleotides tend to localize in lysosomes and endosomes where their antisense properties are poor. The use of vectors (liposomes, i.e., vesicular colloid vesicles) increases stability and cellular internalization. There are commercially available vectors (so-called eufectins), which are used in basic research.

In vivo, the cellular uptake of antisense oligonucleotides into the target tissue is further impaired by several biological barriers (capillary endothelium, extracellular matrix), degradation by serum and tissue nucleases (liver, spleen), and rapid excretion via the kidney; but if oligonucleotides are bound to plasma proteins, ultrafiltration is retarded (Juliano et al. 2008). In order to target the brain tissue, the blood–brain barrier prevents their uptake as polyanionic molecules, and antisense targeting the central nervous system (CNS) requires direct infusion.

In vivo Delivery of Antisense Oligonucleotides

If brain tissue is targeted, antisense oligonucleotides need to be directly infused either into the ventricular system or the target region to circumvent the ► blood–brain barrier; and they are relatively easily taken up by neurons. Prolonged action and slow delivery within the target region can be achieved by use of biotechnical modifications or polymer microparticle encapsulation with high biocompatibility (Choleris et al. 2007).

(**B**) Antisense oligonucleotides bind to the complementary strand of gene target mRNA and (B1), sterically block the translation process or (B2), the mRNA/oligonucleotide complex activates an RNase H cleaving the mRNA and preventing translation. (**C**) Short-term effects of antisense oligonucleotides on neuronal responsiveness via unknown mechanisms. (**D**) DNA and RNA enzymes (ribozymes) result in cleavage of mRNA. (**E**) siRNA activate intracellular mechanisms resulting in mRNA cleavage and translational arrest via the RNA interference (RNAi) pathway (see Fig. 2).

The most common strategy for siRNA in vivo delivery is to construct expression vectors driven by a constitutively active RNA polymerase III (Pol III) promoter (e.g., the U6 promoter), to drive transcription of small hairpin RNA (shRNA). shRNA are sequences of RNA that make tight hairpin turns upon intramolecular Watson–Crick base-pairing (Fig. 2b), with perfect duplex RNA of 18–25 nucleotides in length. Cellular enzymes, most likely involving Dicer, process shRNA into siRNA molecules that are capable of performing gene silencing via the RNAi pathway. Although plasmid vectors are effective at delivering shRNA and consequently, siRNA to cultured cells and for the generation of transgenic plants or mice, there are limitations for their use, e.g., in somatic cells of adult brain tissue. To overcome these limitations, viral vectors for the delivery of siRNA have been developed, including lentiviral vectors derived from human immunodeficiency virus-1 (HIV-1) and adenoviral and adeno-associated viral vectors that are used to deliver siRNA into selected brain regions of rodents (Kühn et al. 2007).

Chemical Modifications of Antisense Oligonucleotides

Antisense oligonucleotides are rapidly degenerated by intracellular enzymatic activity. In order to increase efficiency, the cellular uptake and intracellular stability can be

Alternatively, siRNA can be chemically synthesized and transfected into cells. This leads to selective endonucleolytic cleavage of the matching target mRNA with subsequent elimination by further cellular RNases.

improved by ► chemical modifications of antisense oligonucleotides (Dias and Stein 2002). The most common chemical modifications employed are replacing an oxygen group of the phosphate-diester backbone with either a methyl group (methyl phosphonate oligonucleotide) or a sulfur group (phosphorothioate oligonucleotide) which have been introduced into clinical therapeutic trials. Increased specificity and efficacy of phosphorothioates are achieved with chimeric oligonucleotides in which the RNase H-competent segment (the phosphorothioate moiety) is bounded on both termini by a high-affinity region of modified RNA. Other chemical modifications include 2′-OH modifications, locked nucleic acids, peptide nucleic acids, and morpholino compounds or hexitol nucleic acids. Although high RNA affinity and high stability have been reported, they do not support RNase H activation. Nevertheless, they can exert their antisense activity via translational arrest or modulation of ► alternative splicing.

Antisense Oligonucleotides in Psychopharmacology

Antisense oligonucleotide technologies including oligodeoxynucleotides and siRNA are used in psychopharmacology to sequence-specifically, transiently, and locally downregulate the expression of target genes (neuropeptides and their receptors, neurotransmitter receptor subtypes and subunits, steroid receptors, neuronal enzymes, transcription factors), identified by microarray and proteomic approaches or by human genetic studies in vivo in addition or alternatively to established pharmacological means (selective ► agonists and ► antagonists, generation of knockout mice) (Hoyer et al. 2006; Landgraf et al. 1997; McCarthy 1998) for detailed methodological description (Fendt et al. 2008).

Functional consequences of antisense-induced downregulation of neuronal gene products in the brain can be monitored in a behavioral, neuroendocrine, or neuronal context. Antisense oligonucleotides need to be directly infused into the brain ventricles or into a selected brain target region over several days using an osmotic minipump or repeated infusions. They are relatively easily taken up by neurons, have a relatively high stability in neurons and in CSF – likely due to negligible cell proliferation within the brain and lack of exo- and endonucleases within the CSF (McCarthy 1998). Nevertheless, in order to increase central efficiency, mainly phosphodiester and phosphorothioated antisense oligonucleotides are used in psychopharmacology, but unspecific effects were repeatedly described making respective controls essential.

Both acute effects on neuronal functions after single infusion as well as long-term effects after repeated or chronic administration have been described. Often, short-term, antisense-induced blockade of neuronal activation without altering the availability of the gene product (Figs. 1 and 2) is likely to contribute to the observed behavioral, neuroendocrine, and neuronal effects of antisense oligonucleotides, especially if neuropeptides are targeted and stored in rather large amounts (Neumann and Pittman 1998).

Various neuropeptides and their receptors have been targeted using antisense oligonucleotides in the absence of highly selective receptor antagonists (Hoyer et al. 2006; Landgraf et al. 1997; McCarthy 1998), including the receptors for neuropeptide Y_1, corticotropin-releasing hormone (CRH), oxytocin and its receptor, vasopressin

(Data from Torner et al. 2001.)

and its V1a receptor, or the long form of prolactin receptors (Fig. 3).

Antisense oligonucleotides have also been used to target the expression of other neurotransmitter and steroid receptors including the receptors for 5-HT_{2A}, dopamine (D_2), progesterone, as well as NMDA receptor subunits and metabotropic glutamate receptor subtypes. Also, immediate early genes (c-fos, c-jun) and enzymes essential for neurotransmitter synthesis (GABA, 5-HT) have been successfully targeted in order to reveal local effects and behavioral and other functional consequences.

Essential Controls for Antisense Oligonucleotides

To exclude sequence-independent, unspecific effects of mostly chemically modified antisense oligonucleotides in vivo and in vitro, appropriate control groups are essential, i.e., the use of oligonucleotides with identical chemical modification and length which do not match a particular gene. Possible controls include a sense-strand sequence from the same site of mRNA, a scrambled sequence of the nucleotides used in the antisense oligonucleotides in random order, a nonsense oligonucleotide of same length but consisting of a different nucleotide composition without complementarity to any known mRNA sequence.

siRNA in Psychopharmacology

Among the earliest studies of siRNA in the brain were the attempts to perform icv infusion of synthetic siRNA using osmotic minipumps in rodents and concomitant behavioral analysis (Hoyer et al. 2006). To establish this strategy, enhanced green fluorescent protein overexpressed in a transgenic mouse line was successfully targeted in several brain regions. Also, targeting the dopamine transporter (DAT) resulted in reduced DAT mRNA and protein levels in substantia nigra, ventral tegmental areas (VTAs), and nucleus accumbens (Hoyer et al. 2006) accompanied by behavioral changes. Additional proof of concept for siRNA in rodent models of neuropsychiatric disease was provided by siRNA-induced reduction in serotonin transporter (SERT) mRNA in the raphe nucleus after 2 weeks of icv siRNA infusion with antidepressant-like behavioral consequences.

In addition, targeting the ► metabotropic glutamate receptor subtype 7 (mGluR7) by selective siRNA resulted in robust emotional and stress-related changes despite limited local mRNA knockdown (25%) (Fendt et al. 2008).

The use of viral vectors for RNAi in the mammalian brain is particularly suited for local gene knockdown even in small brain nuclei (Hoyer et al. 2006).

Advantages and Limitations of siRNA Procedures

The major advantages of siRNA over classical antisense oligonucleotides and ribozymes appear to be threefold (Zamecnik and Stephenson 1978): siRNA is generally more potent, efficient, and selective because it utilizes natural and efficient cellular machinery, i.e., the RNAi pathway providing assistance at multiple steps for the actions of siRNA, while antisense oligonucleotides and ribozymes hybridize to their targets without any assistance (Dias and Stein 2002). siRNA approaches always result in efficient endonucleolytic cleavage and subsequent elimination of the target mRNA, whereas antisense oligonucleotides not recognized by RNase H result in translational block only via steric hindrance (Neumann and Pittman 1998). Antisense oligonucleotides require relatively high concentrations to target their matching mRNA because at least one oligonucleotide per target RNA is required for

translational blockade or RNase H degradation resulting in toxic side effects. In contrast, one guide strand of siRNA incorporated in RISC (RNA-induced silencing complex) can sequentially bind to and eliminate several mRNA transcripts (multiple turnover).

Limitations of siRNA approaches include (Zamecnik and Stephenson 1978) their capacity to induce cellular virus defense mechanisms, mainly interferon gene induction and cellular arrest and (Dias and Stein 2002) possible unspecific off-target effects on closely related sequences making careful design of the siRNA sequence and use of different siRNA molecules targeting the same mRNA transcript essential.

Antisense RNA

Definition

Antisense RNA is naturally occurring single-stranded RNA with properties of antisense oligonucleotides that is complementary to an mRNA strand regulating gene expression machinery of the cell as found, for example, in bacterial plasmids. Transcription of longer noncoding antisense RNAs is a common phenomenon in the mammalian transcriptome including within the brain. No general function of these noncoding antisense RNAs has been elucidated. In contrast to antisense oligodesoxynucleotides, antisense RNA still lacks effective design, biological activity, and efficient route of administration. The effects and mechanisms of antisense RNA should be well separated from those of small interfering RNA (siRNA) and RNA interference (RNAi).

Anxiety

Definition

Anxiety is an emotion shared by all mammals when challenged with dangerous threatening situations at risk for their physical or intellectual integrity. In this case, anxiety is an adaptive response and therefore shaped along the ages by the evolution. Anxiety disorders occurs as a pathological condition, involving unwanted reactions (behavioral and neurovegetative) that are either extreme or occur to inappropriate eliciting stimuli or situations.

Definition

Animal models of anxiety refer to experimental preparations developed for one species, generally rodents, with the purpose of studying different facets (e.g., etiology, symptomatology, physiopathological basis, and treatment) of human anxiety. In most of the existing models, anxiety is inferred from defensive responses to artificial (e.g., electric shocks) or ecological (e.g., loud noises and predators) threatening stimuli. Both normal subjects and selected animals (e.g., strain lines resulting from selective breeding, transgenic, knockout animals, and animals with brain lesions) have been used for this purpose.

Current Concepts and State of Knowledge

Anxiety has been defined as an emotional state aroused by the perception of threat, which is subjectively experienced as unpleasant. In its full expression, behavioral, autonomic/endocrine, affective, and cognitive/perceptual changes are manifested. Although usually adaptive, leading to harm avoidance, anxiety may turn out to be disruptive, giving rise to different pathologies. In modern psychiatric classifications, such as the Diagnostic and Statistical Manual, 4th edition, revised (DSM-IV-RT) of the American Psychiatric Association, anxiety is considered pathological when excessive, disproportional to the eliciting event, causing significant distress, disrupting interpersonal relationships, and impairing social and occupational functioning. According to the symptomatology and time course of development, anxiety disorders are classified into different nosological categories, such as ► generalized anxiety disorder (GAD) and ► panic disorder (PD).

The first question one should face while using animal models is that none of the existing models is capable of modeling all aspects of human anxiety. Accordingly, while behavioral and neurovegetative features of this emotion can be successfully assessed in animals, its cognitive/perceptual aspect is invariably left apart, given the vast differences in cognitive abilities between humans and laboratory animals.

After acknowledging this limitation, a subsequent question should be formulated: what makes possible to relate animal defensive behavior to human anxiety? The most accepted answer is phylogenetic continuity as advocated in the theory of evolution.

Charles Darwin himself laid the ground for this line of thought in his book "The Expression of Emotions in Man and Animals" by proposing that behavioral characteristics, no less than physical, would be acquired as a result of natural selection. This view justifies the use of experimental animals to study the neurobiology of psychological functions. Since several environmental constraints are similar across species, many adaptations are species-general, among which stand the basic emotions. Although emotional expression varies from one species to another, functional behavioral classes, such as escape and avoidance from danger or approach to sources of food, remain the same and constitute the basis for the classification of basic emotions (Panksepp 1998). No wonder that the neural substrate of such emotions is conserved along biological evolution. On this basis, Panksepp has proposed that basic emotions are represented by inborn neural networks that coordinate behavioral strategies allowing animals to deal with enduring environmental (including social) challenges.

In this context, anxiety and the related emotional states of fear and panic are rooted in defensive reactions displayed in situations of threat to the physical integrity or survival of the organism. Consequently, anxiety disorders may be viewed as pathologies of defense.

Defensive Reactions in Animal Models of Anxiety

Existing animal models of anxiety may differ in many aspects. For instance, sources of danger that evoke defensive reactions may be manifold, including predators, environmental stimuli or situations, such as height, illumination, painful stimuli, novel places or objects, and confrontation or competition with animals from the same species. To deal with these challenges, animals use defensive strategies such as escape, immobilization, defensive attack, and submission (Blanchard et al. 2008). In the experimental setting, the expression of one particular strategy will be driven by several factors, such as the characteristics of the environment, distance from the threatening stimulus and previous experience with the stimulus and/or environment.

To evaluate to which extent a given response in the animal model is related to the aspect of human anxiety intended to be modeled (generally symptoms of anxiety), three criteria of validation (► Animal Models for Psychiatric States) have been commonly used: analogy or ► face validity, predictability of drug response, and homology or theoretical ► construct validity. As pointed out by Joel (2006), "Face validity refers to a phenomenological similarity between the model and the disorder it simulates. Ideally, the model should resemble the condition it models in its etiology, symptomatology, treatment and physiological basis. ► Predictive validity means that performance in the test predicts performance in the modeled condition. In principle, predictive validity can rely on etiology, physiology and response to treatment, but in practice, predictive validity is usually based in the latter. Construct validity means that the model has a sound theoretical rationale, and depends on the degree of homology between the behavior that is being modeled and the behavior in the model (two behaviors are considered homologous if they share a similar physiological basis), and on the significance of the modeled behavior in the clinical picture."

Earlier attempts to validate animal models of human psychopathologies, including anxiety disorders, have tended to be concentrated largely on the assessment of face validity. It was soon realized that this criterion could be misleading, since in different species similar behaviors often serve different adaptive functions and, conversely, distinct behaviors may lead to the same goal. For instance, rat probe-burying behavior is attenuated by anxiolytics, although it does not resemble any symptom of GAD. However, this model has good correlation with the latter disorder (De Boer and Koolhaas 2003).

With the consolidation of the role of drug therapy in modern psychiatry, the pharmacological investigation of a given model turned out to be the gold standard in the validation process. However, although important, the predictive criterion alone is insufficient to grant a given test the status of an animal model of anxiety, since correlation between the drug response in the model and in the clinics may happen, despite differences in brain mechanisms of pathophysiology and drug effect. For instance, a behavioral index may detect classical anti-anxiety drugs, such as the ► benzodiazepines, and predict their therapeutic outcome only because it involves γ-aminobutyric acid type A ($GABA_A$) receptor mechanisms. However the mechanisms unpinning the behavior may be entirely different from those implicated in the pathophysiology of anxiety and, as a consequence, the model will fail to detect non-GABAergic anxiolytics.

It may be concluded that only homology fully qualifies an animal model as representative of a given psychopathology. Although this goal is being currently pursued, it is hampered by limitation of the available knowledge on the etiology and pathophysiology of anxiety disorders.

Yet, in this respect, animal models of anxiety fare rather well, when compared to other psychiatric disorders, such as schizophrenia or even depression.

Animal Models of Anxiety: Past and Present

Early animal models of anxiety were developed within the conceptual framework of experimental psychology, before classifications of psychiatric disorders split pathological anxiety into distinct nosological entities. These animal models of anxiety rely on either inhibition of ongoing behavior elicited by conditioned stimuli that predict unavoidable electric shock (conditioned suppression) or on the inhibition of rewarded responding by response-contingent electric-shock (► punishment). The latter relates to clinically-derived constructs that emphasize the role of inner conflict in pathological anxiety, and this may be the reason why these tests became known as conflict models. Early pharmacological analysis has shown that conflict tests have a higher predictive value than conditioned suppression and, as a result, punishment tests have become paradigmatic for assaying anxiolytic drugs.

However, classical conflict tests failed to consistently detect the anxiolytic action of drugs that act primarily on serotonin (5-HT)-mediated neurotransmission, such as ► buspirone and ritanserin (Serotonin Agonists and Antagonists). Such false-negative results undermined the general confidence in conflict models, although many arguments may be summoned to their defense, as for instance the time course of drug action. Unlike benzodiazepine anxiolytics, newer drugs need several weeks of continuous administration to become clinically effective, initial doses being sometimes anxiogenic. Therefore, single administration of these agents should not be expected to have anxiolytic effects in animal models. In spite of this, it became generally accepted that conflict tests were good only for anxiolytics that acted primarily on the neurotransmission mediated by ► GABA, such as ► barbiturates and ► benzodiazepines.

A theoretical shift from the experimental analysis of behavior to the systematic observation of animals in their natural environment (Ethology) has also contributed to the discredit of conflict models, which have been

criticized because of their artificiality and the confounding influence of appetitive drives, such as hunger and thirst, and of pain (Graeff and Zangrossi 2002). As a result, a search for ethologically-based animal models of anxiety has occurred. The most widely used animal model of anxiety resulting from this trend has been the ▶ elevated plus maze, which is based on the natural aversion that rats have for the open arms of the apparatus. Yet, this model has also failed to consistently detect non-benzodiazepine anxiolytics, unless behavioral items shown by the rodents while exploring the elevated plus-maze are measured.

As this development was taking place in basic research, the split of anxiety disorders into distinct diagnostic categories, a trend initiated by the DSM III classification, became accepted world-wide. As a consequence, the search for models that represent specific anxiety disorders has started.

The trend towards theoretically-based models that represent specific anxiety disorders has been strongly influenced by the work carried out by Robert and Caroline Blanchard on predatory defense in rats and mice (Blanchard et al. 2008). As a result of this investigation, the Blanchards have established that the type of defense strategy is mainly determined by the presence or absence of the predator, by the distance between the predator and the prey, and by the availability of an escape route. The first pattern of defense occurs when the predator is absent, but had already been met by the prey in the same environment; it also occurs when the context is new, thus containing both potential reward and harm. These instances generate approach-avoidance conflict, and the resulting defense strategy consists of cautious exploration aimed at risk-assessment. The second defense pattern occurs when the predator is present, but is placed at a safe distance from the prey, thus characterizing distal threat. If an exit is available, the animal rapidly escapes, but if not, the animal remains in tense immobility, a posture known as "▶ freezing" behavior that impairs detection by the predator. Finally, when the predator is close or makes actual contact with the prey (proximal threat), the animal reacts with flight or defensive fight.

Although different species show quite distinct behavioral responses to the above types of threat, (e.g., birds fly, while rats run away from danger), antipredator defense is generally organized in the same way, ranging from risk assessment to tense immobility, escape, defensive threat and defensive attack as the danger grows nearer. The same strategies are used in conspecific agonistic interactions, except for submission, an additional defense pattern with the function of establishing social rank, thus minimizing injury and, sometimes, avoiding death of the contenders. Bridging the gap between these defense strategies and animal models of anxiety disorders, the above strategies of antipredator defense have been related to normal and pathological emotions: potential threat with anxiety and GAD, distal threat with fear and phobias (▶ agoraphobia), and proximal threat with dread and PD, respectively. In addition, submission has been related to shyness and ▶ social anxiety disorder.

In terms of neural organization, animal research has indicated that potential and distal threat engage mainly forebrain brain structures, such as the ▶ prefrontal cortex, the ▶ hippocampus and the ▶ amygdala, while proximal defense is chiefly organized in the ▶ hypothalamus and the midbrain periaqueductal gray matter (PAG). Functional neuroimaging results in humans have accordingly shown that brain activation shifts from the prefrontal cortex to the PAG as a virtual threat approaches a virtual prey, and the intensity of punishment increases (Mobbs et al. 2007).

This knowledge underpins theoretical constructs that implicate forebrain structures in the pathophysiology of GAD and the PAG, in PD. Therefore, animal models with theoretical validity can be derived from the same perspective. One clear example of this trend is the elevated T-maze (ETM), which is derived from the elevated plus-maze by shutting off one of its enclosed arms. In this apparatus, the same rat performs two tasks in succession: inhibitory avoidance of the open arm, when placed for three successive times at the end of the enclosed arm, and one-way escape, when placed for three times at the end of one of the open arms. Pharmacological validation studies have shown that not surprisingly, the inhibitory avoidance has predictive value for GAD, since it is another version of a conflict test. More interesting are the findings that chronic, but not acute treatment with antidepressants impairs one-way escape, whereas the panicogenic agent CCK enhances its performance, both changes correlating with drug effects that have been observed in panic patients (Pinheiro et al. 2007). Moreover, the ETM has been successfully used to test hypotheses on the role of serotonin (5-HT) in anxiety and panic, and is being used to screen potentially antianxiety and/or antipanic agents in extracts from plants.

Based on the same rationale, other models of GAD and/or PD have been developed (e.g. the mouse defense test battery and the electrical/chemical stimulation of panic related brain areas such as the dorsal aspect of the PAG and medial hypothalamus). A detailed description of these models as well as a comparative analysis of their

validity and feasibility can be found in Graeff and Zangrossi (2002)

Finally, animal models for social anxiety disorder, ► obsessive compulsive anxiety disorder and ► traumatic stress disorder have also been developed following the present trend towards theoretically-based models addressed to specific anxiety disorders. Nevertheless, their pharmacological validation is still under way.

► Apolipoprotein E

Apolipoprotein E

APOE

Definition

APOE is essential for the normal catabolism of triglyceride-rich lipoprotein constituents. APOE was initially recognized for its importance in lipoprotein metabolism and cardiovascular disease. More recently, it has been studied for its role in several biological processes not directly related to lipoprotein transport, including Alzheimer's disease (AD), immunoregulation, and cognition.

The APOE gene is polymorphic with three major alleles: ApoE2, ApoE3, and ApoE4, which translate into three isoforms of the protein:

E2 is associated with the genetic disorder type III hyperlipoproteinemia and with both increased and decreased risk for atherosclerosis.

E3 is found in approximately 64% of the population. It is considered the "neutral" Apo E genotype.

E4 has been implicated in atherosclerosis and Alzheimer's disease, impaired cognitive function, and reduced neurite outgrowth.

Apomorphine

Definition

Apomorphine is a drug used to treat impairments in motor function (tremor, slow movement, and difficulty walking and speaking) in Parkinson's patients. It is sometimes used for erectile dysfunction. In larger doses, it has emetic effects and was used in aversion therapies. It is a nonspecific dopamine agonist with actions at several subtypes of dopamine receptors, both presynaptic and postsynaptic. As a pharmacological tool for probing the function of dopamine receptors, it has been largely replaced by more selective substances. It does not have morphine-like effects and does not interact with opioid receptors.

Physiological cell death; programmed cell death

Definition

Apoptosis is a form of regulated physiological cell death that is important during ontogenesis but which may also contribute to tissue homeostasis as well as pathology.

Current Concepts and State of Knowledge

Characteristics of Apoptosis

Apoptosis may be triggered by signals from within the cell or proximal and distal cells, as well as exogenous agents; apoptotic cell death may also result from the withdrawal of trophic factors (► nerve growth factors). All of these triggers initiate a cascade of events that results in the elimination of cells without releasing harmful substances into the surrounding areas. Apoptosis is not associated with an inflammatory response; in situ, apoptotic cells are phagocytosed by macrophages or neighboring epithelial cells, whereas the fragments of cells that have undergone apoptosis in vitro are eventually lysed.

In its original sense, the term apoptosis was used to refer to a form of "programmed cell death" that depends on the activation and/or repression of ► gene transcription to delete biologically redundant or dysfunctional cells. Growing knowledge of how cell death is triggered and of the processes that lead up to it indicate a degree of overlapping mechanisms in different forms of cell death; this has resulted in a blurring of how apoptosis should be defined. However, the consensus is that apoptosis can only be ascertained through the morphological observation of chromatin condensation with evidence of DNA cleavage, nuclear fragmentation, cell shrinkage, blebbing of the nuclear and plasma membranes, and formation of membrane-bound apoptotic bodies in cells that otherwise have an integral plasma membrane. At the biochemical level, apoptotic cells show signs of mitochondrial dysfunction. Specifically, the mitochondrial membrane

potential is perturbed and results in a leakage of mitochondrial proteins, such as cytochrome *c*, into the cytoplasm; cytochrome *c* is a soluble protein whose ability to transfer electrons plays a key role in energy generation.

Apoptosis Versus Necrosis

In contrast to apoptosis, cell death through necrosis may be considered to occur "accidentally" following direct disruption of cellular homeostasis of cellular functions by a toxin or noxious stimulus (e.g., hypoxia, hypothermia), resulting in an influx of water and extracellular ions. Morphologically, this form of cell death, which differs from apoptosis, is characterized by swelling of the cytoplasm and mitochondria and the ultimate disintegration of the plasma membrane, leading to the leakage of lysosomal enzymes that lyse a group of contiguous cells (typically apoptosis affects only individual cells), usually followed by an inflammatory response. Other important features that distinguish apoptosis and necrosis are (1) DNA fragmentation in apoptosis occurs through the actions of specific DNA-cleaving enzymes (endonucleases) while the cell is still intact, whereas DNA breakdown in necrotic cells occurs only after cell lysis and the DNA fragments are of random size; (2) apoptosis is an energy (ATP)-dependent process, whereas necrosis is a passive process; and (3) whereas necrosis results from a massive influx of calcium in the cell, apoptosis is triggered by moderate increases in calcium influx. Various assays that are based on the above-mentioned morphological and cytological descriptions serve to discriminate between apoptotic and necrotic cells both in vivo and in vitro; in addition, researchers increasingly rely on other biochemical and molecular markers to detect early- and late-stage apoptosis.

Apoptotic Mechanisms

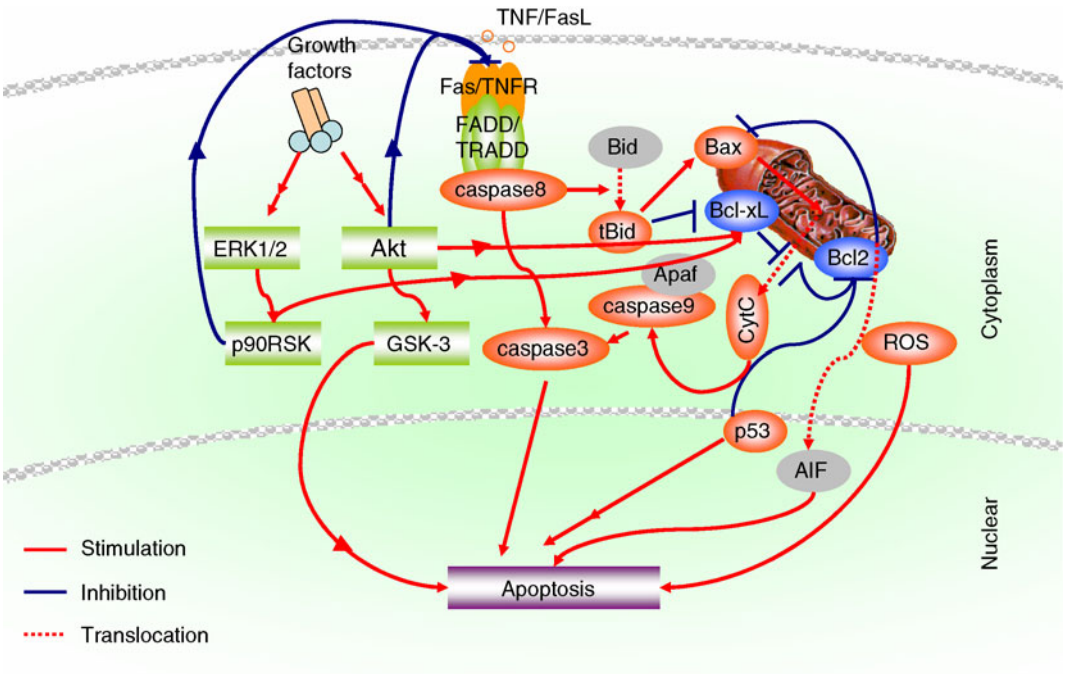
An understanding of the molecular and cellular basis of apoptosis has grown immensely in the last decade. While the molecular processes that lead to apoptosis are initiated in the cytoplasm or the membranes of organelles, the final execution of the apoptotic process takes place in the nucleus where irreversible, Ca^{2+}/Mg^{2+}-dependent internucleosomal DNA fragmentation occurs in a sequential fashion, mediated by endonucleases.

In general, apoptosis results through one of two cellular pathways, the intrinsic and extrinsic pathways; however, growing evidence points to the possibility that these pathways may converge under certain circumstances. The sequential activation of caspases is central to both pathways; the activation of caspase 3, a so-called executor caspase serves as a good biochemical marker of apoptosis. In addition, apoptosis may occur independently of caspase activation. Several stimuli, including DNA damage, and oxidative and excitotoxic stress, cause the translocation of apoptosis-inducing factor (AIF) from the mitochondrial intermembranous space to the nucleus where AIF binds to DNA and initiates apoptosis by promoting chromatin condensation (Fig. 1).

The intrinsic pathway is initiated by the perturbation of the mitochondrial transmembrane potential, which is rheostatically regulated by the availability of pro- (e.g., Bax, Bid) and anti-apoptotic (e.g., Bcl-2, Bcl-X_L) members of the Bcl-2 family of proteins. A shift in the ratio of these proteins in favor of the pro-apoptotic members leads to the release of mitochondrial cytochrome *c* (a heme-containing protein involved in electron transfer) which, in turn, binds to apoptosis protease activator factor-1 (Apaf-1), forming an apoptosome that subsequently cleaves and activates pro-caspase 3. In the extrinsic pathway, the binding of either Fas ligand, tumor necrosis factor (TNF) α, or tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) to their corresponding membrane receptors results in the formation of a complex between liganded and pro-caspase 8. When cleaved, caspase 8 can activate caspase 3 directly, or indirectly by cleaving the pro-apoptotic protein Bid in the cytoplasm; truncated Bid (tBid) translocates to the mitochondrion where it disrupts that organelle's permeability transition pore, resulting in cytochrome *c* release and the ultimate activation of caspase 3.

Neuronal apoptosis may be triggered by both, pro-apoptotic signals as well as limited availability of (neuro) trophic molecules (nerve growth factors); the latter mechanism is important in both physiological and pathological contexts and led to the discovery of pro-survival signaling pathways that act to suppress the cell death machinery. Among the best-characterized survival pathways are the Ras-MAPK (mitogen-activated protein kinase) and the PI3K (phosphatidylinositide-3′-OH kinase)-Akt pathways.

It is estimated that neurons undergo apoptotic death within 6-12 h from first being exposed to a pro-apoptotic stimulus. Under normal circumstances, apoptosis occurs widely in the developing brain; it also occurs throughout postnatal life, albeit at a much reduced rate. It is estimated that apoptosis results in the elimination of up to 70% of neurons during early brain development; accordingly, it is thought to serve a physiological role, serving to ensure appropriate structure and function of the brain and the



Apoptosis. Fig. 1. The pathways to apoptotic cell death. Two pathways, the so-called intrinsic and extrinsic pathways, regulate apoptosis. In both pathways, caspases, a family of cysteine proteases, play a central role. The arrival of apoptotic signals leads to the activation of initiator caspases (e.g., caspase-8, -9) and sequential cleavage/activation of downstream effector caspases; caspase-3 is the last caspase in this cascade and is known as the "executor caspase" since the process cannot be reversed once this caspase is activated. The extrinsic pathway is triggered after the binding of FasL or TNF to their respective cognate receptors (Fas and TNFR), followed by the activation of caspase-8 through the adaptor protein FADD/TRADD. Activated caspase-8 can stimulate apoptosis through one of two cascades: direct activation of caspase-3 or cleavage of Bid. Truncated Bid (tBid) translocates to the mitochondrion where the extrinsic pathway converges with the intrinsic pathway in which the formation of pores in the outer mitochondrial membrane and the leakage of cytochrome *c* is a central event. Cytochrome *c* binds Apaf1 to form an activation complex with caspase-9, an event critical to the activation of the intrinsic pathway. Members of the BCl-2 family of proteins, including the anti-apoptotic proteins Bcl-2 and Bcl-xL and pro-apoptotic protein Bax, rheostatically control apoptosis by determining the integrity and permeability of mitochondrial membranes and thus, cytochrome *c* release. The tumor suppressor protein p53, which is activated following DNA damage, induces the transcription of Bax, which, in turn, disrupts the mitochondrial potential. More recently, another apoptotic mechanism involving mitochondrial release of apoptosis inducing factor (AIF) was identified. AIF translocates to the nucleus and directly triggers the internucleosomal degradation of DNA. Reactive oxygen species (ROS) can also directly induce apoptosis by damaging DNA strands. On the other hand, anti-apoptotic signals, including growth factors and cytokines, act by inducing the phosphorylation of signaling molecules such as Erk1/2 and Akt. Erk1/2 activates p90RSK, which upregulates the expression of the anti-apoptotic proteins Bcl-xL and BCl2 and inhibits the Fas pathway; similarly, activated Akt regulates the expression of members of the Bcl2 family and of Fas while inhibiting GSK-3 signaling.

ability of the brain to adapt to changing demands. As neuronal apoptosis is essential to normal brain development and function, it is conceivable that it may contribute to brain pathology and pathophysiology if it arises at an inappropriate time or location, or in excess or an insufficient extent.

Neuronal Birth, Death, and Plasticity

Ensuring the correct number of functional neurons in a given brain area depends on the coordinated birth and death of neurons. Extensive neuronal birth (► neurogenesis) in the mammalian brain ceases during postnatal life; two areas, the ► hippocampus and

olfactory bulb however continue to show neurogenesis throughout life although the rate of cell birth tapers off with age.

The mechanisms that regulate neurogenesis are common to other forms of cell proliferation, and include the expression of cyclin-dependent kinases that drive the dividing cells through the various stages of the cell cycle in a temporally coordinated fashion. The end of cell proliferation (mitosis) is marked by the expression of proteins that induce cell cycle arrest; however, whereas most other cell types can go through repeated mitotic cycles, differentiated neurons are considered to be in a permanent postmitotic state. While differentiated neurons are sensitive apoptotic stimuli, undifferentiated or migrating young neurons appear to be particularly sensitive and their elimination through apoptosis (probably through the programmed withdrawal of neurotrophic support nerve growth factors) is responsible for giving the brain its final structure. Importantly, a growing body of evidence shows that some mature neurons may reenter the cell cycle, namely by reactivating several of the molecular components that typify mitosis; however, this reentry into the cell cycle is abortive and ends in apoptosis, a mechanism now thought to be of importance during brain development and neurodegenerative disease such as Alzheimer's disease (► dementias and other amnesic disorders).

Brain structure and function undergoe dynamic – plastic – changes from early development through to old age. Neurogenesis and neuroapoptosis are essential parts of this process insofar as they determine communication between individual neurons (adjacent or at a distance), and whole pathways or networks and even whole systems, as well as interactions with supporting glial and vascular tissues. Additionally, the balanced relationship between neurogenesis and apoptosis can be expected to be important to histogenetic constancy (stability) as well as flexibility (► synaptic plasticity); computational models suggest neuronal turnover to play a facilitative role in learning and information recall (memory) by, respectively, filtering relevant information from irrelevant information and reducing interference from other information (► long-term potentiation and memory).

Why IS Apoptosis of Interest to Neuropsychiatry?

In the mature brain, apoptosis occurs at a low rate but that may, nevertheless, be sufficiently significant to contribute to the reorganization of neuronal circuits. Neuropsychiatric diseases are thought to be neurodegenerative or neurodevelopmental in origin. Neuronal death, including that occurring through apoptosis, is a defining pathological feature of neurodegenerative diseases (► neurodegeneration and its prevention) such as ► Parkinson's disease, ► Alzheimer's disease, ► Huntington's disease, amyloid lateral sclerosis (or Lou Gehrig's disease), and human immunodeficiency virus (HIV)-associated dementia. Aberrant neuronal apoptosis may also underlie neurodevelopmental disorders such as ► schizophrenia, ► autism, and ► fragile X syndrome. Some of the known effects of various classes of psychoactive drugs on neuronal survival are summarized in Table 1.

Loss of neurons through apoptosis appears to underlie ► fetal alcohol syndrome, a neurodevelopmental disorder

Agent	Examples	Properties/Uses	Neuronal survival
	► Methylphenidate (cognitive enhancers)	Inhibits DA reuptake; enhances cognition, may cause anxiety and general nervousness, emotional lability, aggression and paranoia; treatment of attention-deficit hyperactivity disorder, narcolepsy, and chronic fatigue syndrome; likely to be abused	Reportedly protective against excitotoxicity but also pro-apoptotic
	Ampakines (cognitive enhancers)	Alkaloid analgesic; tolerance and dependence may develop after chronic use; addictive/clinical management of pain	Neuroprotective (increase neurotrophin production)
	Morphine (prototypic opiate) (► opioids)	Alkaloid analgesic; tolerance and dependence may develop after chronic use; addictive/clinical management of pain	Pro-apoptotic
	Heroin (opioids)	3,6-diacetyl ester of morphine recreational to obtain a "rush"	Pro-apoptotic (intrinsic and extrinsic pathways)
	► Caffeine	Xanthine alkaloid, antagonizes adenosine receptors; may produce tolerance, physical dependence, and craving, irritability, nervousness, anxiety, insomnia, and headache/most common nonprescription psychostimulant ("energizer") in food and beverages	Regulates cell cycle checkpoint proteins and DNA repair and may protect against Parkinson's disease
	► Nicotine	Affects cholinergic, DA-, NE-, and 5HT-ergic, and neuropeptidergic transmission; highly addictive/in cigarettes, to produce euphoria/pleasure, relaxation, increased arousal/alertness and memory (low doses), reduced appetite and induce sedation and pain (high doses); treatment of nicotine addiction (only medical use)	No consensus; suggested reduced risk of Parkinson's and (possibly) Alzheimer's disease; may be risk factor for schizophrenia

Apoptosis. Table 1. (continued)

Agent	Examples	Properties/Uses	Neuronal survival
Sedatives and anxiolytics		Suppress neuronal activity by acting as GABA mimetics, and modulating activity of NMDA, opioid and cannabinoid receptors; highly addictive; reduce attention and slow reflexes; are not addictive but ''discontinuity symptoms'' arise upon abrupt withdrawal	
	Opiates, general anesthetics (► analgesics, ► opioids)	Some, such as phencyclidine (''angel dust'') may cause hallucinations, delirium, mania and disorientation/in anesthesia (phencyclidine now replaced in anesthesia by ketamine, another NMDAR antagonist)/analgesia and anesthesia; opiates are subject to abuse	Phencyclidine and ketamine are pro-apoptotic; opiates also induce apoptosis
	► Barbiturates, ► benzodiazepines and other ► anticonvulsants	Block Na+ channels and bind to GABA receptors; anti-convulsant, anxiolytic, hypnotic/have high-abuse potential/treatment of epilepsy and ► bipolar disorder (barbiturates now rarely used); also used as recreational drugs	Barbiturates and benzodiazepines are pro-apoptotic, especially in developing brain
	Ethanol/(alcohol abuse and dependence)	Impairs problem solving, abstract thinking, concept shifting, psychomotor performance, and performance in memory tasks (severe amnesia in extreme cases), and may cause dementia; causes attention-deficit hyperactivity disorder and learning difficulties in childhood and high incidence of major depression and psychosis in later life/in pharmaceutical preparations; widely used for recreational purposes	Pro-apoptotic; acute doses cause dendritic re-arrangements; fetal exposure results in apoptosis of developing neurons and causes diminished brain size (causes fetal alcohol syndrome by increasing reactive oxygen species production, while reducing defenses against them; and hyperactivation of GABAergic transmission and increase of glutamate excitotoxicity)
	5HT 1a receptor agonists (e.g., buspirone)	Lower anxiolytic potency than benzodiazepines, but do not cause sedation and have less-severe effects on cognition; have no abuse potential	Anti-apoptotic, currently being tested in models of stroke, brain trauma, and ethanol-induced apoptosis

Agent	Examples	Properties/Uses	Neuronal survival
► Anti-psychotic drugs (neuroleptics)	*Typical:* haloperidol, chlorpromazine; *atypical or second-generation*: olanzapine, risperidone, quetiapine	Activate DA D2 receptors and inhibit DA release; may cause one or more of the following: tardive dyskinesia, acute dystonia, akathisia, parkinsonianism (rigidity and tremor), lethargy, seizures, psychosis, intense dreams, or nightmares/treatment of schizophrenia	Possibly induce neuronal apoptosis through excitotoxic mechanisms, disruption of the mitochondrial respiratory chain, or reduced neurotrophic support
► Anti-depressants			Generally, increase neurotrophic support and promote neuroplasticity, although cell culture studies indicate that many have the potential to trigger oxidative stress and activate apoptotic pathways
	► Monoamine oxidase inhibitors (MAO)	MAO-A inhibitors reduce breakdown of 5HT, and NE/treatment of depression, bipolar disorder, and agoraphobia (social anxiety); MAO-B inhibitors reduce catabolism of DA/treatment of Parkinson's disease	Appear not to cause apoptosis in neural cell cultures
	Tricyclic compounds	Inhibit presynaptic reuptake of 5HT and NE; some tricyclics interfere with memory performance, many reduce histamine actions (H1 receptor), producing sedation/treatment of major depression, and insomnia, migraine, anxiety, attention-deficit hyperactivity disorder, chronic pain, (sometimes) schizophrenia	Induce neurogenesis and neuroplasticity
	Selective serotonin- or NE-reuptake inhibitors (► SSRIs and related compounds, ► SNRI antidepressants)	Increase 5HT and NE levels in synaptic cleft by inhibiting their presynaptic reuptake/treatment of major depression and anxiety disorders, as well as eating disorders and chronic pain	Induce neurogenesis and neuroplasticity
	Neuropeptide receptor antagonists	Block pituitary receptors for hypothalamic peptides that stimulate adrenal activity/in trials for use as antidepressants and anxiolytics	► Corticotropin-releasing hormone (CRH), implicated in depression and anxiety, appears to be neuroprotective

Apoptosis. Table 1. (continued)

Agent	Examples	Properties/Uses	Neuronal survival
► Mood stabilizers and ► anti-convulsants	► Benzodiazepines, barbiturates, GABA analogs, and inhibitors of GABA breakdown (e.g., vigabatrin), hydantoins (e.g., phenytoin), carbamates, carboxamides	Anti-convulsant actions result from blockade of Na+ channels and enhancement of GABAergic-mediated inhibition of neuronal firing or block glutamatergic transmission/treatment of acute and recurrent seizures	Reduce neurotrophic molecules, leading to neuronal apoptosis (may account for microcephaly and impaired neurodevelopment and cognitive functions); some drugs disrupt neuronal migration in the developing brain
	► Valproic acid	Inhibits GABA transaminase, increasing GABA production; affects long-term gene expression by inhibiting ► histone deacetylase (HDAC)/treatment of epilepsy and manic phase of bipolar disorder	Interferes with neuronal migration and induces neuronal apoptosis in developing brain; is neuroprotective in postnatal neurons (via insulin-dependent activation of PI3-K/Akt
	► lithium	Respectively, decreases and increases NE and 5HT release; inhibits glycogen synthase 3β (GSK-3β)/treatment of manic phase of bipolar disorder	Promotes neuronal survival by inhibiting GSK-3β, activating the PI3-K/ Akt pathway, increasing neurotrophin production factors, heat shock proteins (hsp 70) and anti-apoptotic proteins (e.g., Bcl-2)
Hormones	Sex hormones (estrogens, androgens, progestins)	Act through nuclear receptors (transcription factors), but may also rapidly alter membrane properties and neuronal firing rates; cognition, reward processes, mood and emotion are positively influenced by estrogens and androgens; progestins induce anxiolysis, sedation and somnogenesis by allosteric modulation of $GABA_A$ receptors; all are involved in aggressive and affiliative behaviors/naturally produced by the gonads, may be prescribed for a variety of endocrine dysfunctions and during aging; androgens may be used as anabolics	Anti-apoptotic actions resulting from phospho-activation of the MAP and Akt pathways, stimulation of neurotrophin production and altered anti- and pro-apoptotic protein ratios; estrogens can scavenge oxygen free radicals

Apoptosis. Table 1. (continued)

Agent	Examples	Properties/Uses	Neuronal survival
	Glucocorticoids (natural hormones include cortisol and corticosterone; synthetic glucocorticoids include prednisolone and dexamethasone)	Bind to nuclear receptors – mineralocorticoid (MR) and/or glucocorticoid receptors (GR) – in an amplitude-dependent fashion to induce or repress gene transcription; have anxiogenic and depressogenic properties, interfere with learning and memory/naturally produced by the adrenal cortex, glucocorticoids may be prescribed as anti-inflammatory agents and for shock and certain cancers; also used in endocrine diagnostics	Activation of GR by high glucocorticoid levels leads to neuronal apoptosis, low glucocorticoid levels that selectively occupy MR are neuroprotective; glucocorticoids also inhibit neurogenesis and neurotrophin synthesis, and induce dendritic retraction

that is associated with hyperactivity, learning disabilities and depression during childhood, and psychoses in adulthood. Convincing data demonstrate that ethanol (► alcohol abuse and dependence) stimulates neuronal apoptosis in a variety of cortical regions by interfering with GABAergic and glutamatergic neurotransmission during developmental stages characterized by a high rate of synaptogenesis. Similar mechanisms are also thought to be responsible for the apoptotic actions of a number of drugs that have medical applications (anesthesia, epilepsy) but which are also subject to abuse.

An etiologic role for enhanced apoptosis has also been proposed in major depression, although post mortem examinations have led some authors to challenge its importance. Although increased levels of apoptosis are observed in some animal models of depression (► depression: animal models) based on chronic stress paradigms that elevate glucocorticoid secretion and despite strong evidence that glucocorticoids are potent pro-apoptotic (and anti-neurogenic) hormones, a causal link between neuroapoptosis and depression remains to be firmly established. Studies showing that stress and glucocorticoids induce dendritic reorganization and synaptic connections suggest a rather more important role for these mechanisms in the etiology of depression. While a number of ► antidepressants have been shown to induce apoptosis in neuronal cultures, the majority of studies in animals indicate that antidepressants might exert their therapeutic actions by stimulating neurotrophin (► nerve growth factors) production and therefore, neuroplasticity. The known inhibition of neurotrophin expression by glucocorticoids may be the link between stress and psychiatric diseases such as depression and anxiety (► emotion and mood). In addition, elevated glucocorticoids have been clearly shown to impair cognition; besides their ability to modulate neuronal firing patterns and synaptic plasticity, ► glucocorticoids have been recently shown to promote the aberrant processing and posttranslational modification of proteins implicated in mild and severe forms of dementia (► dementias and other amnesic disorders).

In addition to glucocorticoids, several endogenous peptidergic and steroid hormones have emerged as being potentially important in neuropsychiatry. ► Corticotropin-releasing hormone and ► arginine vasopressin are examples of neuropeptides that have gained considerable attention; both peptides act on the pituitary and ultimately stimulate glucocorticoid secretion and because they have marked influences on ► emotion and mood and cognition in animals, they have been implicated in ► major and minor and mixed anxiety-depressive disorders. Progestins and their derivatives (► neurosteroids) are well known for their sedative and anxiolytic effects that are mediated by $GABA_A$ receptors, and estrogens (► sex hormones) appear to have mood- and cognition-enhancing (► cognitive enhancers) effects that are attributed to their neurotrophic and anti-apoptotic actions.

Conclusion

Many psychoactive drugs have been studied for their possible apoptotic effects on neurons. Studies of such

effects during brain development raise concerns that drug-induced apoptosis can have a major impact on the development of neuropsychiatric conditions in childhood and later life. Demonstrations of psychoactive drug-induced apoptosis in the mature brain are important in that they may account for some of the undesired side effects of therapeutic agents, the ▶ antipsychotic drugs being a good case in point (see Table 1). However, caution is called for in the interpretation of results since many of them derive from experiments in artificial cell culture settings that may differ in terms of kinetics and which lack the normal drug metabolism mechanisms that operate in the whole organism; also, to be considered is the fact that the disposition and action of a drug varies according to the context in which it is administered (▶ pharmacokinetics, ▶ sex differences in drug effects). Physicians' prescribing decisions are guided by evidence of therapeutic efficacy and immediacy, and careful risk-benefit analysis on a case-by-case basis.

Apoptosis-Inducing Factor

Synonyms

AIF

Definition

It is a protein found on the inner leaflet of mitochondrial membranes. Upon the arrival of an apoptotic stimulus, AIF contributes to the increased permeability of mitochondrial membranes, resulting in its own entry into the cytosol and nucleus.

Apoptosome

Definition

It is the term used to describe the multimeric cytoplasmic complex that forms when cytochrome *c* is released from

mitochondria into the cytosol and binds to apoptosis protein-activating factor 1 (Apaf1), dATP, and initiator caspases such as caspase 9. The apoptosome plays a key role in the activation of ► apoptosis.

Appetite

Definition

The desire to eat. A willingness to consume food that can be indexed by the tendency to engage in activities that will procure food, and by the rate, duration, and quantity of food consumed. Appetite can be aroused by external food stimuli (such as the sight or smell of food) and enhanced or diminished by the oral sensory qualities of the taste, flavor, and texture of foods as they are eaten. Specific appetites (or cravings) may occur in relation to specific physiological imbalance, illness, or external food cues.

Definition

Appetite stimulants are agents that promote the motivation to eat through actions on psychological, neurochemical, metabolic, or endocrine processes. Their actions may increase ► hunger and the desire to eat, promote the anticipation of, or craving for food, and/or enhance hedonic responses to the sensory properties of foods. These psychological effects may cause over consumption by increasing the salience of, and attention to, food stimuli and so advance the initiation of eating, or by increasing meal frequency, meal size, or meal duration. Drugs that increase ► appetite and/or food intake, and that may be used for the amelioration of loss of appetite and body weight associated with illness or radical medical treatments of disease.

Pharmacological Properties

History

Unlike the substantial commercial and academic research efforts that have been devoted to the development of appetite suppressant treatments, relatively few resources have been expended on the rational design of appetite stimulants. Several classes of drug possess the ability to increase appetite and food intake, but these effects are often poorly characterized side effects of treatments that were primarily intended for other clinical purposes. Multiple neurochemical and endocrine systems have been implicated in the stimulation of appetite through the hyperphagic actions of endogenous or synthetic receptor ligands. These include gamma-aminobutyric acid (► GABA), agouti-related peptide (AgRP), neuropeptide Y (► NPY), melanin-concentrating hormone (MCH), ghrelin, the endogenous ► opioids, and the ► endocannabinoids. With recent progress in the characterization of the systems involved in appetite control and body weight regulation, a wide range of experimental compounds that act as agonists or antagonists at specific receptors have been shown to have orexigenic effects in animal models. However, for most of these agents, their use is restricted to experimental probes for the study of neural appetite-control pathways.

Mechanisms of Action

Some drugs have hyperphagic effects that are widely acknowledged in clinical populations, but for which clear mechanisms have yet to be identified – despite considerable knowledge about their principal pharmacological actions being available. Appetite stimulation and the development of overweight or obesity are not uncommon side effects of drugs used to treat psychiatric disorders (Schwartz et al. 2004). Intriguingly, of the more classical drug groups, agents with anxiolytic-sedative properties are most likely to exert hyperphagic actions – at least under laboratory conditions. These agents include ► benzodiazepines, some antihistamines, ► barbiturates, ► opiates, and ► cannabinoids.

The majority of experimental agents that have exhibited orexigenic efficacy in animal models have not been assessed

in relation to that activity in humans: the few that have, rarely – if ever – progress beyond the preclinical stages of development. Similarly, clinical exploitation of the hyperphagic side effects of psychotropic drugs and other medicines are often poorly studied, with a dearth of controlled clinical trials. In the long term, continuing research into the central and peripheral processes that mediate appetite control and energy balance will ultimately clarify specific processes through which the orexigenic properties of drugs come to be expressed. Currently, however, precise mechanisms of action are defined for only relatively few of these drugs. Therefore, the main emphasis here will be on a largely phenomenological description of those drugs which have demonstrable hyperphagic actions in humans and for which clinical applications for the treatment of appetite and weight loss have been actively pursued.

Clinical Application of Appetite Stimulants

An often-overlooked area in a world obsessed by obesity is the treatment of clinical conditions in which the progress of a disease is associated with involuntary weight loss. For example, wasting, or cachexia, is a common feature of the later stages of diseases such as AIDS and metastatic cancer, and is a significant factor in their morbidity. Cachexia is characterized by the loss of fat and lean mass resulting from abnormalities in protein synthesis/degradation, lipid and glucose metabolism, and energy utilization. Additionally, sufferers typically fail to exhibit any compensatory increase in eating motivation to counter these changes – as would be the case with weight loss caused by fasting. Disease-related wasting may be further exaggerated by the effects of radical drug or radiation therapies, which frequently lead to loss of appetite and malnutrition, sometimes as a consequence of treatment-induced nausea, vomiting, and taste aversions. Wasting and loss of appetite are also clinically important features of aging, particularly in relation to the dementias.

Cannabinoids

Of all the drugs that might be discussed here, alkaloids (► cannabinoids) derived from Cannabis *sativa* (marijuana) have the most widely recognized and well-documented hyperphagic actions. Cannabis, or pharmacologically active preparations derived from the plant, has been ascribed appetite stimulant effects for centuries, and this medicinal application is evident in the pharmacopeia of many cultures throughout history. With the identification of the psychoactive molecules in cannabis in the 1970s, such as Δ^9-tetrahydrocannabinol, it became possible to standardize cannabinoid-dosing regimen for both clinical and research purposes - although the extent of research, and clinical use, of THC is relatively limited.

Using animal models, the underlying mechanisms responsible for cannabinoid ► hyperphagia have been established to involve the stimulation of cannabinoid CB_1 receptors within the central nervous system. Exogenous CB_1 agonists, such as THC, and the natural ligands for these receptors (the endocannabinoids; e.g., anandamide, 2-arachidonoylglycerol, noladin ether) all exert orexigenic actions in animal models. Conversely, CB_1 blockade by antagonist drugs such as ► rimonabant will not only prevent agonist-induced eating, but also suppress food intake in its own right. Additionally, brain levels of endocannabinoids have been shown to increase in response to fasting, and increased brain endocannabinoid activity has been associated with overeating of palatable foods and diet-induced obesity.

Overall, current evidence indicates that cannabinoid hyperphagia reflects alterations to the incentive and reward aspects of eating motivation (Kirkham 2005). Cannabinoid receptor agonists can energize food-seeking behavior independently of need or energetic status: advancing the onset of feeding even in satiated animals, and increasing the effort an animal will expend to obtain food. Additionally, there are data that support specific modulation by endocannabinoids of the hedonic aspects of eating, with CB_1 agonists specifically enhancing the liking for foods.

These findings are in line with anecdotal evidence from cannabis users and laboratory experiments in healthy human volunteers with cannabis cigarettes, and oral THC. Thus, it is frequently reported that cannabis can promote the anticipation and enjoyment of food, while it has been demonstrated empirically that THC will amplify the normal pre-meal rise in hunger and promote the overconsumption of palatable foods.

There are indications that cannabinoids produce their effects on appetite in part by the modulation of other neurotransmitters that have been implicated in the control of food intake. For example, cannabinoid receptor antagonists can block the hyperphagic effects of the putative peptide "hunger" signal ghrelin, and of the potent orexigenic peptides NPY and MCH. Of particular interest, is the apparent relationship between endocannabinoids and the endogenous opioid peptides (e.g., beta-► endorphin).

Overall, current evidence supports an important role for endocannabinoids in the instigation of hunger and food seeking, the anticipation of food, and eating pleasure. Within the brain, these different processes are linked to pathways that center upon the ► nucleus accumbens, a region that is intimately associated with incentive and reward processes. Mesolimbic dopaminergic neurons,

originating in the ▶ ventral tegmental area (VTA) and projecting to the nucleus accumbens are linked to incentive motivation, and the generation of emotional arousal and behavioral activation in response to stimuli that predict reward. Food stimuli cause dopamine release in the nucleus accumbens, and this effect is mimicked by both THC and anandamide. By contrast, accumbens dopamine release provoked by palatable foods is blocked by rimonabant, suggesting that endocannabinoids normally facilitate the mesolimbic dopamine signaling that gives rise to appetite. Endocannabinoids may thus be essential for the orientation to food stimuli, the attribution of incentive salience and reward anticipation, and the elicitation of hunger, food seeking, and eating initiation.

Mesolimbic dopamine neurons synapse with accumbens opioid neurons that are critical to the experience of pleasure. The opioid peptides have an established role in the hedonic evaluation of foods, with opioid receptor agonists and antagonists respectively increasing or reducing the liking of foods. The hyperphagic effects of THC and anandamide are both blocked by the opioid receptor antagonist ▶ naloxone; while a simultaneous blockade of cannabinoid and opioid receptors produces a very dramatic suppression of appetite. Such findings provide evidence of an important functional relationship between endocannabinoids and opioids in appetite, particularly in relation to food ▶ palatability and the enjoyment that is derived from eating. THC has been shown to stimulate beta-endorphin release in the accumbens – a phenomenon also associated with the consumption of palatable foods and the associated pleasure response. Importantly, both anandamide and the opiate ▶ morphine increase the liking of sweet solutions when injected into the same sites within the nucleus accumbens.

The ability of cannabinoids such as THC to promote appetite through combined effects on specific neural mechanisms that promote eating and mediate eating pleasure thus provides clear medical opportunities. Given the low toxicity of cannabis or THC, combined with their established ability to elevate mood, prevent nausea and vomiting, and to impede the acquisition of conditioned taste aversions (such as might be associated with the symptoms of disease, or the consequences of chemo- or radiotherapy), cannabinoids could provide effective therapies for appetite loss and wasting. Largely misguided political interference has prevented a comprehensive investigation of medicinal uses of cannabinoids. However, clinical studies in cancer and AIDS patients have shown positive benefits of a pharmaceutical form of THC (▶ dronabinol), leading to approval for the clinical use of the drug in the treatment of AIDS-associated anorexia and weight loss.

Steroids

Although the underlying mechanisms are largely unknown, steroids have been administered for their appetite-stimulating and weight-enhancing properties. The best example is megasterol acetate (a synthetic form of the hormone progesterone), which is reported to improve appetite and promote weight gain in patients with cystic fibrosis, AIDS, and cancer, as well as in the frail elderly (Chinuck et al. 2007). Treatment often involves very high doses (up to 800 mg per day) and is associated with a wide range of, often serious, side effects, with the consequent risks to the patient potentially overriding any desired clinical benefits. In addition, the weight gain that accompanies improved appetite with megasterol may result primarily from an increase in adipose mass rather than of lean tissues, the loss of which is a critical factor in the wasting associated with disease and aging. Growth hormone and testosterone have been shown in some trials to promote increases in lean body mass. However, the extent to which such improvements are related to changes in appetite is unknown, and side effects associated with chronic administration again restrict the use of these agents. Overall, the specific benefits of growth hormone and testosterone in relation to appetite remain to be assessed in properly controlled studies and their likely modes of action are currently little understood.

Antihistamines, Antipsychotics, and Antidepressants

One of the older pharmaceutical orexigenic treatments involves the antihistamine cyproheptadine. This drug, which also has anticholinergic properties and acts as a ▶ serotonin antagonist, has been shown to have beneficial effects in some clinical trials of disorders involving weight loss or wasting, including asthma, tuberculosis, and HIV–AIDS (but is seemingly less effective in relation to cancer cachexia). Additionally, there are some tentative findings that the drug may have positive consequences in relation to the treatment of anorexia nervosa (Powers and Santana 2004). The precise mechanism of cyproheptadine action is unknown, which is perhaps unsurprising given the broad pharmacological profile of the drug. However, animal experiments have implicated histamine in appetite control processes, and specifically the inhibition of eating. Thus, the blockade of hypothalamic histamine H_1 receptors by antagonist drugs stimulates eating, while agonists suppress food intake.

Actions on histamine systems may also partly underlie the well-known weight increasing effects of ► antipsychotic drugs (coincidentally, the first widely prescribed neuroleptic drug, ► chlorpromazine, was initially developed as an antihistamine). Both older neuroleptics and the newer atypical antipsychotics (e.g., ► olanzapine and ► clozapine) can stimulate appetite and promote significant weight gain in patients (Casey and Zorn 2001; Kluge et al. 2007; Wirshing 2004). Some studies have demonstrated significant increases in food craving, and even binge eating, in patients treated with atypical antipsychotics. Obviously, these phenomena can both impair general health (by causing or exacerbating comorbidities such as diabetes and cardiovascular disease) and reduce patient compliance with continuing treatments. Although a variety of possible mechanisms may explain these effects (including changes to the peripheral regulation of glucose utilization and fat storage), preclinical data suggest that antipsychotics that are antagonists with high affinity for H_1 are more likely to promote eating and weight gain. Additionally, antipsychotic-induced weight gain has also been linked with antagonistic actions at dopamine D_2, muscarinic ► acetylcholine M_1 and serotonin 5-HT_{2C} receptors, and agonist actions at 5-HT_{1A} receptors. Weight gain in patients taking atypical neuroleptics has also been linked to increased levels of ghrelin.

Weight gain is also a common feature of ► antidepressant treatment. The older tricyclic and monoamine oxidase inhibitors, and some of the selective serotonin reuptake inhibitors (SSRI) can produce significant weight gain, particularly with longer treatments at higher doses. Of the new atypical antidepressants, ► mirtazapine (a noradrenergic and specific serotonergic antidepressant), has pronounced appetite stimulant– and weight gain–inducing properties that have been explored clinically. Mirtazapine hyperphagia has again been attributed to actions on histamine systems, although other mechanisms cannot be precluded.

Benzodiazepines

The ► benzodiazepines have been widely exploited as anxiolytics, ► anticonvulsants, and hypnotics. But, in addition to these effects (and often in conjunction with them), benzodiazepines can exert extremely potent hyperphagic actions. These agents act via specific high affinity benzodiazepine receptors to enhance the inhibitory effects of GABA neurotransmission. In animal models, the hyperphagic actions of benzodiazepines are among the most profound of any class of orexigen, and involve the specific enhancement of the palatability or rewarding properties of food. These effects on appetite appear dissociable from the other psychological effects of benzodiazepines. Surprisingly, although appetite stimulation and substantial increases in food intake have been shown in humans under laboratory conditions, little is known about benzodiazepine effects on food intake or body weight in clinical populations. Despite their potent hyperphagic actions, and adoption by veterinarians to encourage eating in domestic animals, there is little or no recognition within the human clinical literature of these effects of benzodiazepines. However, it is evident from anecdotal reports on various user-oriented Web sites that increased appetite and overconsumption are recognized by patients themselves.

► Mood Stabilizers

A final group of drugs that may stimulate appetite comprises agents with anticonvulsant and/or mood-stabilizing properties used to treat epilepsy and ► bipolar disorder (Ben-Menachem 2007; Martin et al. 2009; Torrent et al. 2008). Within this group (which may also include the benzodiazepines and atypical neuroleptics), ► valproate and ► lithium in particular are associated with significant, unwanted weight gain. Again, the precise mechanisms have yet to be determined. However, valproate (► valproic acid) has been linked to an increase in the motivation to eat, as well as changes in appetite-related neuroendocrine factors – including an increase in levels of the orexigens ghrelin and NPY. Hyperphagic- and weight-increasing tendencies of valproate treatment are of particular concern in relation to childhood epilepsy and the risk for the development of obesity with lifetime treatment. It should be noted however that other anticonvulsants, such as topiramate, are associated with weight loss.

Specificity of Drug Action

Although there are tentative neuroendocrine mechanisms to account for overeating and increased body weight following the administration of different psychotropic drugs, what is missing in relation to most of the agents we have discussed is a clear description of more fundamental psychological/behavioral factors that might contribute to weight gain. For example, it is likely that (in addition to any specific action on appetite control processes or energy balance), sedative effects of neuroleptics, antidepressants, or other agents compound a patient's already diminished ability to maintain a good diet, or to engage in an active, non-sedentary lifestyle. Even if a drug does exert a specific action on appetite, it is unlikely that these effects have been studied in great detail in people (as

opposed to laboratory species). In the absence of detailed behavioral measurements, there is often the implicit assumption that weight gain results from specific motivational adjustments and increased food intake, but this may not be the case. Similarly, it is common to read statements that are largely unsupported by empirical data – such as that a particular drug causes craving for foods high in carbohydrate. Until these issues are properly addressed, appetite stimulant actions of many drugs are likely to remain as little more than an interesting footnote in clinical pharmacology texts, or a side effect listed in the pharmacopeia. A concerted research effort with properly controlled studies is required to identify the most useful and effective drugs that can be used for the specific purpose of increasing appetite, and to understand the mechanisms by which hyperphagia/weight gain may accompany the principal actions of psychiatric drugs.

Conclusion

Overeating and increased body weight are common side effects of many different psychiatric drugs and other medications. However, these phenomena are generally unwanted consequences of treatments: considerable effort is directed toward ameliorating such effects, rather than exploiting them in clinical situations where facilitating appetite and increasing body mass are the desired outcomes. The majority of drugs discussed here provide uncertain benefits in terms of clinically significant appetite stimulation or weight gain, produce their effects through unknown mechanisms, and their administration may entail a broad spectrum of unwanted and potentially health-threatening side effects. By contrast, cannabinoid receptor agonists have established hyperphagic actions, which can be understood in terms of specific neurochemical pathways that mediate appetite control and eating motivation. That these effects may be obtained in the absence of toxic side effects, and at doses below those that induce unwanted psychotropic actions, indicates that this class of drugs is a suitable target for the development of clinically useful appetite stimulants.

Definition

Any drug that alters ► energy balance by changing eating behavior to reduce caloric intake, thereby producing an energy deficit. These drugs are most often used for the treatment of obesity (excessive body mass) and the cardiometabolic risk factors associated with adiposity (excessive body fat). This contrasts with other pharmacological approaches to weight control which (1) inhibit nutrient digestion or absorption, or (2) prevent the storage or increase the utilization of energy within the body.

Pharmacological Properties

History

Appetite suppressants have traditionally been used to distract patients from feelings of severe ► hunger and for weight control. However, appetite suppressants provide only an option for weight management and historically numerous devices, diets, and other pharmacological treatments have been employed to control body weight. The commercialization of weight control products dates from the start of the mass production of these products and a plethora of "dieting" products have since been marketed. These include diuretics and preparations containing metabolic stimulants such as thyroid hormones.

The first modern appetite suppressant was ► amphetamine. Amphetamine (marketed as Benzedrine) became popular for weight control in the 1930s, and the treatment of obesity became one of its many legitimate medical uses. Amphetamine (dexamphetamine, not metamphetamine) remained available in some countries for weight control until quite recently, despite its psychological effects, effects of blood pressure, and abuse potential. However, after the Second World War amphetamine alternatives were sought. Some of these monoaminergic acting agents were the beta-phenethylamine derivatives, which had lower abuse potential. ► Phentermine became available in 1959 and is still used (under a multiplicity of names including Duromine, Fastin, Adipex, and Lonamin) to treat obesity in many countries despite its amphetamine-like nature. Other amphetamine-like drugs used for weight control, often "off label," include Diethylcathinone (Diethylpropion, Tenuate, Tenuate Dospan, Amfepramone), Mazindol (Mazanor or Sanorex), and ► Phenylpropanolamine (Acutrim and Dexatrim). Along with cardiovascular stimulation, side effects such as insomnia, anxiety, and irritability remain an issue with many of these drugs (Haddock et al. 2002).

From the late 1960s and 1970s the beneficial effects of the amphetamine-related compound ► fenfluramine on body weight were noted. Fenfluramine differed from the other amphetamine alternatives as it primarily acted on serotonergic rather than catecholaminergic systems. It was as effective as amphetamine but lacked the side effect profile and abuse potential (Blundell 1977). Fenfluramine (Pondimin) became available for medical use in the early 1970s and was eventually used in combination with phentermine as "Fen-Phen." The more serotonin (5-HT) selective isomer of fenfluramine, D-fenfluramine (Redux, Adifax), was approved in 1996 in the US for the treatment of obesity, although the drug was widely available outside the US prior to this date. However, in 1997, all forms of fenfluramine were withdrawn from the global market due to serious side effect issues (see side effect section later).

The withdrawal of fenfluramine-based treatments coincided with a growing awareness of the treatment of obesity and obesity-related disease by national health care systems, and the launch of two new antiobesity drugs, the gastrointestinal lipase inhibitor, Orlistat (Xenical, Alli) and the appetite suppressant, ► Sibutramine (Merida, Reductil). Sibutramine is a noradrenergic and serotonergic reuptake inhibitor originally developed in the late 1980s and early 1990s for the treatment of depression. However, it was soon apparent during clinical testing that the drug produced significant weight loss. Further research confirmed that this was primarily due to its selective effects on human appetite. The drug was approved for obesity treatment in the US and other markets in 1997 and despite periodic concerns over safety the drug has remained in use. Despite the growing obesity problems, prescription use of sibutramine and orlistat remained fairly constant and it was not until 2006 that another appetite suppressant successfully came to market.

The endocannabinoid CB_1 receptor antagonist ► Rimonabant (Acomplia) was approved in Europe in 2006 as pharmacotherapy for obesity and resulting comorbidities. However, the drug failed to gain similar approval in the US in 2007 because of persistent concerns over safety data (see later). Due to incidents of adverse psychiatric events, it was later recommended that the drug not be given to those with a history of suicide or related psychiatric problems. In 2009 the drug was withdrawn from all markets. Despite an inability to successfully develop new appetite-suppressing drugs for the treatment of obesity over the last decade, many drugs licensed for other indications produce changes in appetite and body weight. A few of these drugs may eventually become legitimate antiobesity drugs. For instance the glucagon-like peptide (GLP)-1 analog Exenatide (Byetta), approved in the US for the management of type 2 diabetes, has been shown to produce changes in appetite and persistent weight loss in obese diabetics.

Appetite Regulation

Signals that serve to terminate eating behavior and act as powerful inhibitors of further intake are generated from the start of consumption. There is an important distinction between the short-term satiety signals produced by the physiological consequences of meal intake (episodic), and the longer-term signals created by the body's constant metabolic need for energy (tonic). Episodic signals such as GLP-1 are a crucial factor in the meal-by-meal regulation of energy intake, and are critical to both the appetite fluctuations and patterns of eating behavior we undertake throughout the day (Halford and Blundell 2000). Tonic inhibitory signals, by contrast are generated by the storage and metabolism of energy. Whilst episodic and tonic factors comprise separate aspects of appetite regulation, generated by markedly distinct processes, both ultimately act to inhibit food intake via common hypothalamic circuitry (Halford and Blundell 2000).

It is not only the peripheral targets which provide opportunities for drug development. Within the central nervous system (CNS), a complex array of chemicals and structures regulate the expression of appetite, particularly the brain stem and the hypothalamus. The arcuate nucleus (ARC) of the hypothalamus is considered to play a key integrative role between the these afferent signals from the periphery such as glucose, ▶ leptin, insulin, and ghrelin and other CNS changes such as serotonin function. The ARC has neuronal subpopulations that produce ▶ orexigenic (▶ neuropeptide Y (NPY) and ▶ agouti-related peptide (AgRP)) as well as ▶ anorexigenic peptides (α-melanocyte-stimulating hormone (α-MSH)), galanin-like peptide (GALP), and cocaine-and-amphetamine-regulated transcript (CART)). The ARC neurons project to "second-order" neurons implicated in the control of feeding, such as the paraventricular nucleus of the hypothalamus (PVN), the dorsomedial hypothalamic nucleus (DMN), and the lateral hypothalamic area. However, appetite expression is not exclusively a process of homeostatic energy regulation. Our motives for eating are also based in pleasure and other systems, such as the endogenous opioids and endocannabinoids implicated in liking and dopamine implicated in wanting. These are critical in stimulating appetite and sustaining eating behavior (see ▶ Appetite Stimulants). These also provide pharmacological targets for potential antiobesity treatments.

Mechanisms of Action of Past and Present Drugs

With regard to past appetite-suppressing antiobesity drugs, amphetamine and amphetamine-like drugs generally stimulate central noradrenaline and dopamine release and these effects may be mediated by a number of receptors such as α1 and β2 adrenoceptors, and dopamine D_1 and D_2 receptors found in the hypothalamus and other areas of the limbic system. These receptors are probably involved in both, the satiating and rewarding (i.e., "wanting") aspects of food intake. However, any selective effects of amphetamine on the motivation to feed tend be masked by other behavior changes which disrupt feeding (e.g., hyperactivity). Of all the monoamine neurotransmitters, it is ▶ serotonin (5-HT) that has been most closely linked with the process of ▶ satiation and the state of ▶ satiety. Both fenfluramine and D-fenfluramine are 5-HT releasing agents and have been shown to induce satiety in both rodent and animal models. These effects appear to be mediated by the 5-HT_{1B} and the 5-HT_{2C} receptors on neurons projecting from the ARC into the hypothalamus. Unfortunately, activation of other serotoninergic receptors, particularly 5-HT_{2B} receptors in the periphery, led to the withdrawal of these drugs. This has driven research into far more selective 5-HT based antiobesity drugs.

Sibutramine is a selective noradrenergic and serotonergic reuptake inhibitor. Upon administration sibutramine is rapidly broken down into its first (BTS 54354) and then second (BTS 54505) metabolites. The metabolites are both far more potent reuptake inhibitors in vivo and it is to these metabolites that sibutramine predominately owes its action. Selective antagonism of sibutramine ▶ hypophagia has demonstrated that α1 adrenoceptors are critically involved in sibutramine's effect on food intake, with some role also for β2 adrenoceptors and serotoninergic $5\text{-HT}_{2A/2C}$ receptors. Sibutramine produces changes to feeding behavior in rodents and appetite in humans similar to those produced by D-fenfluramine and other 5-HT drugs, suggesting changes in feeding behavior may be mediated by central serotonin mechanisms (Halford et al. 1998; Heal et al. 1998).

With regard to rimonabant, the drug is an ▶ inverse agonist of the CB_1 receptor, which is widely distributed throughout the CNS and periphery. The role of endocannabinoid receptors in the natural operation of appetite has yet to be fully determined (see ▶ Appetite Stimulants) and surprisingly little published data on the effects of CB_1 drugs on human appetite expression are available. However, evidence suggests that the endocannabinoid system may be more involved in hedonic rather than homeostatic aspects of appetite control (Tucci et al. 2006).

Animal Models

Feeding is an essential part of an animal's behavior and, in this respect, need not be artificially modeled. Rodents,

like humans, show a tendency to gain weight when exposed to a highly palatable energy dense diet and during this period they demonstrate marked ▶ hyperphagia. Animal models of obesity provide important indices for the assessment of potential therapeutic effects such as changes in adiposity and body fat distribution, and in key endocrine and metabolic factors. Behavioral indices such as hyperphagia are necessary for assessing the potential efficacy of appetite-suppressing, antiobesity drugs. The nature of drug-induced hypophagia is critical in determining if a potential appetite-suppressing antiobesity drug can progress into clinical trials. Drugs can reduce food intake in rodents and humans in a variety of ways, through the induction of nausea or malaise, or through CNS-related effects such as hyperactivity or sedation. Such effects, even if secondary to drug action on mechanisms of satiety or food preference, prevent the compound being of any clinical value. One of the most detailed behavioral assays of drug action on appetite expression is the behavioral satiety sequence (BSS) (Halford et al. 1998 for review). The BSS examines the microstructure of rodent behavior, and the sequence consists of a stochastic progression of behavior from an initial phase of eating, through peaks of active and grooming behavior, to an eventual phase of predominately resting behavior. The BSS appears robustly related to the processes of satiation (meal termination) and the development of satiety (post-ingestive inhibition of eating).

Assessing the Effects of Drugs on Human Feeding Behavior

A variety of approaches to measuring the effects of antiobesity drugs on human food intake can be employed. Laboratory-based observation studies provide more precision and reliability at the expense of "naturalness" (Hill et al. 1995). In human studies, researchers are able to assess the effects of drugs on subjective experiences of appetite to confirm any satiety-enhancing effect. Self-report scales have been used to determine the nature of a drug's effect on food intake in some of the earliest human studies (Hill et al. 1995). The measures come in a variety of forms but the most widely accepted format is the Visual Analog Scale (VAS). It is interesting to note that ratings of appetite sensations are not only predictors of energy intake but also of body weight loss (Drapeau et al. 2007). The effects of drugs on parameters within a meal have also been studied for nearly 30 years. Rogers and Blundell (1979) clearly demonstrated that whilst amphetamine and fenfluramine both reduced food intake, the increase in eating rate produced by amphetamine represents the activating effects of the drug, whilst the reduction in eating behavior produced by fenfluramine represents enhanced satiety. Sibutramine appears to produce similar effects to fenfluramine on eating rate (Halford et al. 2008).

Efficacy

Many drugs produce changes in appetite expression and reduce food intake in humans. In fact, serotonergic drugs such fenfluramine, D-fenfluramine, the selective serotonin reuptake inhibitors fluoxetine and sibutramine have all been shown to reduce caloric intake, premeal hunger and enhance postmeal satiation in humans. In contrast, other centrally acting agents such as ▶ opioid antagonists have been shown to decrease the liking for pleasant or preferred foods demonstrating the distinct role of the endogenous opioid system in hedonic aspects of appetite control. Endocannabinoid CB_1 receptor antagonists/inverse agonists such as rimonabant and taranabant have been show to reduce caloric intake in humans also. The nature of this drug-induced reduction in food intake remains unclear with little strong evidence to suggest how they alter human appetite expression. A number of peripheral factors have been shown to reduce food intake and enhance satiety. These include CCK, GLP-1 and Peptide YY (PYY). GLP-1 and PYY remain the basis for a number of potential antiobesity drugs under development (Halford 2006).

The ultimate test/indication of efficacy of any antiobesity drug is sustained and clinically meaningful weight loss (usually accepted as 5–10% reduction from baseline) rather than short-term reductions in intake. In addition, regulatory authorities also demand reductions in risk factors for cardiovascular and metabolic diseases. These include high fasting and postprandial blood glucose, HbA_{1c} (glycosylated hemoglobin), insulin, total plasma cholesterol, low density lipoproteins (LDL), triglycerides, uric acid, and blood pressure. Very little reliable data are available regarding the efficacy effects of amphetamine or other early appetite suppressants. Similarly, the published data for fenfluramine and fen-phen are limited. Meta-analysis suggests that fenfluramine could produce placebo-subtracted weight loss of 2.4 kg in trials over an average of 10 weeks. D-fenfluramine produces average placebo-subtracted weight loss of 3.8 kg over an average of 33 weeks. Sibutramine produces averaged placebo-subtracted weight loss in the region of 4.3 kg over 1 year (seen in the first 6 months of treatment), which compares to 2.7 kg over 1 year produced by orlistat (a non-appetite suppressant antiobesity drug) and 4.8 kg produced by the recently withdrawn rimonabant. These changes are accompanied by significant improvements in

aforementioned cardio-metabolic risk factors (Haddock et al. 2002; Padwal et al. 2003).

Safety/Tolerability

Because of their diverse mechanisms of action, the safety and tolerability of appetite suppressants vary greatly between drugs. Amphetamines are now virtually withdrawn across the globe and are not recommended because of significant cardiovascular and CNS side effects and a potential for dependence. However, phentermine and diethylpropion are still used in some countries but are not recommended for routine or prolonged use. Side effects with phentermine include increased heart rate and blood pressure, nervousness, restlessness, and insomnia. Diethylpropion possesses a similar side effect profile including dizziness, headache, sleeplessness, nervousness, and the possible risk of pulmonary hypertension. The side effects associated with fenfluramine-based treatments include diarrhea, dry mouth, and drowsiness. These drugs were withdrawn due to valvular heart disease and pulmonary hypertension.

The side effects associated with sibutramine include cardiovascular effects (such as an increase in systolic and diastolic blood pressure, an increase in heart rate, tachycardia, palpitations, and vasodilatation), and gastrointestinal effects (including constipation and nausea). Other effects include dry mouth, insomnia, light-headedness, paraesthesia, and aesthesia. Most side effects occur within the first 4 weeks of treatment and decrease in severity and frequency with time. With rimonabant, the most commonly reported side effects were nausea, dizziness, diarrhea, and anxiety. FDA approval for rimonabant was withheld over concerns over suicidality, depression, and other related side effects associated with use of the drug. Reports of severe depression were frequent. This led to the recent withdrawal of the drug. With regard to the GLP-analog exenatide (Byetta), the most commonly recorded side effects are gastrointestinal and warnings have been issued by regulatory authorities over acute pancreatitis.

Definition

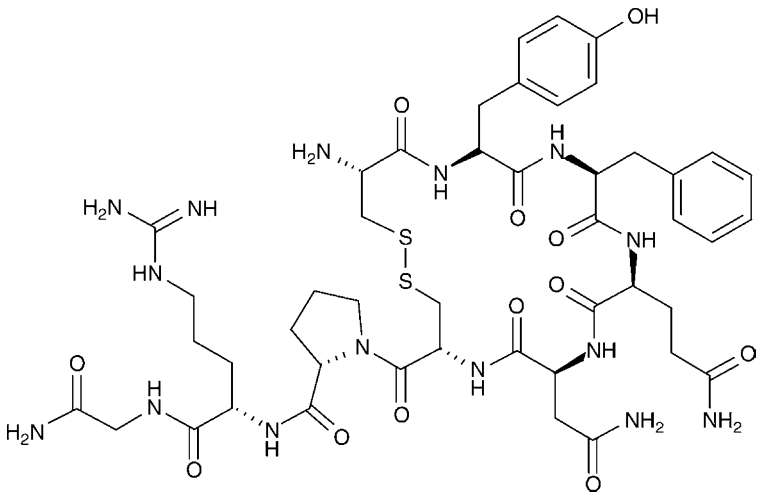
Arginine-vasopressin (AVP) is a nine-amino acid peptide, which is synthesized and released from nerve terminals in the central nervous system (CNS) (Fig. 1). In the brain, AVP acts as a modulator of neuronal function and is involved in the control of stress, anxiety, cognitive behaviors, ► circadian rhythms, and autonomic function. AVP is also released from nerve terminals into the blood stream where it regulates water absorption and urine production



Arginine-Vasopressin. Fig. 1. Arginine-vasopressin (AVP).

in the kidney, and glucose and fatty acid metabolism in the liver, and it increases arterial blood pressure and heart rate.

Pharmacological Properties

The Neuroanatomy of the Central AVP System

AVP is synthesized in neurons of the hypothalamus (Ring 2005). AVP-containing neurons are located in three hypothalamic structures: the supraoptic nucleus (SON), the paraventricular nucleus (PVN), and the suprachiasmatic nucleus (SCN). AVP produced in the SON is transported to nerve terminals of the posterior pituitary and is released in response to changes in plasma osmolality and decreased blood pressure. AVP from the PVN is released into the hypothalamic–hypophyseal portal blood, which supplies the anterior pituitary. The AVP-containing neurons of the PVN also project to the regions of the hindbrain and spinal cord, which are involved in control of the autonomic function. The AVP neurons of the SCN are involved in the control of circadian rhythms. AVP synthesis occurs also in the bed nucleus of the stria terminalis (BST) and the medial amygdaloid nucleus (MeA). The vasopressin neurons in the BST project to the lateral septum, amygdaloid areas, the locus coeruleus, and the dorsal raphe, while MeA neurons project to the ▶ hippocampus and lateral septum. These neuronal pathways are likely to underlie the effects of AVP on stress, anxiety, fear, and social cognitive behavior (▶ Social Recognition and Social Learning). The degree of AVP expression in the brain is gender specific, with males having denser AVP levels than females (Frank and Landgraff 2008) due to an effect of ▶ sex hormones on AVP expression. Sex hormones may exert some of their effects on social cognitive behaviors, such as pair-bonding and parent-offspring relationships, through influencing AVP expression in the CNS.

Arginine-Vasopressin Receptors in the CNS

The biological effects of AVP are mediated via interaction with a family of ▶ G-protein-coupled receptors (▶ GPCRs) (Ring 2005). There are four known vasopressin receptor subtypes (V_{1a}, V_{1b} (V_3), V_2, and oxytocin (OT)) defined on the basis of differences in pharmacology and tissue distribution. Activation of the V_{1a}, V_{1b}, and OT receptors stimulates a number of signal transduction pathways via Gq G-protein coupling to phospholipase C, while activation of the V_2 receptor by AVP stimulates adenylyl cyclase via Gs coupling (▶ Receptors; Functional Assays).

The V_{1a} receptor is the predominant AVP receptor found in the brain, localized in the cortex, hippocampus, ▶ amygdala, septum, ▶ hypothalamus, and thalamus. The V_{1a} receptor plays a dominant role in the behavioral effects of AVP. In the periphery, V_{1a} receptors are expressed in vascular smooth muscle cells, hepatocytes, ▶ platelets, adrenal cortex, uterus cells, kidney, spleen, and testis. The V_{1b} receptor is expressed in corticotrophs of the anterior pituitary and throughout the brain, especially in the pyramidal neurons of the hippocampal CA2 field, although at lower levels than the V_{1a} receptor. In the anterior pituitary, the V_{1b} receptor modulates adrenocorticotrophin (ACTH) secretion. The V_{1b} receptor is also expressed in kidney, pancreas, and adrenal medulla, although the functional significance of expression in these tissues is unclear. Vasopressin V_2 receptors are primarily

expressed in the kidney, where their primary function is to respond to AVP by stimulating mechanisms that concentrate the urine and maintain water homeostasis. The V_2 receptor is understood to have a limited expression in the CNS. The OT receptor is expressed in the CNS in the amygdala and hippocampus and brain regions involved in the regulation of stress (► Social Stress) responses and social behavior (► Social Recognition and Social Learning). The OT receptor is also expressed in uterus and mammary gland, where its primary function is to induce uterine contractions and milk ejection.

The Effect of AVP on CNS Function

Effects on Neuronal Excitability: AVP directly controls neuronal excitability and hence, is described as a modulator of synaptic transmission (Raggenbass 2008). In general, AVP exerts an excitatory effect on neuronal activity (e.g., in hippocampus, amygdala, spinal cord), although an inhibitory influence of AVP has also been described (e.g., in the lateral septum). AVP alters neuronal excitability, and hence synaptic transmission, through modulation of ion-channel activity, leading to activation of a cationic inward current and/or reducing potassium conductance. In the rat hippocampus, for example, AVP enhances excitatory post-synaptic currents and long-term potentiation (LTP) (► Long Term Potentiation and Memory; ► Synaptic Plasticity). Hippocampal LTP is the long-lasting improvement in synaptic communication which is postulated as one of the cellular mechanisms underlying learning and memory. Thus, the benefits of AVP on cognitive function may be exerted by virtue of its influence on LTP.

Control of cardiovascular function: Brain AVP is suggested to play a role in the regulation of blood pressure under both normal and pathophysiological conditions (Toba et al. 1998). Central AVP influences the cardiovascular system via modulation of both sympathetic and parasympathetic function (Raggenbass 2008). Administration of AVP into the CNS results in an increase in blood pressure and heart rate which is most likely to be mediated via enhancement of sympathetic nervous system outflow from the CNS to the heart and vasculature.

Temperature regulation: Administration of AVP directly into the CNS of rats causes a reduction in body temperature, although there is little evidence to suggest that AVP plays a role in normal thermoregulation. However, AVP arising from BST has been described as an antipyretic, in that it can reduce increases in temperature during fever (Pittman et al. 1998).

Water homeostasis: AVP derived from the neurons of the PVN and SON of the hypothalamus is released into the circulation following osmotic challenge, for example, dehydration and high sodium levels. Under these conditions, plasma AVP, via activation of V_2 receptors, induces increased reabsorption of water in the kidney. Inadequate secretion of AVP from the posterior pituitary and/or abnormal kidney responsiveness to AVP results in diabetes insipidus, which is characterized by excessive urination and thirst.

Circadian rhythms. The SCN of the hypothalamus is the site of the master circadian clock which generates 24-h circadian rhythms in mammals. AVP is one of the dominant neuropeptides expressed within the SCN and exhibits a diurnal pattern of synthesis and release, with increased levels of AVP secretion occurring during the day in both rats and humans (Ingram et al. 1998). Brattleboro rats, which lack vasopressin peptide due to a mutation in the AVP gene, still express circadian rhythms, although of reduced amplitude. Thus, AVP is not critical to circadian clock function but plays a role in amplifying clock rhythmicity. The AVP-containing neurons of the SCN transmit a circadian signal to the other parts of the brain by which they may regulate behavioral, neuroendocrine, and autonomic nervous system processes in a circadian fashion, for example, controlling the rhythmic release of cortisol and the circadian pattern of motor behavior and appetite.

Social recognition and social learning: Social relationships are a key feature of many species. Although the underlying neurobiology of social behavior/cognition is not well understood, there is an emerging hypothesis that AVP may play a role (Donaldson and Young 2008). Rats and mice are an excellent model species for studies of the involvement of AVP on social behavior given their natural tendency to explore unfamiliar individuals. In rats and mice, direct administration of AVP into the brain prolongs the duration of social memory. By contrast, vasopressin receptor antagonists impair social memory, probably due to disruption of the acquisition, storage, and/or recall of social olfactory cues (Frank and Landgraff 2008). Studies in which vasopressin receptor antagonists or V_{1a} receptor ► Antisense Oligonucleotides are applied directly into specific brain regions implicate a role for the V_{1a} receptor in the lateral septum in the regulation of social recognition. Furthermore, mice which lack the V_{1a} receptor exhibit deficits in social recognition behaviors which can be restored upon reexpression of the V_{1a} receptor in the lateral septum. Deficits in social recognition behaviors have also been described in V_{1b} receptor knock-out mice. A possible role for AVP in the regulation of parental behavior has also been described. Paternal behavior in the male prairie vole is enhanced following

AVP administration into the CNS, whereas vasopressin receptor antagonists disrupt this behavior. AVP is also implicated in maternal care, with increased brain AVP levels being described during the late stages of pregnancy, parturition, and lactation in the rat. Thus, enhanced parental behavior is correlated with increased AVP function.

The exact effects of AVP on social behaviors can vary from one species to the next, most likely due to differences in the pattern of brain V_{1a} receptor expression between species. For example, the differences in pair bonding observed between the monogamous prairie vole and the polygamous montane vole are regulated by the pattern of V_{1a} receptor expression in the brain (Donaldson and Young 2008). Male prairie voles exhibit mating-induced partner preferences, care for their offspring, and exhibit ► aggressive behavior to other males within the same species, unlike the polygamous montane vole. Analysis of V_{1a} receptor distribution shows that the polygamous montane vole exhibits a lower level of receptor expression in the ventral forebrain/ventral pallidum in comparison with the monogamous prairie vole. Expression of the prairie vole V_{1a} receptor gene in the ventral pallidum of the meadow vole resulted in increased pair bond formation, in a manner similar to the prairie vole. Genetic studies have identified an insertion of approximately 500 base pairs of a repetitive sequence (microsatellite) upstream of the prairie vole V_{1a} receptor gene. By contrast, the same region upstream of the montane vole V_{1a} gene is only around 50 base pairs long. This microsatellite region may influence the expression pattern of the V_{1a} receptor, leading to differences in mating behavior between these two species.

It is a challenge to extrapolate the data obtained from the rodent studies described above, where social behaviors are heavily reliant on olfactory cues, to humans, where social behaviors are more dependent upon auditory and visual cues. To date, the modulatory effect of AVP on social behavior in humans has not been extensively studied. Even so, in humans, there is an emerging hypothesis that genetic variations in the V_{1a} receptor locus may also influence behaviors such as partner bonding and parental care (Donaldson and Young 2008). Variations in the V_{1a} receptor gene have also been associated with the social behavioral deficits underlying autism (► Autism Spectrum Disorders and Mental Retardation). Deficits in social behavior are a key feature of other psychiatric diseases such as ► schizophrenia, social phobia (► Social Anxiety Disorder), and depression. As such, gaining a better understanding of the role of AVP in the regulation of social behavior may lead to the development of treatments that are able to address the social deficits of these disorders.

The involvement of AVP in nonsocial cognitive function is unclear. The majority of studies in rodents point toward a facilitatory effect of AVP on nonsocial memory, mainly via an effect on memory retrieval (► Cognitive Enhancers). Loss of vasopressin receptor function, either via genetic knock-out or through antagonist administration, can alter performance in some but not all tests of nonsocial cognitive behavior. Clinical data also indicate that AVP enhances ► attention and arousal but does not have a direct effect on memory per se. Indeed, AVP does not improve cognitive function in individuals suffering from age-related memory impairment.

Regulation of stress and emotional behaviors. The hypothalamic pituitary adrenal (HPA) axis is the main neuroendocrine system involved in regulation of the "flight, fight, fright" response to a stressful stimulus. Exposure to stress (social stress) results in the release of AVP and ► corticotrophin releasing factor (CRF) from the hypothalamus into the portal vessel system. Both AVP and CRF act on receptors on the anterior pituitary (V_{1b} and CRF1, respectively) to stimulate ACTH release. In turn, ACTH stimulates the release of glucocorticoids such as cortisol (in humans) or corticosterone (in rodents). Glucocorticoids trigger physiological changes (e.g., glucose mobilization, suppression of the immune response, increased cardiovascular tone) required to enable the organism to respond appropriately to a stressor. Studies suggest that CRF plays a critical role in both basal and acute-stress-induced ACTH release whereas AVP, which has weaker secretory activity, may have a lesser role (Aguilera and Rabadan-Diehl 2000). However, when co-released, AVP can act synergistically with CRF to amplify the ACTH release response.

There is mounting evidence suggesting that abnormalities in HPA axis responsiveness may underlie psychiatric disorders that are associated with impaired stress-coping (e.g., depression, anxiety) and a shift toward AVP drive of HPA axis function underlies these abnormalities. Exposure to repeated or chronic stress causes an upregulation of AVP levels, increased V_{1b} receptor expression, and downstream signaling. Through this mechanism, AVP may contribute to the sensitization of the ACTH/cortisol response that occurs following chronic stress. Both clinical and animal studies show a correlation between increased anxiety behavior and elevated AVP levels. In studies where the cholecystokinin B receptor agonist, pentagastrin, (► Cholecystokinins) is used to stimulate anxiety in healthy volunteers, a correlation between the severity of symptoms and AVP levels has been observed. Vasopressin-deficient Brattleboro rats exhibit less anxiety-related behaviors in comparison with normal rats. Rats and mice that have been selectively bred

for high anxiety-related behaviors in the ► elevated plus-maze anxiety model (► Anxiety: animal models) exhibit increased brain AVP expression in comparison with low-anxiety behavior counterparts (Frank and Landgraff 2008). Application of V_{1a} receptor antagonists to "high anxiety" rats reduces anxiety-related behaviors. In addition, over-expression of the V_{1a} receptor gene in the lateral septum significantly increases anxiety-related behavior, implicating the V_{1a} receptor in the anxiety response.

► Aggression: There are strong data from animal studies suggesting that AVP promotes aggressive behavior (Ferris 2005). Administration of AVP directly into the brain facilitates attack behavior in rats and hamsters. The effects of AVP on aggressive behavior probably occur through an interaction with the serotonin system (Serotonin agonists and antagonists); serotonin being associated with a reduction in aggressive behavior. Studies with knock-out mice or vasopressin receptor antagonists indicate that the effects of AVP on aggressive behavior are mediated through both the V_{1a} and V_{1b} receptors. In patients with personality disorders, increased cerebrospinal fluid (CSF) levels of AVP are correlated with a life history of aggressive behavior. Furthermore, intranasal AVP administration in men causes an enhanced emotional response to neutral stimuli, consistent with an increased perception of threat. From a clinical perspective, interpersonal violence can be a feature of antisocial behavior which can exist alongside psychiatric illnesses, such as ► bipolar disorder, ► attention-deficit hyperactivity disorder (ADHD) (► Attention Deficit and Disruptive Behavior Disorders), post-traumatic stress disorder (► Traumatic Stress (Anxiety) Disorder), and autism (► Autism Spectrum Disorders and Mental Retardation). However, the involvement of AVP in regulation of aggressive behavior associated with psychiatric disorders in humans has not yet been established.

Involvement of AVP/Vasopressin Receptors in Psychiatric Disorders

Anxiety: Anxiety disorders (► Generalized Anxiety Disorder) are associated with feelings of apprehension, tension or uneasiness. The ► amygdala is the region of the brain which is proposed to play a pivotal role in anxiety and fear. This brain structure contains high levels of vasopressin receptors and AVP causes excitation of amygdala neurons. Furthermore, animal studies have demonstrated a clear correlation between AVP levels and anxiety behavior (► Anxiety: animal models), and data are emerging to suggest that this correlation may also exist in humans. Unfortunately, the data linking alterations in the AVP system to clinical anxiety disorders are sparse, and more research in this area is warranted. Nevertheless, the preclinical data indicate that vasopressin receptors are a suitable target for the development of drugs for the treatment of anxiety-related disorders.

Depression: Major depressive disorder is characterized by depressed mood and lack of pleasure or interest and may include symptoms such as appetite disturbances, sleep abnormalities, concentration difficulties, and suicidal thoughts. Clinical studies have shown that the central AVP system is altered in depressed individuals (Ring 2005). Elevated AVP concentrations in the brain and CSF, and alterations in V_{1a} receptor density in post-mortem analysis of brain tissue from depressed individuals have also been described. Elevated AVP levels in the plasma of depressed patients have also been observed, and the neuroendocrine response to vasopressin agonists is increased in depressed subjects in comparison with healthy volunteers. These data have led to the suggestion that AVP receptor antagonists may prove useful for the treatment of the symptoms of depression (► Antidepressants: Recent Developments).

Schizophrenia: A feature of ► schizophrenia is a deficit in the ability to filter out unnecessary information. These deficits are exhibited in measures such as ► prepulse inhibition (PPI) in which a weaker prestimulus inhibits the reaction of an organism to a subsequent strong startling stimulus. Deficits in PPI have been described in V_{1b}-receptor knock-out mice, indicating that loss of vasopressin receptor function can cause sensorygating abnormalities. Abnormalities in levels of plasma, CSF, and brain AVP in schizophrenic patients have been described, but not consistently across all studies. Given that AVP has been implicated in regulation of social cognitive behaviors and dysfunction of these behaviors are a core symptom of schizophrenia, it is possible that abnormalities in the central AVP system may underlie these symptoms. However, the data supporting this hypothesis should be considered as being preliminary.

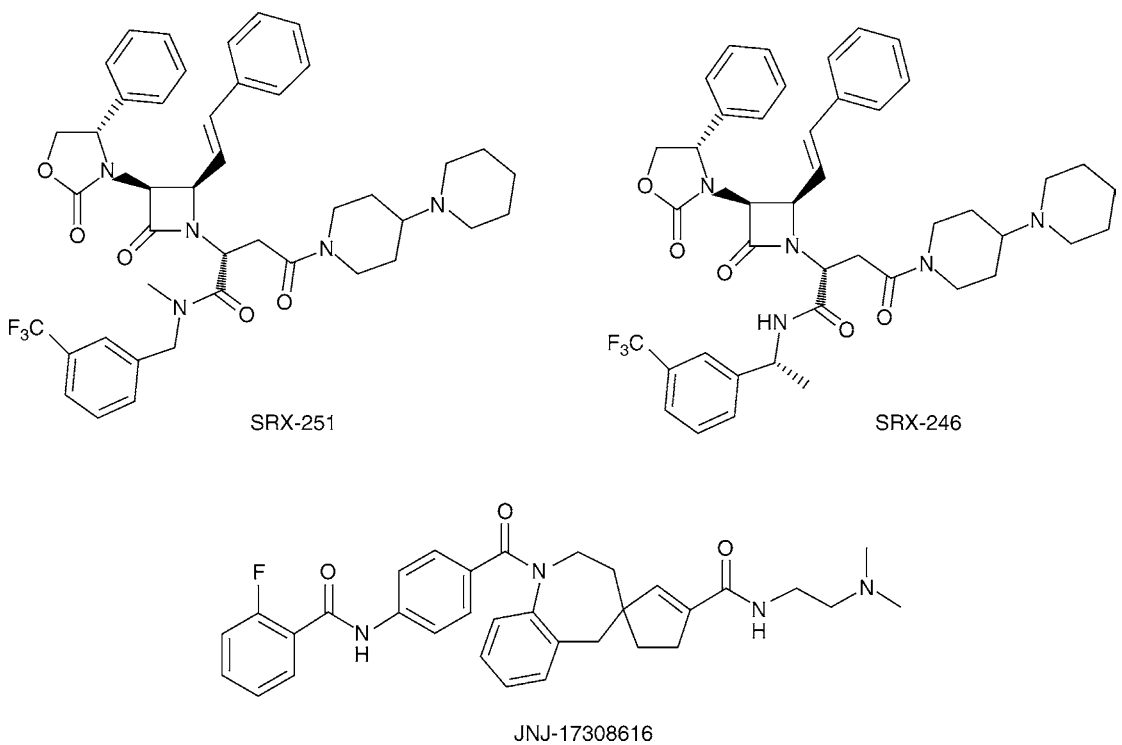
Autism: Individuals diagnosed with autistic disorder (► Autism Spectrum Disorders and Mental Retardation) generally appear to be uninterested in social contact, exhibit impaired communication, and display patterns of repetitive behavior. Autistic disorder is believed to result from a complex interaction between several genetic and environmental factors, although the exact mechanisms involved are poorly understood. Considering that a role for AVP in modulation of social behavior has been established, it is plausible to suggest that alterations in the AVP system may underlie at least some of the behavioral abnormalities that are associated with autism (Frank and Landgraff 2008). Genetic analysis of the regulatory region

upstream of the V_{1a} receptor gene has identified a polymorphic microsatellite which is associated with autism. However, little is known about the functional impact of these genetic variations on V_{1a} gene expression, and whether they contribute to the behavioral changes associated with autism is open to debate. Further studies are therefore required to establish whether alterations in the AVP system contribute to the symptoms of autism.

Vasopressin Receptor Antagonists in Psychiatric Drug Development

Vasopressin V_{1a} and V_{1b} receptor antagonists are widely recognized to represent a novel approach for the treatment of depression and anxiety. The identification and development of high-affinity, nonpeptidic ligands with the desired drug-like properties for oral bioavailability (and CNS penetration), however, is proving challenging.

V_{1a} Antagonists: A number of pharmaceutical companies have developed potent-selective V_{1a} antagonists for peripheral indications such as cardiovascular/circulatory indications and dysmenorrhoea (pelvic pain associated with menstruation). Few V_{1a} antagonists, however, have been identified with good brain penetration, a prerequisite for psychiatric drug development given the localization of the V_{1a} receptor. Azevan Pharmaceuticals describe two CNS penetrant compounds: SRX-246 (4-(bipiperidin-1′-yl)-4-oxo-2(R)-[2-oxo-3(S)-[2-oxo-4(S)-phenyloxazolidin-3-yl]-4(R)-(2-phenylvinyl)azetidin-1-yl]-*N*-[1(R)-phenylethyl]butyramide) and SRX-251 (4-(bipiperidin-1′-yl)-*N*-methyl-oxo-2(R)-[2-oxo-3(S)-[2-oxo-4(S)-phenyloxazolidin-3-yl]-4(R)-(2-phenylvinyl) azetidin-1-yl]-*N*-[3-(trifluoromethyl)benzyl]butyramide), achieving brain levels of compound ~100 times in vitro receptor affinities following oral dosing. SRX-251 is being evaluated in the clinic for the treatment of pain associated with primary dysmenorrhoea and preclinically for the management of agitation and violence. SRX-251 reduces aggression in a hamster model of offensive aggression with no effect on olfactory communication, motor activity, or sexual motivation (Ferris 2006). SRX-246 is currently in preclinical development for the treatment of anxiety/depression. Johnson and Johnson have described JNJ-17308616 (*N*-(2-(dimethylamino)ethyl)-1-(4-(2-fluorobenzamido)benzoyl)-1,2,3,5-tetrahydrospiro[benzo[b]azepine-4,1′-cyclopent[2]ene]-3′-carboxamide), a potent and selective V_{1a} antagonist both in vitro and in vivo. The anxiolytic activity of JNJ-17308616 has been demonstrated by a number of groups in a variety of



Arginine-Vasopressin. Fig. 2. V_{1a} Antagonists in psychiatric drug development.

animal models of anxiety behavior (► Anxiety: animal models), including the rat-elevated plus-maze, rat-elevated zero-maze, rat-conditioned lick suppression, rat- and guinea pig-pup separation-induced ultrasonic vocalization and mouse marble burying. JNJ-17308616 was also shown to reduce isolation-induced aggression in mice. JNJ-17308616 neither impaired social recognition, induced sedation nor reduced locomotor activity (Fig. 2).

V_{1b} Antagonists: Given the localization of the V_{1b} receptor in the anterior pituitary, and the role of this receptor in driving the neuroendocrine stress response, CNS penetration may not be a requirement for a V_{1b} antagonist aimed at treating psychiatric disorders. To date, only two pharmaceutical companies, Sanofi-Aventis and Abbott Laboratories, have progressed selective V_{1b} antagonists into clinical development. Nelivaptan (SSR-149415) was being evaluated by Sanofi-Aventis in clinical trials for the treatment of anxiety and depression, but was discontinued for both indications in 2008. Preclinical data reported by Sanofi-Aventis have shown that nelivaptan (SSR-149415) (Fig. 3) reduces CRF- and AVP-induced increases in plasma ACTH in male rats (Frank and Landgraff 2008). Nevilaptan (SSR-149415) is reported to strongly reverse stress-induced behavior as measured in the rat-elevated plus-maze, mouse defense test battery, rat- and guinea pig-pup separation-induced ultrasonic vocalization models (► Anxiety: animal models), supporting the rationale for a V_{1b} antagonist in the treatment of stress-induced anxiety. Anti-depressant-like activity was also demonstrated in the forced swim test model of depression (► Depression: Animal Models) and in the differential reinforcement of low rate 72s (DRL-72s) model (► Operant Behavior in Animals). Abbott Laboratories are investigating a series of selective V_{1b} antagonists in the clinic for the potential treatment of depression and anxiety. In preclinical studies, two compounds ABT-436 and ABT-558 (structures not reported) were shown to inhibit vasopressin- and stress-induced increases of stress hormones in mice, a preclinical model of the HPA axis dysregulation implicated in depression and anxiety. ABT-436 and ABT-558 were shown by Abbott to have comparable antidepressant and anxiolytic effect to nelivaptan (SSR-149415) in preclinical behavioral models (Fig. 2).

The identification and development of vasopressin antagonists targeting CNS receptor subtypes represents a promising new therapeutic class for the treatment of anxiety and depression. As such, selective V_{1a} and V_{1b} and mixed V_{1a}/V_{1b} antagonist programs remain a focus for many pharmaceuticals with increasing numbers of novel chemical series appearing in the patent literature.

Definition

Atomoxetine is a highly selective centrally acting norepinephrine reuptake inhibitor (SNRI), licensed for the treatment of attention-deficit hyperactivity disorder (ADHD) in USA, United Kingdom, and elsewhere. Atomoxetine is a white solid intended for oral administration.

Pharmacological Properties

► Pharmacokinetics

Following oral ingestion with or without food, atomoxetine is rapidly absorbed with peak plasma levels occurring at approximately 1–1.5 h (Sauer et al. 2005). With regular dosing, steady-state concentrations are obtained by day 10, with trough plasma concentrations of ~30–40°ng/mL. The metabolism of atomoxetine is dependent primarily on the hepatic ► cytochrome P450 (CP450) system, which is highly polymorphic such that individuals can be classified into extensive metabolizers (EMs) or poor metabolizers (PMs) (Trzepacz et al. 2008). The majority of people (>90%) are EMs, while rarer PM individuals or individuals taking enzyme inhibitor medications, show fivefold greater peak plasma concentration and slower ► half-life elimination. Following a single oral dose, EMs exhibit an atomoxetine half-life of ~5.2 h with plasma clearance of ~0.35 L/h/kg, while PMs exhibit half-life of ~21.6 h and clearance of ~0.3 L/h/kg.

Neurochemical Mechanisms

Atomoxetine selectively inhibits human ► norepinephrine transporters in vitro with high potency, and has relatively low affinity for ► serotonin and ► dopamine transporters (Bymaster et al. 2002). In vivo, atomoxetine rapidly penetrates the rat ► blood–brain barrier via mainly passive mechanisms; and increases levels of noradrenaline and dopamine (but not serotonin) approximately threefold in the rat ► prefrontal cortex, a region critically implicated in cognition (Bymaster et al. 2002). In contrast to ► psychostimulants, atomoxetine does not increase dopamine levels in the accumbens and striatum, thereby limiting its abuse potential as compared to this other class of agent (Wee and Woolverton 2004). Thus, atomoxetine may offer benefits over psychostimulants in terms of lower addictive potential due to its more selective neurobiological effects.

Cognitive Effects

Noradrenaline and dopamine have been strongly implicated as neurochemical substrates of cognition. Consequentially, and in light of the above findings, it is important to question whether atomoxetine can enhance cognition and ameliorate cognitive deficits in the context of neuropsychiatric disorders. Most translational studies to date have focused on measuring the effects of short-term atomoxetine treatment on laboratory-based measures of impulsivity, assessed in terms of inappropriate and/or premature motor responses on cognitive tasks. This focus on impulsivity stems from the utility of atomoxetine in the treatment of ADHD (discussed in the following section).

On the ► five-choice serial reaction time task (5-CSRT), atomoxetine reduced premature impulsive responses in rats across three studies (Robinson et al. 2008). In humans, atomoxetine was found to improve impulse control on the ► stop signal reaction time task (SSRT) in healthy volunteers, and in adult patients with ADHD (Chamberlain et al. 2006, 2007). By combining the SSRT with ► functional magnetic resonance imaging (fMRI), it was subsequentially found that atomoxetine augmented activation in the right inferior frontal gyrus during inhibitory control in healthy volunteers, with this region being critically implicated in impulse control and in the neuropathology of ADHD (Chamberlain et al. 2009).

The effects of longer-term treatment with atomoxetine on cognition have received scant attention. In work by Spencer and colleagues, 3-week treatment with atomoxetine was associated with improvements on a measure of inhibition from the Stroop task in adult ADHD patients, particularly in those patients with poor baseline performance (Spencer et al. 1998).

Treatment of Neuropsychiatric Disorders

Atomoxetine was first explored as a potential antidepressant, but then the focus shifted to its potential utility in the treatment of ADHD. Atomoxetine is licensed for the treatment of ADHD in children and adults in USA and UK. Meta-analysis of data from nine randomized placebo-controlled trials indicated that atomoxetine was superior to placebo in the treatment of childhood and adolescent ADHD (number needed to treat, NNT, 3.43) (Cheng et al. 2007). Adverse events occurring significantly, more commonly than under placebo, were reduced appetite, somnolence, abdominal pain, vomiting, dyspepsia, dizziness, fatigue, infection, and pruritis (listed in decreasing frequency of occurrence; number needed to harm, NNH, range 9–120). No evidence of liver injury was detected in initial clinical trials. Two reported cases of elevated hepatic enzymes and bilirubin linked with treatment have been detected in >2 million patients during the first two years after initial marketing (www.fda.gov/medwatch). As with other medications used in the

treatment of childhood psychiatric disorders, there has been some concern regarding atomoxetine and suicidality. In one analysis, six suicide related events were identified in 1,357 pediatric ADHD patients taking atomoxetine compared to zero events in 851 patients taking placebo (Virani 2005), leading to the FDA instructing that increased risk of suicidal thinking be added to the box-warning for this product. Although rare, these findings indicate the importance of monitoring for the emergence of adverse events relating to hepatic function, and suicidality in patients.

Atomoxetine appears similarly effective versus ► methylphenidate in the treatment of childhood ADHD albeit with evidence of significantly higher rates of mild to moderate adverse events. In UK, guidance from the National Institute for Health and Clinical Excellence (NICE), published in 2008, posits either methylphenidate or atomoxetine as first-line drug treatment in children with severe ADHD, as part of a comprehensive treatment program (www.nice.org). In terms of cost-effectiveness, a UK economic modeling study indicated that the cost of atomoxetine compared favorably with immediate release methylphenidate per Quality Adjusted Life Year gained in the treatment of childhood ADHD (Cottrell et al. 2008).

It is established that 40–60% of children with ADHD continue to exhibit clinically impairing symptoms into adulthood. However, in comparison to the child literature, few adult treatment studies using atomoxetine exist to date. The available data suggest similar efficacy and side-effects profiles to those identified in the treatment of children and adolescents (Faraone et al. 2005).

Summary

The SNRI atomoxetine is playing a growing role in the treatment of ADHD. Translational studies indicate that this agent modulates prefrontal noradrenaline (and dopamine), and is capable of improving response inhibition, a cognitive function dependent on the right inferior frontal gyrus and under likely noradrenergic control. Further clinical trials are required to explore the efficacy and safety of atomoxetine into the longer term in the treatment of ADHD, in children and in adults, and to evaluate the efficacy of this agent in the treatment of other disorders. For example, registered ongoing trials are exploring the utility of atomoxetine in the treatment of alcohol/substance abuse, Parkinson's disease, and Binge Eating disorder (www.clinicaltrials.gov). In addition to further clinical trials, it will also be important to explore the role of different components of the brain noradrenaline system in cognition (i.e., sub-receptors) in translational research; and to evaluate the effects of atomoxetine on the spectrum of cognitive deficits exhibited across neuropsychiatric disorders.

Definition

Attention describes a range of cognitive processes and capacities that support the ability to detect stimuli that occur rarely, unpredictably, and over longer periods of time (sustained attention), to discriminate such stimuli from non-target stimuli (or "noise"; selective attention), and to perform in situations requiring attention to multiple stimuli, multiple sources of stimuli, stimuli presented in multiple modalities, and/or the processing of multiple and competing stimulus–response rules (divided attention).

Impact of Psychoactive Drugs

Psychopharmacological research on attentional functions has intensified during recent years, fostered in part by an increasing understanding of the fundamental relevance of attentional capacities for learning and memory (Sarter and Lustig 2008), the identification of neuronal mechanisms and brain systems mediating attention (Raz and Buhle 2006), and the development and validation of tasks for the measurement of attentional processes and capacities in laboratory animals and humans. Psychopharmacological research in rodents has enormously progressed as a result of the introduction of translational tasks for the measurement of attentional capacities, particularly the ▶ five-choice serial reaction time task (Robbins 2002) and operant sustained and divided attention tasks (Arnold et al. 2003). Research in humans likewise has evolved, due in part to advances in cognitive theories of attention and the development of new test paradigms and their successful use in neuroimaging studies (Awh and Jonides 2001). The assessment of effects of psychoactive drugs on attentional performance-associated brain activity patterns ("pharmaco-fMRI") represents a particularly informative new approach as effects on attention can be attributed to modulation of activity in the distributed neuronal circuits known to mediate attention. The literature on psychotropic drug effects on attention is extensive and diverse; below, selected major research themes on the psychopharmacology of attention are briefly discussed.

Do the ▶ amphetamines facilitate attention and benefit the attentional symptoms of ADHD? Amphetamine and related stimulants, including ▶ methylphenidate, produce a wide range of effects in laboratory animals, including effects on response output and response speed that are a function of baseline response rates and the type of response required. Furthermore, these drugs affect complex motivational processes, often in interaction with the requirements for responding, the testing environment, and the animals' motivational state. Attentional performance can be affected indirectly as a result of such effects on response output or motivational processes. However, the available evidence does not conclusively indicate that psychostimulants generally and selectively enhance attentional processes or capacities. Evidence from healthy humans likewise does not indicate robust support for psychostimulant-induced enhancement of attention (Koelega 1993).

Psychostimulant treatment benefits the behavior and academic performance of patients with ADHD. However, similar to effects of these drugs in laboratory animals, the behavioral and cognitive mechanisms underlying the beneficial treatment effects in ADHD patients have remained unsettled. Furthermore, psychostimulants may act primarily by attenuating the high levels of cognitive and behavioral impulsivity of ADHD patients. Studies show that the benefits of psychostimulants on overall behavior and academic performance, indicated typically by ratings from parents and teachers, in fact were not associated with normalization of cognitive deficits. Thus, collectively, psychostimulants produce a wide range of effects that may, depending on the testing conditions, produce limited beneficial effects on attentional performance. However, it seems less likely that these compounds specifically enhance the attentional capacity of healthy subjects and/or that they specifically attenuate the attentional impairments associated with ADHD.

Do wake-promoting drugs such as modafinil enhance attention? ▶ Modafinil is a well-tolerated and relatively safe drug, and has therefore become a widely and increasingly recreationally used treatment to combat sleepiness and the cognitive components of sleepiness, including attentional impairments (Minzenberg and Carter 2008). However, numerous studies also suggested that administration of modafinil enhances cognitive performance per se, independent of its main wake-promoting properties. Similar to the psychostimulants, modafinil appears to act via stimulation of dopaminergic neurotransmission, requiring functional ▶ dopamine D1 and D2 receptors to induce wakefulness. Likewise, modafinil was not found to produce selective effects on attention in animals that were

not sleep-deprived. Furthermore, and also similar to the effects of psychostimulants, modafinil was demonstrated to enhance inhibitory response control in laboratory animals and to improve the symptoms of ADHD.

Modafinil was found to benefit the impaired attentional set-shifting capacities of schizophrenic patients, suggesting that this drug may have significant clinical usefulness as a co-treatment for this disorder. As the treatment of schizophrenic patients with amphetamine was also reported to benefit their cognitive abilities, it is intriguing to hypothesize that modafinil produces effects on attentional set-shifting by stimulating the down-regulated dopamine D1 receptors observed in the prefrontal cortex of these patients. Collectively, new wake-promoting compounds such as modafinil may produce relatively specific attentional enhancement in disorders associated with dopaminergic abnormalities in prefrontal regions.

Noradrenergic agents. Hypotheses concerning the contributions of forebrain noradrenergic afferents to the mediation of attention have originated from observations demonstrating increases in cortical "signal-to-noise" ratios following local administration of noradrenaline and the increased distractibility of animals with noradrenergic depletions. Neurophysiological recordings of the locus coeruleus, the main source of noradrenergic projections to the cortex, indicated multiple and complex contributions of phasic and tonic changes in noradrenergic activity to attention. However, the determination of specific attentional functions of the noradrenergic system in behavioral experiments, and their dissociation from more general effects on "arousal" or "alertness," continues to represent a challenging subject. These problems generalize to psychopharmacological studies on the effects of noradrenergic compounds on attention. The studies have focused overwhelmingly on the effects of alpha-2 adrenergic receptor agonists (clonidine, guanfacine, dexmedetomidine) and, more recently, the noradrenaline-reuptake inhibitor ► atomoxetine.

The evidence concerning the attentional effects of alpha-2 agonists in animals and humans is conflicting and remains inconclusive. In animals and humans, beneficial as well as detrimental effects on attention following the treatment of clonidine and guanfacine were reported. The presence and direction of the attentional effects of these drugs appear to depend on specific task parameters, testing conditions, and the subjects' level of "alertness" at baseline. The interpretation of these conflicting findings is further complicated by results indicating that alpha-2 *anta*gonists such as idaxozan and atipamezole likewise enhance aspects of attentional performance in healthy volunteers and patients. A definition of the experimental conditions that foster the demonstration of beneficial versus detrimental attentional effects of alpha-2 agonists is clearly needed. Treatment with drugs such as guanfacine may benefit the attentional impairments of particular disorders, based perhaps on an "optimization" of noradrenergic neurotransmission (Arnsten et al. 2007).

This latter statement may also hold true for the attentional effects of the noradrenaline uptake inhibitor atomoxetine. Beneficial attentional effects of this drug were demonstrated in animals with reduced levels of noradrenergic neurotransmission, but not consistently in intact animals. While recent clinical studies suggested efficacy in patients with ADHD, the precise cognitive mechanisms that are enhanced by atomoxetine is not known. Extensive psychopharmacological research, involving controlled studies and the test of hypotheses predicting specific attentional mechanisms that are modulated by noradrenergic drugs, are required in order to render conclusions about the general pro-attentional efficacy of noradrenergic drugs.

Attentional enhancement by agonists at ► nicotinic acetylcholine receptors (nAChRs). The cortical cholinergic input system represents a key branch of the forebrain circuits that mediate attentional functions and capacities (Sarter et al. 2005). Recent evidence indicated that prefrontal cholinergic activity mediates a switch from intrinsic or associational processing to the processing of external stimuli, and thereby the detection and selection of stimuli in attention-demanding situations. Neuroimaging studies suggested that administration of nicotine enhances the processing of attentional information by attenuating the activity of the brain during resting periods.

Therefore, it would be expected that drugs that block or stimulate the fast and reversible component of post-synaptic cholinergic neurotransmission, the nAChR, robustly impair or benefit, respectively, attentional performance. While robust impairments in attentional performance following nAChR blockade with ► mecamylamine can be readily shown in humans and animals, the demonstration of nicotine-evoked attentional enhancement in healthy (nonsmoking) humans and drug-naive animals has been less straightforward. Several experiments in humans and animals clarified that in interaction with increased demands on attentional performance, including the demands for top-down processing (e.g., by requiring performance during the presence of distractors), ► nicotine reliably enhances attentional performance. Collectively, these findings indicate the importance of integrating variations of the demands on attention as a secondary independent variable into experiments testing the effects of nicotine on attentional performance (Hahn et al. 2003).

Compared to the effects of nicotine, drugs that act at subtypes of the nAChR, particularly at alpha4/

beta2*nAChRs, were found to produce more robust effects on attentional capacities in humans and animal experiments. Ligands that selectively stimulate alpha4/beta2*-nAChRs and have been under investigation for treating cognitive disorders include ABT-089, ABT-418, ispronicline, and SIB1765F. Furthermore, promising effects of such drugs in tests of their therapeutic efficacy in patients with ADHD, schizophrenia, and dementia were reported. The attentional benefits of compounds acting at other nAChR subtypes, such as alpha7 nAChRs, remain less clear, largely because little evidence on the effects of these drugs has accumulated.

The neuropsychopharmacological reasons why agonists at alpha4/beta2*nAChRs may exhibit greater attentional enhancement than nonspecific agonists such as nicotine are largely unknown. However, evidence from experiments determining the effects of nAChR agonists on the transient increases in prefrontal cholinergic activity that mediate the detection of cues begins to form the basis for hypotheses. This evidence indicated that selective agonists at alpha4/beta2*nAChRs augment these transient increased without altering the "shape" (rise and clearance rates) of these transients. In contrast, nicotine, via stimulation of additional receptors and mechanisms, not only is less potent in augmenting the amplitude of these transients but drastically prolongs the duration of cholinergic activity. It is intriguing to speculate that such "blunting" of a critical neuronal signal interferes with, or at least limits, the enhancement of the detection process that is key to improving attentional performance.

Collectively, drugs that directly stimulate subtypes of nAChRs or modulate the stimulation of these subtypes by acetylcholine appear to produce specific and efficacious effects on attentional functions and thus are promising candidates for clinical use. Moreover, the accumulating evidence on the attentional effects of these drugs informs theories concerning the general neurobiological mediation of attention.

Conclusion

Although research on the modulation of attentional processes and capacities by psychotropic drugs, primarily by drugs acting at ascending modulator systems, has rapidly expanded during recent years, much of the evidence remains rather preliminary and inconclusive. The attentional effects of drugs acting at nAChRs, particularly those that bind selectively to subtypes of this receptor family, form a more consistent set of evidence than the effects of psychostimulants or noradrenergic drugs, or drugs not discussed herein, including drugs acting at serotonergic receptors. Furthermore, the interpretation of the psychopharmacological effects of nAChR agonists is supported by converging neurobiological evidence on the mediation of attentional functions by cholinergic systems. Ongoing research will demonstrate the clinical usefulness and also the psychopharmacological limitations of these treatments, in part by addressing the important question about the degree to which treatments that focus primarily on the improvement of attentional capacities benefit the overall cognitive abilities of patients. Finally, and similar to the presently increasing use of modafinil by nonclinical populations, drugs that enhance attentional abilities, particularly if associated with limited side effects, are likely to be used in the near future by non-patient groups as general cognition enhancers.

Definition

► Attention-deficit/hyperactivity disorder (ADHD) affects about 8–12% of school age children, being more common in boys than in girls by a ratio of approximately 3:1. This condition is characterized by excessive inattention and impulsivity/hyperactivity for a given developmental level. In at least 50% of cases, this condition produces enduring impairment in adulthood. ADHD has deleterious impact on several areas of social development such as educational attainment, family life, and occupational stability. ADHD has a strong hereditary basis, with genetic factors accounting for about 80% of the phenotypic variance. Weak associations with ADHD have been reported for the 7-repeat polymorphism of the D4 dopaminergic receptor gene, the 10-repeat allele of the dopamine transporter (DAT1), alleles of the D2 and D5 dopaminergic receptors, the gene coding for catechol-O-methyl-transferase, and genes related to the noradrenergic and serotonergic systems.

The estimated rate of comorbidity (co-occurrence) between ADHD and other psychiatric and learning disorders is between 50% and 90%. The most common comorbidities are with disruptive behavior disorders, which includes oppositional defiant disorder, present in some 40% of patients; conduct disorder, present in ~14% of children with ADHD; anxiety disorder (~34%); tic disorders (~11%), and others such as depression, bipolar disorder, substance use disorders, and learning disabilities (Kunwar et al. 2007). ADHD is a risk factor for the appearance of disruptive behaviors, as the onset of these symptoms occurs earlier in ADHD subjects than in non-ADHD patients. Children with ADHD and conduct disorder are at a higher risk of antisocial behavior and substance abuse as adolescents and adults. This motivates attempts to provide early treatment with the hope of preventing malignant behavioral outcomes, although such has not been demonstrated.

Role of Pharmacotherapy

Currently, ADHD is subdivided into three diagnostic subtypes, defined by predominance in inattention, hyperactivity, and impulsivity, or as the combined type that includes both inattention and hyperactivity/impulsivity.

Pharmacological treatments for ADHD enhance catecholaminergic neurotransmission. This repeated observation, combined with neuroimaging evidence strongly implicate fronto-striatal and fronto-cerebellar circuits in deficits affecting behavioral organization and the ability to predict events and behavioral outcomes; a further deficit in the fronto-amygdalar loop that assigns emotional significance to predicted and detected events is also hypothesized (Swanson et al. 2007). However, no differences in medication response have been reported among the three subtypes.

Treatment: Stimulants

The first-line pharmacological treatment for all types of ADHD consists of the psychostimulants ► methylphenidate (MPH) or ► amphetamines (Table 1). The overall short-term efficacy and tolerability of these compounds have been conclusively demonstrated in both children and adults (Findling 2008; Stein 2008). About 70–80% of the patients showed improved attention when treated with a stimulant (Rappley 2005). Owing to its lower cost, the generic amphetamine, dextroamphetamine, is most frequently used in developing countries. However, between 30% and 50% of patients discontinue pharmacotherapy due to adverse effects or inadequate response. In most such cases, the next step should include changing to the other type of stimulant. Also widely approved for the treatment of ADHD is the nonstimulant, noradrenergic reuptake inhibitor ► atomoxetine (ATX). Guanfacine is an alpha2A adrenoceptor agonist indicated for the treatment of essential hypertension that also appears to be efficacious as monotherapy, but may also be particularly useful as an adjunctive agent.

Mechanism of Action of Stimulants

Amphetamines are considered to exert their effects partly by promoting the liberation of ► dopamine from vesicular transporters and inhibiting the degradative enzyme

monoamine oxidase. These effects dramatically increase intracellular concentrations of dopamine in the presynaptic terminal, which results in massive efflux of neurotransmitter into the extracellular synaptic space. Additionally, amphetamine reversibly blockades the dopamine transporter (DAT) and enhances the internalization of DAT. These actions inhibit reuptake and prolong the increased concentration of catecholamines in the presynaptic terminal. Methylphenidate (MPH) is a pure reuptake blocker, with potent affinity for DAT and for the ▶ norepinephrine transporter (NET). The extrasynaptic dopamine increasing effect of MPH through DAT blockade has been documented in the human ▶ striatum and nucleus accumbens, and found to be qualitatively similar to ▶ cocaine effects (Volkow et al. 1998). However, pharmacodynamic kinetics differentiates MPH from cocaine in important ways that appear to account for the lower addictive potential of MPH.

Although most of the researches focus on the mechanism of action of the stimulants on the striatum, recent work in the ▶ prefrontal cortex suggests that MPH improves cognitive function (particularly the maintenance of items in working memory) by increasing endogenous stimulation of both alpha2A adrenoreceptors and dopamine D1 receptors. MPH also robustly blocks the NET, which is expressed in high concentrations throughout the cerebral cortex and cerebellum. The NET is reported to have an even higher affinity for dopamine than for norepinephrine. This finding is of interest in light of the demonstrated albeit less robust efficacy of atomoxetine and may also be related to the less thoroughly demonstrated efficacy of alpha-2 agonists like clonidine and guanfacine, which are also used to treat ADHD.

Adverse Effects

Immediate adverse effects of stimulants tend to be mild, dose-dependent, and usually diminish with continued use. The most common include loss of appetite and difficulty going to sleep; headache and stomachache are also reported but occur with almost equal frequency on double-blind placebo. More worrisome concerns have been raised regarding delayed or suppressed growth, appearance of motor and vocal tics, and possible sensitization leading to ▶ substance abuse (Biederman and Faraone 2005). Since stimulants nearly always reduce appetite to some extent, the concern over growth rates and possible enduring loss of height cannot be discarded. Nevertheless, existing albeit flawed evidence suggests that growth deficits from MPH are generally reversible. However, the much longer excretion half-lives of amphetamines would suggest that possible growth suppression effects may also be stronger than for MPH. With regard to the emergence of ▶ tics, early anecdotal evidence suggesting a causal link has been disconfirmed by systematic studies, which have highlighted familial factors. In the United States, MPH remains contraindicated for use in patients with a personal or family history of tics, although amphetamines are not so labeled, for historical reasons. Several controlled studies have shown that many children with pre-existing tic disorders can benefit from stimulants, although some do experience exacerbations that exceed the benefits derived. Nonstimulant medications are considered as a second line option in cases of risk of substance abuse, tics, and when weight loss is a significant concern.

Perhaps the most sensitive issue is the long-term risk of substance addiction. Long-term studies and meta-analyses have mostly not detected the increased risks following early stimulant treatment, and some studies have suggested that such early use may proffer a protective effect. Furthermore, despite similar mechanisms of action, the abuse potential of methylphenidate seems to be much lower than cocaine owing to the latter's more abrupt pharmacokinetic profile. This difference is especially marked for oral administration of MPH. Nevertheless, considering that ADHD subjects represent a population at risk of substance abuse, and the advantages of single daily dosing, many extended release stimulant formulas have been developed in the recent years. Comparing immediate release with extended release formulations of methylphenidate, similar peak DAT blockade levels are reached, but at different times (1.7 and 5 h, respectively), with mild reinforcing effects noted for the immediate release formula (Swanson et al. 2007). Thus, it has been proposed that kinetic factors, rather than absolute plasma concentrations may be the most relevant factor in producing subjective responses to MPH (and by extension to other stimulants). Along this line, a 10-year longitudinal study determined that misuse of stimulants only occurred with immediate-release forms; epidemiological reports indicate that users of immediate-release formulas are at a greater risk of substance abuse than users of extended release formulations (Findling 2008).

Recommended Medications for ADHD

There are three critical parameters in determining the appropriate pharmacological treatment in ADHD:

1. The duration of the effect, as multiple daily dosing increases the risk of discontinuation
2. An acceptable risk profile
3. The concern of abuse potential, especially in a population such as ADHD that may already have an elevated risk.

Methylphenidate

MPH is available in immediate release formulation (IR-MPH), in different extended release forms (ER-MPH), and as dexmethylphenidate (DMPH, the active D-isomer of MPH), which is also marketed in both immediate and extended release forms. The short-term efficacy of MPH for treating ADHD has been conclusively demonstrated by showing significant improvements on standardized rating scales, such as the Conners Global Index, the Conners Inattention/Hyperactivity with Aggression subscale, or the Clinical Global Impressions Improvements Scale (CGI-I). The landmark study, The MTA Cooperative Group report (1999), established that carefully adjusted stimulant medication (predominantly immediate release MPH, given three times per day, 7 days per week), either in combination with behavioral therapy or alone, produced a significantly greater improvement during the 14-month trial than behavioral management alone or standard community care in reducing core ADHD symptoms. In the intent-to-treat analyses, groups assigned to medication alone or medication combined with behavioral treatment did not differ, suggesting that MPH alone provides the best ratio of cost to benefit. Likewise, adverse effects were generally mild, the most common being appetite suppression, stomachache, and headache.

While the first generation "slow-release" MPH formulation left much room for improvement, formulations using an osmotic controlled release system (OROS MPH) and formulations combining rapid delivery and extended delivery elements in various proportions have been embraced by clinicians and patients. Efficacy is reported to be comparable with that of IR-MPH, with robustly significant improvements over placebo (Findling 2008). Mild adverse effects are comparable, e.g., headache (2–14% vs. 3–10% for placebo), abdominal pain (6–7% vs. 1% for placebo), emotional lability, anorexia (3–10% vs. 0–3%), and insomnia (3–7% vs. 0–5%). A new formulation consists of a MPH transdermal delivery system (MTS), which has been reported in a study sponsored by the manufacturer to show good efficacy and tolerability, with minimal adverse effects (headache was reported by 4% in both treatment and placebo groups), but a subsequent study found somewhat higher rates of adverse effects with MTS treatment than with OROS-MPH treatment (reduced appetite 26% MTS, 19% OROS, 5% placebo; insomnia 13%, 8%, and 5%, respectively; and nausea 12%, 8%, and 2%, respectively). Dexmethylphenidate (the active D-isomer of MPH) has been reported to be efficacious and well tolerated in children, and there is an extended release formulation.

Amphetamines

The first stimulant used for hyperactivity was Benzedrine, which contains equal proportions of dextro- and levo-amphetamine isomers. Because of weaker sympathomimetic effects with the dextro-amphetamine isomer, it was preferred for behavioral effects over the levo-isomer. However, the manufacturer of branded dextroamphetamine generally eschewed advertising and marketing despite substantial evidence of efficacy and nearly comparable tolerability to MPH. An alternative formulation that combines 4 amphetamine salts (75% dextro-isomer, 25% levo-isomer) has been extensively marketed in immediate release tablets and extended release capsules (mixed amphetamine salts, MAS). Whereas studies sponsored by the manufacturer have generally reported that MAS produced significantly greater improvement than MPH or placebo in aggression, defiance, and inattention/hyperactivity, children treated with MAS evidenced higher incidence of sadness and stomachache than those receiving MPH (Faraone et al. 2002; Rappley 2005). Where available, MAS is marketed in a wide range of doses, which facilitates tailoring of dose and improves compliance. Extended release MAS (XR-MAS) formulations are also efficacious and relatively well tolerated, although the duration of adverse effects can greatly exceed the duration of direct benefits. The substantial intersubject variation in pharmacokinetic parameters highlights the need for personalized treatment.

► Pemoline is a stimulant with an distinct pharmacokinetic profile that may have accounted for its greatly diminished abuse liability. Despite having been shown to be efficacious for ADHD, it is no longer recommended owing to confirmed reports of fatal liver damage (Rappley 2005) and the availability of nonstimulant alternatives.

Nonstimulants

Nonstimulant medications that modulate noradrenergic neurotransmission have also been found to be efficacious for ADHD. The first class of such medications are the tricyclic ► antidepressants, which have comparable efficacy with MPH. However, purely noradrenergic compounds such as desipramine may be more cardiotoxic than mixed noradrenergic/serotonergic drugs, although all tricyclics also produce prominent anticholinergic side effects (Biederman and Faraone 2005). The use of tricyclics, in general, and desipramine, in particular, has diminished sharply following reports of deaths of four children who were treated with recommended doses of desipramine.

In clinical trials, atomoxetine (ATX) separates from placebo in symptom improvement at all ages, with efficacy being

the strongest at the highest doses tested (1.2–1.8 mg/kg per day; Table 1). Trials sponsored by the manufacturer found no significant differences in efficacy between ATX and IR-MPH, but other trials, also commercially sponsored, have found XR-MAS and OROS-MPH to be somewhat more efficacious than ATX. In clinical practice, ATX is rarely considered a first-line medication, except for patients with ADHD and a history of substance abuse, comorbid anxiety, tics, or history of nonresponse to stimulants. Despite the generally benign effect on tics, some patients have been reported to develop tics after ATX use. Higher doses of ATX are associated with anorexia (12%) and somnolence (7–11%). ATX may produce delayed growth, which is reported to be reversible after discontinuation. Overdoses of ATX may result in seizures, which requires patients with seizure histories to take caution. Unlike tricyclic antidepressants, ATX does not have anticholinergic or cardiovascular side effects. However, a rare risk of liver injury (two cases in two million), which recovers after interruption of treatment has been reported. Therefore, ATX is not recommended in patients with jaundice or evidence of liver injury; treatment should be discontinued if patients develop pruritis, dark urine, or other symptoms of liver damage (Biederman and Faraone 2005).

The antidepressant ► bupropion has shown modest efficacy in ADHD treatment, but has been proposed to control cigarette smoking in ADHD patients, and for patients with comorbid depression, ► bipolar disorder, or substance abuse. In general, bupropion is well tolerated but is less efficacious than MPH and has a substantial risk of inducing seizures at higher doses (Biederman and Faraone 2005; Findling 2008). ► Modafinil has also some efficacy in ADHD and some studies suggest it is well tolerated, with insomnia, abdominal pain, anorexia, cough, fever, and rhinitis being the most common adverse events. However, more clinical studies are needed to determine the utility of this drug as an alternative treatment (Rappley 2005).

The alpha adrenergic agonist clonidine has been evaluated in ADHD treatment, with relatively poor results. Although it provides some benefit to patients and is well tolerated (main adverse effect is drowsiness), it is significantly less efficacious than MPH (Rappley 2005). Guanfacine is a more specific alpha agonist (alpha2A) whose effectiveness has been assessed recently in ADHD in an extended release formulation providing 1–4 mg/day (Strange 2008). Although initial studies have had confounding design flaws, improved trials have confirmed a decrease in hyperactivity/impulsivity scores and in tic frequency, even in subjects who had not responded to MPH. As with clonidine, the major adverse effects of guanfacine are sedation (16–35%) and fatigue (12–60%). Depression, headache, and upper abdominal pain have been also reported as possible adverse effects. Not surprisingly, given its primary indication, a tendency to lower blood pressure has been found compared with placebo, but the drug was well tolerated, and there was no relation between blood pressure changes and headaches or dizziness.

Prodrug Stimulants

A prodrug is a substance that needs to be transformed within the organism before it can produce its effects (Findling 2008). ► Lisdexamphetamine dimesylate (LDX) is converted into L-lysine and D-amphetamine, and its absorbance is independent of gastrointestinal processes. At least two studies reported a significant improvement in ADHD symptoms when compared with placebo, which was comparable with the benefit of XR-MAS. This finding is of interest given that, contrary to extended release formulas, the variability in absorption kinetics is much lower. Furthermore, LDX has similar tolerance levels than current stimulants. The hedonic impact of LDX was found to be much lower than that of D-amphetamine in subjects with a history of stimulant abuse, who were rated with the Drug Rating Questionnaire-Subject (DRQS), which suggests that this may be an alternative for patients with histories of substance abuse, although this indication has not yet been evaluated systematically.

Comorbidities

The NIMH Multimodal Treatment Study of ADHD found that children with ADHD and disruptive behavior disorders benefit from stimulant treatment, showing a significant decrease in aggressive behaviors (Kunwar et al. 2007). Nevertheless, behavioral intervention is recommended to promote social integration and academic performance. Though stimulants may be an effective treatment for aggressive or antisocial behavior in ADHD, ► mood stabilizers or atypical ► antipsychotics have become widely used with the intent of treating manic symptoms or aggression. Concerns are being raised regarding the serious potential for metabolic derangements with such treatments, especially with certain atypical antipsychotics. Stimulants exacerbate psychotic symptoms in a sizeable proportion of such patients. While stimulants may be modestly helpful for children with learning disabilities without prominent hyperactivity/impulsivity, they are never sufficient. Such children require additional educational support. Coexisting anxiety appears to attenuate impulsivity in ADHD. Contradictory results regarding stimulant response in ADHD children with comorbid

anxiety have been reported by well designed studies, with both poorer and equivalent response being found. Systematic studies have not examined the extent to which children with ADHD/depression or with ADHD/bipolar disorder can benefit from stimulants, although stimulants in conjunction with antidepressants have been recommended in cases of ADHD/major depressive disorder. Finally, anti-tic agents in combination with stimulants can be useful for children with ADHD and tic disorders.

Conclusions

Methylphenidate and amphetamines, preferably in extended release formulations, are the recommended first choice in children, adolescents, and adults with ADHD, including those with comorbid disruptive behavior. In cases of history of substance abuse, the use of nonstimulants or LDX may be preferred. Medications for ADHD are chronically administered over years, and require sometimes subtle adjustments in dosing, timing, and adjuncts. Establishing and maintaining a therapeutic alliance with adolescents remains one of the greatest challenges of providing psychopharmacological care for ADHD.

Attention Deficit Hyperactivity Disorder

Synonyms

ADHD

Definition

An axis-I neuropsychiatric disorder listed in the Diagnostic and Statistical Manual (DSM-IV, American Psychiatric Association). ADHD is characterized by inattentive, hyperactive, and/or impulsive symptoms that interfere with everyday functioning. Although initially presenting in childhood, ADHD symptoms often persist into adulthood where they can impede social relationships, contribute to criminality, and have a negative impact on the ability to work effectively.

Definition

Nonhuman animals, because of their specific characteristics that resemble human attention deficit/hyperactivity disorder (ADHD), were selected for use in ADHD experimental research, testing, or teaching. They provide an invaluable tool for investigating ADHD etiology, its diagnosis, and treatment.

Animal models of ADHD can be induced by genetic manipulation, physical or chemical means, or selected from the normal population on the basis of their behavioral characteristics.

Current Concepts and State of Knowledge

ADHD research has long employed animal models in the study of the neural basis of this multifactorial and heterogeneous pathology. The core clinical symptoms of ADHD – namely, inattentiveness, ► hyperactivity and ► impulsivity – have been used as constructs in animal research for a long time. Following early attempts to model these symptoms in animals such as dogs and cats, laboratory models of ADHD have been developed mostly in rodents, partly because more is known about their biology and genetics. Several authors have put forward some essential characteristics of a good animal model of ADHD. They can be summarized as follows: (1) behavioral symptoms should be evident only in particular environments and stage of development, according to the specific characteristics of ADHD symptom manifestation; (2) biochemical and morphological abnormalities – as well as their etiology – should be similar to those shown by ADHD sufferers; (3) the model should respond to the same drugs used for the treatment of ADHD with a measurable improvement of the main symptoms and be able to predict the efficacy of new treatments. Thus, in preclinical ADHD research, a particular emphasis should be put on the techniques used to assess the behavioral symptoms and on the peculiar response of the model to drugs used in ADHD pharmacotherapy on those behavioral measures.

Animal models of ADHD can be divided into genetic, chemical intoxication/physical trauma, behavioral, and brain lesion models. These models are of great value because their use can help in defining the causal relations between the symptoms and the applied experimental manipulation. Moreover, they allow us to test the efficacy of new pharmacological and behavioral interventions for the treatment of ADHD, and to understand the mechanisms underlying currently used therapies.

Assessing Impulsivity and Attention Deficits in Rodents

The diagnosis of ADHD is based on behavioral criteria. Many behavioral tests commonly used in human neuropsychology have been modeled in animals. Though relatively simple tasks have been extensively used to measure locomotor activity (e.g., ► open field test), anxiety (e.g., ► elevated plus-maze), and learning and memory (e.g., ► radial-arm maze) in animal models of ADHD, more sophisticated tasks have been developed to specifically measure impulsivity and ► sustained attention.

Tasks assessing impulsivity can be broadly divided into those measuring impulsive decision-making and those measuring ► behavioral inhibition (Winstanley et al. 2006). Both subtypes of impulsivity are highly relevant to ADHD research, given the fact that affected individuals react differently to reinforcers when compared with normal subjects and that one of the core deficits in ADHD is response inhibition.

The most widely used tests of behavioral inhibition are the ► go/no-go task and the ► stop-signal reaction time task (SSRTT) (Eagle et al. 2008). These tasks have been successfully adapted to be used in animals and have shown good face and predictive validity. In the go/no-go paradigm, subjects have to respond to a cue – the "go" signal – and not to respond to a different infrequent stimulus – the "no-go" signal – to be rewarded. Children with ADHD showed impaired ability to succeed in this task when compared with control subjects.

The SSRTT is a sophisticated variant of the go/no-go task, in which the subject is required to cancel an already initiated motor response on receiving an unexpected stop signal. By varying the timing of the stop signal presentation, it is possible to measure the speed of the inhibitory process (the SSRT) (Logan 1994), which has been shown to be consistently longer and more variable in ADHD individuals. The SSRT in animals is speeded by drugs

commonly used for the treatment of ADHD, although for some drugs, the effect depends on baseline performance (Eagle et al. 2008).

Both stopping and no-go types of behavioral inhibition in humans are under the control of fronto-striatal circuits, which are differently modulated by psychostimulants in ADHD and control subjects. When putative homologous areas are lesioned in rodents by microinfusion of neurotoxins, they show inhibitory deficits qualitatively similar to those seen in ADHD patients. Eagle and colleagues showed that lesions of the orbitofrontal cortex (OFC) impair stopping performance in the rat. Moreover, SSRT is slower in rats with medial striatal lesions, a region homologous to the caudate nucleus in humans, which has been shown to be smaller or dysfunctional in ADHD patients.

Impulsive decision-making in animals is commonly assessed by means of the ► delay-discounting (DD) paradigm. In this task, impulsive choice is defined as the preference for a smaller immediate reward over a larger but delayed one. ADHD patients show faster switches of preference toward the smaller but more immediate reward when the delay to the bigger reward is gradually increased. In rodents, ► atomoxetine, ► amphetamine (AMPH), and ► methylphenidate (MPH) – drugs commonly used in ADHD pharmacotherapy – reduce impulsive choice in the DD paradigm, and some animal models of ADHD show intolerance to delay in this task (see Table 1). Cardinal and colleagues showed that lesion of the NAc core renders animals less tolerant to delays, leaving intact the preference for the large reward when no delays are interposed. In the same task, OFC lesions had less consistent effects.

Intermediate between tasks measuring impulsive decision-making and motor disinhibition are the behavioral tasks, in which the rat has to perform an action for a predetermined number of times – or to withhold from responding for a predetermined amount of time – before emitting the response that will be rewarded. Any premature interruption of these chains of actions is considered as an impulsive response. Examples of this kind of tasks are the differential reinforcement of low rates of responding (DRL) schedule, the lever-holding task (LHT), and the fixed consecutive number (FCN) schedules. In DRL schedules, a response is rewarded only if made after the predetermined amount of time has elapsed since the last response. Available studies on DRL yielded contrasting results in ADHD sufferers as well as in rodent models of ADHD. In the LHT, the subject is required not to release a lever or a button for a predetermined amount of time to be rewarded. FCN schedules require a certain number of responses in one location, before producing a single response in a different one, to receive the reward; premature interruption of these chains of responses is usually punished with a short time-out.

One of the most used tests of sustained ► attention in rodents is the ► 5-choice serial reaction time task (5-CSRTT), which was developed partly with the aim of investigating and better understanding the deficits underlying ADHD (Bari et al. 2008). The basic task is modeled on the continuous performance task used to study human attentional processes. The rat version of the task requires animals to detect brief flashes of light presented pseudorandomly in one of the five holes and to make a nose-poke response in the correct spatial location to receive a food reward. The rat is required to monitor a horizontal array of apertures and to withhold from responding until the onset of the stimulus. Generally, the accuracy of stimulus discrimination provides an index of attentional capacity, while premature responses – made before the presentation of the stimulus – are regarded as a form of impulsive behavior and hence a failure in impulse control.

Performance on the 5-CSRTT has been evaluated after lesions of discrete areas of the rat brain. Anterior cingulate (ACg) cortex lesions impair selective attention, whereas infralimbic (IL) and postgenual ACg lesions increase impulsivity, and damage to the OFC results in perseverative responding. Lesion to the medial striatum impairs response accuracy and increases both premature and perseverative responses, whereas NAc core lesions increase impulsivity without affecting response accuracy.

Depleting brain 5-HT by intracerebroventricular infusion of 5,7-dihydroxytryptamine (5,7-DHT) during adulthood produces long-lasting hyperactivity and impulsivity in the 5-CSRTT, but no attentional impairments. Finally, attentional deficits with no increase in impulsivity have been obtained by globally interfering with cholinergic neurotransmission and, under certain conditions, with the noradrenergic system (Robbins 2002).

Genetic Models

One of the most investigated animal models of ADHD is the spontaneously hypertensive rat (SHR), an inbred genetic model derived from the Wistar Kyoto (WKY) rat. Hyperactivity and impulsivity in the SHR develop over repeated testing and are particularly evident in settings with a low rate of reinforcement (Sagvolden 2000). These traits are present before the SHR develops hypertension and remain stable during adulthood. Compared with Sprague–Dawley (SD) rats, SHR show a neurochemical profile characterized by subcortical hyperdopaminergic tone and reduced ► noradrenaline (NE) function in the

► prefrontal cortex (PFC) (Heal et al. 2008). In theory, such catecholaminergic imbalance would predict the increased locomotor activity of SHR and the beneficial effect of drugs that regulate noradrenergic transmission on impaired ► executive functions. Conversely, there is also evidence from *in vitro* experiments for the opposite biochemical profile in SHR. NE concentrations and tyrosine hydroxylase ► gene expression have been found to be higher, whereas dopamine (DA) efflux was reduced in the striatum of SHR compared with WKY rats. These results led researchers to hypothesize that ADHD is characterized by hypofunctional dopaminergic system and hyperfunctional NE transmission in the PFC, with the latter being congruent with poor PFC regulation of NE levels by noradrenergic receptors found in the SHR. Moreover, the SHR brain displays anatomical abnormalities similar to ADHD patients as well as a decreased expression of the ► dopamine transporter (DAT) gene, which could explain the reduced responsiveness to psychostimulants (Russell 2007). Serotonin (5-HT) transmission also seems

to be abnormal in the SHR and administration of the 5-HT transporter (SERT) inhibitor ► citalopram decreases hyperactivity in the ► elevated Plus-Maze. Despite its high face validity, the SHR does not show cognitive deficits across all behavioral tasks of impulsivity and sustained attention. Moreover, the ability of drugs used in the treatment of ADHD to improve performance in this animal model have also been inconsistent, probably depending on the behavioral test employed and on the rat strain used as a control.

Mice lacking the dopamine transporter (DAT-KO) are hyperactive in new environments, have learning and memory deficits as well as impaired inhibition of ongoing behavior. DAT-KO mice are characterized by high levels of extracellular DA in the striatum and reduced phasic DA release. Hyperactivity in this model is reduced by psychostimulants and serotonergic manipulation, but not by NE transporter (NET) inhibitors. This would suggest that in this model, psychostimulants do not decrease hyperlocomotion by increasing catecholamine levels via DAT or NET blockade, but probably by modulating the serotonergic system (Gainetdinov et al. 1999). A 5-HT(2A) receptor gene ► polymorphism has been associated with human ADHD and antagonists of this receptor ameliorated DAT-KO mice deficits. However, drugs targeting the 5-HT system are of limited use in the treatment of human ADHD and it is not clear yet whether this pathology is characterized by increased or decreased DAT function.

Naples high-excitability (NHE) rats are selected for high levels of activity in the Làt maze. This model exhibits decreased DA D1 receptor availability and increased DAT and tyrosine hydroxylase activity within the PFC. It has been suggested that impaired attention and hyperactivity in NHE rats may be caused by a hyperfunctional mesocorticolimbic DA system.

The Coloboma mutant mouse bears a mutation of the synaptosomal-associated protein 25 (SNAP-25) gene and has been proposed as a model of ADHD. SNAP-25 is an important protein required for neurotransmitter release and protein translocation. Coloboma mice display impulsivity in the delayed reinforcement task and their hyperactivity is decreased by AMPH but not by MPH. It has been suggested that the hyperactive phenotype of this model is caused by an imbalance between noradrenergic hyperfunction and dopaminergic hypofunction.

Recently, a genetic mouse model based on the deletion of the β2-subunit of the nicotinic receptor has been described as having ADHD-like behavioral inflexibility and inhibitory deficits. Considering a reported association between polymorphisms of the nicotinic receptor subunit and ADHD, a high incidence of cigarette smoking in individuals with ADHD and the beneficial effects of ► nicotine administration on attentional functions, further investigation of this model is warranted.

Male transgenic mice expressing a mutant form of the human thyroid hormone receptor (TRβ-1) display increasing hyperactivity over time, impulsivity, and inattention. Thyroid hormone controls the development of brain areas involved in the regulation of executive functions. This genetic model shows increased striatal dopamine turnover and its hyperactivity is reduced by MPH administration.

Chemical Intoxication and Physical Trauma Models

Despite its high heritability, some forms of ADHD are thought to be caused by heavy metal exposure, drug intoxication, or physical traumas, at pre-, peri- or post-natal developmental stage. Some environmental factors may in fact have ► teratogenic effects on the fetus during pregnancy, which will cause ADHD symptoms in the offspring. Although exposure to chemicals and complications during pregnancy and/or delivery represent independent risk factors for the development of ADHD, it is useful to create animal models that mimic such conditions.

Heavy metal exposure in early ► ontogeny causes hyperactivity, which improves after acute AMPH or MPH administration. In animals exposed to lead, 5-HT and DA turnover is decreased in the PFC and striatum, respectively. Other heavy metals, such as manganese and cadmium, are believed to cause similar effects as lead exposure in producing hyperactive rats.

Other chemical-induced animal models are created by pre- or post-natal administration of polychlorinated biphenyls (PCBs), methylazoxymethanol, and transretinoic acid. However, these conditions have had only limited success as models of ADHD.

Prenatal ethanol and nicotine exposure can cause ADHD-like symptoms in humans and other animals. Accordingly, rats prenatally exposed to ethanol display dysregulation of dopaminergic neurons in the VTA, which is normalized by AMPH or MPH administration. However, this condition is probably better suited to model ► fetal alcohol syndrome rather than ADHD.

Physical trauma models of ADHD include, amongst others, neonatal anoxia and X-ray exposure. Neonatal anoxia is a risk factor for human ADHD and causes long-lasting behavioral impairment and monoaminergic dysregulation in the rat brain. Exposure to X-radiation during development damages the ► hippocampus and causes hyperactivity and learning deficits in rats. These models both possess predictive validity since they respond to acute AMPH administration, but are created by means

of physical insults, which are unlikely to be the cause of the majority of ADHD cases in humans.

Chemical Lesion and Behavioral Models

Animal models relevant for ADHD research can be created by lesioning of selective brain areas or interfering with neuromodulatory systems. These lesions are mainly created by microinfusion of neurotoxins during animal adulthood or at early postnatal days, to mimic abnormal neurodevelopmental processes.

The most widely used neurodevelopmental model of ADHD is the neonatal ▶ 6-hydroxydopamine (6-OHDA) lesioned rat. Shaywitz and colleagues, in 1976, showed that rats lesioned 5 days after birth by intracerebroventricular infusion of 6-OHDA display marked hyperactivity and other cognitive deficits that were claimed to be attenuated by acute administration of AMPH. Further research demonstrated that the behavioral phenotype of this model also improves after MPH administration, and that these animals (rats or mice) have decreased striatal DAT density, increased dopamine D4 receptor expression, and alterations in central 5-HT neurotransmission. These rats show patterns of hyperactivity similar to those of childhood ADHD in that their hyperlocomotion is less evident in novel environments, but then increases with repeated exposures to the testing apparatus. Thus, the 6-OHDA model presents good face and predictive validity, but lacks construct validity, as it is very unlikely that the almost complete destruction of the dopaminergic system caused by the neurotoxin mirrors the ADHD condition (Kostrzewa et al. 2008). Nevertheless, this model could provide important insights on the relationship between monoaminergic alterations in ADHD and the mechanisms underlying hyperactivity.

Rats achieving poor levels of attentional performance on the 5-CSRTT have been proposed as a model of the inattentive subtype of ADHD. These rats are hyperactive, show impulsivity – as measured by the number of premature responses – in addition to low levels of attentional accuracy. In cortical areas, 5-HT turnover of these animals is inversely related to choice accuracy, while DA and 5-HT turnover correlate positively with attentional performance and premature responses, respectively. On the other hand, rats specifically selected for high levels of premature responses in the 5-CSRTT (high-impulsive rats) have lower DA D2 receptor density in the ventral, but not in the dorsal striatum, compared with nonimpulsive rats (Dalley et al. 2007). Moreover, dopamine release and metabolism are unchanged in the nucleus accumbens (NAc) of high-impulsive rats. These behavioral phenotypes have been validated in part by their capacity to predict susceptibility to drug use (Belin et al. 2009) – for which ADHD is known to be a risk factor – and by their sensitivity to drugs used for the treatment of ADHD.

Rats that show slow inhibitory processes, as measured by the SSRTT, display differential responses to drugs used in ADHD pharmacotherapy when compared with fast stoppers in the same task. Thus, AMPH and modafinil speed stop processes only on slow stoppers and have limited effect on fast-stopping animals; MPH improves action inhibition in slow stoppers, but impairs it in fast stoppers and, finally, atomoxetine speeds SSRT in all animals independent of baseline performance (Eagle et al. 2008).

Summary

This chapter reviewed the main behavioral and neurochemical characteristics of some of the most investigated rodent models of ADHD. The collection of animal models of ADHD described here is far from complete, but is illustrative of the different approaches. Table 1 summarizes some of the behavioral tasks used to characterize ADHD-like symptoms – namely, impulsivity, hyperactivity, and attention deficits – in selected animal models and the drugs that were efficacious in ameliorating the performance of the models when compared with control animals. Some of these behavioral tasks – borrowed from clinical neuropsychological research – have highlighted the translational value of ADHD research in animals. They not only prove useful in the definition of the behavioral phenotype under investigation, but also have the potential to investigate the mechanisms of action of drugs used in ADHD. Their use, in conjunction with appropriate animal models of ADHD, can help in discovering new treatments with fewer side effects and enhanced therapeutic value.

Definition

Attentional bias refers to the observation that motivationally relevant cues can "grab" or "hold" selective attention, and this is related to individual differences in appetitive and aversive motivation. For example, individuals with eating disorders tend to get readily distracted by cues related to food, whereas individuals with anxiety disorders are hypervigilant for threat-related cues. In the context of psychopharmacology, the term is usually used to refer to attentional processes among individuals with drug problems. As predicted by numerous theoretical models, drug dependent individuals have an attentional bias for drug cues, such as drug-related pictures or words.

Current Concepts and State of Knowledge

Measurement

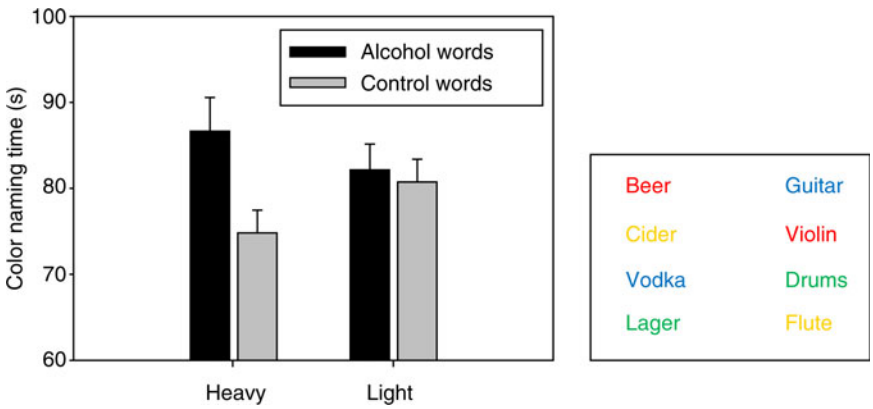
The last two decades have seen a large body of research devoted to the study of attentional biases in addiction and other disorders. A variety of experimental tasks, derived from those used in mainstream experimental psychology, have been used to assess attentional bias. For example, MacLeod et al. (1986) adapted the visual probe task, which is described below, to demonstrate that clinically anxious patients but not nonanxious controls tend to direct their attention toward threat-related words. Since this seminal study, a large volume of research has been devoted to the characterization of such attentional biases in a variety of emotional disorders (for a recent review, see Bishop 2007). More recently, researchers have used these tasks to study attentional biases for drug-related cues in addiction. With few exceptions, these tasks do not provide a direct readout of attentional processes; instead, the allocation of ▶ attention must be inferred based on a secondary measure, such as response time.

Perhaps the most commonly used task is a modified version of the classic "Stroop" task. In the classic Stroop task, participants are required to name the color in which different words are printed. A highly robust observation is that when color-related words are presented in an incongruent color (e.g., the word GREEN printed in red ink), participants are relatively slow to specify the ink color, compared to a control condition (e.g., the word TABLE printed in red ink). The interpretation of this "Stroop interference" is that people automatically process the semantic content (meaning) of words that they encounter; when the semantic content of a word (e.g., the word GREEN) conflicts with the required response (to say "red"), this leads to a slowing down of color-naming, or errors in color-naming. In the modified version of this task (the addiction Stroop), participants are required to

name the color in which drug-related words are printed, and their color-naming times for these drug-related words are compared to those for a control category (e.g., words related to musical instruments). See Fig. 1 for an example of the procedure and some illustrative findings. As reviewed by Cox et al. (2006), a highly robust finding in the literature is that drug users are slower to name the color in which drug-related words are presented, compared to words from a control category, but control participants do not exhibit this pattern of Stroop interference. Such Stroop interference has been demonstrated in users of a variety of different drugs, including alcohol, cannabis, cocaine, heroin, and tobacco (reviewed by Cox et al. 2006). This suggests that, compared to nonusers, drug users engage in excessive semantic processing of drug-related words, i.e., those words can "grab their attention." However, it is important to note that other explanations for this Stroop interference have been put forward, including delayed color-naming as a consequence of attempts to suppress the processing of drug-related words, or a generic slowdown in cognitive processing induced by the drug-related words, perhaps independently of any bias in selective attention (see Field and Cox 2008). Indeed, any Stroop interference that is observed may reflect the combined influence of all of these factors, and the specific influence of selective attention to drug-related words may be minimal; these issues mean that results from this task must be interpreted with some caution.

The visual probe task is an alternative measure of attentional bias that has been extensively used in psychopharmacology research, particularly over the past 5 years. In this task (see Fig. 2), a pair of pictures are presented on the left and right of a computer screen. One of the pictures is drug-related (e.g., an image of a person smoking a cigarette), and the other picture contains no drug-related content. The pictures are shown for a short period (typically between 50 and 2,000 milliseconds (ms)), and after pictures have been removed from the computer screen, a visual probe stimulus (for example, a small dot) is presented on either the left or right of the screen, in the spatial position that had been occupied by either the drug-related or the control picture. Participants are instructed to respond to the probe as quickly as possible. As reviewed by Field and Cox (2008), a robust observation is that drug users are faster to respond to probes that replace drug-related pictures, than to probes that replace control pictures. Control participants are equally fast to respond to probes that replace drug-related and control pictures. This has been demonstrated not only with tobacco smokers in several studies, but also with cannabis users, heroin users, and heavy drinkers.

Given that people are faster to detect and respond to a stimulus if it appears in a location of the visual field that they were attending to, this finding (faster reaction times to probes that replace drug-related pictures, rather than control pictures) is usually interpreted as indicating that drug users were directing their attention toward drug-related pictures. Indeed, when participants' eye movements are monitored while they complete the task (as detailed below), there is usually a large positive correlation between the index of "attentional bias" (derived from reaction times to probes) and the amount of time that



Attentional Bias to Drug Cues. Fig. 1. The addiction Stroop test. Participants are required to quickly identify the color in which words are printed. One list of words is drug-related; the other is neutral. In this study, adolescent heavy drinkers were slower to name the color of alcohol-related words, than to name the color of neutral words, but light drinkers took a similar amount of time to name the color of words in the two word lists. Attentional Bias to Drug Cues. Fig. 2. The visual probe task. Following a centrally presented fixation cross, a drug-related picture and a neutral picture are presented side by side on a computer screen for a brief period. After the pictures disappear, a visual probe is presented, and participants are required to rapidly respond to the probe. In this study, tobacco smokers were faster to respond to probes that replaced smoking-related pictures, than to probes that replaced neutral pictures, but nonsmokers did not show this difference. (Reprinted with permission from Mogg K, Bradley BP, Field M, De Houwer J (2003) Eye movements to smoking-related pictures in smokers: relationship between attentional biases and implicit and explicit measures of stimulus valence. Addiction 98:825–836.)

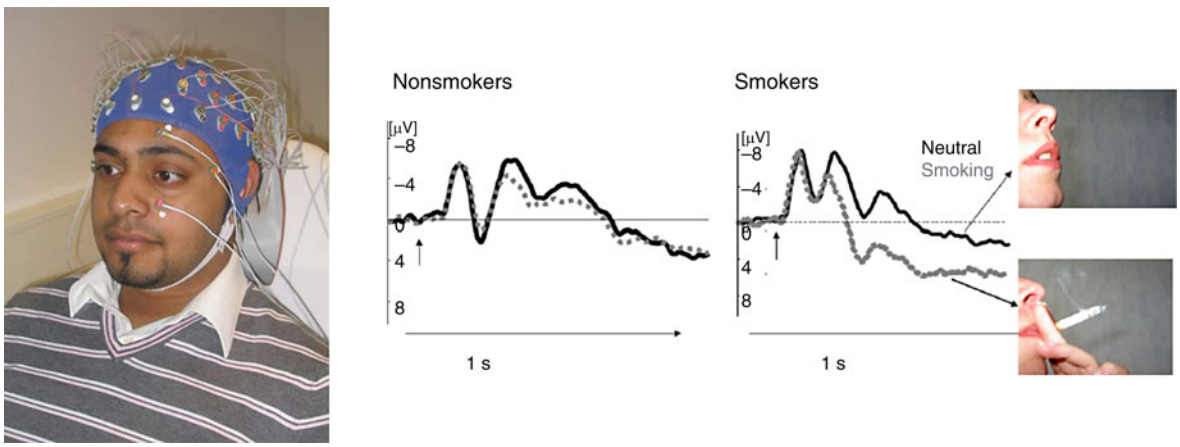
people maintain their gaze on the drug-related cues. So, it appears valid to use reaction times to visual probes to infer the allocation of attention to drug-related cues that precede those visual probes. A further issue with the visual probe task is that researchers have experimentally manipulated the amount of time that picture pairs are presented on the screen before they are removed and replaced by the visual probe. By varying the stimulus onset asynchrony (SOA), in this way, for example, using very short exposure durations (e.g., 50–200 ms) or longer durations (e.g., 2,000 ms), it is assumed that reaction time can capture the extent to which cues "grab" the attention (with very short SOAs) or "hold" the attention (with longer SOAs). Some studies suggest within-subject and between-group differences in attentional bias when short and long SOAs are used, which is consistent with the notion that these different SOAs can be used to measure different aspects of cognitive processing of drug cues. However, there is currently some controversy over whether reaction times obtained from the visual probe task can ever be used to

index orienting of attention, regardless of how brief the SOA is (Field and Cox 2008).

Given these issues with interpreting results from the visual probe and addiction Stroop tasks, there is a need to use measures of attentional bias that provide more direct readouts of selective attention. Eye movement monitoring is one such measure, because people are usually attending to whatever is currently the focus of gaze. Some researchers have monitored participants' eye movements while they complete a visual probe task in which drug-related and control pictures are presented. It is possible to then look at the orienting of attention to drug-related cues, by measuring which picture (drug-related or control) participants initially direct their gaze toward on each trial of the task. It is also possible to measure the maintenance of attention on, or latency to disengage attention from, drug-related cues, by comparing the amount of time that participants direct their gaze toward drug-related pictures with the amount of time that they direct their gaze toward control pictures. Tobacco smokers, ► cocaine users, and cannabis users (but not control participants) tend to preferentially maintain their gaze on drug-related pictures; however, the evidence for a bias in the initial orienting of attention toward drug-related pictures is currently equivocal (Field and Cox 2008).

Additional laboratory measures have been used in recent years to investigate attentional bias for drug-related cues. These include tasks such as the flicker induced change blindness task and the attentional blink task (see Field and Cox 2008). However, these are not discussed in detail in this section as they are not currently widely used, although both methods may have advantages over existing measures. The final measure that we consider here is ► electroencephalography (EEG), particularly the study of event-related potentials (ERPs) elicited by drug-related cues. EEG recording involves attaching electrodes to various sites on the scalp of participants (see Fig. 3) that measure the electrical activity produced by the brain. Participants are then shown drug-related (or control) pictures, and activity in the cortex can be measured in the form of electrical activity on the scalp in response to presentation of the pictures (ERPs). Although there are many different forms of ERPs, which differ in their latency, magnitude, and brain region of origin (see separate entry), researchers have focused on ERP components such as the P300 (a slow positive wave that typically occurs about 300 ms after stimulus presentation). This particular ERP component has been implicated in selective attention, such that its magnitude (in response to a visually presented stimulus) seems to correlate highly with the degree to which participants attend to that stimulus. This has particularly been observed for motivationally relevant stimuli. In several studies, it has been demonstrated that P300 magnitude in response to drug-related



Attentional Bias to Drug Cues. Fig. 3. Measuring event-related potentials (ERPs) in response to smoking-related cues. Smoking-related and neutral pictures were presented for 2 s, and participants were asked to watch the pictures attentively. The ERP results indicate that both the P300 and the subsequent slow wave amplitudes in response to smoking-related pictures are significantly enhanced in smokers compared to nonsmokers at frontal and central sites, whereas the magnitude of the P300 and SPW amplitudes in response to neutral pictures does not differ between the groups. Accordingly, it can be concluded that smokers show more bias for smoking-related pictures than smokers. (Data published in Littel M, Franken IHA (2007) The effects of prolonged abstinence on the processing of smoking cues: an ERP study among smokers, ex-smokers and never-smokers. J Psychopharmacol 21:873–882.)

cues is significantly larger in drug-users than in control participants (see Fig. 3 for an example). This has been demonstrated in heroin, cocaine, alcohol, and tobacco users (e.g., Franken et al. 2008).

Theoretical Relevance

Arguably, interest in attentional bias in humans originated from animal models of incentive learning processes. It has been known for decades that after ► classical (Pavlovian) conditioning, laboratory animals will direct approach behaviors to conditioned stimuli that are reliable predictors of appetitive rewards, such as food or addictive drugs. This conditioned approach behavior is known as autoshaping. Interestingly, animals show increased interest in conditioned stimuli that predict appetitive rewards, and they orient their attention to them ("sign-tracking") before those cues elicit an overt behavioral approach response. In an influential theory, Robinson and Berridge (1993, cited in Field and Cox 2008) argued that these incentive learning processes are mediated by dopaminergic activity in the ► nucleus accumbens and related structures within the mesolimbic dopamine system. According to the theory, chronic exposure to drugs of abuse leads to sensitization of dopamine activity in this ► dopamine circuit. As a consequence, these incentive learning processes are exaggerated, and drug-related cues acquire very powerful incentive properties, meaning that their capacity to grab the attention and elicit approach behaviors is enhanced. As reviewed by Hogarth and Duka (2006), an emerging body of evidence suggests that a classical conditioning process may be responsible for the development of attentional bias in humans: people tend to direct their attention toward a cue that was previously paired with the availability of ► alcohol or ► nicotine in the laboratory.

Alternative theoretical models are more explicitly grounded in clinical and experimental psychology, yet their predictions are not inconsistent with the aforementioned learning processes. For example, the theory of current concerns (see Cox et al. 2006) suggests that drug users have a dysfunctional motivational structure, such that their goal to use drugs takes precedence over all other goals, leading to a general cognitive hypersensitivity to goal-related (i.e., drug-related) environmental cues. Ryan 2002; cited in Field and Cox 2008) emphasized the need to consider cognitive processes when trying to understand why drug users react to drug-related cues with physiological and subjective changes. In essence, Ryan argued that drug users find it difficult to ignore drug-related cues in their environment, which exacerbates subjective craving in response to those cues; this in turn leads to drug-seeking behavior. Finally, Franken (2003) integrated predictions made by Robinson and Berridge (1993) with some observations of human patients. Franken's (2003) model suggests that attentional bias for drug cues occurs as a consequence of a dysfunctional, dopamine mediated incentive learning process, as discussed above. This causes drug users to be more likely to detect drug-related cues in their environment. Once drug cues have been detected, the drug user experiences subjective ► craving, which leads to a further increase in the salience of drug-related cues (i.e., drug-related cues become even more difficult to ignore). In addition, attentional bias and subjective craving mean that the cognitive resources required for coping strategies (e.g., attempts to resist craving) are further diminished, and the combined effect is that drug-seeking behavior is more likely to occur. All of these theoretical models converge on the common prediction that attentional bias should be positively correlated with subjective craving, and we discuss relevant evidence in the following paragraphs.

Clinical Relevance

The theoretical models discussed above suggest that attentional bias is likely to develop as a consequence of chronic exposure to drugs of abuse, perhaps through a conditioning process. Once established, attentional bias may be long-lasting and difficult to reverse, and this is consistent with results from one study that demonstrated no difference in attentional bias between current tobacco smokers and individuals who had been abstinent from smoking for 6.5 years, on average. These theoretical models also suggest that attentional bias can contribute to the maintenance or escalation of drug-seeking behavior, perhaps because it increases the magnitude of subjective drug craving, or even triggers drug-seeking behavior directly. As such, attentional bias may be clinically relevant, and therefore it could be a viable target for clinical intervention. Two primary clinical applications of attentional bias research can be described. First, if attentional bias causes (or at least indexes the underlying processes that cause) drug-seeking behavior, then individual differences in attentional bias might indicate vulnerability to relapse among drug users who are currently abstinent, possibly in ways that cannot be captured by self-report measures. Consistent with this notion, a number of recent studies demonstrated that individual differences in attentional bias (among tobacco smokers, alcohol abusers, and heroin users) predicted subsequent clinical outcome (either treatment dropout, or time to relapse to drug-seeking after treatment completion; see review by Field and Cox 2008). However, all of these studies used the addiction Stroop task to measure attentional bias; given the problems with interpreting results from this task,

there is a need to replicate these findings with more direct measures of selective attention, such as eye movement measures. The second clinical implication is that attentional bias itself might be a suitable target for treatment intervention: if individuals can be "trained" to reduce the extent to which they get distracted by drug-related cues, they might be less likely to relapse to drug-seeking behavior in the future. There is currently a great deal of enthusiasm for this type of intervention, although it should be noted that the early results are not promising. That is, when attentional bias is experimentally reduced, it does not consistently lead to a reduction in drug-seeking behavior (see Field and Cox 2008).

The association and causal relationship between attentional bias and subjective craving (rather than drug-seeking behavior) is currently more compelling. Among drug users, all measures of attentional bias are positively correlated with subjective drug craving (Field and Cox 2008; Franken 2003), and the association is particularly robust for more "direct" measures of attention, such as eye movement monitoring or the P300 component of ERPs (see Field et al. 2009). As predicted by some of the theoretical models discussed earlier (e.g., Franken 2003; Ryan 2002), there appears to be a reciprocal causal relationship between attentional bias and subjective craving. That is, when subjective craving is experimentally manipulated (e.g., through stress, enforced abstinence), attentional bias seems to increase in line with subjective craving; on the other hand, when attentional bias is experimentally increased, this leads to a small but significant increase in subjective craving (all reviewed by Field and Cox 2008).

So attentional bias may be related to drug-seeking behavior, although the evidence for this is limited at present. The evidence for an association, and mutual causal relationship, between attentional bias and subjective craving is much more compelling. Given that some investigators (e.g., Tiffany 1990; cited in Field and Cox 2008) believe subjective craving to be of little relevance to drug-seeking behavior itself, it remains to be seen whether attentional bias could have a clinically meaningful role in the prediction of treatment outcome in drug abusers, or whether it is a suitable target for treatment.

Pharmacological Modulation

The effects of a variety of pharmacological challenges on attentional bias have been studied. Firstly, administration of small to moderate doses of alcohol seems to increase attentional bias for alcohol- and smoking-related cues in heavy drinkers and tobacco smokers, respectively (see Field and Cox 2008). Alcohol affects a variety of neurotransmitter systems, but its direct effects are to increase ▶ GABA activity and reduce ▶ glutamate activity, which then has knock-on effects on other neurotransmitter systems, such as ▶ dopamine and ▶ serotonin. The precise mechanism of action through which alcohol increases attentional bias is unclear, but it may be related to some of the other effects of alcohol priming doses, such as increased craving or a decreased ability to regulate attention. Investigators have also increased or decreased dopamine and serotonin function before examining the effects on attentional bias (reviewed in Munafo and Albery 2006). In one study, ▶ Haloperidol, a dopamine antagonist, was seen to eliminate Stroop interference produced by heroin-related words in heroin addicts. In another study, researchers depleted dopamine levels by administering an amino acid mixture which was devoid of the amino acids tyrosine and phenylalanine, which are required for dopamine synthesis. Compared to a control manipulation (consumption of an amino acid mixture that did not deplete tyrosine and phenylalanine), this led to reduced Stroop interference for smoking-related words in tobacco smokers. However, these effects were not particularly robust, as they were only seen in female participants, but not in males. In a further study, researchers replicated this effect of tyrosine depletion on Stroop interference, but again the effects were not robust: in this study, effects were moderated by the sequence in which participants consumed the two different amino acid mixtures.

So, there is emerging evidence that a dopaminergic mechanism is involved in attentional bias, with manipulations that reduce dopamine function leading to a reduction or abolition of attentional bias in tobacco smokers and heroin users. This is very important theoretically because it is consistent with the dopamine sensitization theory of addiction, which was discussed previously (Robinson and Berridge 1993; see Field and Cox 2008). To briefly recap, according to the theory, chronic drug use leads to sensitization of dopamine function in the nucleus accumbens and interconnected structures, which leads to an increase in the "salience" of drug-related cues. As predicted by the model, pharmacological manipulations that reduce dopamine function seem to reduce the salience of drug-related cues, i.e., they reduce attentional bias. However, dopamine is unlikely to be the only neurotransmitter involved. One group of investigators were able to increase Stroop interference for smoking-related words in tobacco smokers by depleting levels of ▶ typtophan, an amino acid required for the synthesis of serotonin (5-HT). So, although the evidence is limited, different neurotransmitter systems may have conflicting roles in attentional bias, with some (e.g., dopamine) increasing it and others (e.g., serotonin) reducing it. Finally, we note

that these pharmacological challenge studies used the addiction Stroop task to measure attentional bias. Given that it is difficult to accurately characterize the roles of selective attention versus other cognitive processes (e.g., generic slowdown, thought suppression) in the production of Stroop interference, future researchers should explore the effects of pharmacological challenges on other, more direct measures of attentional bias, such as eye movement monitoring or ERPs.

Attentional Effect

Definition

Attentional effect refers to the immediate effect of a drug on the allocation of cognitive resources required for timing. These effects are reflected, for example, in the alteration of the delay in responding that follows a retention interval. Should subjects pay more attention to timing, they would be able to stop timing during the delay and resume timing afterward with little or no loss of accumulated time prior to the interruption. Should subjects pay less attention to timing, they would not be able to stop timing during the delay, and they will restart (reset) timing afterward. In the PI procedure with gaps, an attentional effect is observed by an immediate shift in the response function in trials with gaps (retention intervals), indicative of more or less attention paid to the timing task (see Buhusi 2003).

Attentional Retraining Intervention

Definition

Attentional retraining interventions involve procedures that are designed to assist individuals in maintaining, focusing, redirecting, and dividing attention. Extrapolated from neuropsychological testing and interventions, attentional retraining utilizes auditory and/or visual stimuli to isolate different areas of attention. Through repeated completion of specific tasks, attentional retraining can lead to increased overall attention, reduced distractibility, and increased ability to shift attention. In relation to drug effects, attentional retraining interventions are designed to redirect automatic attentional bias in order to lessen the impact of drug-related cues. By redirecting attention, these interventions decrease distractibility from drug cues and subsequently disrupt the activation of drug-seeking behavior.

Attentional Set

Definition

Attentional set refers to the bias to attend to restricted perceptual aspects of the environment. Organisms learn to attend to the sensory features and responses that are relevant to performing a task and ignore the features and responses that are irrelevant. When certain features and responses retain their relevance across tasks, an

"attentional set" may develop that bias perception and responses and increases the speed of learning new tasks as long as those features and responses remain relevant.

All conventional antipsychotics (also called first-generation antipsychotics) share the central property of dopamine 2 receptor antagonism and, in association with this property, can cause extrapyramidal side effects (EPS). Atypical antipsychotics are so-called because they generally have a lower propensity to cause EPS than the older agents; the exact reason for this is unknown but is believed to be due to the fact that these agents have the additional property of 5HT2A antagonism and/or dopamine 2 partial agonism (as opposed to antagonism).

Definition

Autism is a neurodevelopmental disorder characterized by impairments in social interaction, verbal and nonverbal communication, and restricted, repetitive, and stereotyped patterns of behavior, interests, and activities appearing before the age of three (American Psychiatric Association 1994). Its clinical manifestations and severity of impairments vary from mild to severe. The core symptoms are frequently accompanied by a spectrum of neurobehavioral derangements, including: hyperactivity, aberrant sensitivity to sensory stimulation, anxiety, mental retardation, seizures, self injury, sleep disturbances, and upset to change in routine. The etiology of autism is thought to involve an interaction between genetic susceptibility, mediated by multiple genes, and environmental factors. Epidemiological studies find a four times higher incidence of autism in boys than in girls. Because the primary diagnostic criteria of autism are abnormal behaviors, rather than biochemical or neuroanatomical factors, the use of animal models in the study of autism is unavoidable, as this is the only way to study behavioral defects in context of a whole organism.

Current Concepts and State of Knowledge

Concepts for In Vivo Modeling

There is an ongoing discussion about the criteria to be used in the evaluation of animal models. It has been suggested that the only meaningful initial evaluating criterion for an animal model is its ability to lead to accurate predictions (predictive validity). Other authors stressed that the demonstration of construct validity (similarity to the underlying causes of the disease) represents the most important and necessary component in validation of an animal model. Others claim that the modeling of symptoms (face validity) must remain the primary goal of animal models of psychiatric disorders. The resolution of this puzzling controversy depends on the desired purpose of the model that one wishes to validate. Although, regarding complex psychiatric disorders such as autism, a multidimensional approach should be used as an optimal strategy.

Challenges for Animal Models of Autism

In recent years, several rodent models of autism have been developed that reflect some behavioral, genetic, and neuroanatomical alterations associated with this disorder. One of the main problems for the development of a relevant model is to define markers of autism, addressing its complexity and diversity. An ideal rodent model of autism should display symptoms of aberrant social interaction and communication, as well as repetitive behaviors. Tasks that could examine these behavioral symptoms in rodents have been already developed and are summarized in Table 1. However, an animal model of autism based solely on behavioral assays would be incomplete. Animal model should also address a combination of the neuropathological, biochemical and genetic factors implicated in autism. Another challenge lies in the fact that many clinical hallmarks of autism are difficult or almost impossible to replicate in rodents, e.g., theory of mind (ability to intuit the feelings and intentions of others) or speech deficits. It is also important to realize that assumed "core" psychopathological phenomena observed in autism are present as common clinical features in schizophrenia, depression, obsessive-compulsive disorder and other medical and psychiatric illnesses. What is specific for autism is a pattern of socio-behavioral aberrations and their appearance before the age of three, and animal models should try to address this fact.

Behavioral Tests for Autistic-Like Aberrations in Rodents

As an important prerequisite, it is necessary to use appropriate behavioral test batteries for the validation of an animal model of autism. The three core symptoms of autism should be targeted first:

1. Impairment in social interaction is a critical component for such models. Rodents are highly social animals displaying a plethora of different social behaviors. The propensity of animals to spend time with conspecific rather than non-social novel objects shall be used as one of the measures. This can be best done in an automated three-chambered apparatus in which social interactions, social recognition, and social memory can also be scored (Crawley 2007). Measures of the level of social approach should be accompanied by more specific analyses of reciprocal social interactions, including, nose-to-nose contacts, anogenital inspections, aggression, escape behavior, nesting patterns, juvenile rough and tumble play, etc.
2. Impairments in social communication may be meaured in rodents using olfactory and auditory communication tasks. Different kinds of ► ultrasonic vocalizations can be elicited in rodents, starting from separation calls in pups isolated from their mothers, to frequency modulated vocalizations in social situations in adult animals, treated, at least in rats, as indicators of positive and negative affective states (Portfors 2007). Both frequency and time structures of ultrasonic vocalizations should be analyzed. Olfactory social signals, including deposition of ► pheromones,

Impairment in social interactions • Reciprocal social interactions (partner grooming, nose-to-nose contacts, anogenital inspections, aggression, escape behavior, juvenile rough and tumble play etc.) • Propensity to spend time with conspecific vs. novel objects • Conditioned place preference to conspecifics • Preference for social novelty • Aggression (resident-intruder test) • Social recognition • Nesting patterns in the home cage 2. Impairments in social communication • Behavioral responses to social olfactory cues from conspecifics • Deposition of social olfactory pheromones • Vocalizations emitted during social interactions • Responses to vocalizations from conspecifics • Parental retrieval of separated pups • Ultrasonic vocalizations by separated pups 3. Repetitive, stereotyped patterns of behavior, interests, and activities • Motor stereotypies • Extinction of a learned response in an operant chamber • Reversal of a position habit in an appetitive T-maze task, aversive Y-maze task or the Morris water maze • Spontaneous responses to errors during reversal tasks	1. Anxiety: elevated plus maze; light-dark box exploration; Vogel conflict licking test; marble burying 2. Theory of Mind deficits: location of buried food following observation of conspecifics; social transmission of food preference; avoidance of aggressive encounters 3. Cognitive aberrations: acquisition of different maze tasks; operant learning tasks; attentional measures in the five choice serial reaction time task; contextual and cued fear conditioning; discriminative eyeblink conditioning and reversal 4. Seizure susceptibility: spontaneous seizure activity; sensitivity to audiogenic and drug-induced seizures 5. Motor clumsiness: balance beam foot slips; rotarod motor coordination and balance; gait analysis 6. Sleep disturbances: circadian running wheels; home cage sleep and activity patterns 7. Responses to sensory stimuli: acoustic startle; tactile startle; hot plate; Von Frey filaments; unresponsiveness to sensory attentional cues (failure to disengage attention) 8. Developmental progression: maturational and developmental milestones; brain weight and volume; size of structures

are another form of rodent communication (Arakawa et al. 2008). Rodents' chemical signals play a particularly important role in determining social dominance and intersexual relationships.

3. Finally, repetitive behavior encompasses both motor stereotypy and self-injury, can be scored using standardized scales, and behaviors reflecting general cognitive rigidity, such as ability to change, resistance to change, and responses to the change in routine can be investigated by exploratory choices and reversal tasks using spatially contingent reinforcers, e.g., reversal learning in T-maze or water maze.

Because autism is accompanied by a plethora of neurobehavioral aberrations, it is important to include a range of additional behavioral tasks assessing, e.g., anxiety, seizure susceptibility, sleep patterns, sensitivity to sensory stimuli, learning and memory, and maturation and development. Finally, both pathological features of autism (e.g., decreased number of Purkinje cells) and biological findings (e.g., increased serotonin levels) should be addressed.

Current Animal Models of Autism

More than a dozen of different rodent models of autism are currently used. They can be classified into three categories: (1) models created by neonatal lesions of brain areas shown to be abnormal in autism, e.g., cerebellum, the ► amygdala, ► hippocampus, or the medial ► prefrontal cortex; (2) models mimicking environmental factors that increase the risk for autism in humans, e.g., prenatal exposure to ► valproic acid (VPA) or pre- and neonatal immunological challenges; and (3) ► genetically modified animals, e.g., targeted mutations in genes associated with autism or localized in chromosomal regions identified by linkage analyses.

Lesion Induced Models

The exact locus of brain dysfunction in autism remains a point of debate (Bauman and Kemper 2005). Many brain regions, ranging from brainstem and cerebellum to association areas of the neocortex, have been suggested as potential candidates. Nevertheless, converging lines of evidence suggest that dysfunctions and morphological abnormalities in the medial temporal lobe, especially

amygdala, and the prefrontal cortex (PFC) might underlie social deficits in autism. On that basis several models of autism have been proposed (Tordjman et al. 2007). For example, neonatal ibotenic acid lesion of the amygdala on PND 7 in rat produces a spectrum of behavioral abnormalities resembling those described in autism: decreased social interaction, increased stereotypic-like activity and decreased exploratory behavior. Similarly, neonatal ventral hippocampus lesion in rats leads to impaired social behaviors, motor hyperresponsiveness to stress, enhanced stereotypies, deficits in pre-pulse and latent inhibitions, and working memory problems. Rats with neonatal PFC lesions display reduced social play and non-play behavior in early adolescence, and reduced amount of self-grooming in adulthood. However, as these injuries destroy entire brain regions they have little relationship to the mild neuroanatomical pathologies observed in autism. Furthermore, abilities to investigate genetic or developmental mechanism in such models are very limited.

Models Created by Environmental and Immune Factors

An exposure during embryogenesis to at least three teratogens appears to be a risk factor for autism: ► thalidomide, VPA, and ► misoprostol (Arndt et al. 2005). Accordingly, one of the best validated animal models of autism is induced by prenatal exposure to VPA on the twelfth day of gestation (reviewed in Markram et al. 2007). VPA rats show several brainstem and cerebellar abnormalities resembling those found in autistic patients. At the behavioral level, VPA rats exhibit decreased social interactions, increased repetitive behaviors, enhanced anxiety, locomotor hyperactivity combined with lower exploratory activity, lower sensitivity to pain, higher sensitivity to non-painful sensory stimulation, impaired pre-pulse inhibition, and faster acquisition of eye-blink conditioning. Interestingly, behavioral aberrations described in VPA rats are observed mostly in males and can be reversed by ► environmental enrichment procedure. These might resemble both disproportion in boys to girls ratio in autism and efficacy of early behavioral-cognitive intervention in some patients with autism. VPA rats express also molecular and immunological aberrations resembling those observed in autism, e.g., increased serotonin level in several brain structures and ► hyperserotoninemia, increased frontal cortex dopamine level, enhanced excitatory transmission, and decreased cellular immune response.

Another factor implicated in the pathogenesis of autism is disturbed functioning of the immune system, especially pre- and/or neonatal immunological challenge. The best characterized model of autism utilizing this approach is induced by neonatal Borna disease virus (BDV) infection in rat (Pletnikov et al. 2005). Infected animals have injured cerebellum, progressive loss of Purkinje cells and dentate gyrus neurons, and cortical shrinkage. Neonatal BDV infection induce abnormal social interaction and communication, increased emotional reactivity, reduced cognitive abilities in spatial memory and learning, hyperactivity, stereotypies, and decreased startle responsiveness. These abnormalities mimic the impaired social interaction and atypical responses to sensory and emotional stimuli characteristic in autism. Similarly, mouse prenatally exposed to maternal infection or inflammation also displays autistic-like phenotype, including deficiencies in social interaction, exploration and sensorimotor gating. The disadvantage of infection models is that they lead to a persistent infection of the brain precluding more precise characterization of the time course and structural specificity of the created neuronal aberrations.

Genetically Induced Models

To date, several genetically induced mouse models of autism have been proposed (Moy and Nadler 2008). They were created using three general approaches. One approach is to induce mutations in genes regulating social behavior. For example, oxytocin gene knockout pups display reduced exploration, less separation distress calls, and later on a diminished social recognition. Reduced social interaction and decreased exploration were also observed in serotonin transporter-null mice.

A second approach uses monogenic aberrations, such as loss of Fmr1 or methyl-CpG-binding protein-2 (Mecp2) function, that underlie syndromes associated with autistic-like behavior. The Fmr1-null mice display increased levels of social anxiety, reduced social interaction, hyperactivity, and deficits in spatial and reversal learning. Interestingly, exposure to an enriched environment can reverse some behavioral deficits in this model. The Mecp2-null mice show deficits in social behavior, hypoactivity, impaired learning and memory, and increased anxiety.

A third approach uses gene mutations relevant to loci for autism susceptibility, identified by association or linkage studies. For example, $Reln^{rl/+}$ mice show lower rates of separation distress calls, impairments in reversal learning, increased anxiety, decreased pre-pulse inhibition, and a progressive loss of Purkinje cells. Similarly, Gabrb3 gene deficient mice exhibit impaired social and exploratory behaviors, deficits in non-selective attention and hypoplasia of cerebellar vermal lobules. Another example, mutants of genes regulating synaptic function may show highly specific deficits in social interaction, like mouse with a loss-of-function mutation in X-linked Nlgn4, or a

combination of symptoms, including social deficits, hyperactivity, reduced spatial learning, impaired motor coordination, smaller cerebellum and reduced numbers of Purkinje neurons, like En2-null mice. An important drawback of a targeted gene disruption in animal models of autism is that the null allele is not what is normally observed in humans, and that autism, as a polygenic disorder, is probably a result of an interaction of several dozens of genes.

Conclusions

The advantage of animal models of autism is to study developmental and behavioral deficits in context of a whole organism. We can use such models to clarify complex relationships between genetic, behavioral and environmental variables to better understand and potentially cure autism. What we need now is to combine these different approaches into multidisciplinary studies determining the consequences of environmental factors (e.g., stress, teratogenic substances, enriched environment) on the development of autistic-like behavioral changes in genetically modified animals, and *vice versa*, to determine the genetic basis of negative and positive effects of environmental factors in animal models. It is also critical to facilitate the process of identifying reliable measures of the human phenomenon, as better understanding of the neuropathology of autism will be essential to continue to build and improve animal models in the future.

Definition

Autism Spectrum Disorders

Autism spectrum disorders (ASDs) are a group of neurodevelopmental disorders that involve qualitative

impairments in social interaction and communication, and restricted repetitive and stereotyped patterns of behavior (► stereotypical and repetitive behavior), interests and activities. The ASDs include ► autism or autistic disorder, ► Asperger's disorder, and ► pervasive developmental disorder not otherwise specified (PDD NOS). The category of ► Pervasive Developmental Disorders (PDDs) is broader and also includes ► Rett's disorder and ► childhood disintegrative disorder. All these disorders cause significant impairment in functioning.

Mental Retardation

Mental retardation (MR) is described as an IQ of 70 or below, age of onset less than 18 years, and deficits in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety. The severity of MR is based on intellectual impairment. Mild MR is described as an IQ of 50–55 to 70, moderate MR 35–40 to 50–55, severe MR 20–25 to 35–40, and profound MR below 20–25 (American Psychiatric Association 2000).

Role of Pharmacotherapy

Autism Spectrum Disorders

In ASDs, there are several symptom domains, some core and some associated, that are common targets of pharmacological therapy. These domains are frequently seen in individuals with ASDs and may interfere with their ability to adapt and function. Among others, these symptom domains include motor hyperactivity and inattention, interfering stereotypical and repetitive behavior, aggression and self-injurious behavior (SIB), and core ► social impairment. We will not discuss all possible pharmacotherapies for ASDs in this entry. For example, mood, anxiety, and sleep disorders are often treated with drugs in individuals with ASDs. However, due to a paucity of randomized controlled trials (RCTs) in these areas, they will not be reviewed.

Although the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition – Text Revision (DSM-IV-TR) precludes individuals with ASDs from being diagnosed with attention-deficit/hyperactivity disorder (ADHD) (American Psychiatric Association 2000), symptoms of hyperactivity, distractibility, and motor restlessness are common in this population. Stimulants such as the norepinephrine reuptake inhibitor ► atomoxetine, and alpha2 adrenergic agonists have all been used to treat these symptoms in individuals with ASDs. Stimulants are the treatment of choice for typical developing children with ADHD. Early trials of stimulants in ASDs concluded they were not effective in this population. Several newer RCTs have suggested that stimulants may in fact be helpful, to some extent, for this group of symptoms in ASDs. A recent RCT sponsored by the National Institute of Mental Health (NIMH) on children with ASDs found that 49% of the subjects responded to ► methylphenidate; 18%, however, discontinued the drug due to adverse events. It was concluded that children with ASDs, compared with typically developing children diagnosed with ADHD, have a decreased response rate and an increased likelihood of side effects when prescribed methylphenidate (McDougle et al. 2006).

Clonidine and guanfacine are two alpha-2 adrenergic agonists that have been studied to treat ADHD symptoms in ASDs (Stigler et al. 2008). Clonidine was investigated in two small, controlled trials in individuals with autism. The results of one study yielded improvement on both a teacher and parent rating scale, but not a clinician rating scale. The other study of transdermal clonidine noted significant improvement in hyperactivity and anxiety. Side effects included sedation, hypotension, irritability, and fatigue.

Guanfacine requires less frequent dosing, may be less sedating and decreases the chance of rebound hypertension due to a longer half-life than clonidine (McDougle et al. 2006). RCTs of guanfacine have not yet been performed in ASDs. However, a systematic review of 80 patients with these disorders found improvement in hyperactivity, inattention, and impulsivity, with a response rate of 24%. Overall, participants tolerated guanfacine well and no significant changes in vital signs were noted (Stigler et al. 2008).

Repetitive thoughts and behaviors (stereotypical and repetitive behavior) are a core component of the ASDs (McDougle et al. 2006). These repetitive phenomena can be intrusive and interfere with day-to-day functioning. Due to the success of treating the repetitive thoughts and behaviors of obsessive–compulsive disorder with serotonin reuptake inhibitors (SRIs), studies have been performed with these agents in ASDs. Controlled trials of ► clomipramine, ► fluvoxamine, and ► fluoxetine have been published. Treatment effects on this symptom domain have also been assessed in controlled trials of the antipsychotics ► haloperidol and ► risperidone in individuals with ASDs.

Clomipramine has been evaluated in individuals with PDDs in multiple open-label and two controlled studies (Stigler et al. 2008). Both of the controlled trials found the drug to be superior to placebo. However, side effects were a significant problem and included the prolongation of the

cardiac QTc interval, tachycardia, grand mal seizure, sedation, and tremor.

Results of three double-blind, placebo-controlled studies of fluvoxamine have yielded mixed results (Stigler et al. 2008). It appears that adults with ASDs are better able to tolerate this drug than young children. Side effects included sedation, nausea, hyperactivity, insomnia, aggression, agitation, and behavioral activation.

There have been multiple open-label and two controlled trials published with fluoxetine (Stigler et al. 2008). The drug was generally found to be effective in the majority of open-label trials and superior to placebo in the two placebo-controlled trials. Side effects included aggression, hyperactivity, and decreased appetite.

RCTs of haloperidol and risperidone have both shown efficacy in decreasing stereotypic behavior (► stereotypical and repetitive behavior) in subjects with ASDs (McDougle et al. 2006).

The overall findings of these studies concluded that prepubertal children with ASDs may not respond to or tolerate SRIs as well as postpubertal adolescents or adults with these disorders (McDougle et al. 2006). There are several factors that could contribute to this. It may be that changes in the serotonin system over the course of development in individuals with ASDs could influence their ability to tolerate and respond to SRIs.

Irritability that can be manifested as aggression, SIB, or severe tantrums is another target symptom domain associated with ASDs that can be amenable to pharmacological management (Stigler and McDougle 2008). The ► atypical antipsychotics are emerging as first-line agents for this purpose. Other classes of drugs that have been studied include typical ► antipsychotics, ► anticonvulsants, and ► mood stabilizers.

Early studies found haloperidol effective for treating maladaptive symptoms in children with ASDs (Stigler and McDougle 2008). However, significant side effects were noted with this drug, including dystonic reactions and dyskinesias (especially on withdrawal of the drug). Due to its side effect profile, haloperidol is normally limited to treatment-refractory patients.

The atypical antipsychotics have replaced the typical antipsychotics as the first-line treatment for irritability in ASDs due to their decreased propensity for dyskinesias and extrapyramidal symptoms (EPS) (Stigler and McDougle 2008). ► Clozapine, ► risperidone, ► olanzapine, ► quetiapine, ► ziprasidone, and ► aripiprazole all have published reports of their use in the ASDs.

There are only three published reports of clozapine in the ASD population describing a total of five patients (Stigler and McDougle 2008). All showed significant improvement with clozapine. The paucity of reports is likely due to clozapine's potential to cause agranulocytosis, its ability to lower the seizure threshold, and the need for weekly to biweekly venipuncture.

Risperidone is a well-studied drug for the treatment of irritability in ASDs (Stigler and McDougle 2008). Multiple case series, open-label trials and double-blind placebo-controlled studies have found risperidone to be effective for treating irritability in individuals with ASDs. Due in part to the results of two RCTs demonstrating the efficacy and tolerability of risperidone for the treatment of irritability in children and adolescents with autism aged 5–16 years, it was approved by the US Food and Drug Administration (FDA).

Olanzapine has been studied in several open-label trials and one small placebo-controlled trial (Stigler and McDougle 2008). It has been shown to be effective for irritability and behavioral symptoms of autism. Side effects noted in the studies included increased appetite and often significant weight gain.

Four open-label reports of quetiapine have been published involving the treatment of ASDs (Stigler and McDougle 2008). The results have been mixed. Side effects reported included increased appetite, weight gain, sedation, agitation, aggression, and sialorrhea.

Two different open-label trials with ziprasidone reported it to be effective in treating irritability and aggression in individuals with ASDs (Stigler and McDougle 2008). Side effects included transient sedation, a clinically insignificant increase in the QTc interval and dystonic reactions. There is an FDA warning regarding the use of ziprasidone in relation to its potential to increase the cardiac QTc interval. It should not be given without consultation with a cardiologist to individuals with a known cardiac history, a long QT syndrome or in those taking other medications that can prolong the QTc interval.

Two open-label studies and one retrospective chart review found aripiprazole to be effective for treating irritability in individuals with ASDs (Stigler and McDougle 2008). Adverse events included transient sedation and weight gain (greater in individuals less than 12 years of age).

Mood stabilizers and anticonvulsants have also been used to treat irritability in ASDs (Stigler and McDougle 2008). Reports have been published for the use of ► lithium, divalproex sodium, ► lamotrigine, ► topiramate, and levetiracetam. However, RCTs supporting the use of mood stabilizers and anticonvulsants for the treatment of irritability in ASDs have not been published. The current literature suggests that atypical antipsychotics are more effective for the treatment of this symptom domain in

ASDs than mood stabilizers or anticonvulsants. Only one report has appeared demonstrating the effective use of lithium in one individual with autism that had significant irritability.

One open-label and one double-blind, placebo-controlled study have been published with divalproex sodium (Stigler and McDougle 2008). The open-label study determined divalproex to be effective. However, the double-blind, placebo-controlled trial found no significant difference between the two groups in irritability after 8 weeks. Adverse events included sedation, weight gain, behavioral activation, hair loss, elevated liver enzymes, increased appetite, skin rash, and hyperammonemia.

A double-blind, placebo-controlled study of lamotrigine did not find a significant difference between drug and placebo on several standardized outcome measures (Stigler and McDougle 2008).

One published report on the use of topiramate in five youths with autism and treatment-refractory severe behavioral problems found most children able to tolerate the drug but did not show notable improvement (Stigler and McDougle 2008).

One double-blind, placebo-controlled study of levetiracetam has been performed in 20 children and adolescents with autism to assess its efficacy in treating aggression and affective instability (Stigler and McDougle 2008). No difference was found between the drug and placebo groups. Adverse events included agitation and aggression.

One fundamental core deficit in ASDs is social impairment that is severe and persistent (McDougle et al. 2006). Social impairment can be seen through deficits in nonverbal behavior, for example, eye contact, facial expression, and body gestures. These children often fail to develop age appropriate relationships. They also may not seek to share achievements or enjoyment with others. Initially, preliminary reports of fenfluramine and naltrexone to treat social impairment were encouraging. However, subsequent placebo-controlled studies of these drugs failed to show any difference between groups for this core symptom deficit.

There has been consideration that ▶ glutamate may have a role in the pathophysiology and treatment of autism (McDougle et al. 2006). Thus, several drugs that affect the glutamate system have been studied for treating the social impairment seen in ASDs.

Two case reports described an improvement in autistic patients' social impairment after being prescribed lamotrigine, an anticonvulsant that slows glutamate release (McDougle et al. 2006). However, a double-blind, placebo-controlled study of lamotrigine in 28 children with autism failed to show a difference between drug and placebo.

▶ Amantadine, an antagonist at the *N*-methyl-D-asparate (▶ NMDA) subtype of glutamate receptor, has also been studied in autism (McDougle et al. 2006). An initial open-label study showed improvement in half the children given the drug. However, a double-blind, placebo-controlled trial failed to show a difference based on a parent rating scale. A clinician rating scale showed significant improvement in hyperactivity and inappropriate speech.

D-cycloserine is an antibiotic used to treat tuberculosis (McDougle et al. 2006). It is a ▶ partial agonist at the NMDA receptor. A small pilot study showed a statistically significant improvement on the Aberrant Behavior Checklist (ABC) Social Withdrawal subscale. Adverse events included transient motor tics and increased echolalia.

Research in the pharmacotherapy of ASDs will continue to pursue treatment for the core and associated symptoms related to this condition. Many individuals with ASDs have interfering symptoms in multiple domains. Thus, coactive pharmacological treatment strategies, involving concomitant treatment with more than one drug at a time, will be a future area of research (Stigler et al. 2008).

Mental Retardation

In the past, there was a belief that individuals with MR could not have co-occurring mental illness. It is now widely accepted that these patients develop such comorbidity at a higher rate than the normal population. Most studies estimate the prevalence of mental illness in the MR population at between 30 and 70% (Szymanski and King 1999). Approximately 20–45% of individuals with MR are prescribed psychotropic medications (Deb et al. 2007). All DSM-IV-TR diagnostic categories are potentially represented in these patients. However, the evaluation and diagnostic determination can be difficult due to inherent limitations, including communication deficits, physical limitations (Szymanski and King 1999), and lack of collateral information regarding the patient and their environment (Madrid et al. 2000). Additionally, due to a lack of capacity to give informed consent, there are relatively few RCTs in individuals with MR (Deb et al. 2007). This leads clinicians to base treatment decisions on a few well-designed investigations or to use studies in individuals without MR to guide treatment (Madrid et al. 2000).

Common reasons for pharmacologic referrals of patients with MR include SIB, aggressive behavior, impulsiveness, and hyperactivity. These symptoms are nonspecific and can be the result of anything from a medical illness to a mood, anxiety, psychotic or impulse control disorder. The context surrounding the onset of symptoms,

associated symptoms, and environmental changes can all be clues to the diagnosis. If there are associated sleep and appetite changes, a mood disorder may be considered. If the symptoms occur only in certain environments, then a psychotic or mood disorder is less likely. If the symptoms are of sudden onset, a medical illness may be contributing to the presentation (Madrid et al. 2000).

The MR population is two times more likely to suffer from a medical disorder than other mental health populations. One study showed 75% of the referrals for psychiatric assessment had undertreated or undiagnosed medical illnesses. In addition, psychiatric symptoms can be caused by several medical illnesses (Szymanski and King 1999). Thus, it is always important to consider a medical illness as a cause of psychiatric symptoms in the differential diagnosis of individuals with MR.

Screening assessments can be used to identify individuals with MR who need psychiatric referral. Some of these instruments can also be used for determining and evaluating symptoms over the course of treatment. The more commonly used scales in the MR population include the Reiss Screen for Maladaptive Behavior, the Reiss Scales, the Psychopathology Inventory for Mentally Retarded Adults (PIMRA), the ABC, and the Diagnostic Assessment for Dual Diagnosis (Madrid et al. 2000; Szymanski and King 1999).

Anxiety disorders can be difficult to diagnosis in MR individuals because of the necessity of subjective complaints. However, by observing patients, symptoms such as avoidance, autonomic arousal, psychomotor agitation, or irritability can help to clarify the diagnosis (Madrid et al. 2000). Specifically, posttraumatic stress disorder should be considered in the differential diagnosis. Individuals with MR are an inherently vulnerable population; they have difficulty reporting events and often want to please their caretaker (Szymanski and King 1999).

Psychotic disorders should be considered in individuals with MR that present with observable hallucinations such as yelling or hitting at empty space, catatonic posturing that appears psychotic in nature, negative symptoms or grossly disorganized behavior. Imaginary friends should not be confused with psychosis (Madrid et al. 2000; Szymanski and King 1999).

Mood disorders are common in individuals with MR. They can be diagnosed when there is a significant change in the baseline affective state. Observations of change in sleep, activity level, and appetite can be obtained from caretakers to help to confirm the diagnosis. Mood disorders can also present atypically in this population. Sometimes aggressive behavior can be a symptom of depression. This is sometimes termed "► behavioral equivalent" in the literature. A recent change in the environment, death of a family member, rejection, or abuse can also cause depression in the MR population (Hurley 2006; Madrid et al. 2000; Stigler et al. 2005).

► Disorders of impulse control may be considered one of the most common justifiable indications for psychotropic use in the MR community. The three most common behaviors include SIB, stereotyped behavior (stereotypical and repetitive behavior), and aggressive behaviors (Szymanski and King 1999). Studies indicate that 14–30% of the MR population receiving psychotropics are prescribed them for these types of behavior problems (Deb et al. 2007).

Pharmacotherapy in the MR population should only be a part of the overall treatment plan. The lowest possible dose of drug that is effective for the patient should be used and should not adversely affect the individual's ability to function. Drug treatment should follow the adage "start low, go slow." Certain drugs are more likely to cause side effects in MR individuals. Some of these patients seem to be more sensitive to the disinhibiting effects of ► benzodiazepines. There has been some evidence to suggest that the combination of stereotypy (stereotypical and repetitive behavior) and SIB may be a significant risk factor for benzodiazepine-induced disinhibition. There is also the potential for benzodiazepines to cause hyperactivity, SIB, or withdrawal-induced manic symptoms in the MR population. Individuals with compromised central nervous system function may be more sensitive to drugs with anticholinergic side effects, as well (Madrid et al. 2000; Szymanski and King 1999).

Antipsychotics are often used in the MR population to target aggressive or stereotyped behavior (stereotypical or repetitive behavior) and SIB, but can also be given for psychotic symptoms. Careful attention to side effects of these drugs should be paid. Patients with MR are more susceptible to tardive dyskinesia, withdrawal irritability, and EPS than other mental health populations. This is one of the reasons for the increasing trend of using atypical antipsychotics over typical antipsychotics (Madrid et al. 2000; Szymanski and King 1999). The RCTs that do exist have demonstrated the efficacy of risperidone for aggressive behavior in individuals with MR. However, most studies found side effects of weight gain and somnolence. To date, studies have not systematically reviewed adverse metabolic issues arising from risperidone. Evidence for the use of the other atypical antipsychotics in the adult MR population is mostly based on case studies. Short follow-up periods were used in these trials, making it difficult to know if the drugs would provide sustained

behavioral effects. In addition, several studies used the antipsychotics as add-on therapy (Deb et al. 2007).

► Antidepressants are used to treat depressive symptoms in individuals with MR as in the general population (Madrid et al. 2000; Stigler et al. 2005). ► Selective serotonin reuptake inhibitors (SSRIs) are frequently the first-line pharmacotherapy for individuals with MR due to their tendency to cause fewer side effects. Tricyclics are not used as often due to their side-effect profile of potentially lowering the seizure threshold, cardiac arrhythmias, and cognitive dulling. However, to date, there have been no published RCTs of antidepressants supporting their use for the treatment of depression in patients with MR (Stigler et al. 2005). One retrospective chart review of treatment with an SSRI or clomipramine for aggression, SIB, destructive/disruptive behavior, and depression/dysphoria showed a significant decline in these symptoms. This study gives support to "behavioral equivalents" being used as signs/symptoms of depression in the MR population (Hurley 2006). Other open-label studies of SSRIs have been conducted for behavioral problems in MR individuals with mixed results. Due to these findings, it is difficult to come to a clear conclusion regarding the use of antidepressants for treating behavioral problems in individuals with MR. The noted favorable outcomes were mostly for SIB and perseverative/compulsive behaviors. In addition, many of the studies used antidepressants as an add-on drug to an existing psychotropic regimen (Madrid et al. 2000; Stigler et al. 2005).

Mood stabilizers and anticonvulsants are often used to treat cyclical mood disorders in the general population. To date, there have been no published RCTs for the treatment of comorbid bipolar disorder in patients with MR (Stigler et al. 2005). Based on open-label reports, first-line options for this purpose in patients with MR include ► carbamazepine and ► valproic acid. Although lithium may be effective, it can cause a magnified cognitive dulling in this population that would make it a less attractive choice. Individuals with MR may also be more likely to develop lithium toxicity due to a change in their fluid intake (Szymanski and King 1999). Some studies have been performed regarding the use of mood stabilizers and anticonvulsants for the management of behavior problems in the MR population. The conclusion from three trials of lithium indicated an improvement in behavioral problems in a large portion of the individuals studied. Lithium toxicity was mostly absent in these studies. Two studies with valproate add-on therapy indicated improvement in SIB and aggression. One retrospective study with topiramate as an add-on therapy also indicated improvement in SIB and aggression. One double-blind, controlled, crossover study with carbamazepine indicated no difference between drug and placebo in decreasing overactivity. Although most of these studies indicate improvement in behavioral problems with these medications, methodological problems compromised many of them (Deb et al. 2007). Side effects that may be more common with carbamazepine in the MR population compared with the general population include the elevation of carbamazepine–epoxide levels during polypharmacy (resulting in seizure exacerbation), hyponatremia, hypovitaminosis D, folic acid and riboflavin deficiency, and irritability. Side effects of concern for valproate include pancreatitis, hepatotoxicity, and myelodysplasia (Szymanski and King 1999).

Even though between 20 and 45% of people with MR are receiving psychotropic drugs, there are very few published RCTs to guide practitioners. Much more research is needed to determine the efficacy and tolerability of psychotropics in individuals with MR for treating the majority of comorbid DSM-IV-TR diagnoses that commonly co-occur with the core intellectual disability.

Balanced Placebo Design

Definition
The balanced placebo design is an experimental method created to simultaneously evaluate expectancy and drug effects. The type of drug (active drug versus placebo) and the instructions (receive active drug versus receive placebo) are used to create four distinct conditions. These conditions are (1) receive active drug and told that they receive active drug, (2) receive active drug and told that they receive placebo, (3) receive placebo and told that they receive active drug, and (4) receive placebo and told that they receive placebo. Condition (1) provides information about combined drug and expectancy effects, whereas condition (4) should result in no effect. Conditions (2) and (3) provide differential information about the strength of placebo and pharmacological effects. In condition (2), expectancies are not activated because the individuals are told that they are receiving a placebo; thus, pure pharmacological effects can be studied. In condition (3), individuals' expectancies are activated but no drug is given, allowing for the isolation of the effects of expectancies.

Barbital

Synonyms
Barbitone

Definition
Barbital was the first barbiturate to be developed and is considered a prototype. It is a sedative and hypnotic and was used as a sleeping aid and anxiolytic, although now largely replaced by nonbarbiturate agents. Due to its slow onset of action, fatal overdosing is a risk. Prolonged usage of barbital, like other barbiturates, results in tolerance, abuse, dependence, and withdrawal.

Definition

Barbiturates have been used in addiction medicine for stabilizing inpatients during alcohol detoxification, in psychiatry for long-sleep therapy, phobia desensitization, and as purported "truth serum" in narcoanalysis of patients with stupor, mutism, dissociative fugue, or suspected conversion and malingering. Rapid-acting intravenous barbiturates are used in anesthesizing of patients undergoing electroconvulsive therapy or acute Caesarian section. Intravenous barbiturates are also used for execution by lethal injection, and oral solutions for physician-assisted suicide and euthanasia by consent. Barbiturate tablets and elixirs are still available as sedatives and hypnotics in general medicine. The long-acting phenobarbital is effective in seizure disorders, and barbiturates are used in treatment-resistant status epilepticus and neonatal seizures. Barbiturates are used as an intravenous or intracarotid diagnostic presurgical aid in intractable epilepsy to localize an epileptic focus. In traumatic brain injury, barbiturates have been used to reduce intracranial pressure, cerebral edema, blood perfusion, and metabolism. They have been used in essential tremor, acute migraine, and tension headache. In veterinary medicine, barbiturates are used to tranquilize animals and for euthanasia.

Barbiturates are contraindicated in intermittent porphyria. Their use in outpatients has been more or less eliminated due to the narrow margin of safety, and risk of suicide in overdose.

Barbiturates are by international convention controlled substances to be prescribed, yet are available over the Internet for nonmedical purposes, such as to potentiate the effects of opioids and alcohol, and to alleviate withdrawal from CNS stimulants.

Pharmacological Properties

Pharmacodynamics

Uric acid, discovered in 1776 by Scheele, is the basis for the 2,500 barbiturates synthesized over the years with antimicrobial, antitumor, spasmolytic, anticonvulsant, hypnotic–sedative, anti-inflammatory, analgesic, diuretic, or herbicidal properties. Those with past or current clinical applications are displayed in Table 1.

The parent compound barbital, first synthesized in 1882 and distinguished by an alkyl group on the fifth carbon (CH_3CH_2), was the first barbituric acid recommended for clinical use in 1903 based on its hypnosedative effects. Substitution of sulfur for the oxygen at the second carbon produced thiobarbiturates (thiopental, thioamylal, methohexital) that are highly lipid-soluble with a rapid onset of action and metabolic degradation.

The mechanism of action of pentobarbital has been elucidated. At lower doses, it modulates the GABA-mediated chloride conductance into the neuron, thus inhibiting neuronal activity in the CNS and spinal cord (Mercado and Czajkowski 2008). At intermediate doses, this does not require the presence of ► GABA, and at high doses the chloride channel activity is blocked. ► Pentobarbital binds to the GABA receptor below the binding site of GABA. Furthermore, barbiturates decrease excitatory amino acid release and postsynaptic response, primarily blocking excitatory ► glutamate response. The effect of barbiturates on calcium conductance probably accounts for their anticonvulsant action.

Furthermore, there is a barbiturate binding site on the nicotinic receptor, with specific structural requirements (Nordberg and Wahlström 1992). There are also interactions with cholinergic agonists and antagonists. Cholinergic systems are involved in the barbiturate withdrawal syndrome, and muscarinic receptors in withdrawal convulsions, indicative of a hypersensitivity to acetylcholine that can be prevented by administering atropine. Long-term barbital treatment induces long-term presynaptic cholinergic deficiencies conducive to cognitive decline in experimental animals, and accompanied by a reduction in brain weight. Such effects on cholinergic

neurotransmission have not been noted with ethanol or the ► benzodiazepines. Barbiturates cause a widespread increase in fast activity (20–30 Hz) in the EEG beginning in frontal areas.

Clinically, the effects of barbiturates on neurotransmission translate into raising the threshold for seizures, lessening anxiety, inducing sedation, sleep, coma, and subsequently death. At toxic doses, respiration is inhibited, requiring assisted ventilation in management of overdose.

The ► abuse liability of barbiturates has been studied experimentally by assessing their reinforcing properties and "liking" (Griffiths and Johnson 2005). Notably, reinforcement can be augmented by the subject's perceived risk (nocebo) of precipitating withdrawal symptoms when

the drug is discontinued. In a comparison of 19 hypnotics, pentobarbital ranked highest both with regard to abuse liability and toxicity (idem). In contrast to heroin, ► cocaine, cannabis, and ► alcohol, which cause positive rewarding effects by increasing dopamine release, barbiturates do not release extracellular ► dopamine in the nucleus accumbens. In baboon and rhesus monkey experiments, the reinforcing properties of ► secobarbital were similar to those of cocaine, while the benzodiazepines were frequently indistinguishable from placebo. Secobarbital and pentobarbital caused more subjective "liking" in humans while phenobarbital had a considerably lower liking potential. In experiments with male sedative abusers, subjects consistently preferred pentobarbital over the benzodiazepine ► diazepam.

All hypnotics with abuse liability work on the GABA receptor site. Since hypnotics are widely used, particularly in the elderly, the clinical risk/benefit ratio for barbiturates in outpatient use is unacceptable in comparison with the benzodiazepines.

► Pharmacokinetics

Phenobarbital, a long-acting barbiturate with selective anticonvulsant activity, is absorbed with peak plasma levels after 6–18 h and is clinically active for 24 h. The $t_{½}$ is 86 h in adults and 50 h in children. The short-acting pentobarbital and secobarbital are more lipid-soluble and thus enter the CNS rapidly with effects after 30 min. Anesthetic barbiturates (thiopental and methohexital) administered intravenously cause sleep within 1 min, but only transitorily due to the rapid redistribution.

Barbiturates are mostly metabolized by the liver and excreted in the urine. Elderly patients and those with hepatic disease have a reduced metabolic capacity. Hepatic enzyme induction is a phenomenon occurring with long-term administration. The activity of bilirubin glucuronyl transferase can be enhanced by barbiturate enzyme induction, which is of potential therapeutic use in Gilbert's Syndrome to reduce plasma bilirubin levels. Secobarbital is highly protein-bound and overdoses are thus difficult to treat by dialysis.

Safety

Prolonged administration of barbiturates narrows the safety margin by inducing both pharmacodynamic and pharmacokinetic ► tolerance. As with rapidly acting benzodiazepine hypnotics (► zaleplon, ► zolpidem, and ► zopiclone), lipid-soluble barbiturates can cause a paradoxical excitation or "high" rather than sedation and sleep if the subject is determined to remain awake, or is kept awake by others.

Concurrent use of alcohol aggravates CNS toxicity, sometimes resulting in death due to respiratory depression in intentional or unintentional overdoses. The barbiturates interact not only with alcohol but with commonly used medications such as antihistamines, warfarin, digitoxin, and anticancer chemotherapeutics. Phenobarbital was the first drug shown to induce drug/steroid metabolism by activating the transcription of genes encoding various metabolizing enzymes (Kakizaki et al. 2003).

The ► withdrawal syndrome following long-term barbiturate use was first described in 1914 by von Muralt, and in 1934 by Pohlisch and Panse. Sands at the Psychopathic Service of Bellevue Hospital described the clinical signs of acute and chronic intoxication in detail, stating that "the largest number of chronic barbital patients belong to the emotionally unstable type of constitutional psychopathic inferiority group. . .in his inability to face reality because of the painful effect it might entail". Harry Isbell in 1949 administered barbiturates (secobarbital, pentobarbital, or ► amobarbital) experimentally to five male substance abusers for 100 days and then withdrew the drugs abruptly. A withdrawal syndrome was precipitated that included anxiety, muscle twitching, intention tremor, weakness, hypotension, nausea, and perceptual distortions. It was followed in four subjects by tonic-clonic convulsions and by a delirium that lasted for up to 15 days. This syndrome appeared more severe than morphine withdrawal.

Clinical Uses

The efficacy of using barbiturates for treating *any* psychiatric condition is not evaluable by modern criteria of evidence-based medicine. ► Randomized controlled trials versus placebo or active comparators in anxiety or sleep disorders are generally lacking. In a few comparative studies, the benzodiazepines consistently showed a more favorable risk-to-benefit ratio. Yet, regulatory bodies keep barbiturates on the pharmacopeia, e.g., in the USA. Among 13 hypnotics on the US market in 2008, three were barbiturates: Butisol Sodium^{R} (butabarbital), Carbrital^{R} (carbromal+pentobarbital combination), and Seconal^{R} (secobarbital). There are also fixed combinations of barbiturates with nitroglycerin, ► caffeine, ► amphetamine, theophylline, and various gastrointestinal drugs.

How did the barbiturates become the major drugs in sedating patients in mental asylums and in general medicine? This is only partly elucidated, but the path must have been very different from today's highly regulated process of phase I to phase III studies based on regulatory and industrial conventions such as Good Clinical Practice. The original publication in 1864 of Adolf Baeyer (1835–1917; Nobel Prize in chemistry 1905) described in detail the chemical

synthesis of different malonylureas, one of which was also given the name *Barbitursäure*. In 1903, 49 years later, the chemist Emil Fischer (1852–1919; Nobel Prize in chemistry 1902) and the pharmacologist Josef von Mering (1849–1908) reported studies of 16 dogs that were given two different malonylureas, one of which they recommended as a hypnotic. The body weights and the behaviors of the dogs were observed during 1-day periods. At least two dogs died, and some fell asleep. The authors then moved on to recommendations for clinical doses, stating the hypnotic power of diethyl barbituric acid as four times that of the contemporary sulfonal, and that it was easily synthesized. They proposed the trade name Veronal, supplied by E. Merck in Darmstadt, and recommended a 0.5 g initial dose (in "weaker" persons such as women 0.3 g) and that 1.0 g needed rarely be exceeded. The effect appeared after 30 min, and the drug could be given in a cup of warm tea. Unwanted adverse effects had not been noted according to this seminal paper, but further study of long-term adverse effects should come with continued therapeutic research. The paper does not refer to or include any experiments on humans. Barbital became the name in the USA, and barbitone in the UK as a result of World War I trade negotiations.

► Barbital (Veronal) was subsequently applied to calm manic patients and to promote sleep in melancholic patients, thereby substituting bromide and opium as the drugs of choice. Phenobarbital (Luminal) was introduced in 1912, and was used for "sleep therapy" in psychosis by Giuseppe Epifanio in Turin in 1913, a substitute for "the Bromide Sleep" of 1897. The idea was modified on psychoanalytical grounds by Jakob Klaesi in Zurich in 1922 to facilitate reaching into unconscious material during psychotherapy of patients with ► schizophrenia with a combination drug called Somnifaine (López-Muñoz et al. 2005).

Sleep therapy was also tried in battle neurosis following the Dunkirk evacuation in World War II, in delirium tremens, autism, obsessive-compulsive disorder, and morphine withdrawal. The "Cloetta Mixture" with seven compounds including barbiturates was administered rectally to schizophrenic, manic, hysterical, or psychoneurotic patients to induce continuous sleep for 2–3 weeks under nurse supervision. The sleep therapies were phased out due to the mortality (5%), pulmonary embolism, bronchopneumonia, and other adverse effects, and when insulin shocks were introduced in 1935. Subsequently, chlorpromazine was launched in 1952, its trade name Hibernal stemming from "hibernation therapy." In the 1950s, the Central Intelligence Agency carried out trials to quicken the recovery of "brainwashed" repatriated soldiers in the Korean War with propaganda during barbiturate sleep.

The lethality of a barbiturate overdose was exploited for other means. Alfred Ploetz (1860–1940), father of racial hygiene, had argued in 1895 for an authorized board of physicians to kill children with congenital defects with morphine. When the National Socialist Party came to power in Germany in 1933, such boards were established, and 5,000 children with neuropsychiatric abnormalities were secretly killed by means of phenobarbital (Lauter and Meyer 1982).

Other clinical applications of barbiturates were essential tremor, tension headache, migraine, rheumatic pain, and intractable pain conditions. Barbiturates were added to fixed combination medications for bronchial asthma, hypertension, and functional gastrointestinal complaints. It has been estimated that 408 tons of barbiturates were manufactured in the USA at the peak of usage in 1947, sufficient to treat ten million patients for a year. Only in 1952 did the World Health Organization recommend that they should be prescribed by physicians only.

In the 1970s, there was a shift from barbiturate to benzodiazepine prescribing, partly influenced by campaigns to reduce barbiturate prescribing. Between 1959 and 1974, 27,000 deaths were caused by barbiturates in the UK, based on 225 million prescriptions that peaked in 1965. There were 134 barbiturate combinations on the market. In 1977, the UK Committee on Review of Medicines recommended restricting the use of barbiturates to patients with severe intractable insomnia, owing to the lack of proof of efficacy in any other psychiatric indication, and due to safety concerns. These concerns were primarily the risk of lethal overdoses, but also the risk of addiction, particularly of the fixed combinations of two barbiturates such as Tuinal, Diminal duplex, and Vesparax. Also noted was the risk of enzyme induction upsetting the metabolism of anticoagulants, steroids, phenytoin, and other psychoactive drugs. Studies of elderly people with hip fractures found that most had been prescribed barbiturate hypnotics, implying that they may have fallen due to drug-induced dizziness.

Clinical studies of patients detoxified from dependence and abuse of prescribed medications revealed that they had taken a range of different medications for pain, insomnia, and anxiety, including the barbiturates and their combinations (Allgulander 1986). The risk of suicide was particularly high among physicians, nurses, pharmacists, and their spouses admitted for inpatient detoxification from prescription drug abuse, as they had access to medications and knew how to administer them to die (Allgulander et al. 1987). It was a relief to the medical community when the benzodiazepines were introduced in the 1960s with a negligible risk of death in overdose.

Amobarbital (Pentymal) was used in the 1970s to treat alcohol-dependent patients during detoxification to prevent delirium tremens and seizures. Benzodiazepines (primarily diazepam) have since taken over.

The concept of *truth serum*, a drug to make people speak only the truth, arose in the 1920s, as a substitute for torture in war and religion (e.g., the Catholic Inquisition), mesmerism, and psychoanalysis. Paradoxically, ▶ scopolamine, which caused amnesia during labor, was proposed by a Texas rural obstetrician to extract the truth in criminal proceedings, an idea that was amplified by media at the time. Amytal was first tried in the 1930s to recover memories of sexual abuse, the idea stemming from the Freudian credo of the unconscious. A variant called *narcoanalysis* or Amytal interview (intravenous administration of amobarbital) was used to promote self-disclosure in patients with mutism, psychogenic amnesia, suspected conversion disorder, depression, and dementia. There is no evidence to support this procedure (Kavirajan 1999). In fact, false memories from childhood or adulthood can be implanted in hypnosis, in product marketing, and by a biased psychotherapist.

The *anticonvulsant* property of phenobarbital was discovered serendipitously in 1912 by Alfred Hauptmann in Munich, and it became the first effective medication for epilepsy. Its application was delayed until the 1930s when phenobarbital superseded potassium bromide as a drug of choice. Phenobarbital is effective in adults with partial, complex (motor and sensory) partial, and generalized tonic-clonic seizures, in treatment-resistant status epilepticus, for complex febrile and nonfebrile seizures in children, and for neonatal seizures. It is on the World Health Organization list of essential drugs, and is exempted from international conventions regulating controlled substances, as it is not of interest for nonmedical use.

Thiopental (Pentothal^{R}) became the drug of choice for intravenous *anesthesia* when introduced in 1935 by Ralph M Walters in Wisconsin. Other barbiturates had been used previously, but thiopental had superior pharmacodynamic and ▶ pharmacokinetic properties. Intravenous barbiturate anesthesia combined with muscle relaxant drugs came to be used for sleep induction in electroconvulsive therapy.

Barbiturates have been widely used in acute *traumatic brain injury* in the belief that such treatment can reduce intracranial pressure by suppressing metabolism. Six controlled trials were evaluated with Cochrane methodology. The author concluded that there was no evidence that barbiturates improved mortality or morbidity, and that the hypotensive reaction to barbiturates in one of four patients offset any benefit from reduced intracranial pressure.

A number of fixed combinations of barbiturates (mostly butalbital) and analgesics (acetylsalicylic acid, codeine) and caffeine were marketed to treat various *pain* disorders. A review of controlled studies concluded that there was no evidence that barbiturates enhance analgesic efficacy, and that the safety risks were substantial.

Lethal injections as a means of capital punishment were first applied in the USA in 1982. Most such protocols use a sequence of intravenous thiopental 3–5 g (increased if the subject is still conscious after 60 s), followed by pancuronium bromide 50 mg to prevent movements for the benefit of staff and witnesses, and potassium chloride 100–240 mEq to cause asystole, followed by saline flush. Death usually occurs in 7–10 min. There is controversy over the efficacy of these procedures, partly based on the biphasic pharmacokinetics of thiopental and with lower procedural standards than those developed for euthanasia in veterinary medicine. Between 1977 and 2005, there were 839 such deaths by injections among a total of 1,007 commuted death penalties in the USA.

Euthanasia by consent and *physician-assisted suicides* are illegal in most countries, yet legal in Oregon, Thailand, Canton Zurich, and in the Netherlands. A Dutch study found that over 40 different drugs had been used, most frequently a barbiturate or an ▶ opioid (Willems et al. 1999). Most patients (85%) died within an hour, and physicians were satisfied with the procedure in 90% of cases. However, delayed drug absorption, dehydration, and malnutrition may delay or upset the process. The Royal Dutch Pharmaceutical Association in its 1994 revised guideline recommend that patients are given an antiemetic (metoclopramide 20 mg every 8 h) 24 h before administering an oral 100 mL solution of 9 g of either pentobarbital or secobarbital. Death occurs usually within 1 h, but can take up to 24 h. For parenteral euthanasia by consent, 10 mL intravenous solution of thiopental 20 mg/kg is recommended, followed by pancuronium bromide 20 mg. There were 2,425 such physician-assisted deaths in the Netherlands in 2005, mostly in patients with cancer before the age of 80. Assisted suicides at Dignitas in Zurich by means of pentobarbital were performed in 876 persons from 26 countries in the first 10 years, 59% of whom were women.

Comment

The barbiturates played an important role as sedative–hypnotics for 100 years and were succeeded by the benzodiazepines in the 1960s. Their pharmacodynamic and

pharmacokinetic properties caused unacceptable risk/benefit ratios for use in outpatient care. Phenobarbital is still appreciated for controlling seizure disorders, and intravenous formulations are useful in rapidly inducing sleep prior to ► electroconvulsive therapy and brief surgical procedures. Pentobarbital and secobarbital are effective in euthanasia by consent and physician-assisted suicides in humans, and in mercy killing of animals.

Basal Forebrain Cholinergic Neurons

Definition

These are CNS neurons located in the fairly ventral (basal) and anterior (forebrain) regions of the CNS which display a cholinergic phenotype (i.e., generating and releasing the neurotransmitter ► acetylcholine (ACh)). Two main neuronal nuclei have shown marked dependency on NGF support: the medial septum and the nucleus basalis. The first provides the main cholinergic input to the hippocampal complex and the second to the cerebral cortex. These systems are thought to be very relevant for attention, memory, and learning mechanisms. These neurons are affected by the aging process and they are the earliest compromised and the most vulnerable to the Alzheimer's pathology. In the human species and primates, the nucleus basalis is also referred to as the nucleus magnocellularis of Meynert. This nomenclature does not apply to rodents, given fundamental differences in the nuclear organization.

Definition

Tests of behavioral despair are used to measure the effects of ► antidepressant drugs on the behavior of laboratory animals (typically rats or mice). Examples of these tests include the forced swimming test (a.k.a., the FST or Porsolt test) and the tail suspension test (TST).

When forced to swim in a restricted space without the possibility of escape, rats and mice will, after a period of vigorous behavior directed toward escape, adopt a characteristic immobile posture, where they remain passively floating in the water, making only those movements necessary to keep their heads above water. The immobility response is usually measured by the latency until development or the overall duration during the session. The immobility in the forced swim test is thought to indicate resignation to a state of despair, in which the rodent has learned that escape is impossible (Porsolt et al. 1977, 1978a). The immobility response is reduced by administration of antidepressant drugs and other treatments that are therapeutically effective in depression.

The tail suspension test was developed later as a second test for use with mice (Steru et al. 1985). Mice that are hung by their tail from a bar will, after some time spent trying to escape, adopt a characteristic immobile position. The test relies on the same behavioral principle as the forced swimming test, since mice are not able to escape from being attached to the bar. Administration of antidepressant drugs reduces the time spent immobile.

Principles and Role in Psychopharmacology

Procedures

Rats and mice are used most often in tests of behavioral despair, although gerbils and guinea pigs have also been tested. Different procedures are commonly used for rats and mice. It must be emphasized, however, that procedural modifications for particular experimental purposes, e.g., to measure effects following chronic treatment or in genetically modified rodents, are common.

Rats are usually given two trials separated by 24 h. The first trial lasts 15 min and is usually referred to as a pretest. Antidepressant or test drugs are given to rats 2 or 3 times between the trials, as a loading protocol. The second trial lasts only 5 min, because the onset of the immobility is sensitized by the pretest. Antidepressant drug effects are evident in a reduction of duration of immobility during the second test (Porsolt et al. 1977).

Important procedural changes were introduced to the rat forced swimming test because the effects of selective serotonin reuptake inhibitors (► SSRIs) could not be measured using the original testing method (Cryan et al. 2005b; Detke et al. 1995). The modified rat FST measures the frequency of two active behaviors, swimming and climbing, in addition to passive immobility during the second trial. A larger cylinder (at least 20 cm diameter) and higher water level (30 cm depth) was recommended, to keep rodents from positioning themselves to thwart the stressful aspects of the test by using the bottom or sides for support. The new conditions also improved the measurement of swimming behavior produced by the SSRIs. Antidepressant drugs produce different effects on the active behaviors in the modified rat FST. The SSRIs (e.g., ► fluoxetine, ► paroxetine, ► citalopram) reduce immobility and increase swimming behavior, ► tricyclic antidepressants and selective ► NARI antidepressants (e.g., desipramine, maprotiline, reboxetine) reduce immobility and increase climbing behavior, and ► SNRI antidepressants with effects on both, serotonin and catecholamines or ► monoamine oxidase inhibitors reduce immobility and increase both swimming and climbing behavior (Cryan et al. 2005b; Lucki 1997).

Mice are tested in the forced swimming test or the tail suspension test with just a single trial, lasting usually for 6 min. In the forced swimming test, only the last 4 min may be scored. Cylinders of varying sizes have been used, although larger cylinders (>20 cm) may avoid detecting ► false positives and ► false negatives (SSRIs) in the test. Antidepressant drugs usually have to be given only once to produce a behavioral effect. The total duration of immobility, and the duration until an initial bout of immobility, are usually scored. Some studies have measured immobility, swimming, and climbing behaviors in the mouse FST.

Predictive Validity for Antidepressant Treatments

The FST and TST demonstrate good ► predictive validity for measuring the effects in animals of drugs that are used clinically to treat depression. Antidepressant drugs

produce various pharmacological effects on diverse neurotransmitters and have been divided into different structural classes. All clinically effective antidepressant treatments produce reductions of immobility, including tricyclics, monoamine oxidase inhibitors, SSRIs, and atypical ▶ antidepressants. In addition, somatic treatments for depression, such as ▶ electroconvulsive shock, sleep deprivation, chronic exercise, and ▶ transcranial magnetic stimulation, also produce reductions of immobility. Reviews of drugs that have been successfully tested, have appeared for the traditional FST (Borsini and Meli 1988), the modified rat FST (Cryan et al. 2005b) and the mouse TST (Cryan et al. 2005a).

The FST also distinguishes many drugs that are not antidepressants. For example, ▶ anxiolytic drugs with anti-anxiety effects, such as ▶ benzodiazepines, are not active in the FST, with the exception of ▶ alprazolam, the lone benzodiazepine with antidepressant effects. The chief consistent false positives in the FST and the TST are psychomotor stimulants such as ▶ amphetamine, which reduce immobility because of general motor stimulation but are probably ineffective clinically as antidepressants. Most studies of established or novel antidepressants employ secondary tests of locomotor activity to distinguish treatments that produce unambiguous indications of antidepressant activity from those that may be caused by increased motor stimulation. Nearly, all clinically established reference antidepressants produce no effect, or decrease locomotor activity at the same doses that are active in antidepressant tests. Although drugs that decrease immobility in the FST and increase locomotor activity may still be antidepressants, their antidepressant activity would be characterized as ambiguous unless demonstrated to be unaccompanied by motor activating effects. Activity in the FST by anticholinergic or antihistamine drugs, effects that may simulate side effects of tricyclic antidepressants, have been both detected and rejected by different laboratories and may depend on test conditions.

Common Uses of the FST and TST

Antidepressant discovery research. The FST and TST are used primarily as behavioral screens for antidepressant discovery research in the pharmaceutical industry, because the tests are relatively easy to administer and demonstrate good predictive validity for measuring clinically effective drugs. Hundreds of compounds with differing pharmacological mechanisms of action have been tested for potential antidepressant activity, using these behavioral screens. A frequent issue in antidepressant discovery research is whether the tests of behavioral despair that are tuned to measure the effects of the traditional drugs used for treating depression, are able to measure the effects of novel classes. The answer is unknowable until a novel class of antidepressants is discovered. However, a second issue, somewhat incompatible with the first, is that a large number of drugs demonstrate effects in the FST and TST, and it is difficult to know which of these compounds could eventually be developed into effective antidepressants in humans.

Validation of pharmacological effects. The antidepressant response in behavioral despair tests has been used to test a functional role for particular neurotransmitters. For example, brain lesions, receptor antagonists, or inhibitors of neurotransmitter synthesis can produce changes in performance in the FST and TST. Studies have shown that SSRIs are not behaviorally active if synthesis of the neurotransmitter serotonin (see ▶ Indoleamines) is prevented. Tricyclic antidepressants are not behaviorally active if synthesis of the neurotransmitter ▶ norepinephrine is prevented or noradrenergic pathways have been destroyed. However, it is not known whether facilitating monoamine transmission or stimulating monoamine receptor mechanisms is an essential property for all drugs to produce antidepressant-like effects in the FST and TST.

Neural circuitry. The FST has been used in combination with site-specific injections to identify circuits with potential for mediating the effects of antidepressant drugs. Specific injection into brain regions, such as the frontal cortex, ▶ hippocampus, ▶ amygdala, and ▶ nucleus accumbens, have been shown to mediate reductions of immobility in the FST. Other studies have used the FST to measure changes in neurotransmitter release in discrete brain regions or activation of local circuits. However, thus far, the integrated circuitry that identifies the behavioral effects of antidepressant drugs has not been established.

Genetics. Until there is agreement on identified genetic causes of depression, it will not be possible to test rodents generated with a homologous genetic condition. However, a large variety of ▶ genetically modified mice have been examined using tests of behavioral despair to identify genes that produce either an antidepressant-like or a prodepressive effect (Cryan and Mombereau 2004). Genetically modified mice have also been used to identify the functional significance of cell signaling pathways such as CREB, or of ▶ neurotrophic factors such as ▶ BDNF, in the behavioral effects of established antidepressant drugs. Inbred strains of rats and mice demonstrate different baseline levels of response in the FST and TST. Breeding techniques, combined with modern maps of chromosomal structure, have been used to identify genes associated with behavioral despair. Another genetic technique allows for rodents with high or low levels of immobility on tests of behavioral despair to be bred over successive generations. These animals demonstrate rapid genetic separation

into separate populations, and show different responses to antidepressant treatments.

Different inbred rodent strains also vary in their behavioral response to specific types of antidepressant drugs (Porsolt et al. 1978b). Swiss mice and BALB/c mice appear to respond to the greatest variety of antidepressants in the FST, NMRI mice were commonly used in the TST, and Sprague–Dawley or Wistar are the most commonly used strains of rats. However, some rat strains considered as genetic models for depression (Flinders sensitive line (FSL) or Wistar-Kyoto (WKY)) demonstrate higher levels of immobility in the FST and selective responses to different types of antidepressant drugs. The correct detection of antidepressant activity may depend on the selection of the appropriate rodent strain for use.

Models of disease. Although tests of behavioral despair are ordinarily conducted in normal, or otherwise unstressed populations of rodents, this may not always be the case. Baseline performance in the tests is sensitive to changes by conditions or models of diseases that cause depression by showing changes in the opposite direction of antidepressant drugs. ► Chronic mild stress, or acute drug withdrawal, conditions that are highly correlated with depression, produce an increase in the duration of immobility. Depression is economically burdensome because the disease is frequently comorbid with other chronic medical diseases, such as cardiovascular disease, diabetes, and stroke. Models of diabetes, cardiovascular disease, stroke, and ischemia in rodents have been shown to produce increased immobility in the FST and TST, and performance using such tests with these models can be used to detect drug treatments that may be especially effective in treating depression under these conditions. Gonadectomy or models of postpartum depression in rodents also increase immobility in tests of behavioral despair and may be used to study endocrine and neural correlates of depression.

Validity of the FST

There has been debate about the validity of behavior despair tests as good models of depression. There is general agreement that the FST and TST measures the effects of most antidepressant treatments that are currently approved for clinical use (good predictive validity).

The original idea that immobility in the FST emerged from feelings of behavioral despair in the rodents caused many to consider the FST as a model of depression. However, because the FST is a short-term behavior test rather than a condition that attempts to recreate the symptoms of human depression in rodents, the FST lacks ► construct and ► face validity to model clinical depression. Logically, symptoms would be expected to persist for weeks in a valid model of depression, instead of just minutes in the FST. The most efficient use of the FST has been as an indicator test of stress-induced behavior, rather than as a condition that simulates depression as the term behavioral despair implies. FST performance can be interpreted in ways that are behaviorally descriptive, rather than referring to internal motivational factors such as behavioral despair, and still remain relevant to a behavioral state associated with depression. For example, one such scheme stresses the differential behavioral consequences of active (swimming and climbing) versus passive (immobility) coping behaviors in the ambiguous situation of the forced swimming test (Cryan et al. 2005b). Depressed patients are more sensitive to the display of passive behavior. Active and passive coping behaviors is a homologous distinction described for coping behaviors displayed by humans when they are stressed. The FST will also model depressive behavior more effectively if used in combination with genetic and environmental factors that contribute to the development of clinical depression (see above).

Definition

Behavioral economics is the study of drug consumption conceived as decision-making behavior under an economic framework. It is the combination of two separate disciplines: economics – the study of rational decision-making – and psychology – the study of human behavior. These two disciplines have been combined to examine actual decision-making behavior under an economic framework. This concatenation of paradigms has identified a number of relationships that have been found to influence the consumption of commodities. We will illustrate how behavioral economics, including the study of demand and temporal discounting, describes these interdependencies using examples from drug research.

The fundamental concept in behavioral economics is ▶ demand, the amount of a commodity consumed at a specific price (Pearce 1989). This relationship between price and consumption has a natural translation to behavioral psychology, where a commodity can be considered as a *reinforcer*, something that increases the likelihood of the response occurring again, and price, which can be considered the *response requirement* to obtain that reinforcer (Lea 1978). The relationship between price and consumption is expressed as a demand curve and typically follows a negative slope – as price increases consumption falls – and is referred to as the "law of demand."

Demand curves are categorized by ▶ elasticity – the degree to which a change in price changes the demand for a commodity. Demand is thought to be *unit-elastic* when increases in price results in proportional decreases in consumption, *elastic* when the change in price produces greater-than-proportional changes in consumption, and *inelastic* when a change in price causes smaller-than-proportional changes in consumption. Thus, the slope of the demand curve represents the elasticity of the price-consumption relationship.

Principles and Role in Psychopharmacology

Price Elasticity and Demand Curves of Goods

MacKillop and Murphy (2007) investigated the relationship between price and demand for ▶ alcohol in college drinkers. They asked subjects the number of drinks they would consume at different prices and found that increasing drink prices decreased the anticipated consumption of heavy drinking episodes for both men and women. Moreover, they found that heavy drinking episodes appeared to be inelastic at low prices and elastic at higher prices, indicating a mixed elasticity demand curve.

Changes in price can also affect the consumption of concurrently available commodities. For example, Nader and Woolverton (1991) trained rhesus monkeys to choose between food and intravenous injections of ▶ cocaine or procaine. When the amount of food available was increased for the same response requirement (i.e., the price of food was decreased) and the doses of both drugs were held constant (i.e., the price of drugs was unchanged), the frequency of drug consumption decreased suggesting positive ▶ cross-price elasticity – a decrease in price for one commodity resulted in the decreased consumption of the alternative.

These results illustrate another feature of behavioral economics, the characterization of the interaction between commodities of qualitatively different goods and services along one continuum. At one end of the continuum, ▶ substitutes exist where increases in the price of one good correlate with increases in the consumption of an alternative commodity. For example, when the increase in the price of cocaine/procaine results in a decrease in consumption of cocaine/procaine and an increase in the consumption of food, the goods, food and cocaine/procaine, are considered substitutes. At the other end of the continuum, ▶ complements exist where increases in the price of one good correlate with decreases in the demand for that good and the alternative good. In the middle of the continuum, where changes in the price of one commodity have no effect on the demand of the alternative, goods are considered ▶ independents. Thus, the price of alternatively available commodities, whether they are substitutes, complements or independents influences demand.

In addition to demand and price, *income*, or the total purchasing power or the overall rate of reinforcement, also influences consumption. This occurs to the degree to which normal and inferior goods can be bought. For example, an increase in income can lead to purchasing a more preferred good, such as smokers who buy a preferred brand of cigarette rather than the less valued alternative with the same nicotine level (DeGrandpre et al. 1993). These items would be *normal* goods and *inferior* goods, respectively. Income can also affect the elasticity of demand, where increases in income can lead to increased consumption of normal goods and decreased

consumption of inferior goods. Thus, the effects of price and income on demand interact, indicating a complex system of interdependencies between goods, prices, elasticities, and incomes.

Effect of Unit Price on Operant Behaviors

These interrelationships can be addressed using the concept of ▶ unit price, or cost per unit of a commodity. Unit price is often represented as the schedule requirement or response effort, divided by reinforcer magnitude (quantity of reward commodity) (Hursh et al. 1988). It is formally expressed as:

$$\text{Unit price} = \frac{\text{Response Requirement}}{\text{Reinforcer Magnitude}} \quad (1)$$

where either decreasing the magnitude of the reinforcer (commodity) or increasing the response requirement (cost) can increase the unit price of a commodity. This simple calculation predicts that when a commodity has the same response requirement and magnitude as another their unit prices will be equal. Thus, when represented in unit prices, commodities can be compared to each other despite different levels of magnitude and cost. Behavioral economic researchers have suggested that unit price may be the single construct that underpins both reinforcer-magnitude and schedule-of-reinforcement effects (DeGrandpre and Bickel 1996). For example, Bickel et al. (1991) assessed cigarette smoking under varying response requirements (fixed-ratio 200, 400, and 1,600 level pulls) and reinforcer magnitudes (1, 2, and 4 puffs per bout). For each subject, Bickel et al. found a positive relationship between unit price and responses per session, and a negative relationship between unit price and consumption of puffs. Moreover, the responses per session and the consumption of puffs were generally comparable among subjects at the same unit price; that is, an increase in response requirement is functionally equivalent to a decrease in the number of puffs. This positively decelerating demand curve appears to be a ubiquitous phenomenon: meta-analysis of smoking studies showed positively decelerating demand curves across all reported data sets (DeGrandpre and Bickel 1996).

The positively decelerating function has an implication when response rate rather than consumption is plotted as the dependent variable. During low prices consumption is typically inelastic, with smaller-than-proportional changes in response rate in relation to changes in price. However, as consumption increasingly decelerates with increases in price, the changes in response rate become elastic and response rate declines at a faster rate than the change in price. This causes the response rate to follow a bitonic function (exhibiting both inverse and direct relationships) where response rate increases at low prices and decreases at higher prices.

Unit price has also been applied in characterizing the interaction between commodities in pharmacology and drug consumption. For example, the effects of agonists and antagonists have been modeled using unit price; that is, unit price can describe the specific drug effects of ▶ methadone and ▶ naltrexone (DeGrandpre and Bickel 1996). DeGrandpre and Bickel reanalyzed the animal self-administration of opioid antagonists (▶ naltrexone) and agonists (▶ methadone) for heroin self-administration. They found, relative to saline, doses of antagonists increased the consumption of heroin at low unit prices, and decreased the consumption of heroin at high unit prices. Similar results have been found using ▶ morphine administration and cigarette smoking (ibid).

Interrelating Variables Predicting Drug Demand and Consumption

Other behavioral economic concepts also contribute to drug consumption. For example, Bickel et al. (1995) studied the effects of concurrently available alternatives to drug taking. They examined drug consumption using a fixed ratio (FR) response requirement when drug consumption was available and an alternative activity, employment (experiment 1), or another activity such as reading, playing games, etc. (experiment 2), was either available or unavailable. Fig. 1 illustrates these results.

Another variable that affects choice behavior is temporal duration. Elsmore et al. (1980) examined the effects on income when the inter-trial interval, the time between trials, changed. Elsmore et al. found that although there was the same number of choices for heroin and food at low inter-trial intervals, the consumption of heroin decreased to a greater extent than for the food alternative. Thus, temporal effects modify the subjective "value" of a commodity as indicated by choice responses. Similar temporal interactions are also important for another behavioral methodology describing decision-making – temporal discounting.

Discounting of Delayed Reward: Choice and Addiction

Research examining the effect of changing the temporal delay between choice and obtaining the reward has found that ascribed value changes, i.e., the subjective value is discounted. Specifically, the longer the delay that precedes the reward the less the reward is valued. This discounting

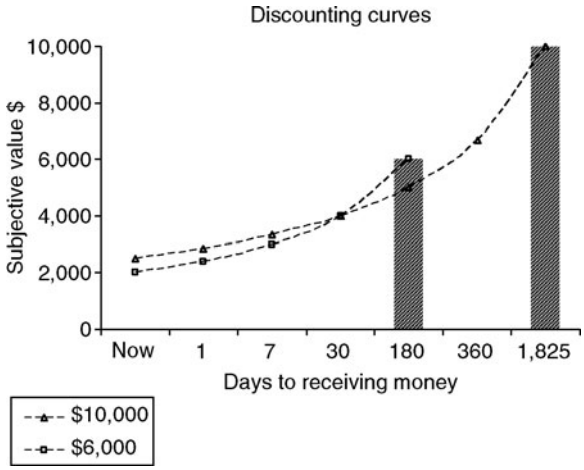
The top panel shows the effects of available and unavailable employment, and the bottom panel shows the effects of available and unavailable recreation for one participant (similar curves were obtained for the other participants in these experiments). Drug consumption decreased as a positively decelerating function of unit price in each experiment. Moreover, available alternative reinforcers led to greater decreases in consumption compared to unavailable reinforcers indicating both employment and activities were acting as substitutes to drug consumption.

process can be represented as a hyperbolic curve, most commonly represented by Mazur's (1987) hyperbolic function:

$$V = \frac{A}{1 + kD} \tag{2}$$

where V is value, A is the undiscounted reward value, D is delay, and k is a free parameter describing the ► temporal discounting rate. The hyperbolic discounting relation implies that value decreases based on the total delay rather than a constant decline as suggested by other interpretations.

The hyperbolic function of temporal discounting has been used to describe the behavioral phenomena of ► preference reversal, or "switching" between alternatives when the delay to the outcomes changes. For example, given a choice between $100 now and $50 now most people would choose the larger alternative. However, as delays to obtaining the larger alternative increase the subjective value of this alternative declines, and given a long enough delay to reinforcement, organisms will switch their preference from the larger delayed alternative to the smaller immediate alternative. The switching phenomenon is illustrated in Fig. 2.



Behavioral Economics. Fig. 2. Hypothetical discounting curves. Hypothetical discounting curves for $10,000 and $6,000 delayed 5 years and 6 months, respectively. The dotted lines represent the hyperbolic decay of the subjective value of receiving the money as the delay increases. Delay is represented on the *x*-axis and the two alternatives are represented as vertical bars. The changes in value are represented by the dotted lines for each alternative, and the point where switching occurs is predicted by their intersection.

The methodology of mathematically describing preference reversals requires applying an equation, such as equation 2, to the obtained data. This "fitting" process requires the free parameter in the model, *k*, to change in an attempt to minimize the difference between the prediction and the obtained data across different delays calculated by a computer algorithm, e.g., Microsoft Excel Solver©. The parameter iteration that has the most accurate prediction of the data – the free parameters that achieve the lowest variance from the obtained data – is roughly considered the best estimate of the theorized model to the data.

Advantages and Limitations of Behavioral Economics in Modeling Drug Addiction

Temporal discounting has been found to be an accurate framework for describing preference reversals. For example, Yoon et al. (2007) investigated whether sociodemographic characteristics or discounting of hypothetical money could predict smoking relapse for post partum women. They found that only discounting data predicted smoking status at 24 weeks post partum, and greater baseline discounting rates was also a significant predictor of relapse.

Delay discounting rates have been found to differentiate between nonaddicted and addicted people (see Bickel and Marsch 2001). Research has found that heterogeneous groups of drug addicts discount hypothetical money more steeply than controls, where higher discounting rates are taken for greater preference for more immediate alternatives, suggesting that addicts were more impulsive than controls in their discounting behavior. This preference for immediate alternatives suggests the addicted groups have a "myopic" temporal view when considering alternatives.

Recently, research has suggested that ► temporal myopia appears to extend both toward future outcomes and also to past outcomes. Bickel et al. (2008) examined temporal discounting by cigarette smokers and non smokers. They found relative symmetry between past and future discounting curves, including comparable hyperbolic functions, sign effects, and greater discounting for smokers than nonsmokers. This convergence across temporal epochs suggests similar discounting processes are involved for future and past discounting. Furthermore, as past gains have already happened, subjects receive no reinforcement value from past gains. Thus, the symmetry between past gains and future gains indicates subjects are valuing something other than biological salient cues. A possible explanation is that discounting reflects the width of their temporal window rather than their internal feelings of impulsivity (Bickel et al. 2008). This could explain why addicts have difficulty learning from previous behaviors, even though they recognize their earlier actions have long-term consequences (Franken et al. 2007).

One limitation of these economic models is although they are well suited to describe in parsimonious terms the current behavior of individuals suffering from addiction, they do not suggest the conditions or reasons why an individual becomes an addict or discounts the future. Perhaps, some answers will result from the study of the economics of addiction at the neuroscientific levels. The development and growth of the translational field of neuroeconomics may provide that promise.

Conclusion

In conclusion, behavioral economics, and in particular unit-price and temporal discounting, have been found to describe consumption across a range of commodities, including drugs of abuse. This approach suggests that commodities are valued in a dynamic relationship between the environment and the available reinforcers. Moreover, these relationships appear multifaceted – some commodities exhibit certain characteristics in certain situations and others in different situations. Furthermore, relational understandings appear to describe molecular understandings about drug pharmacology, such as whether a certain substance is acting as an assumed agonist, antagonist, or mixed agonist–antagonist. Thus, behavioral economic methods provide a quantification of demand that seems a broad and coherent description of drug consumption.

Behavioral Equivalents

Definition

Behavioral equivalents are maladaptive behaviors that can be seen in individuals with intellectual disability that have been historically substituted for standard diagnostic criteria when diagnosing mood disorders in this population. These maladaptive behaviors can include, but are not limited to, aggression, self-injury, and destruction.

Definition

Behavioral flexibility refers to the adaptive change in the behavior of an animal, in response to changes in the external or internal environment. Ongoing behavior (which might include inactivity) is stopped or modified and new behavior is initiated. Adaptive changes in behavior can vary by degree, ranging from changes that are little more than reflexes or tropic reactions (i.e., reflecting a change in environmental conditions but without the involvement of cognitive processes) to behavioral changes that are anticipatory of environmental changes. Unlike ► impulsivity, which is responding without inhibitory control and can be maladaptive (see ► impulse control disorders), behavioral flexibility reflects a change in cognitive state in response to the perceived environmental contingencies.

Given that there is a wide range of adaptive responses, it is important to be clear about terminology, particularly if the intention is to make comparisons between different species in order to draw inferences concerning neural mechanisms. The term behavioral flexibility is preferably used to refer only to behavior that reflects a cognitive change, thereby excluding reflexive behaviors. To illustrate this distinction, behavioral change in response to a drop in temperature includes shivering (reflexive), but this is contrasted to cognitive flexibility involved in choosing whether to put on a coat or light a fire (flexible). Cognitive changes might be in response to changes in the internal environment (such as planning how to find food in response to hunger) or changes in the external environment (such as planning a route of escape in response to a threatening stimulus).

Although it is helpful to regard behavioral flexibility and cognitive flexibility as synonymous – indeed the terms are often used interchangeably – it is important to remember the distinction between them. Cognitions are covert and cannot be directly observed, but they can be inferred by observing overt behavior. This means that while it is possible to conceive of cognitive flexibility in the absence of behavioral evidence, in general, whenever

one discusses evidence for cognitive flexibility, the evidence is of behavioral flexibility. On the other hand, the inverse is not necessarily the case: it is possible to observe behavior that appears to be flexible but does not reflect cognitive flexibility. For example, a learned response to alternate presses on two levers in an ► operant chamber may be considered as an example of behavioral flexibility, but, once learned, this behavior may not require cognitive flexibility.

Use in Psychopharmacology

In behavioral neuroscience and psychopharmacology, the most commonly used measures of behavioral flexibility are tests of attentional shifting, rule switching, and reversal learning. In all three cases – whether shifting, switching, or reversing – the key feature is that the behavior is adaptive. For this reason, it is clearly important to ask whether, and to what extent, the behavioral flexibility being measured is the same in each of these three cases and, thus, whether they reflect a common mechanism of cognitive flexibility.

Mental set is a concept that has been used by psychologists for many decades to refer to an acquired cognitive predisposition or bias that influences subsequent behavior (see Gibson 1941 for a useful review). Mental set is manifest in many domains, but of most relevance here are ► attentional set and ► learning set. Attentional set can be formed by prior experience of the relevance of one aspect or ► dimension of a multidimensional stimulus. Thus, repeatedly sorting or selecting stimuli according to their color, while ignoring their shape, is the basis of both the "► Wisconsin Card Sort Task" (WCST) (Berg 1948) and the "Intradimensional–Extradimensional" (ID/ED) task (Lawrence 1949). In both of these tasks, the subject learns which dimension of a stimulus is relevant by trial and error, getting positive feedback for responses that are made in accordance with the relevant dimension. The strength of the attentional set is indicated by the difficulty the subjects have in shifting their focus of attention to a different stimulus dimension. Set shifting is thus the ability to overcome an attentional set. The ease with which a shift is made is indicated by fewer ► perseverative responses in the WCST and by more rapid acquisition, with fewer errors, in the ID/ED task.

Rule switching is the ability to overcome a learning set: the relative difficulty of new learning is indicative of the strength of the learning set. Thus, both set shifting and rule switching represent the dynamic operation of mental set and describe the processes by which the mental set is weakened or altered as circumstances, or reinforcement contingencies, demand. They further have in common that both the perceptual dimensions and the rules by which response might be selected are potentially relevant throughout the task. That is to say, the focus of attention (i.e., attentional set) or the problem-solving strategy (i.e., learning set) are a feature of the respondent and, while they may be elicited by the demands of the task, they are not a feature of the task. Indeed, without the formation of an attentional or a learning set, the tasks could still be performed perfectly adequately. Indeed, sometimes the absence of a "set" would result in better performance, as at the ED stage in the ID/ED task or as demonstrated by the "Einstellung effect," which refers to the retardation of new learning when a previously learned rule or principle does not apply (Luchins 1942).

Thus, mental set might be regarded as cognitive short hand: knowing about contingencies, rules and probability or likelihood, enables an animal to anticipate and prepare for future events, and, by decreasing the range of available options, can improve the speed of processing and likely suitability of a response choice. Mental set is best understood as being an example of preconception (when thinking is influenced by prior experience), and/or predisposition (when responding is influenced by prior experience). The corollary of this is that forming a mental set is the antithesis of cognitive flexibility: the act of "thinking outside the box" means abandoning the preconceptions and predispositions of mental set. Thus, having a mental set is good for predictable events (including predictable changes), but when the unexpected occurs, optimal responding requires that mental set be overridden – that is to say, it requires cognitive flexibility.

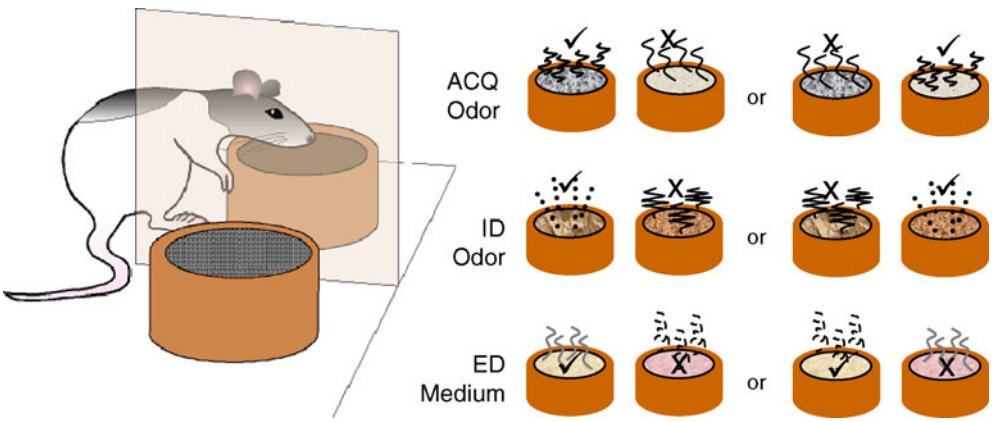
Flexibility and behavioral change are sometimes confused, with new or unpredicted behavior being more likely to be considered flexible than is repeated or predictable behavior. The important point is that any objective assessment of the predictability of behavior is much less relevant than whether the behavior is consistent with the mental set: as long as the required response is consistent with set, cognitive flexibility (the overriding of set) is not required. Thus, response alternation requires no more flexibility than response repetition as long as it is consistent with the response set. It is for this reason that reversal learning poses an interesting case.

Reversal learning refers to the reversal of previously established stimulus-reward contingencies. In its most simple form, it is the reversal of a Pavlovian conditioned response (► Classical (Pavlovian) conditioning), such that the conditioned response (CR) to a CS+ is extinguished. The old-CS is now paired with the US and so, as the new CS+, it comes to elicit a CR. However, the term

"reversal learning" is used much more widely and, particularly in studies of behavioral flexibility, it is most often used to refer to instrumental learning (▶ Instrumental conditioning) of a two-choice discrimination task, such as a T-maze or two lever operant task. In these tasks, there is a reinforced response (R+) and a response that is not reinforced (R−), and it is this response–outcome association that is reversed. Sometimes, reversal learning is used yet more generally, to describe any task in which a previously reinforced response is no longer reinforced, even where there is, strictly speaking, no reversal. For example, in a ▶ water maze the location of a submerged platform might be moved or, in a multiarm maze, the location of food bait might be changed, such that a previously reinforced response (e.g., "swim to the North-East quadrant" or "go to the right") is no longer reinforced but the reward is now associated with a response not previously reinforced (e.g., "swim to the South-West quadrant" or "go to the left"). However, such spatial relocations are not necessarily equivalent to reversal learning of nonspatial discriminations.

Reversal learning is different to tests involving acquisition of new discriminations. As noted above, the formation of a mental set is not required to perform the tasks in which the presence of set is determined: not only is mental set incidental to the task but also the presence of a set is detected due to the detrimental effect it has on performance. This is not true for reversal learning, which involves "unlearning" an old association before a new association is formed.

Ideally, a task will not conflate reversal learning with either response switching or attentional shifting. It is possible to dissociate switch/shift effects from reversal-learning effects, but only if there is a change of stimuli at the critical stages, such that, at these stages of testing, previously rewarded stimuli or responses are no longer presented and the subject must acquire a novel discrimination. One of the challenges in devising suitable tasks to probe attentional set or learning set in animals is finding a sufficient number of suitable stimuli to enable testing in multiple stages with novel stimuli at each. For example, when visual stimuli are used in studies with rats or mice, the stimulus sets are limited by the limited visual acuity of rodents. For this reason, attentional set is often measured in rodents using baited digging bowls, which are distinguishable on the basis of haptic or odor properties, so exploiting the animals' natural tendency to forage (see Fig. 1). In a single session lasting a few hours, a rat learns a series of discriminations between two bowls. The odor and haptic stimuli are both replaced at the ID and the ED



Behavioral Flexibility: Attentional Shifting, Rule Switching and Response Reversal. Fig. 1. Rats are presented with a pair of bowls on either side of a divider. Both bowls contain a different digging medium filling the bowl and they smell differently (odors are represented by lines above the bowls), but only one of the bowls is baited with food. In an initial acquisition phase (ACQ), either the odor (as shown in the illustration) or the medium indicates which bowl is baited. At the intradimensional (ID) stage, the media and the odors are replaced with novel stimuli. The relevant dimension (in the illustration, the odor) remains relevant for finding the food. At the extradimensional (ED) stage, the media and odors are again replaced with novel stimuli. The previously relevant dimension no longer indicates the location of the food. The animal must change its attentional focus to the other dimension – the medium. Typically, animals require more trials to learn new discriminations when they must reorient their attention (ED stage) compared to when their attention is already appropriately focused (ID stage).

stages, but, at the ED stage, the characteristic of the bowl that is relevant to solve the discrimination is also changed. The additional trials required to learn the discrimination are indicative of the strength of attentional set. The fact that the rodent can discriminate between a very large number of odors and haptic stimuli overcomes the limitations of using visual stimuli.

In the case of rule-switching tasks, it is not stimuli, but responses that must be novel; however, it is not trivial to devise a task for a rodent in which a rule will be extrapolated to form a learning set, which will then benefit new learning, while not being "the same" discrimination. With foraging animals, spatial discriminations are powerful tools as a variety of rules (e.g., egocentric ("turn right"), visual ("approach the light"), and allocentric ("head South")) can be generated to solve them. However, it is problematic to prevent the partial reinforcement of the application of a previously correct rule because there are not a similar variety of responses to express the learning of those rules. If there is still the possibility of making a previously rewarded response by applying an old rule, then the previously learned discrimination will be unintentionally partially reinforced and this might retard learning of the new rule, rather than an attentional switch-cost *per se*.

Impact of Psychoactive Drugs

Impairments in behavioral flexibility have been reported in many different psychiatric and neurological conditions, including ▶ schizophrenia, ▶ attention deficit hyperactivity disorder, ▶ Parkinson's disease, ▶ mild cognitive impairment, Alzheimer's disease, and ▶ bipolar disorder. Most of our current understanding of impairment in behavioral flexibility derives from studies of these conditions, or animal models of these conditions (▶ Primate models of cognition, ▶ Rodent models of cognition, ▶ Dementias: animal models, ▶ Depression: animal models, ▶ Animal models for psychiatric states, ▶ Schizophrenia: animal models), compared to control subject performance. Thus, (dorso)lateral prefrontal cortex of primates (medial prefrontal cortex of rodents) has been implicated in both attentional shifting and rule switching, while impairments in reversal learning are associated with orbital prefrontal cortex. Investigations of the effects of psychoactive drugs on behavioral flexibility have served either to model human pathological conditions by inducing neurochemical imbalance, or to ameliorate the effects of those models. In particular, dopamine (DA), serotonin (5-HT), norepinephrine (NE), and acetylcholine (ACh) have all been implicated in shifting/switching and/or reversal learning.

Dopamine (DA)

Most of the evidence, from patients and experimental animals, implicates prefrontal cortical, and not striatal, ▶ dopamine in shifting/switching performance while striatal dopamine has been implicated in reversal learning.

Impairments in attentional shifting are consistently reported in patients with schizophrenia, a disorder long associated with dopamine overactivity. However, while ▶ first-generation antipsychotic treatments, which block striatal dopamine D_2 receptors, are effective treatments for positive symptoms of schizophrenia, they do not improve and may further impair cognitive (including shifting) impairments. ▶ Second-generation antipsychotics, such as clozapine, olanzapine, and risperidone, do offer some cognitive benefits, perhaps deriving from their actions on prefrontal cortical function and perhaps mediated by effects on receptors other than dopamine.

Parkinson's disease is associated with both frontal and striatal dopamine depletion, either of which could account for the shifting deficits reported in these patients. Nevertheless, converging data suggest that it is prefrontal, rather than striatal, dopamine that is responsible.

Shifting and/or switching impairments in rats have been reported in a variety of animal models of schizophrenia). Subchronic ▶ phencyclidine (PCP) impairs shifting and second-generation, but not the first, antipsychotics ameliorate the deficits. Similarly, ▶ amphetamine sensitization (▶ Sensitization to drugs) impairs shifting and reversal learning. Infusion of the D_1 receptor agonist 1-phenyl-2,3,4,5-tetrahydro-(1H)-3-benzazepine-7,8-diol hydrochloride (SKF38393) into medial prefrontal cortex ameliorates the effect of amphetamine sensitization on shifting, without improving the impairment in reversal learning.

Antagonism of the D_1 receptor by 7-chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrochloride (SCH 23390) impairs switching, with the D_1 agonist 6-chloro-2,3,4,5-tetrahydro-1-phenyl-1H-3-benzazepine hydrobromide (SKF 81297) having no effect. Switching is also impaired by the D_4 agonist, *N*-(Methyl-4-(2-cyanophenyl)piperazinyl-3-methylbenzamide maleate (PD168077), and improved by the D_4 antagonist, 3-[{4-(4-chlorophenyl)piperazin-1-yl}methyl)-1H-pyrrolo[2,3-*b*]pyridine (L745870).

Serotonin (5-HT)

▶ Serotonin is implicated in various forms of behavioral flexibility, including shifting, switching, and reversal learning. There may be a direct effect in the orbital prefrontal cortex on reversal learning. For example, serotonergic depletion of frontal cortex with 5,7-dihydroxytryptamine

(5,7-DHT) has been reported to impair reversal learning without impairing rule-switching.

A variety of serotonergic compounds improve shifting, but the serotonergic action might be indirect, via a modulation of levels of dopamine, norepinephrine, and/or acetylcholine. For example, the 5-HT_6 receptor antagonist *N*-[3,5-dichloro-2-(methoxy)phenyl]-4-(methoxy)-3-(1-piperazinyl)benzenesulfonamide (SB399885T) improves shifting in normal rats and both the selective 5-HT_6 antagonist 5-chloro-*N*-(4-methoxy-3-piperazin-1-yl-phenyl)-3-methyl-2-benzothiophenesulfonamide (SB271046A) and the antipsychotic, sertindole, ameliorate PCP-induced impairment in shifting. Asenapine (a second-generation antipsychotic, which has higher affinity for 5-HT_{2A}, 5-HT_{2C}, 5-HT_6, and 5-HT_7, as well as α_2-adrenergic receptors than it does for D_2 receptors) ameliorates shifting impairments following a lesion of the prefrontal cortex.

Norepinephrine (NE)

Increasing prefrontal cortical ▶ norepinephrine in normal rats has been reported to improve shifting. However, increasing norepinephrine also increases prefrontal cortical dopamine and this co-modulation means that it is difficult to separate their effects on behavioral flexibility (for review see Arnsten and Li 2005). Nevertheless, there may be specific and selective effects: noradrenergic-specific lesions have been reported to result in impairments in shifting/switching in rats, which can be reversed by the selective NE reuptake inhibitor ▶ atomoxetine, at doses reported to have no effect on prefrontal cortical dopamine.

Acetylcholine (ACh)

Scopolamine (▶ Muscarinic agonists and antagonists) impairs shifting and switching in rats and there have been reports of beneficial effects of nicotine (▶ Nicotinic agonists and antagonists). However, selective lesions of prefrontal or basal forebrain cholinergic neurons impact reversal learning and not shifting (for review see Robbins and Roberts 2007).

Conclusion

Specifying the neurochemical profile of behavioral flexibility is made complex by the co-modulatory effects of the monoaminergic systems in frontal cortex. Nevertheless, there is little doubt that the prefrontal cortex and the innervating neurochemical projection systems are important for executive control, of which behavioral flexibility is a key component.

Definition

In cognitive neuroscience, behavioral inhibition is an active inhibitory mechanism that allows us to withhold unwanted or prepotent responses. These responses could be actions or movements and be triggered by either internal or external stimuli. The ability to exert inhibitory

control over automatic reflexes and conditioned responses has been suggested to have evolved in higher mammals to allow slower cognitive processes to guide behavior in certain circumstances. Deficient behavioral inhibition is one of the most prominent symptoms in ADHD.

Definition

▶ Behavioral tolerance describes the diminution of a drug-induced disruption of a goal-oriented behavior that is dependent upon learning processes, i.e., performance of the behavior while intoxicated.

Impact of Psychoactive Drugs

Behavioral Tolerance

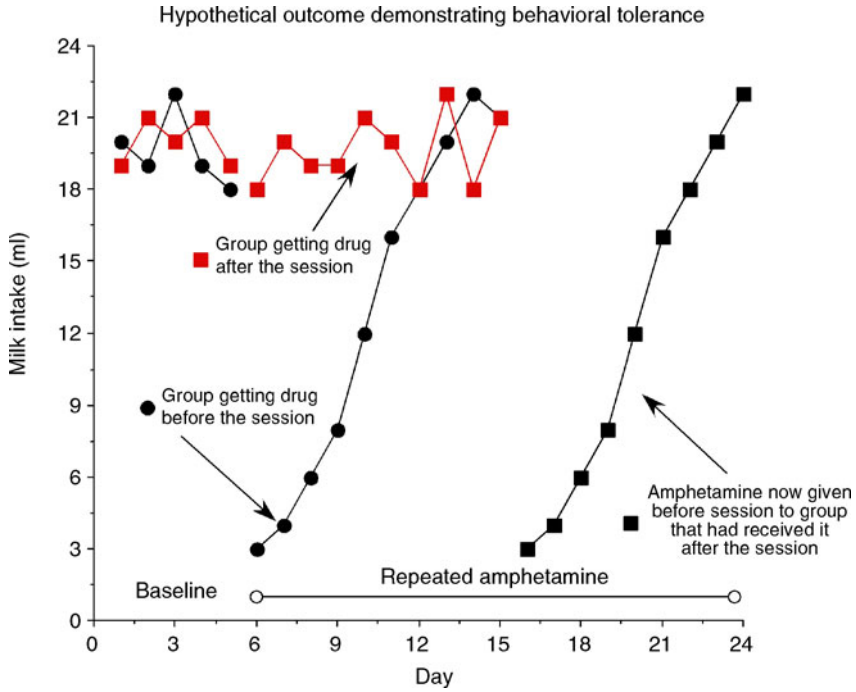
▶ Tolerance refers to the diminution of a drug's effect with repeated dosing. In controlled laboratory settings, tolerance is measured by giving a drug repeatedly, and assessing a dependent measure as a function of drug history. In clinical settings, tolerance is inferred when a person reports that she/he thinks it currently takes a greater amount of drug to achieve an effect than it did when use of the drug first started. A modifier is often used to indicate a type of tolerance or a mechanism responsible for tolerance. Some modifiers are used to further describe the conditions under which tolerance is observed. For example, ▶ acute tolerance refers to a diminution of effect during a single drug taking episode such that the drug produces greater effects as blood concentration increases, i.e., on the ascending limb, compared to when blood concentration decreases, i.e., on the descending limb of the drug concentration curve. Other modifiers are used to describe the mechanism by which tolerance occurs. For example, ▶ pharmacodynamic tolerance describes a diminution of a drug effect due to a more rapid elimination of the drug from the body. Behavioral tolerance actually combines both types of meanings; descriptive and mechanistic. Behavioral tolerance describes the diminution of a drug-induced disruption of a goal-oriented behavior with repeated dosing that is dependent upon learning processes, i.e., performance of the behavior while intoxicated. Given the use of many words to modify the term tolerance, it is not surprising that some terms related to tolerance are poorly used. Behavioral tolerance does not simply mean tolerance to a behavioral effect of a drug.

While scientists and drug users alike had long noticed that practicing a behavior while under the influence of a drug helped one overcome disruptions in behavior, the basic tenets of behavioral tolerance were well demonstrated by Schuster et al. (1966). For years, it had been noticed that tolerance developed at different rates to different behaviors, and that some drug effects became greater with time, i.e., ► sensitization. A key issue was what factors determined the development of tolerance versus sensitization. It was well-known that ► amphetamine and other stimulants commonly increased rates of responding (rate-dependency). Schuster and colleagues hypothesized that tolerance would develop to responding that was disrupted by the rate-increasing effects of amphetamine, but tolerance would not develop to responding that was *not* disrupted by the rate-increasing effects of amphetamine. What was needed was an operant schedule of responding that reinforced low rates of behavior and one that did not. Thus, the effects of acute and repeated amphetamine administration in rats responding under a multiple response schedule were examined: responding during 1 component was reinforced under a DRL, or differential reinforcement of low rates of responding schedule in which reinforcement is based on time since last response, and responding during another component was reinforced under an FI, or fixed interval schedule in which reinforcement is based on time since last reinforcer. Using these schedules, an increase in response rate will disrupt DRL performance, but have minimal effects on FI performance. Tolerance should develop specifically to the effects of amphetamine on DRL performance which decrease reinforcer deliveries.

As expected, amphetamine increased the rate of responding and the increases were associated with a decrease in food pellet deliveries during the DRL component, but *not* during the FI component. During repeated amphetamine dosing, tolerance developed to the rate-increasing effects of amphetamine on DRL responding such that after 30 days, rats earned as many food pellets as they did during baseline. There was no evidence of tolerance to the rate-increasing effect of amphetamine during the FI component; an action that did not decrease food pellet deliveries. Tolerance development was dependent upon the environmental contingencies. Hence, behavioral tolerance is also sometimes referred to as contingent tolerance. Schuster et al. (1966) proposed the reinforcement-loss hypothesis to account for behavioral tolerance. "Behavioral tolerance will develop in those aspects of the organisms' behavioral repertoire where the action of the drug is such that it disrupts the organism's behavior in meeting the environmental requirement for reinforcements. Conversely, where the actions of the drug enhance, or do not affect the organism's behavior in meeting reinforcement requirements we do not expect the development of behavioral tolerance." p. 181

While Schuster et al. (1966) used a within-participants design to show differential development of tolerance, other researchers, e.g., Carlton and Wolgin (1971) used a between group design to assess the role of behavioral experience in tolerance development. In order to demonstrate that behavioral factors played a role in tolerance development, it is important to have a group of animals who have the same drug history, but a different behavioral history. This can be accomplished by giving one group of animals drug before the experimental session so that these animals can experience the drug effect in combination with the behavioral requirement, while another group of animals receive the drug after the behavioral session so that they do *not* experience the drug–environment interaction (before vs. after design; see Fig. 1). A popular approach for examining the effect of repeated dosing with the anorectic drug amphetamine on milk drinking involves one group of rats given amphetamine before the session and one group of rats given amphetamine after the milk-drinking session. Thus, drug exposure is matched between the two groups. In this case, amphetamine substantially decreases milk drinking when given before the session, but tolerance developed rapidly and milk drinking is back to baseline levels in less than 10 days. If drug exposure alone was sufficient to induce tolerance then the animals who had received amphetamine after the session should also have be tolerant to the effect of amphetamine when it is then given before the session. This is not the case. Amphetamine exposure alone is not sufficient to induce tolerance. In fact, when the group that had received amphetamine after the session is given repeated amphetamine before the session it takes as long to develop tolerance as it did in the other group of rats; amphetamine experience after the session did not increase the rate of tolerance development. Clearly, drinking milk under the influence of amphetamine was necessary in order to develop tolerance to the anorectic effect of amphetamine.

Data collected using similar procedures support the idea that reinforcer loss and instrumental learning of behaviors that remediate the loss are a key component in the development of behavioral tolerance, i.e., tolerance occurs because new compensatory behaviors are learned. One mechanism by which stimulants can decrease food intake is by eliciting behavior, such as stereotypy that is incompatible with milk drinking that requires organized licking and spout contact. Stereotypy is not incompatible



Behavioral Tolerance. Fig. 1. Hypothetical data, based on Chen (1968) and Carlton and Wolgin (1971) showing how behavioral tolerance can be measured using one group of animals that initially receives a drug (in this example amphetamine) that disrupts reinforcement (milk drinking in this example) before daily access to the reinforcer, and a second group of animals that initially receives a drug that disrupts reinforcement after daily access to the reinforcer. The appetitive behavior decreases in the group that received drug before the session, but tolerance develops over time with performance returning to baseline levels. If behavioral factors were not involved then when the animals in the after group were given drug before the session they too should also show tolerance, i.e., intake would be at baseline levels. If experience with the behavior and reinforcement while under the influence of drug were necessary then behavior would be disrupted as if they had not received any drug yet. Furthermore, if behavior recovers at the same rate as it did in the group first exposed to drug before the session then this indicates that the prior pharmacological drug experience produced no savings or increase in the rate of tolerance development.

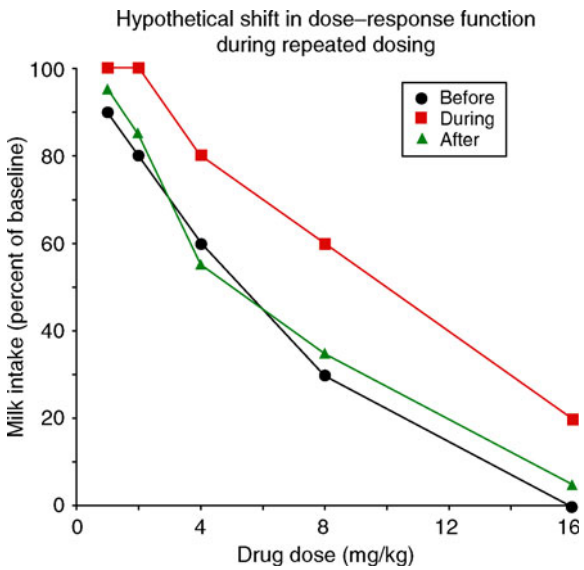
with milk drinking that only requires swallowing milk that is delivered intraorally. One approach for testing the learning hypothesis of behavioral tolerance is to compare the effects of an anorectic stimulant drug on milk swallowing versus milk drinking, e.g., Wolgin and Munoz (2006). You would hypothesize that stereotypy induced by a stimulant would disrupt milk drinking, but not milk swallowing such that tolerance would only be observed in the rats that must learn to approach and lick the fluid spout in the presence of drug-induced stereotypy. This is indeed the case. When the animals that received drug and drank milk intraorally were switched to licking the fluid spout, the previous exposure to the stimulant did not provide savings in the rate of tolerance development. Thus, tolerance development required the contingency between licking and fluid delivery to suppress stereotypic movements.

These data are exciting in that they clearly showed a role for environmental contingencies in modulating the response to long-term drug administration. The development of tolerance only in the animals drinking milk after drug administration strongly argues that dispositional and pharmacodynamic factors alone cannot account for tolerance development, and also strongly supports the reinforcement-loss hypothesis to account for behavioral tolerance. The demonstration of behavioral tolerance does not rule out a contribution for dispositional tolerance or some other factor related to the environment modulating tolerance development. For example, the increase in food deprivation due to reinforcement loss or some motor component of behaving could alter the physiological response to a drug, and in turn alter drug disposition.

An ideal study on behavioral tolerance would determine complete dose–response functions for a drug effect

on behavior before, during, and after a period of repeated administration in one group of animals receiving drug prior to the session, and another group of animals receiving drug post session. In this way tolerance development could be clearly quantified and defined as a shift to the right in the dose-response function during the period of repeated administration (see Fig. 2). Behavioral tolerance would be defined as a shift to the right in the dose-response function during the period of repeated administration only in those animals receiving drug prior to the session. Although ideal, many studies do not determine dose-response function during the period of repeated administration. In the absence of a shift to the right in the dose-response function one must be cautious in assuming tolerance development. It is possible that the animals may have learned the compensatory behavior only under the influence of the dose given repeatedly. In that case, the repeated drug dose may be functioning as a discriminative stimulus for responding.

Behavioral tolerance, i.e., tolerance to a behavioral effect of a drug that is dependent upon experience with reinforcement while intoxicated, has been well documented. Although the reinforcement-loss hypothesis that requires instrumental responding for tolerance to develop has received much support, the exact biological mechanisms accounting for the drug–environment interaction have not been identified. Future work in neuroscience may wish to take advantage of the specificity of behavioral tolerance development to examine the central nervous system changes associated with learning including analysis of neural pathways and cellular mechanisms. Such work will not only provide valuable insight into the central mechanisms underlying behavioral tolerance, but also elucidate mechanisms associated with learning in general.



Behavioral Tolerance. Fig. 2. Hypothetical data showing how complete dose–response functions are used to demonstrate the development of tolerance. During repeated administration the effect of each dose is less than observed before the period of repeated administration, i.e., there is a shift to the right in the dose–response function. After repeated administration the effect of each dose is similar to what was observed before the period of repeated administration, i.e., the dose–response function has shifted back to baseline.

Benserazide

Synonyms

2-amino-3-hydroxy-N'-[(2,3,4-trihydroxyphenyl) methyl] propanehydrazide; Ro 4-4602; Serazide

Definition

Benserazide is a peripherally acting aromatic l-amino acid decarboxylase or DOPA decarboxylase inhibitor and as such inhibits the early degradation of L-DOPA, the dopamine precursor in blood. Benserazide is always used in combination with L-DOPA in the management of ► Parkinson's disease. Benserazide does not cross the blood–brain barrier and has no anti-Parkinson's effects in its own right, nor does it treat ► dyskinesias. It is also used in the treatment of restless leg syndrome.

Benztropine; Endo-3-(diphenylmethoxy)-8-methyl-8-azabicyclo[3.2.1]octane methanesulfonate

Definition

Benztropine is a centrally acting anticholinergic drug. It is primarily used as an adjunct in the treatment of drug-induced Parkinsonism and other forms of Parkinsonism, and ► akathisias. Benztropine can also be used as second line treatment of ► Parkinson's disease; it improves tremor, but not rigidity. Benztropine may also be used to treat acute dystonia, which results in abnormal muscle contractions with twists in limbs, trunk, or face. Anticholinergics are generally less effective than ► L-DOPA, but are of use in all forms of Parkinsonism as their side effect profile is rather mild.

BZs are used for a number of indications in general practice, neurology, anesthesiology, and psychiatry:

Insomnia
Adjuvants in anesthesia
Anxiety disorders (GAD, specific phobias, panic disorder, social anxiety disorder)
Adjustment disorders
Organic brain syndrome (acute, e.g., delirium tremens, and chronic, e.g., dementia)
Anxiety in depression (as an adjunct at initiation of antidepressant therapy)
Schizophrenia (catatonic type, and for rapid tranquillization)
Acute mania
Avoidant personality disorder
Alcohol and sedative withdrawal
Suicidal patients with prominent anxiety symptoms
Status epilepticus
Tardive dyskinesia, akathisia
Spasticity (e.g., spastic paraplegia), acute torticollis
Contraindications: Myasthenia gravis, sleep apnea, severe pulmonary disease

Intolerance of SSRIs/SNRIs is another important reason to prescribe benzodiazepines. SSRIs/SNRIs sometimes cause a paradoxical increase in anxiety at initiation of treatment that calls for adjunct prescribing of a BZ. Although anxiety is not a DSM-IV criterion for a major depressive episode, clinicians should be aware of the frequent anxiety component in depression that needs to be addressed, as anxiety may precipitate suicidal acts.

BZ anxiolytics are recommended for short-term (<1 month) relief of anxiety and insomnia and as an adjunct

to initial antidepressants, according to a 1997 guideline of the Royal College of Psychiatrists. It is stated that "dose escalation in uncomplicated cases is rare," and that "The decision to allow dependence to develop is sometimes defensible, but it must be appreciated that, once dependence has become established, it is often extremely difficult to treat and may become a long-term or even permanent state."

Another guideline emanating from the Psychopharmacology Unit at the University of Bristol in 1995 advises that patients with panic, generalized, or social anxiety disorder be started on an SSRI/SNRI and given adjunct BZ for 3–4 weeks. If the SSRI/SNRI turns out to be ineffective, BZs are used as single therapy after careful discussion with the patient. BZs are also used to alleviate acute (trauma-induced) anxiety on the grounds that it would by unethical to deny patients with severe anxiety the benefits of immediate relief.

A 2007 survey among specialists found that BZs were the last resort for a minority of complicated patients, also pointing to the value of using BZ in rapid tranquillization. A 2008 task force for the World Association of Societies of Biological Psychiatry issued similar recommendations.

Pharmacological Properties

Pharmacodynamics

Early work on central monoaminergic mechanisms concluded that the reduction of fear-motivated behavior and aggressiveness in rats could be due to reductions of noradrenaline, serotonin, and dopamine turnover. Later, it was shown that the principal effect of ▶ chlordiazepoxide and diazepam is by enhancing the action of the inhibitory transmitter ▶ GABA on the GABA-A receptors. The hypnotics ▶ zopiclone, eszopiclone, ▶ zolpidem, and ▶ zaleplon, although structurally different from the BZs and different from each other as well, also act on the same site on the GABA-A receptor as the effects of all these drugs are blocked by the antagonist ▶ flumazenil. Many other substances act on the GABA-A receptor but at different modulatory sites, such as ▶ neurosteroids, anesthetics, and ▶ alcohol. If taken together, these can all potentiate the actions of the benzodiazepines, leading to dangerous levels of sedation (Nutt and Malizia 2001).

There are 14 genes identified encoding GABA-A receptor subunits, and 5 of these come together to make a functioning receptor. BZs may produce their anxiolytic effects by stimulating certain GABA-A receptor subunits (especially $\alpha 2$ and $\alpha 3$) in limbic structures such as the ▶ amygdala and the septum. Deficits in inhibitory neurotransmission may increase anxiety-related behavior, and increased inhibitory GABAergic activity causes behavioral inhibition in mice, a proxy for anxiety-related behavior. When the BZ antagonist flumazenil is administered, human subjects on maintenance benzodiazepine treatment react with a withdrawal state characterized by anxiety, dizziness, nausea, sweating, and perceptual distortions. Recent work shows that the ▶ hypothalamic pituitary axis activity is modulated by effects of BZs on the ▶ corticotropin-releasing factor.

Pharmacokinetics

There are two key ▶ pharmacokinetic elements to the BZs; speed of onset and speed of offset. In general, faster onset is better for BZ hypnotics and those used for status epilepticus. In the former case, more rapid uptake from the gut is obtained using drugs with certain physicochemical properties such as zolpidem. For seizures, the fastest route for a clinical effect is intravenous or rectal. There are also formulations for nasal administration, e.g., of midazolam.

Speed of offset is determined by several factors of which the most important is the metabolic ▶ half-life of the drug. The first-generation BZs had half-lives of more than 24 h, with active metabolites with even slower clearance rates. While this was useful in conditions such as epilepsy, drug accumulation was an issue when they were used for anxiety and insomnia as it might cause sedation with a risk of fall hip fractures, especially in the elderly. To reduce this problem, ▶ lorazepam and ▶ alprazolam with a shorter half-life were developed. For hypnotic use, ▶ temazepam and ▶ triazolam were developed followed by the Z-drugs. All these have short half-lives with low risk of daytime sedation (Table 1).

Safety

Heritability and Pharmacodynamics of Addiction and Dependence

The heritability for addictions is the focus of intense research efforts. A set of 89 genes has been identified for phenotypes of alcohol, methamphetamine, nicotine, and barbiturate addiction that regulate explicit memory systems. This long-term effect on memory may be more important than the initial drive for euphoria, turning an individual into compulsive drug use, and to drug craving being precipitated by social reminders of drug use for many drugs, especially cocaine and metamphetamine. ▶ Dopamine release is an important determinant of reinforcing drug experiences and increased self-administration. However, in contrast to these substances that cause positive rewarding effects by increasing

dopamine release, BZs have not been shown to enhance extracellular dopamine in the ▶ nucleus accumbens, but actually *reduce* dopamine levels (Licata and Rowlett 2008). Thus, the BZs are not capable of inducing dependence by the same mechanism as addictive drugs. The connecting mechanism between GABA-A receptors and the reduction in dopamine appears to be by a modulation in the glutamatergic transmission of ▶ ventral tegmental area dopamine neurons (Heikkinen et al. 2009). Recent evidence points to a role for extrasynaptic GABA receptors regulating intake and dependence development, although these mechanisms are not clearly identified. ▶ Barbiturates have three distinct effects on GABA-A receptor activity, but little is known about the structural rearrangements underlying these functional effects.

BZ Discontinuation Symptoms

BZ ▶ discontinuation symptoms appear in some patients upon rapid cessation of therapeutic dose treatment, first called low-dose dependence by Malcolm Lader in 1981. Such symptoms occur at rates varying between 5 and 75% after therapeutic use for at least 1 year, probably reflecting selection bias in different study populations. Only a fraction of patients experience major distress. The discontinuation symptoms reportedly manifest themselves as a rebound of anxiety/insomnia, agitation, dysphoria, fatigue, nausea, tremor, tinnitus, muscle twitches, paraesthesias, perceptual distortions, and confusion. The partial BZ agonist flumazenil significantly reduces withdrawal symptoms and craving in patients in comparison with ▶ oxazepam tapering over a 7-day period, and with placebo. The mechanism is believed to normalize and upregulate BZ receptors by restoring GABA receptor allosteric structure.

Several other classes of psychoactive and other drugs cause discontinuation or rebound phenomena: SSRIs, SNRIs, antipsychotics, lithium, corticosteroids, beta-blockers, beta-stimulants and other medications that are rapidly discontinued in humans. The type of discontinuation symptoms is related to the pharmacodynamics of the medication, pharmacokinetics, and negative expectations (*nocebo*) (Nutt 2003).

Tolerance

Acquired ▶ tolerance to the effects of a substance is a complex mechanism based on the pharmacogenetic make-up of an individual, the duration and amount of substance administered, and other unknown factors. BZ tolerance to the anticonvulsant action may develop with chronic exposure as a consequence of regulatory changes in the expression of GABA-A receptor subunits in specific brain areas. Tolerance develops quickly to the sedative and motor coordination effects of BZ anxiolytics, but not necessarily to the anxiolytic or memory impairing effects, and therapeutic drug doses are rarely increased with time (Licata and Rowlett 2008). Some patients develop tolerance to the hypnotic effects of BZs including the Z-drugs, as evidenced by rebound insomnia on withdrawal, and there are reports of abuse (Hajak et al. 2003).

Problem Patients

Several individual components other than the affinity with which a drug binds to the benzodiazepine modulatory site have been identified in discontinuation symptoms: dependent (harm avoidant) personality traits, negative expectations (*nocebo*), and relapse and rebound of the anxiety or sleep disorder for which treatment was instituted. Studies of the medical files of patients claiming iatrogenic BZ-induced neuropsychiatric symptoms found that the symptoms attributed to BZ treatment were present before it was instituted (Mattila-Evenden et al. 2001).

In 1990, a task force appointed by the American Psychiatric Association issued a report on the potential hazards of BZs. The report stopped short of concluding that all criteria for dependence occurred. It further stated that

- Physiologic dependence on benzodiazepines, as indicated by the appearance of discontinuance symptoms, can develop with therapeutic doses. . . . Benzodiazepines

do not strongly reinforce their own use, and are not widely abused drugs. When abuse does occur, it is almost always among persons who are also actively abusing alcohol, opiates, or other sedative hypnotics.

The Scottish pharmacologist LF Prescott stated in 1983 that

- In contrast to the enormous general consumption of benzodiazepines, their abuse "for kicks" by young drug takers is distinctly uncommon and they have no street value. Unlike barbiturates, methaqualone, and ethanol, the benzodiazepines do not normally cause disinhibited behavior and excitement. They are not "fun" drugs and have a deadening rather than stimulating effect. In Edinburgh, chemists' shops (drug stores) are often broken into; the thieves are very discriminating and clear out all the narcotics, barbiturates, methaqualone, and amphetamines but leave the benzodiazepines behind.

The founder of the Haight-Ashbury free medical clinic for the flower-power generation in San Francisco, David E. Smith was of a similar opinion in 1985:

- . . . most benzodiazepine abuse is secondary drug abuse: self-medication of adverse effects of other drugs (e.g., to reduce the nervousness induced by cocaine, or self-medication of heroin withdrawal symptoms). Because of benzodiazepines' effectiveness in ameliorating symptoms induced by other drugs or withdrawal, benzodiazepines have drug value in the illicit drug marketplace. . .The amount of primary abuse of the benzodiazepines in the drug culture is minimal. . .

Is it possible to identify risk factors for BZ abuse in patients? Individual risk factors for BZ abuse include antisocial, borderline, and histrionic personality disorders, alcohol and stimulant abuse, somatization, and familial sociopathy. Another typical behavior of such sedative–hypnotic abusers is "doctor shopping" – seeing multiple doctors to acquire BZs to potentiate effects of street opioids or alcohol, or to facilitate getting out of a period of a CNS stimulant high (Allgulander 2000). Such antisocial behavior violates the bond of trust, yet can be done with impunity in most countries. It can also include forging and manipulating of prescriptions, smuggling in used, labeled pill bottles, and prescribing by proxy (colluding with a spouse or a friend posing as patient with simulated symptoms). The internet has become a major source of BZs, anabolic steroids, opioids, and other drugs for nonmedical uses. The risk of suicide in such patients is extremely high, partly because many of them are doctors, nurses, or pharmacist with access to lethal drugs and with the skills to use them (Allgulander et al. 1987). Still, some argue that there is no reason to exclude patients with a history of substance abuse and dependence from BZ treatment, while others see a need to preclude such patients.

Memory Impairment

One important adverse effect of long-term benzodiazepine use is memory impairment. In a meta-analysis of tested subjects after a mean of 10 years of BZ treatment, significant impairment was found in all cognitive domains (Barker et al. 2004). Restoration of cognitive function was also noted, although impairment persisted for up to 6 months in comparison with controls or normative data in 11 of 12 tested domains, most notably verbal and working memories, psychomotor speed, and motor control/performance. No neuroimaging abnormalities have been noted in long-term users of BZs.

Clinical Uses

Historical Notes

From the early 1900s and for 60 years, barbiturate derivatives were the sedative–hypnotics of choice, in spite of their narrow safety margin (see ▶ Barbiturates). Following the breaking news of chlorpromazine as an antipsychotic in 1952, several new sedative–hypnotics were developed, such as methaqualone, ▶ meprobamate, ▶ clomethiazole, and gluthetimide. They had all been overtaken by ▶ diazepam and chlordiazepoxide by the mid-1960s. Hoffman-La Roche patented the first benzodiazepine chlordiazepoxide in 1959, and it was approved by the FDA under the trade name Librium in 1960, soon followed by diazepam, oxazepam, and ▶ nitrazepam. The more potent alprazolam was introduced in the early 1980s. The United Nations Convention on Psychotropic Substances Schedule IV lists 34 BZs for the purpose of restricting import and export, to require licenses for manufacture and trade, and to be available by prescription only. Diazepam is the only benzodiazepine on the WHO list of essential medicines.

The BZs were enthusiastically marketed in the 1960s, their use peaking in the mid 1970s. They were accepted by clinicians as being safe, effective, and predictable, much more so than the barbiturates. The prominent psychopharmacologist, Malcolm Lader, reacted to the increasing sales of BZs in the 1970s with social explanations (Lader 1978). He argued that BZ prescribing had become a solution to emotional problems in the lower social classes; a substitute for counseling that initiated a self-perpetuating treatment for fear of precipitating discontinuation

symptoms. Lader argued that this use of BZs medicalized social problems:

> It is much cheaper to tranquilize distraught housewives living in isolation in tower blocks with nowhere for their children to play than to demolish these blocks, and to rebuild on a human scale, or even to provide playgroups. . . An educational campaign to make doctors realize the more nebulous dangers of our present scale of use of the benzodiazepines is urgently needed.

Malcolm Lader then appeared on the BBC; an activist group was formed in the UK, lawyers got involved, and legal class actions were set up.

When the BZs became an ethical, social, and political target, prescribing was substantially reduced, precipitating a need for new evidence-based treatments of anxiety disorders. This coincided with the emerging DSM-III nosology for ▶ anxiety and ▶ mood disorders. ▶ Buspirone was readily accepted by regulatory bodies for anxiety symptoms. In the 1990s, the SSRIs/SNRIs became a substitute for the BZs as the primary drugs of choice, approved by regulatory authorities for the new DSM-III anxiety disorders: generalized, social, and ▶ panic anxiety, ▶ posttraumatic stress disorder, and ▶ obsessive-compulsive disorder. Although much slower in anxiolytic response, these medications had the advantage of acting both as antidepressant and anxiolytic, and with no street value for nonmedical use. These drugs became the drugs of choice in the absence of comparative trials with BZs, and in spite of a considerable side effect burden such as sexual dysfunction, sweating, nausea, and headaches (Baldwin et al. 2005). The "Z-drugs," zopiclone, eszopiclone, zaleplon, and zolpidem, were subsequently approved for insomnia.

BZs in Public Health and Inpatient Surveys

The Pharmacy Corporation, Sweden, analyzes prescriptions that have been issued to the patient, using the mean therapeutic dose per 1,000 inhabitants per day as an index (DDD/TID). In 2006, there were 50 DDD/TID of BZs in the Swedish general population, 60% of which were Z-drugs (zopiclone, zolpidem, zaleplon), 28% daytime BZ anxiolytics (diazepam, oxazepam, lorazepam, alprazolam), and 12% BZ hypnotics (flunitrazepam, nitrazepam). Z-drugs were mostly prescribed to elderly patients. For comparison, SSRI/SNRI prescribing in 2006 in Sweden was 65 DDD/TID, and the rates of BZ prescribing in other European countries varied between 43 and 62 DDD/TID (Petitjean et al. 2007).

In the Swedish public health survey in 2007, 5% of men and 8% of women aged 16–84 years, reported use of anxiolytics (including BZs) during the last 3 months. Antidepressant use was reported by 6 and 9% of men and women, respectively. For both drug classes, much higher rates were reported by those unemployed or on disability pension, and by immigrants from non-EU countries, corresponding to higher rates of reported mental health problems among these subgroups.

Although utilization rates of anxiolytics and other psychotropic drugs differ markedly between European countries, there were generally strong associations between the severity of mental health problems and reported treatment with such medications. A Swiss survey found that 44% of patients received only one BZ prescription, while those who continued treatment used lower than recommended doses except in 1.6% of patients who used more than twice the recommended therapeutic dose (Petitjean et al. 2007). It was projected from the data that 0.16% of the adult Swiss population abused or were dependent on benzodiazepines.

Admissions with a diagnosis of ▶ sedative/hypnotic dependence were studied in a national hospital data registry on random samples of adult Swedes (Allgulander 1989). There were 38 such admissions in 15 years among 32,679 Swedes, 21 of which were in polydrug users taking street drugs and/or alcohol as well. This result yielded a risk of 3.5 per 100,000 person years. In another inpatient registry analysis covering a 14-year period in Stockholm County (pop. 1.6 million), substance use disorders on prescribed medications (sedatives, hypnotics, and analgesics) were diagnosed in 676 inpatients, yielding a risk of 3.0 per 100,000 person years.

Two Dutch studies of first-time BZ users found an overall improvement in health-related quality of life over a 6 month period, compared to a matched reference group, and no increase in long-term utilization compared to community controls during a 4 year follow-up, respectively.

Appendix

The DSM-IV states in section 304.10 Sedative, Hypnotic, or Anxiolytic dependence

> There may be evidence of tolerance and withdrawal in the absence of a diagnosis of Substance Dependence in an individual who has abruptly discontinued benzodiazepines that were taken for long periods of time at prescribed and therapeutic doses. A diagnosis of Substance Dependence should be considered only when, in addition to having physiologic dependence, the individual using the substance shows evidence of a range of problems (e.g., an individual who has developed drug-seeking behavior to the extent that important activities are given up or reduced to obtain the substance. . . Sedative, Hypnotic,

or anxiolytic Dependence and Abuse may often be associated with Dependence on, or Abuse of, other substances (e.g., alcohol, cannabis, cocaine, heroin, amphetamines). Sedatives are often used to alleviate the unwanted effects of these other substances... Antisocial behavior and Antisocial Personality Disorder are associated with Sedative, Hypnotic, or Anxiolytic Dependence and Abuse, especially when the substances are obtained illegally... Most of these individuals take the medication as directed, without evidence of misuse... The more usual course involves young people in their teens or 20s who may escalate their "recreational" use of sedatives, hypnotics, and anxiolytics to the point at which they develop problems that might qualify for a diagnosis of Dependence or Abuse... Although the great majority of those who are prescribed a medication from this class do not develop problems, a small proportion do... substance-seeking behavior becomes more prominent and the person may seek out multiple physicians to obtain sufficient supplies of the medication.

With regard to benzodiazepines, the DSM-IV states that

- It should be noted that there are individuals who continue to take benzodiazepine medication according to a physician's direction for a legitimate medical indication over extended periods of time. Even if physiologic dependent on the medication, many of these individuals do not develop symptoms that meet the criteria for Dependence, because they are not preoccupied with obtaining the substance and its use does not interfere with their performance of usual social or occupational roles.

Beta-Adrenoceptor Antagonists

Peter J. Tyrer
Department of Psychological Medicine, Imperial College, London, UK

Synonyms

Beta-adrenoceptor blocking drugs; Beta-blockers

Definition

Beta-adrenoceptor antagonists (β-blockers), created by Sir James Black after research in the 1950s and 1960s, are well-known drugs in cardiology and circulatory diseases, and their role in psychiatry is limited. As their name implies, they inhibit the effects of adrenaline and ► noradrenaline on β-receptors, but the members of the drug class vary in their affinity for the two main types of β-receptor and in the extent to which they have stimulant (i.e., partial agonist) effects on these receptors. Stimulation of β_1-receptors by adrenaline has its main effects on the heart with increased speed of cardiac conduction velocity and cardiac output, with a lesser effect on the kidney in stimulating the release of renin. Stimulation of β_2-receptors induces tremor in striated muscle but relaxation in smooth muscle, and by increasing glycogenolysis in both liver and striated muscles, it promotes the production of glucose for increased pumping action. There are also β_3-receptors involved in the breakdown of fat (lipolysis), which may also have a role in smooth muscle and cardiac function, but their effects are minor compared with the other β receptors.

Pharmacological Properties

β_1-Adrenoceptor antagonists act on the receptors in heart and kidney and their blockade reduces the demands on cardiac muscle, and by concomitant reduction of renin secretion in the kidney, blood pressure is lowered. They also act on β_1-receptors in the eye and may be used to reduce glaucoma. β_2-blocking drugs act on receptors in skeletal muscle, smooth muscle in the gastrointestinal tract, liver, uterus, and lungs, and thereby reduce tremor in voluntary musculature, reduce the opening of bronchi in the respiratory tract, and lessen the breakdown of glycogen. It has also been suggested that β-adrenoceptor antagonists may block ► serotonin autoreceptors, and thereby have a role in the augmentation of antidepressant therapy with selective serotonin reuptake inhibitors, and one β-blocking drug, pindolol, has been used specifically for this purpose. However, this pharmacological action is far from being confirmed and remains a speculative suggestion. In general, the β_1-blocking effects are regarded as therapeutically valuable and β_2-blockade as unhelpful with a tendency to create adverse effects, of which reduced bronchial dilation, provoking asthma in susceptible subjects, is one of the most prominent. In higher doses, β-adrenoceptor antagonists have some central nervous system effects including drowsiness, insomnia, and impairment of reaction time, but it seems unlikely that these are due to β-blockade. As some drugs (e.g., sotalol, atenolol) are water soluble and do not penetrate the central nervous system easily, they may reduce the incidence of such effects. As some of the more peripheral indications for β-adrenoceptor antagonists (e.g., reduction of aggression) are likely, if confirmed, to be due to central nervous system action, this is relevant to the choice of drug. One of the well-documented adverse effects of β-adrenoceptor antagonists in general medicine is depression; it is not clear how this is generated.

Mechanisms of Action

There are many β-adrenoceptor antagonists; the main ones and their indications are summarized in Table 1. It is noted that very few of them are used for psychiatric purposes. The possible action of pindolol in promoting the effect of ► SSRI antidepressants mentioned earlier has not been tested with other drugs in this group; its value remains to be determined.

The β_1-blocking effects that are so helpful in cardiology have a potential use in the treatment of various forms of anxiety. There has been considerable argument over the mechanism whereby such effects are mediated. Most available data support the hypothesis that the action is a direct consequence of peripheral ► β-blockade, not of any central effects. This is based on several lines of reasoning: the fact that water-soluble β-blocking drugs are as effective as lipid-soluble ones in anxiety, the evidence that the specific somatic symptoms of tremor and palpitations are helped most by treatment, the lack of efficacy of the d-isomer of ► propranolol, which has no β-blocking activity, and the relatively low doses of drug necessary to reduce anxiety symptoms when compared with the higher doses normally associated with central nervous system effects.

Some studies have suggested that many other symptoms found in ► generalized anxiety, completely

unconnected to β-blockade such as sweating, irritability, nausea, and frequency of micturition, can also be helped by β-adrenoceptor antagonists. This may be true, but it does not follow that these are direct consequences of β-blockade. If a cardiac symptom such as palpitations is prominent in the expression of anxiety, its alleviation will reassure and help the patient so that other symptoms of anxiety are reduced as well.

The need for selection in β-blockade is less relevant in the treatment of anxiety unless the patient has cardiac comorbidity. The reduction of tremor is a result of β_2-blockade, and so nonselective β-adrenoceptor antagonists are preferred for this indication. Tremor is reduced at all frequencies and irrespective of its pathology, so the tremor accompanying treatment with lithium, the syndrome of parkinsonism, whatever its cause, and essential tremor are all equally influenced by the tremor reducing effects of propranolol and similar drugs. Exactly the same is true of anxious tremor, and the efficacy of nonselective β-adrenoceptor antagonists is most marked when tremor is a highly important and sensitive adverse or troublesome effect. Thus, the public speaker who is afraid of tremor affecting vocal performance, the snooker player who wishes to keep his cue direction absolutely still, and the violin player who wishes to confine tremulo and vibrato playing to only selected parts of public performance will all receive benefit from the effects of nonselective β-blockade. Indeed, such is the concern of the advantages gained by these drugs in competitive sports such as snooker and archery that they are now generally banned. The main clinical usage is in specific forms of ▶ social anxiety (phobia), in which blushing and tremor are prominent symptoms.

Other potential uses of β-adrenoceptor antagonists include the reduction of aggressive and challenging behavior, the treatment of schizophrenia (now virtually abandoned), and the management of movement disorders such as ► akathisia and ► tardive dyskinesia. Here, both the evidence and the ways in which β-adrenoceptor antagonists might assist in reducing the symptoms are very limited. It appears unlikely that peripheral β-blockade is relevant here, except possibly with the more simple movement disorders, but no other good explanation of action is forthcoming.

Value in Psychiatry and Psychology

The clinical usage of β-adrenoceptor antagonists drugs is discussed elsewhere in this volume (► generalized anxiety disorder, social anxiety disorder), and although there has been very little research into their efficacy in most recent years, they are still frequently prescribed for up to 10% of patients presenting with various forms of anxiety in primary care. In general, it is reasonable to consider the use of a β-blocking drug at least on a temporary basis, for patients who are especially troubled by symptoms such as blushing, tremor, palpitation, and general concern about excessive cardiac activity. They may also be helpful in reducing some of the withdrawal symptoms associated with cessation of benzodiazepines and similar drugs when they are accompanied by marked somatic accompaniments (► benzodiazepines, ► withdrawal syndromes). Most of the drugs are best given on an as required basis rather than regularly.

Binding

Definition

In general, the term binding refers to signaling molecule binding to target receptors. More specifically, binding represents an assay used both in vivo (PET studies) and in vitro for the characterization of receptor density and for the assessment of the affinity of a ligand versus a target receptor. This method is based on the use of radioligands (radioisotope-labeled compounds) specific for a target biding site.

Binding Potential

Synonyms

BP; BP_1; BP_2; BP_F; BP_{ND}; BP_P; V_3''

Definition

A composite parameter used in ▶ PET and ▶ SPECT imaging that is proportional to the product of receptor density and affinity of the radioligand for the receptor, or B_{max}/K_D. The binding potential is also equal to the limiting value of the ratio of receptor-bound to free radioligand as the free concentration approaches zero. The nature of the constant of proportionality depends on the free pool being referred to. When the binding potential is measured relative to a reference tissue, the constant of proportionality is f_{ND}, the free fraction of the free plus nonspecifically-bound ligand in brain, and the binding potential is termed BP_{ND}. When measured relative to the radioligand concentration in arterial plasma, the constant is f_P, the fraction of radioligand in arterial plasma that is not protein bound, and the binding potential is termed BP_P. Finally, if f_P is measured and accounted for so that the true free concentration in arterial plasma is known, the constant of proportionality is 1 and the binding potential is called BP_F. These naming conventions have been agreed upon relatively recently in the imaging community. In older literature, BP_{ND} was variously referred to as BP, BP_2, or V_3'' BP_P as BP or BP_1; and BP_F as BP.

Binge

Synonyms

Binge eating

Definition

An episode of binge eating, known as a binge, is a period of rapid food intake during which a person consumes more than would be expected of a normal individual over the same time period. To qualify as a binge, this episode must also be accompanied by a subjective loss of control and inability to stop eating. Binges most commonly involve foods high in fat or sugar, but this is not a requirement. Recurrent binge eating is a core symptom of bulimia and binge eating disorder.

Bioavailability

Definition

The fraction of the dose of a drug that is absorbed and that reaches the systemic circulation or target organ unaltered by a biotransformation. By convention, drugs administered intravenously have 100% bioavailability since 100% of the drug has reached systemic circulation. Bioavailability is one of the essential tools in pharmacokinetics and must be considered when calculating dosages for therapeutic use.

Bipolar Disorder

R. H. Belmaker
Ben Gurion University of the Negev, Beersheva, Israel

Synonyms

Bipolar illness; Manic-depressive illness

Definition

The unique phase of ► bipolar disorder is ► mania. In many ways mania is the opposite of depression and is characterized by elevated mood or euphoria, overactivity with a lack of need for sleep, and increased optimism that usually becomes so severe that judgment is impaired. Other drives such as sexual desire are also enhanced: manic patients are disinhibited in their speech about sexual matters, making jokes or talking about subjects not normally allowed in their culture. Manic patients are sometimes disinhibited in their sexual actions as well, and may endanger their marriages or relationships as a result. A key point is that manic behavior is distinct from a patient's usual personality, but may have a gradual onset over weeks or months before the syndrome is full-blown. In the absence of effective treatment, manic episodes could last months and years, although ultimately most are self-limited. Even after a long manic episode in the era before effective treatments, patients were known to recover to a state closely approximating, if not identical with, their premorbid personality.

The depression that alternates with manic episodes (bipolar depression) is characterized by the familiar symptoms of depression. A single manic episode is sufficient to diagnose bipolar illness. Some patients might have one manic episode at a young age and frequent depressive episodes for the rest of their life; others might have alternating manias and depressions on a yearly basis; still others might have manic episodes every 5 years and never a single depression.

Mild episodes of mania without psychotic symptoms and without symptoms dangerous to self or others are called hypomania. Hypomanic episodes can occur in patients with diagnosed full-blown bipolar illness, but they can also occur in patients with histories of depression only. This syndrome of major depressive episodes and hypomanic episodes has been called bipolar II and distinguished from the full-blown bipolar illness called bipolar I. However, the reliability of the diagnosis of bipolar II disorder is lower than for bipolar I disorder, and drug response and family history do not convincingly demonstrate that it is truly a milder version of full-blown bipolar disorder. Bipolar I illness affects approximately 1% of the population. Bipolar II disorder is reported to be much more prevalent, and a spectrum of bipolar disorders has been described that includes states of chronic mild hypomanic personality. However, the risks of the wide spectrum concept for the clinician include drug overprescribing and medicalization of psychosocial issues.

Patients who have four or more episodes of mania or depression a year are called rapid cyclers and are difficult to treat. However, life course studies are few and many clinicians find that a patient may have a period of a few years of rapid cycling and then go to much less frequent episodes, or vice versa.

The lifetime incidence of about 1% for bipolar disorder contrasts by an order of magnitude with the range of estimates of the prevalence of unipolar (i.e., nonbipolar) depression, which is a much more common phenomenon in the population. However, bipolar disorder, especially in its manic phase, is so destructive to work and family function that it constitutes a substantial public health problem even in comparison to the more common unipolar depression. The genetic and biochemical causes of bipolar disorder are still unclear.

Role of Pharmacotherapy

Management decisions for the bipolar patient include decisions on voluntary or involuntary hospitalization, achievement of a workable treatment setting for regular and affordable follow-up, and establishment of communication

with significant others to provide collateral history and warning of affective relapse. Without proper management, no pharmacotherapy can be effective. Many bipolar patients can be best managed in specialty clinics, once called "lithium clinics," but which now have a large armamentarium of effective treatments. Moreover, pharmacotherapy of bipolar disorder is now known to be best supplemented by one or more proven psychotherapies such as psychoeducation or social rhythms therapy (Osher et al. 2010).

Treatment of Acute Mania

Acute mania is a medical emergency. If not treated rapidly, a manic patient is likely to engage in activities that will endanger his or her marriage, job, and possibly, life. Acutely manic persons may seem rational one moment yet out of control the next. For example, a manic patient driving at 110 miles an hour through the city may have just had a rational conversation with his family physician in which he or she denied delusions or hallucinations and seemed pleasant, if speaking rapidly. It is critical to obtain collateral information from relatives, friends, or coworkers about such a patient's behavior in recent days to supplement the clinical interview.

Numerous effective treatments exist for acute mania (see Table 1). The neuroleptic drugs, also known as ► antipsychotics, are clearly effective in acute mania. These drugs are not recommended for long-term prophylaxis because of the danger of ► tardive dyskinesia. In the acutely manic patient, these medications have the advantage of readily available parenteral as well as oral forms, as well as rapid onset of psychomotor inhibition that may be lifesaving in the violent or psychotic patient. These medications are generally disliked by patients with milder disease, who are more compliant. The newer ► atypical antipsychotic medications are effective in these more compliant patients and may also pose lower risks of inducing depression as compared to classical neuroleptic drugs. Parenteral preparations of some atypical antipsychotic drugs are available. Some worrisome side effects of the atypical antipsychotic drugs include weight gain, lipid changes and glucose tolerance abnormalities. Thus, a patient who responded well in the past to a classic neuroleptic should probably be treated similarly for a recurrent manic episode (Belmaker 2004).

Research studies have demonstrated that ► lithium, ► valproate, and ► carbamazepine have proven efficacy in acute mania and are effective as monotherapy in clinical practice for occasional episodes of mild mania in the unusually compliant patient. Practice surveys, however, suggest that these drugs work too slowly for the great majority of patients with acute mania. Treatment should generally be initiated, then, with a typical or atypical neuroleptic and the addition of a mood stabilizer such as lithium, valproate, or carbamazepine as soon as oral

Bipolar Disorder. Table 1. Pharmacotherapies of bipolar disorder.

Treatment	Side effects	Indications	Effectiveness
Classical oral neuroleptics	Extrapyramidal syndrome, hypotension	Moderate to severe mania with good compliance	Highly effective, risk of depression
Clozapine	Agranulocytosis	Severe nonresponse	Highly effective
Atypical neuroleptics	Diabetes and weight gain (olanzapine) Hyperprolactinemia (risperidone) Q-T prolongation (ziprasidone) Sedation (quietiapine)	Replacing classical neuroleptics	Definite for moderate mania, not proven for severe mania
IM neuroleptics	As for oral neuroleptics	Noncompliance	Highly effective, risk of depression
Lithium	Polyuria, hypothyroidism, weight gain, nephropathy	Good compliance	Highly effective, slow onset, low risk of depression
Valproate	Rare hepatotoxicity, tremor, weight gain	Good compliance	Highly effective, slow onset, low risk of depression
Lamotrigine	Rare Stevens-Johnson Syndrome	Predominant depression	Good in depression, poor in mania
Carbamazepine	Rare hepatotoxicity, rash	Good compliance	Only small studies available
Clonazepam and lorazepam	Excessive sedation	Anxiety, psychomotor tension, insomnia	Questionable for core syndrome, useful adjunct

compliance is assured. The newer anticonvulsant lamotrigine is useful in prophylaxis of bipolar depression (see below) but its value in acute mania is unlikely (Cousins and Young 2007; Fountoulakis and Vieta 2008).

Treatment of Bipolar Depression

Bipolar depression (depressive episodes in a patient with bipolar illness) may respond to ► tricyclic antidepressants, serotonin-specific reuptake blockers, and ► monoamine oxidase inhibitors. The time course for response in a patient with bipolar depression is similar to that seen in unipolar depression. However, treatment for bipolar depression must be carried out with the knowledge that antidepressants may induce a switch from depression to mania. A patient with a history of at least one dangerous episode of mania that endangered family or work should probably avoid antidepressants, even if residual low mood or low energy continues. However, patients who have had one diagnosable moderate episode of mania in which neither self-injury nor damage to family occurred but who have had recurrent crippling depressions following the single manic episode may benefit from an antidepressant without sustaining undue risk (Belmaker 2007).

Some studies suggest that newer antidepressants such as ► selective serotonin uptake inhibitors (SSRIs) or bupropion are less likely to induce mania in persons with bipolar depression, but the relevant data are often restricted to patients with very mild manias ("bipolar II") and should not be extrapolated to all patients with bipolar illness. Omega-3 fatty acids are experimentally reported to be antidepressant in preliminary studies and might potentially be a new direction for treatment of bipolar disorder. Inositol is another natural compound that has been experimentally studied in bipolar depression (Belmaker and Agam 2008).

Mood Stabilizers and Prophylaxis

Lithium is the quintessential and classic mood stabilizer. ► Lithium was developed in an era in which drug regulatory agency standards were less stringent, and the newer agents used for mania may be promoted as the only treatments that meet particular methodological standards. However, over a 50-year period, lithium has been shown to have antimanic efficacy, prophylactic efficacy in bipolar disorder, and some efficacy in prophylaxis of bipolar depression. Lithium has a narrow therapeutic index and must be monitored with blood levels. Severe toxicity and sometimes death can occur when renal excretion is impaired even by such apparently innocent changes as initiation of diuretic treatment for hypertension. Progressive renal failure after decades of lithium use has been reported, though some have questioned the specificity of lithium as the causative agent in these cases (Lepkifker et al. 2004).

► Carbamazepine was the major anticonvulsant drug reported to treat bipolar illness through the 1980s. In the 1980s it was estimated that as much as one half of the sales of carbamazepine were for bipolar illness. Throughout the 1980s large numbers of small studies reported therapeutic efficacy for carbamazepine in mania, bipolar depression, and bipolar disorder prophylaxis, sometimes as monotherapy but often as an add-on to other treatment. This literature has lately been reevaluated critically in the light of the standards required for licensing of new anticonvulsants for bipolar disorder by the US Food and Drug Administration (FDA), and sometimes found wanting. However, the clinician must include the relative long and successful clinical experience with this compound in his judgment.

► Valproate was the next anticonvulsant reported to have anti-bipolar properties. As with carbamazepine, the first reports were from outside the USA and these early reports were criticized by Americans as poorly controlled. However, when an American pharmaceutical company, Abbott, reached agreement with the FDA to patent a new formulation of valproic acid, a large-scale controlled study was carried out, leading to a profitable compound on the American market, divalproex sodium. Some feel that divalproex sodium is of dubious pharmacologic advantage over valproic acid, and despite heavy advertising and promotion of divalproex sodium, lithium still controls a large market share of treatment of bipolar disorder in the US and elsewhere. A large study suggests that lithium prophylaxis is more effective than valproate prophylaxis in the prevention of suicide in bipolar disorder (Goodwin et al. 2003).

The success of carbamazepine and valproate and the recent development of newer anticonvulsant drugs for epilepsy have led to their use in bipolar disorder as well. Case reports and small studies suggest that ► topiramate is effective in bipolar illness, although a large study sponsored by Janssen-Cilag failed, perhaps because of a large number of mild, antidepressant-induced manias that subsided in the placebo group. ► Lamotrigine has also been reported to exert a positive effect in bipolar illness, particularly in the depressive phase of the disorder. Clinicians for many years have felt that lithium, valproate, and carbamazepine more successfully control the manic phase as compared to the depressive phase of bipolar disorder, and a clear need exists for a depression-oriented drug in bipolar disorder. A large company-sponsored study suggested that lamotrigine was effective in prophylaxis in bipolar

depression as compared to lithium and placebo. However, the actual size of the effect was small, and criticism has been raised as to whether an excessive number of lithium non-responders are attracted to such a study.

► Benzodiazepine drugs, which act on the benzodiazepine receptor component of the GABA-benzodiazepine complex, are effective in status epilepticus, and these drugs may be useful adjuncts for the treatment of mania, reducing tension, and improving sleep as discussed above; however, they do not seem to have true "antimanic" efficacy. ► Gabapentin has been studied in a well-designed fashion and is not antimanic despite earlier reports suggesting this. ► Zonisamide and felbamate are also new anticonvulsants for which efficacy in bipolar disorder has been suggested in some case reports, but they have not yet been studied in a controlled fashion.

Dopamine receptor-blocking drugs (neuroleptics) that are used in schizophrenia are therapeutic in acute mania (American Psychiatric Association 2002). A few studies have found them efficacious in bipolar prophylaxis as well, but the risk of tardive dyskinesia limited their use in bipolar disorder. More recently, atypical neuroleptic drugs such as ► clozapine, ► quietiapine, ► olanzapine, ► risperidone, and ► ziprasidone have been found to have efficacy in at least some phases of bipolar disorder. Such efficacy blurs the distinction between antischizophrenic therapy with neuroleptics and mood stabilizer therapy, and future prophylactic studies with atypical antipsychotics in bipolar disorder will perhaps lead to an entirely new diagnostic system for psychoses (Aubry et al. 2007).

While lithium or an anticonvulsant provide many bipolar patients remarkable prophylaxis over many years, referral centers see large numbers of patients with breakthrough manias and even more commonly, breakthrough depression. The effectiveness of using a polypharmacy approach – lithium plus anticonvulsant, two anticonvulsants, lithium plus atypical neuroleptic, and occasionally lithium plus antidepressant – are all supported by research data (Post et al. 1996).

The ethics of future trials of anti-bipolar drugs are controversial. A manic episode can be a life-threatening condition and many psychiatrists and physicians feel that bipolar patients, given the existence of effective treatment, should not be recruited for placebo-controlled trials. The FDA, however, continues to demand in most cases placebo-controlled monotherapy trials for registration of new compounds in psychiatry. Some statisticians support the FDA position, calculating that more patients will be exposed to poor treatment if no placebo control is used, since it may take a much higher number of subjects to prove lack of efficacy of a new treatment as compared to a standard control medication such as lithium. These statistical calculations do not take into account the distortions induced by unrepresentative patient populations in placebo-controlled studies, since only a very select group of patients consent to participate in such studies. The clinician must not only consider, in deciding on treatment, the results of randomized placebo-controlled trials but also the history of smaller trials and clinical experience with a specific compound. Moreover, bipolar disorder is likely a heterogeneous illness with early-onset forms, late-onset forms, forms with mostly depressions and forms with mostly mania, forms with mild mania, and forms with severe psychotic mania. Studies of large numbers of patients meeting criteria for bipolar disorder do not always provide clear guidance to the physician regarding specific cases. For instance, patients with mostly depressions may have a favorable risk-benefit ratio for prophylactic treatment with a lithium-antidepressant combination even if this is not indicated for all, or even most bipolar patients. In addition, many patients do not respond to treatments that are evidence based on the strict criteria of large ► randomized placebo-controlled studies (2002). At that point in treatment the physician must rely on smaller studies and pharmacologic extrapolation to plan individualized, creative treatment. This often works and can make the difference between severe disability and a useful life for bipolar patients who do not respond to standard treatment guidelines.

Definition

Bipolar disorder (BD) is a chronic psychiatric condition that occurs throughout the life cycle. It is characterized by several different mood states (► bipolar disorder). Pediatric BD (PBD) is oftentimes associated with psychiatric comorbidity. When bipolarity does occur in children and adolescents, it is usually serious, chronic, and debilitating (McClellan et al. 2007). Therefore, treatment research has considered means by which to reduce the symptomatology and suffering associated with BD in the young.

Role of Pharmacotherapy

For adults, pharmacotherapy is the cornerstone of intervention for BD. However, agents that may be safe and effective for the treatment of BD in older patients may not be associated with similar outcomes in juveniles. For that reason, treatment studies of methodological stringency that consider medication response in youths with BD are needed in order to make scientifically informed treatment decisions. Unfortunately, very less is known about the pharmacotherapy of BD in youths when compared to what is known in adults.

It should be noted that the overwhelming majority of pharmacotherapy studies in BD have examined the acute treatment of manic or mixed episodes, rather than depressed states. This is likely due to the observation that youths with BD appear to suffer from depressive episodes substantially less frequently than adults (Findling 2008). There is an unfortunate paucity of data regarding intervention in juvenile BD's psychiatric comorbidities, its maintenance treatment, and intervention studies in symptomatic genetically at-risk youths. Thus, this summary will focus on what is known about the acute treatment of manic and/or mixed states in this patient population.

Lithium

► Lithium is a benchmark treatment for the pharmacotherapy of BD in adults. It was the first treatment approved by the United States Food and Drug Administration (FDA) for use in adolescents of ages 12 and older with BD. However, it should be noted that this approval was not based on definitive, well-controlled studies of adolescent patients. While there have been multiple studies on the use of lithium for the treatment of BD in children, most have lacked methodological rigor (Findling and Pavuluri 2008). As a result, the lithium treatment for youths suffering from BD is oftentimes based upon extrapolation from adult research.

Lithium has been shown to have a narrow therapeutic window (0.6–1.2 mEq/L). For that reason, dosing is a key consideration for this drug in order to maximize clinical benefit while minimizing potential risks and toxicities. In the absence of data specifically considering this topic, it has been assumed that therapeutic levels of lithium in children and adolescents are the same as in adults. As a result of this assumption, dosing strategies that yield "adult" therapeutic levels of lithium have been developed for youths. One possible strategy is to initiate lithium at a dose of 20 mg/kg/day, or 900 mg/day (whichever is less) divided into two or three daily doses. The initial dose is then gradually increased to achieve a target blood level of 0.6–1.2 mEq/L. Doses are generally not increased if (1) blood levels of the drug exceed 1.2 mEq/L, (2) side effects preclude dose increases, or (3) adequate symptom reduction has already occurred (Findling and Pavuluri 2008).

In regard to effectiveness, lithium has been reported to be associated with reductions in symptomatology as a drug monotherapy in multiple reports pertaining to its use in young people suffering from manic or mixed states. However, it has been repeatedly noted that while many patients benefit from lithium monotherapy, a substantial number of young patients do not fully achieve remission when prescribed lithium alone. For that reason, lithium is a drug that has been examined under the auspices of combination drug studies. In such clinical trials, benefit

from drug combinations that include lithium as an agent has been described.

As far as safety is concerned, the side effects that can occur in adults treated with lithium may also occur in young patients who are administered this agent. Although it has been asserted that younger children may be more vulnerable to lithium-related side effects than older adolescents, this assertion has yet to be definitively confirmed or refuted.

In summary, despite the lack of definitive efficacy studies, lithium appears to be a reasonably safe and generally effective treatment of acute mixed and manic states in pediatric patients, both as monotherapy and when co-administered with other mood stabilizers. Definitive studies pertaining to the dosing, short-term efficacy, maintenance treatment, and safety (both acute- and long-term) are currently underway.

Anticonvulsants

Several medications originally marketed as ▶ anticonvulsants have been shown to be beneficial in treating BD in adults. As a result, it was believed that these medications may have mood-stabilizing properties in PBD as well. What follows is a summary of what is known about this class of medication in PBD.

Carbamazepine

While there have been studies demonstrating the efficacy of ▶ carbamazepine in the treatment of adults with mania, there are limited data regarding the safety and efficacy of this drug in the treatment of PBD. In an open-label study in which patients were randomly assigned to receive lithium, divalproex, or carbamazepine, clinically meaningful benefit was reported for all three study groups. In addition, carbamazepine was reasonably well tolerated in the study with no serious adverse outcomes reported. Some case reports have suggested that carbamazepine can be effective in adolescents with mania that have been nonresponsive to lithium. In addition, it has been suggested that the combination of lithium and carbamazepine may be a reasonable treatment option. On a cautionary note, there have been case reports that suggest that carbamazepine may actually worsen mania. Despite these preliminary observations, there are no randomized placebo-controlled studies on the use of carbamazepine in the treatment of BD in children and adolescents, and definitive proof of its safety, tolerability, and efficacy, both as monotherapy and as an agent used in combination with other compounds, remains to be established (Danielyan and Kowatch 2005).

Divalproex (▶ Valproate)

Divalproex sodium has demonstrated efficacy in the treatment of adults with acute mania. However, much of the data on the use of divalproex in the pediatric population are from case reports. One randomized, double-blind, industry-sponsored study investigating the use of divalproex in 150 children and adolescents with BD found no statistically significant improvement in acute manic symptoms when compared with placebo. However, another randomized, NIMH-supported double-blind trial investigating 153 youth found that divalproex was superior to placebo for treating children and adolescents with BD during a mixed or manic episode. A possible explanation for the discrepant results of these two studies may be due to issues related to between-site variability. The NIMH-supported study was conducted at substantially fewer sites than the industry-supported trial. Furthermore, there have been combination studies that suggest that divalproex may be beneficial when co-administered with lithium, quetiapine, or risperidone (Findling and Kuich 2008).

Common side effects of divalproex in children are weight gain, nausea, sedation, and tremor. In addition, particular concern has been raised regarding the relationship between divalproex and the development of polycystic ovarian syndrome (PCOS) in girls. Therefore, it is recommended that clinicians should monitor female patients treated with divalproex for any signs of PCOS, including weight or menstrual abnormalities, hirsutism, or acne.

Topiramate

Preliminary data has indicated that ▶ topiramate may be effective for PBD. These data come primarily from a study that was discontinued prematurely secondary to early evidence that topiramate was not beneficial in treating BD in adults. However, when these preliminary data were analyzed from the pediatric study, it was found that topiramate would have likely proven beneficial had the study continued (DelBello et al. 2005). Key side effects of topiramate include anorexia, weight loss, and sedation. It should be mentioned that although there are no methodologically rigorous data on this topic, some clinicians appear to utilize topiramate's weight loss properties and prescribe this drug as an adjunctive treatment for youth with BD who have gained weight as a result of treatment with other psychotropic agents.

Oxcarbazepine

A randomized, double-blind placebo controlled study by Wagner and colleagues investigated the use of ▶ oxcarbazepine versus placebo in 116 youth with BD. The

authors found that the response to oxcarbazepine was no different than the response seen with placebo. As a result, these findings do not support the use of oxcarbazepine as monotherapy in the treatment of the manic phase of PBD (Wagner et al. 2006).

Gabapentin

► Gabapentin has not been found to be effective for the treatment of BD in adults, and there is currently no evidence to support its use in the treatment of PBD (Smarty and Findling 2007).

Lamotrigine

► Lamotrigine has been shown to be efficacious for the maintenance treatment of bipolar disorder in adults, and data support its use in the long-term treatment of bipolar depression in adults. There have been open studies indicating that lamotrigine may be beneficial for adolescents with bipolar depression as well. However, randomized, controlled studies are still needed. The risk of potentially lethal cutaneous reactions, such as Stevens–Johnson syndrome and toxic epidermal necrolysis, is greater in youth younger than 16 years old than in adults. However, dosing guidelines using a more conservative dose titration lower the risk of such serious rashes.

Antipsychotics

► Atypical antipsychotics (► antipsychotic drugs) have been shown to be efficacious in treating bipolar disorder in adults. Evidence from recently completed placebo-controlled trials provide evidence that atypical antipsychotics may be beneficial for the acute treatment of manic and/or mixed states in youths suffering from bipolarity. However, as with adults, the possible metabolic complications of these drugs are important considerations, particularly over the long term. Unfortunately, there is a paucity of information about the long-term effects of these agents in juveniles. In addition, there are no methodologically stringent studies that have specifically compared the safety and efficacy of one atypical to another. Moreover, there are almost no data about the use of ► typical antipsychotics in this patient population.

Clozapine

There is some evidence from open trials and case reports that ► clozapine may be beneficial in the treatment of PBD patients who have not shown adequate response to other agents. However, the side effects of clozapine, which may include sedation, weight gain, increased salivation, seizures, and myocarditis, as well as potentially lethal agranulocytosis, limit the usage of this medication. For these reasons, clozapine is generally recommended only for children and adolescents who have not responded to multiple treatment courses with other medications.

Risperidone

► Risperidone, either as monotherapy or in combination with a mood stabilizer, has been reported to be effective in the treatment of juvenile bipolarity in case reports and open-label studies. Of note, one randomized, placebo-controlled study of youth with bipolar disorder found that risperidone was efficacious and relatively well tolerated at doses as low as 0.5–2.5 mg per day in the acute treatment of manic or mixed episodes in youth ages 10–17.

Olanzapine

One double-blind, randomized, placebo-controlled trial in adolescents 13–17 years of age with a manic or mixed episode found that ► olanzapine, at doses between 2.5 and 20 mg per day, was superior to placebo in the treatment of these adolescent patients. However, the study also found that youths treated with olanzapine had significantly greater weight gain and increases in the levels of hepatic enzymes, prolactin, fasting glucose, fasting total cholesterol, and uric acid when compared to those treated with placebo (Tohen et al. 2007).

Quetiapine

Quetiapine was one of the first atypical antipsychotics to be studied in a double-blind, placebo-controlled trial for the treatment of mania in adolescents. This study found that combination therapy with ► quetiapine and divalproex was more effective than divalproex and placebo in the acute treatment of adolescents suffering from manic or mixed episodes (DelBello et al. 2006). In addition, a randomized, placebo-controlled study of 277 participants, ages 10–17, concluded that quetiapine, at doses of 400 and 600 mg/day, was significantly more effective than placebo in treating acute manic symptoms in children and adolescents with bipolar disorder.

Ziprasidone

Ziprasidone has been shown to be effective in treating mania in adults. In addition, ► ziprasidone is typically associated with less weight gain than risperidone and olanzapine. One randomized, double-blind, placebo-controlled study of 150 youth ages 10–17 years old with bipolar disorder found that ziprasidone at doses of 80–160 mg per day was effective and generally well tolerated.

Aripiprazole

One randomized, double-blind, placebo-controlled study has shown ► aripiprazole, at doses of 10 and 30 mg, to be superior to placebo in the acute treatment of manic and mixed episodes of children and adolescents with bipolar disorder.

Conclusion

Historically, the pharmacological treatment of pediatric bipolar disorder in clinical practice was based on data collected from the treatment of adults with this disorder. More recently, clinical trials have been conducted in PBD and new data are now available, particularly concerning the efficacy of the atypical antipsychotics in treating children and adolescents. However, some medications that have been shown to be useful in treating adult patients remain unstudied in children. In addition, long-term safety and efficacy data are lacking for many drugs. Thus, unknown risks to this vulnerable population may exist. However, with continued research and forthcoming data from ongoing trials, clinical decisions predicated on scientifically stringent evidence will become increasingly feasible.

Definition

Blocking is a reliable cross-species learning effect. It has been studied primarily using ► Classical (Pavlovian) Conditioning in which animals come to show their learned anticipation of a biologically significant outcome, typically food or foot shock, through a behavioral conditioned response. This conditioned response often resembles the unconditioned response for the outcome (► unconditioned stimulus, UCS) – for example, in Pavlov's original studies, the salivation response to food came to be elicited by a bell, termed the ► conditioned stimulus (CS), that preceded food delivery. This anticipatory responding allows us to quantify the strength of the conditioned association.

Importantly, classical conditioning is selective to the best predictors of outcomes, raising the possibility that

here is a mechanism allowing animals to build up a representation of the causal structure of the environment. In any event, in the absence of selectivity, the learning mechanism would be overloaded and inefficient. The blocking effect, discovered by Kamin in 1968, is an example of selectivity based on the redundancy of a potential CS (B). This redundancy arises because there already exists a reliable CS (A) for the outcome in question.

Impact of Psychoactive Drugs

The impact of psychoactive drugs on blocking can only be evaluated with respect to the behavioral controls in place, and these vary from study to study. Blocking in its simplest form is demonstrated in a two-stage procedure: (Stage 1) present A followed by the UCS; (Stage 2) present A in combination with B, followed by the same UCS. Ideally, several controls are needed: For example, because A might be intrinsically more salient than B, the best designs counterbalance the stimulus identities; most importantly, because conditioning to B might be reduced due to competition with A, the Stage 2 conditioning is also compared with that seen in a separate group of animals conditioned to the compound. This control group is given equivalent Stage 2 training in the absence of any Stage 1 pre-training with A. Thus, we can separate out the reduced conditioning to B, which results from direct cue competition through ► Overshadowing as distinct from the pre-training with A to establish B as redundant. Overshadowing refers to the attenuation of learning to B as a consequence of conditioning in compound with A, relative to a group who are conditioned to B in isolation. The most essential experimental comparison groups to demonstrate blocking and overshadowing are shown in Table 1.

Thus, blocking is typically examined together with overshadowing in the same procedure. The fact that the blocking effect is reliably demonstrated over and above the reduction in learning to B produced by overshadowing in the control group suggests that it may rely on additional mechanisms (beyond direct cue competition). At the psychological level, the prior learning in Stage 1 is most likely an important factor.

Related Selective Learning Effects

There exist a number of other selective learning phenomena, likely to be related to blocking or overshadowing in terms of underlying mechanisms. Like blocking, ► Latent Inhibition is a two-stage procedure in which Stage 1 experience reduces subsequent Stage 2 conditioning. A variety of mechanisms have been proposed to contribute to this effect (Escobar et al. 2002; Gray et al. 1991; Hemsley 1993; Weiner 2003). For example, selectivity in learning could arise from changes in the effective salience of less predictive cues or interference between competing associations. Like overshadowing, ► Relative Validity procedures show the superiority of one available CS at the expense of another. In this case, the best predictor is established on a probabilistic basis over a number of conditioning trials. All of these selective learning effects reflect competition between the range of experimental cues available, including those provided by the context.

Blocking as an Endophenotype for Schizophrenia

Selective learning effects like blocking have become targets for translational research. Overconditioning to cues that would normally be treated as irrelevant or redundant provides an ► Animal Model of disorder. First, when selectivity in learning fails, the animal is flooded with a profusion of potential conditioning cues and aberrant associations will be formed. Second, the neural substrates implicated in selective learning effects point to a key role for the dopamine system known to be dysfunctional in ► schizophrenia (Gray et al. 1991; Hemsley 1993; Kapur 2003; Weiner 2003). Furthermore, studies with human participants show that the normal blocking effect is abolished in schizophrenia (Fig. 1). Thus, like impaired latent inhibition, impaired blocking shows excellent validity, both at the behavioral and the neurochemical level, as an ► Endophenotype for schizophrenic attention deficit (Gottesman and Gould 2003).

Blocking, Overshadowing and Related Concepts. Table 1. Basic design to show a blocking effect (learning in group 2 minus learning in group 1) and overshadowing (learning in group 3 minus learning in group 2). A and B represent the alternative CSs.

Blocking, Overshadowing and Related Concepts. Fig. 1. Blocking in human participants shown in normal participants as an increased number of trials (to the learning criterion) required in the blocking condition relative to the overshadowing controls. This blocking effect was abolished or even reversed in schizophrenic participants (Schiz) and their relatives (Rels), irrespective of levels of schizotypy (st) as measured by questionnaire. Blocking, Overshadowing and Related Concepts. Fig. 2. Overshadowing shown as reduced learning relative to the conditioning control group in a standard fear conditioning (lick suppression) procedure. The dependent variable is the log transform of the time taken to complete 10 licks in the presence of the CS. Overshadowing was shown in the saline- (SAL) and haloperidol- (HAL) injected groups. Overshadowing was abolished by treatment with amphetamine (AMP) and the amphetamine-induced abolition of overshadowing was not reversed by treatment with haloperidol, suggesting that dopamine D2-like receptors do not mediate the amphetamine-induced abolition of overshadowing. Animal Studies of Blocking and Overshadowing

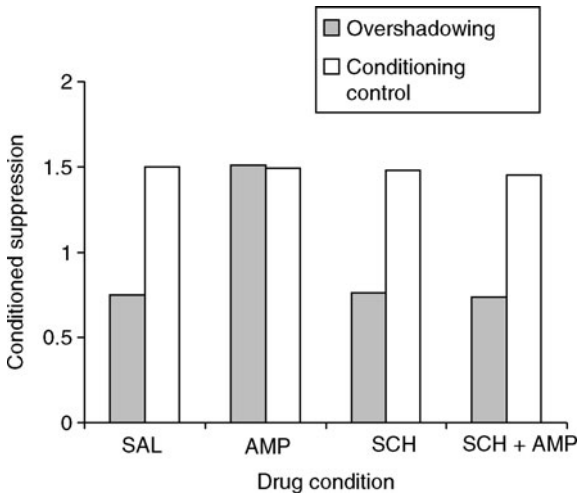
In animals, psychopharmacological studies have shown that treatment with indirect ▶ dopamine agonists given systemically (typically ▶ amphetamine at around 1.5 mg/kg in rats) abolishes blocking and overshadowing. In every case, abolition of the normal effect results in overconditioning, with the consequence that the CS that would normally be treated as uninformative, whether because of redundancy in the case of blocking or relatively low intensity in overshadowing, accrues more associative strength than in non-drug-treated groups (Cassaday and Moran 2010).

In part for practical reasons, because of the need to test for dose-related effects, psychopharmacological studies are not always run with full behavioral controls. In the case of blocking, further reduction in learning produced by the Stage 1 pre-training can be a relatively small effect when compared to that seen in an overshadowing group. In some studies, apparent amphetamine-induced abolition of blocking may be entirely attributable to impaired overshadowing under amphetamine (Fig. 2).

However, patients with schizophrenia have been reported to show impaired blocking, over and above any change in overshadowing (Fig. 1) and in animal studies blocking and overshadowing may be dissociable in terms of their differential sensitivity to dopamine D2-like (Fig. 2) vs. dopamine D1-like (Fig. 3) receptor agents.

With respect to the neural mediation of the systemic effects of amphetamine, dopamine activity in part of the ventral striatum, specifically ▶ nucleus accumbens, has been reported to modulate blocking in the absence of any effect on overshadowing in the control group (Fig. 4). Similarly, the evidence for a pivotal role of nucleus accumbens and related structures is overwhelming in the case of latent inhibition (Gray et al. 1991; Weiner 2003). However, it is important to note that the nucleus accumbens is a heterogeneous structure and opposing effects of drug treatments and lesions can be seen in relation to very small differences in the laterality of the cannula placement. Moreover, the evidence with respect to the neural substrates of other selective learning phenomena is patchy, in part because of the poor selectivity of the lesion methods used to date. Techniques in neuro-psycho-pharmacology such as lesions selective to dopamine and precisely targeted microinjection studies are required to delineate the underlying substrates of



Blocking, Overshadowing and Related Concepts. Fig. 3. Overshadowing shown as reduced learning relative to the conditioning control group in a standard fear conditioning (lick suppression) procedure. The dependent variable is the log transform of the time taken to complete 10 licks in the presence of the CS. Overshadowing was shown in the saline- (SAL) and SCH23390- (SCH, dopamine D1-like antagonist) injected groups. Overshadowing was abolished by treatment with amphetamine (AMP) and the amphetamine-induced abolition of overshadowing was reversed by treatment with SCH23390, suggesting that dopamine D1-like receptors mediate the amphetamine-induced abolition of overshadowing. Blocking, Overshadowing and Related Concepts. Fig. 4. Blocking shown as a low percentage of baseline learning in a contextual fear conditioning procedure. The comparison group controls for overshadowing by context which it can be seen was unaffected by any of the drug treatments. Blocking was increased by injection of amphetamine in n.acc and decreased by combined D1 and D2 receptor antagonism produced either by injection of cis-(z)-flupenthixol or combined treatment with SCH23390 and sulpiride. In isolation, SCH23390 and sulpiride were without effect, suggesting that a combined action at dopamine D1-like and D2-like receptors mediates the amphetamine-induced abolition of blocking. blocking, overshadowing, and related effects. To date, the role of dopamine has been an understandable focus for pharmacological studies, principally of latent inhibition, though also of blocking and other selective learning effects, due to the fact that established ► antipsychotics are dopamine antagonists. The modulation of these effects by other neurotransmitter systems remains to be established. For example, based on the known effects of serotonergic treatments on latent inhibition (Weiner 2003), ► serotonin would similarly be expected to modulate blocking and related effects.

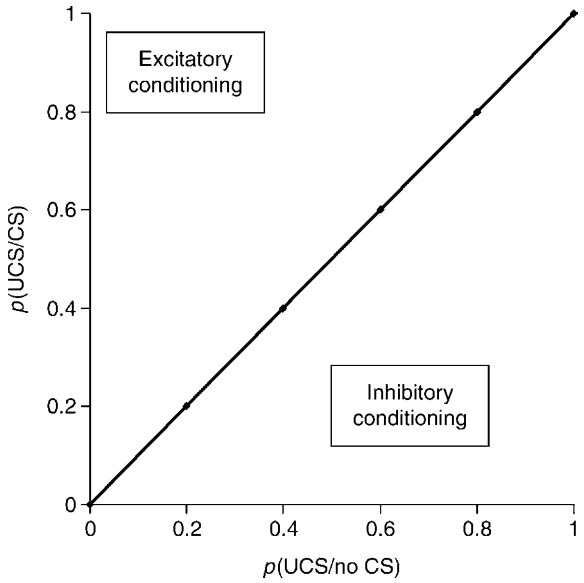
Blocking and Prediction Error

The blocking effect has been targeted, to understand the biological basis of attentional abnormality, to a large extent without a full consideration of its underlying psychological mechanisms. This situation may soon be remedied in that blocking has recently assumed prominence as a tool to investigate the neural basis of ► Prediction Error. Prediction error is fundamental to normal associative learning because it provides the basis on which to learn when there is a discrepancy between what is expected, and what actually occurs. Thus, uncertainty is an important factor in determining attention in learning and dominant learning theories propose that new learning requires that an association is not already at full strength. Positive prediction error generates excitatory conditioning; negative prediction error generates inhibitory conditioning (Fig. 5).

Electrophysiological studies show the pivotal role of ► dopamine as a neurochemical substrate of prediction error (Schultz 2006; Schultz and Dickinson 2000). Blocking was the key paradigm that drove our understanding of associative learning in terms of prediction error: the Stage 1 pre-training means that the UCS is fully predicted by the time that the competing cue is introduced in Stage 2. Thus, there can be no prediction error and thus no additional conditioning to the redundant cue. However, prediction error can be systematically manipulated by changing the UCS delivered. If the UCS is other than expected, ► Unblocking occurs. This can take the form of additional excitatory conditioning to the additional CS

if the UCS is more than expected (e.g., a higher intensity foot shock is delivered in upshift unblocking) or inhibitory conditioning to the additional CS if the UCS is less than expected (e.g., a lower intensity of foot shock is delivered in downshift unblocking). Electrophysiological studies have confirmed that some of the same populations of dopamine neurons that show increased activation following the presentation of excitatory CSs, that signal "more than expected," show depressed neuronal firing following the presentation of inhibitory CSs, that signal "less than expected" (Schultz 2006). These neurons show no change in neuronal firing when there is zero prediction error, in other words when things remain "as expected." Such a case is provided in the blocking procedure. Pretraining with CS A normally blocks learning about CS B because the prediction error is small. The standard blocking procedure is readily adapted to study the neural bases of excitatory and inhibitory learning (Fig. 5) by manipulating the UCS delivered (Table 2).



Blocking, Overshadowing and Related Concepts. Fig. 5. Positive prediction error when the probability (*p*) of the UCS is increased on presentation of the CS in question generates excitatory conditioning. Negative prediction error when the probability of the UCS is decreased on presentation of the CS in question generates inhibitory conditioning. When *p*(UCS/CS)=*p*(UCS/no CS) along the diagonal trend line, there can be no new learning.

Thus, blocking and unblocking variants provide target tasks to identify the neuropharmacological substrates of prediction error, for example, using microinjections into the nucleus accumbens (Fig. 6).

Thus, analysis of blocking from an associative learning theory perspective has identified the same underlying neural substrates that are the target of translational studies of blocking as an endophenotype for schizophrenia. At the behavioral level, abnormalities in the processing of prediction error may be the cause of the formation of inappropriate associations in schizophrenia. In other words, studies of prediction error, known from electrophysiological studies to depend on the dopamine system, also further our understanding of dopaminergic disorders such as schizophrenia. Deficits in blocking, seen both in schizophrenia and under amphetamine, represent a paradigm instantiation of abnormalities in the processing of prediction error. Future studies of the relevant neural substrates of prediction error should include, but are not restricted to, those identified in blocking procedures. Downstream from these Pavlovian effects, abnormal processing of prediction error has been linked to abnormalities of action, including drug addiction where overconditioning in hyperdopaminergic states could promote cue-driven relapse because of the increased representation of drug-related cues (Montague et al. 2004; Schultz and Dickinson 2000).

Advantages and Limitations of Blocking and Overshadowing

Latent inhibition, now well established as a model for schizophrenia, shows the predicted sensitivity to psychoactive drugs, and human participants with schizophrenia

Blocking, Overshadowing and Related Concepts. Fig. 6. Blocking shown as a low percentage of baseline learning in a fear conditioning procedure. Unblocking was produced by halving the UCS (shock intensity) and was demonstrated as relatively increased percentage learning. The control level of learning was around 50%. show impaired latent inhibition (though this demonstration depends on medication status). Similarly, there is good evidence for impairments in blocking in schizophrenia; hence blocking provides a potential animal model in which to assess the effects of psychoactive drugs; for example, to distinguish the role of dopamine D1 and D2 receptor families in this aspect of attentional learning, as distinct from overshadowing (Figs. 2–4). Much of this work has yet to be done, in part because reliable parameters to demonstrate blocking can be difficult to establish. An additional disadvantage in the use of blocking arises because a fully controlled study necessitates the use of an overshadowing comparison condition and overshadowing is itself affected by some of the same dopaminergic treatments. Future studies should address this confound. However, overshadowing remains of interest in its own right as a procedure to present stimuli that should normally show reduced salience for learning, to test for overconditioning to weak cues in hyper-dopaminergic states (Cassaday and Moran 2010; Gray et al. 1991; Kapur 2003).

In principle, blocking has an additional attraction in that it relates an issue of fundamental importance in normal associative learning, namely the role of surprise, encapsulated in the study of prediction error. Through unblocking manipulations, we can study the liberation of attention by surprise and drug effects thereon. However, the reliable demonstration of unblocking can require extensive behavioral pilot work. Moreover, attention is only half the story in that successful associative learning should reflect the direction of change when the outcome is more or less than expected. Aficionados have noted that inhibitory learning is not consistently demonstrated in aversively motivated downshift unblocking procedures – on the contrary, a weaker UCS than expected can result in excitatory conditioning to the additional CS B (Fig. 6).

Definition
Blonanserin is a second-generation (atypical) antipsychotic drug indicated for the treatment of schizophrenia. It belongs to a series of 4-phenyl-2-(1-piperazinyl)pyridines and acts as an antagonist at D_2, D_3, and 5-HT_{2A} receptors. Its affinity for D_2 receptors is approximately six times greater than that for 5-HT_{2A} receptors. It has low affinity for α_1, 5-HT_{2C}, H_1, and M_1 receptors, but displays relatively high affinity for 5-HT_6 receptors. Its safety profile compared favorably with haloperidol, particularly with respect to prolactin elevation and the frequency of extrapyramidal motor side effects.

Current Concepts and State of Knowledge

Basic Properties of the Blood–Brain Barriers

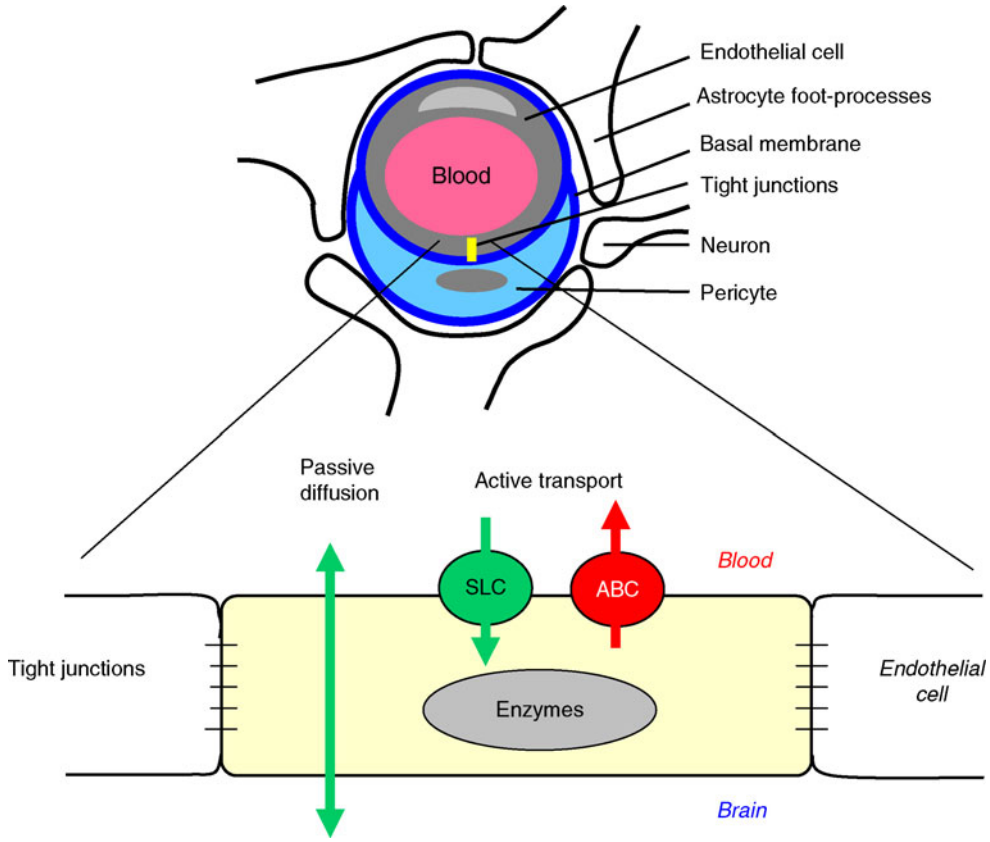
The Two Barriers
The general concept of a restricted passage of solutes out of the blood into the brain dates from the early studies of Lewandowsky and Ehrlich in the 1900s who described that dyes injected intravenously were not taken up by the brain (Goldstein and Betz 1986). Only a few small regions of the brain, collectively known as the ► circumventricular organs making up less than 1% of the cerebrovascular bed have no barrier, enabling substances in the blood to reach the brain extracellular fluid.

There are two physiological barriers separating the brain from its blood supply; they control the entry and exit of endogenous and exogenous compounds. This allows the body to maintain a constant internal milieu in the brain, protecting it from fluctuations in circulating hormones, amino acids, ions, and other nutrients, thereby preventing uncontrolled disturbances of the central nervous system (CNS). One is the blood–brain barrier (BBB), and the other is the ► blood–cerebrospinal fluid barrier (BCSFB). In 1919, Goldmann carried out experiments with trypan blue injected directly into the cerebrospinal fluid. These studies helped to differentiate the two barriers, as the dye left only the blood vessels of the choroid plexuses. The BCSFB is located at the choroid plexuses. These plexuses float freely in the brain ventricles and are formed by epithelial cells held together at their apices by tight junctions (junctional complex between two cells whose membranes join together forming an impermeable barrier to fluid). Beneath the epithelial cells is a stroma containing the blood vessels, which lack tight junctions. Thus, the fenestrated blood vessels of the choroid plexus allow large molecules to pass, but the tight junctions at the epithelial cell surfaces restrict their passage into the CSF (Spector and Johanson 1989).

Since the surface area of the human BBB is estimated to be 20 m or around a thousand times greater than that of the BCSFB, the BBB is considered to be the main region controlling the neuronal environment and the uptake of drugs into the brain parenchyma. It is also the main target for delivering drugs to the brain via carrier-mediated strategies (Scherrmann 2002).

From BBB to the Neurovascular Unit
The BBB is defined by the microvasculature of the brain, which consists of a monolayer of polarized endothelial cells connected by complex tight junctions having a high

electrical resistance (>1,000–3,000 Ω/cm). This structure prevents paracellular transport across the brain endothelium. These endothelial cells are separated from the astrocyte foot processes and pericytes by a basement membrane (Fig. 1). The astrocyte foot process are about 20 nm from the abluminal (the layer of plasma membrane of polarized cells that is adjacent to the basement membrane, also called basolateral membrane) surface of the endothelial cells and this space is mainly filled with the microvascular basement membrane and the brain extracellular fluid. The endothelial cells actively regulate vascular tone, blood flow, and barrier function in the brain microvasculature. Endothelial cells are thin, about 0.1 µm thick, and thus occupy about 0.2% of the volume of the whole brain. They are polarized, like epithelial cells; the luminal (the layer of plasma membrane on the side toward the lumen of polarized cells, also called apical membrane) and abluminal endothelial membranes each segregate specific transcellular transport across the brain endothelium (Zlokovic 2008). This cell polarity is well illustrated by the distribution of several enzymes. Alkaline phosphatase is equally distributed between the luminal and the abluminal membranes but Na, K-ATPase and 5′-nucleotidase are present primarily on the abluminal side, and gamma-glutamyl transpeptidase is found mainly on the luminal side. Goldmann first postulated that the brain capillaries provide the anatomical basis of a barrier in 1913, but this was not conclusively demonstrated until the 1960s, when electron microscope studies revealed that the endothelial cells of a brain capillary form electron-dense junctional contact between two adjacent cells. There are no gap junctions (specialized intercellular connections



Blood–Brain Barrier. Fig. 1. Anatomical and functional definition of the blood–brain barrier (BBB). The cross-sectional scheme shows that the brain capillary endothelial cell is sealed by tight junctions which are surrounded by the pericyte and astrocyte foot processes. All these cellular components are separated by a basal membrane and constitute the neurovascular unit. Solutes can cross the cerebral endothelial cells by passive diffusion or active transport involving influx and efflux transporters from the solute carrier (SLC) and ATP-binding cassette (ABC) superfamilies. Enzymes can also metabolize solutes.

between cells allowing solute exchanges between adjacent cells) in brain capillaries and postcapillary venules and the tight junctions are responsible for sealing adjacent cells and maintaining cell polarity. Tight junctions are membrane microdomains made up of many specific proteins engaged in a complex membranar and intracytosolic network. Continuous tight junctions are not the only feature that makes the blood vessels of the brain different from those of other tissues. There are no detectable fenestrations or single channels between the blood and interstitial spaces. They contain fewer pinocytotic vesicles (cytoplasmic vesicles resulting from a mechanism by which extracellular fluid is taken into a cell following the invagination of the cell membrane) than do endothelial cells in the peripheral microvasculature and there is evidence that the majority of what appear to be independent vesicles in the endothelium cytoplasm are part of membrane invaginations that communicate with either the blood or the perivascular space. The endothelial cells that form the BBB also contain many mitochondria. They occupy 8–11% of the cytoplasmic volume, much more than in brain regions lacking a BBB and tissues outside the CNS. This indicates that the BBB also functions as a metabolic barrier, in addition to its physical barrier properties (Ballabh et al. 2004). There are highly specific transport systems carrying nutrients at the luminal or abluminal sides, or at both sides of the endothelial cell membrane. These carrier-mediated transport systems regulate the movement of nutrients between the blood and the brain. The brain capillary endothelium also bears specific receptors for circulating peptides or plasma proteins and these mediate the ► transcytosis of peptides or proteins through the BBB. More recently, the discovery of active carrier-mediated transporters which are not involved in transporting substrate from the blood to the brain, but from the brain to the blood, has greatly reinforced the barrier properties of the BBB. Most of these transmembrane proteins are located at the luminal or abluminal membranes of the endothelial cells and restrict the uptake of numerous drugs by the brain. Thus a large number of amphipathic cationic drugs are effluxed by one ATP-binding cassette (ABC) protein, the ► P-glycoprotein (P-gp) which is present at the luminal surface of the BBB. Brain vessels also have more classical types of receptors, including α-and β-adrenergic receptors and receptors for serotonin, adenosine, histamine, angiotensin, and arginine vasopressin. The brain capillaries are also almost completely surrounded by other cells, like pericytes and the astrocyte foot processes. Pericytes lie periendothelially on the abluminal side of the microvessels (Fig. 1). A layer of basement membrane separates the pericytes from the endothelial cells and the astrocyte foot processes. Pericytes send out cell processes which penetrate the basement membrane and cover around 20–30% of the microvascular circumference. Pericyte cytoplasmic projections encircling the endothelial cells provide both a vasodynamic capacity and structural support to the microvasculature. CNS pericytes can be viewed as housekeeping scavenger cells and a second line of defense in the BBB. The blood capillaries of the CNS of vertebrates are also enveloped by a perivascular sheath of glial cells, mainly astrocytes (Fig. 1). Immunohistochemical and morphometric studies on astrocytes and the microvasculature of the human cerebral cortex have shown that the astrocyte perivascular processes form a virtually continuous sheath around the vascular walls. While the astrocytes themselves do not form the barrier, they have an important role in the development and maintenance of the BBB. Astrocytes release factors that can induce the BBB phenotype and/or the angiogenic transformation of brain endothelial cells in vitro and in vivo. All these cellular components of the brain capillaries are joined by junctional systems. Zonal and extensive tight junctions seal the endothelial cells and gap junctions connect the endothelium to the subjacent pericyte layer, allowing their functional coupling and also weld them to the astrocyte processes (Abbott et al. 2006). The last component of the neurovascular unit is the nerve fibers, which may be seen close to the cerebral blood vessels; these may be noradrenergic and peptidergic nerves (Fig. 1). They influence the cerebrovascular tone and blood flow by secreting classical transmitters and a number of peptides, including substance P and vasoactive intestinal peptide. This neurogenic influence could also explain the circadian variation in the permeability of the BBB under noradrenergic influence. The intimate relationships between these cells make the BBB a pluricellular interface between the blood and the brain extracellular fluid.

Role of the Neurovascular Unit in Psychopharmacology

This overview points out the complexity of the BBB, as at least four types of cells plus the basement membrane are implicated in its structure and function. Thus many genes and the proteins they encode play a critical role in the broad pharmacological spectrum of activities carried out by the BBB. As psychoactive drug responses depend on numerous proteins in the body, including metabolizing enzymes, transporters, receptors, and all signaling networks mediating the response, it is very likely that gene–protein-mediated events at the BBB can play a role in the efficacy and safety of psychopharmacotherapies. For example, polymorphisms in genes encoding drug-metabolizing enzymes or transporters expressed at the

BBB could affect the transport of a drug across the BBB and consequently the patient's response to it.

Drug-Metabolizing Enzymes in the BBB

Although the absence of paracellular transport across the BBB impedes the entry of small hydrophilic compounds into the brain, low molecular weight lipophilic substances may pass through the endothelial cell membranes and cytosol by passive diffusion. While this physical barrier cannot protect the brain against chemicals, the metabolic barrier formed by the enzymes from the endothelial cell cytosol may transform these chemicals. Compounds transported through the BBB by carrier-mediated systems may also be metabolized. Thus, L-DOPA is transported through the BBB and then decarboxylated to dopamine by the aromatic amino acid decarboxylase.

This metabolic barrier was first postulated for amino acid neurotransmitters in the 1960s. The presence of enzymatic systems suggests that a battery of enzymes may modulate the entry of neuroactive molecules into the brain. Several phase 1 enzymes, such as cytochromes P450 (CYP), monoamine oxidases (MAO-A and -B), flavin-containing monooxigenases, reductases and oxidases and phase 2 enzymes catalyzing conjugation, such as UDP-glucuronosyltransferases (UGTs) and glutathione and sulfotransferases have been found in the rat and human CNS, as well as in isolated brain microvessels and cerebrovascular endothelial cells, which constitute the BBB (El-Bacha and Minn 1999).

Drug-Carrier Transporters in the BBB

A second type of drug pharmacokinetic event at the BBB is mediated by proteins on the luminal and/or the abluminal membranes of the endothelial cells (Ohtsuki and Terasaki 2007). These proteins can mediate influx or efflux transport from the blood to the brain or vice versa. They belong to two superfamilies, the solute carrier (SLC) and the ABC. This type of active transport was first discovered for nutrients that are not lipid soluble and cannot cross the barrier by simple diffusion. Most of these transporters are SLC members and like the glucose carrier, the carrier for large neutral branched and aromatic amino acids, the so-called L-system – now designated LAT – 1 (Large Neutral Amino acid Transporter) is present at both sides of the endothelial cell membranes and transports at least ten essential amino acids. ► L-DOPA used to treat ► Parkinson's disease and other CNS pharmaceuticals, such as baclofen and ► gabapentin, cross the BBB via the L system.

The monocarboxylic acid transporter (MCT1) is present on both the luminal and abluminal membranes of the BBB and seems to transport substrates in both directions. MCT1 is responsible for the transport of several substances, including the gamma-hydroxybutyrate sleeping and anesthetic agent, which can be also used as a recreational drug at higher doses. Interestingly, the anticonvulsant, ► valproic acid, is more efficiently transported from the brain to the blood than the other way round because an organic anion transport counterbalances the uptake mediated by MCT1 at the BBB.

The BBB also has sodium and pH-independent transporters of organic cations. They are important for the homeostasis of choline and thiamine in the brain and for the permeation of cationic drugs like, ► fentanyl, H_1-antagonists and choline analogs. These organic cation transporters are mainly located at nerve terminals, glial cells and in the BBB.

The identification of the ABC brain-to-blood efflux transporter, P-glycoprotein (ABCB1, P-gp), in 1992 has added a novel property to the concept of the BBB (Scherrmann 2005). P-gp decreases the permeability of the BBB to lipophilic drugs by actively impeding their crossing of the luminal membranes or by transporting them out of the endothelial cells to the bloodstream. P-gp was originally found as an over-produced membrane protein in multidrug resistance tumor cells, and was found to be responsible for reducing the intracellular accumulation of several anticancer drugs. Transport mediated by P-gp is coupled with ATP hydrolysis and affects many substrates that have a planar structure, neutral, or cationic charge and are hydrophobic. While humans have only one gene (MDR1) encoding the drug-transporter P-gp, rodents have two genes, mdr1a and mdr1b, that encode P-gps with overlapping substrate specificities. The availability of mice with disrupted mdr1 genes has helped to demonstrate that the P-gp in the BBB limits the entry of many drugs into the brain by actively pumping them back into the blood. Most light-microscope and electron-microscope immunochemical experiments using several specific antibodies to P-gp indicate that the luminal membrane of the brain endothelial cells normally has a high concentration of P-gp (Fig. 1). Its role as a barrier to the entrance of small lipophilic compounds across the luminal membranes of the brain capillary endothelial cells is now clearly established.

One such is the dopamine antagonist, domperidone, which only produces an antiemetic effect in P-gp competent mice due to its selective peripheral activity. The antipsychotic effect of domperidone becomes its main effect when it is given to mice lacking P-gp, indicating its distribution and activity in the CNS. Similarly, the antinociceptive effect of ► morphine and other opioids

is increased in mice lacking P-gp and the brain distribution of risperidone, its active metabolite 9-hydroxyrisperidone and metoclopramide is affected by P-gp.

Several functional polymorphisms of the human MDR1-gene were recently described and correlated with the synthesis and activity of P-gp in vivo and this might be an extremely important factor influencing between-subject variations in the uptake of a large number of pharmaceuticals by the CNS.

There is always a risk of interaction between P-gp-mediated drugs at the BBB. Any resulting modulation of P-gp transport activity may also give rise to variations in the response of the CNS to drugs, both between individuals and within the same individual, depending on the other drugs being administered. The interaction of loperamide, an antidiarrheal drug that is transported by P-gp, with quinidine has been evaluated in healthy volunteers. Loperamide had several side effects on the CNS phenotype, including respiratory depression, demonstrating that the inhibition of BBB P-gp by quinidine allowed loperamide to be transported across the BBB.

There seem to be several other transporters that exclude drugs from the brain, in addition to P-gp such as the breast cancer resistance protein (BCRP, ABCG2) which is also expressed at the luminal side of BBB.

Conclusion

The functional characterization and identification of the proteins and genes of so many nutrient and drug enzymes and transporters at the BBB over these last 25 years has led to a change in our understanding of the way psychoactive drugs are transported across the BBB. This has opened an important avenue for the development of attractive strategies for delivering drugs to the brain using some of these enzymes or transporters. This new information may also shed light on the factors involved in inter- and intra-subject variations in the uptake of drugs by the CNS.

Blood–Cerebrospinal Fluid Barrier

Definition

Regions of the brain ventricles where choroid plexus epithelial cells, the anatomical site of BCSFB, produce the cerebrospinal fluid (CSF). These cells are connected by tight functions that restrict solute exchange between blood and CSF. Unlike capillaries of the blood–brain barrier, capillaries enveloping the epithelium are fenestrated and have no tight junctions allowing free movement of solutes.

Blood oxygenation level-dependent contrast

Definition
BOLD contrast has emerged as one of the most potent noninvasive tools for mapping brain function and has been widely used to explore physiological, pathological changes and mental activity in the brain. The physiological basis underlying the BOLD contrast is based on the neurovascular coupling. Neuronal activity leads to a hemodynamic response resulting in a concentration change of oxygenated and deoxygenated hemoglobin. As oxygenated and deoxygenated hemoglobin have different magnetic properties, this concentration change can be detected using MRI. Thus, the MR image contrast depends on the blood oxygenation level.

Definition
A method of administration of a substance intended to introduce a steady state concentration in plasma. An initial bolus is given, followed by an extended infusion at a much slower rate. An optimal ratio of bolus to infusion rate is chosen to induce steady state as rapidly as possible. The pharmacokinetics of many radioligands, relative to the decay rate of the isotope, are too slow for this method to be practical. But for those radioligands amenable to it, the bolus plus constant infusion method has several advantages, including robust parameter estimates and less vulnerability of outcome measures to errors produced by changes in cerebral blood-flow rates than the bolus approach.

Definition

Brain-derived neurotrophic factor (BDNF) is a polypeptide factor that binds to and activates ► TrkB, which is a receptor protein tyrosine kinase (Soppet et al. 1991). There is considerable interest in BDNF as a pharmacological agent for the treatment of neurodegenerative diseases [► Neurodegeneration and Its Prevention]. In addition, contemporary data indicate that BDNF may be required for the action of ► Antidepressants (Kozisek et al. 2007). The role BDNF may have in the mechanism of action of other psychotropic drugs, such as opiates, ► Benzodiazepines and ► Antipsychotic Drugs is less clear, but remains a subject of considerable research.

Pharmacological Properties

Introduction

History. Brain-derived neurotrophic factor (BDNF) is a member of a family of neurotrophins related by sequence homology and was originally identified as a factor that promoted the survival of cultured embryonic chick sensory neurons. ► Nerve Growth Factor is the prototypic member of this neurotrophin family, which also includes

Neurotrophin-3 (NT-3) and Neurotrophin 4/5 (NT-4/5). Pro-BDNF (~28 kDa) is processed into BDNF (14 kDa), both of which may have biological activity. BDNF is known to promote activity-dependent synaptic plasticity, axonal guidance, and neuronal survival. BDNF is required for the normal development of several areas of the nervous system.

Physiological role in plasticity. Following early evidence that BDNF was important for the survival of hippocampal and motor neurons, data have been accumulating demonstrating that BDNF has a major role in the physiological processes underlying the plasticity and development of the nervous system. BDNF and TrkB are required for normal hippocampal ►Neurogenesis in the adult rodent (Li et al. 2008). Moreover, BDNF is required for long-term potentiation [►Long-Term Potentiation and Memory], which involves BDNF regulating both presynaptic and postsynaptic mechanisms. It may be that antidepressant drugs regulate synaptic plasticity by inducing the expression of BDNF, which in turn may underlie some of the behavioral effects of these drugs (Brunoni et al. 2008; Kozisek et al. 2007).

Cellular signaling pathways activated by BDNF. In addition to activating the receptor protein tyrosine kinase TrkB (Soppet et al. 1991), BDNF also binds to the p75 low affinity neurotrophin receptor. The expression of the TrkB gene results in a full-length receptor protein tyrosine kinase (gp145 kDa) and truncated receptors (~gp90 kDa) (Middlemas et al. 1991). BDNF activates several signaling pathways that are involved in both mitogenesis and survival of cells as well as in regulating synaptic function and adult hippocampal neurogenesis. Neurogenesis in the adult ►hippocampus involves mitogenesis, migration, differentiation, and survival of neural precursor cells. Whether the role of BDNF in neurogenesis is mitogenic or trophic is hotly debated. BDNF could also be involved in differentiation or migration of these newborn cells.

BDNF, via its receptor, TrkB, activates major signaling pathways requiring phosphatidylinositol 3-phosphate kinase and the microtubule-associated kinases (MAPKs). With regard to putative roles for these signaling pathways in hippocampal neurogenesis, the phosphatidylinositol 3-phosphate kinase pathway is a cellular survival pathway whereas the MAPK pathway is the major mitogenic pathway activated by growth factors. Notably, BDNF activates multiple pathways leading to MAPK activation (Easton et al. 2006), which may underlie some of the physiological differences between BDNF and traditional growth factors such as the epidermal growth factor. The phospholipase C-gamma (PLC-gamma) pathway, which is also activated by BDNF, is involved in the regulation of long-term potentiation.

There is keen interest in BDNF, both as a possible pharmacological agent and for its potential role in the therapeutic action of psychotropic drugs. BDNF is required for survival of some populations of neurons during development. These neurotrophic properties of BDNF led to testing BDNF for amyotrophic lateral sclerosis (ALS). Unfortunately, the phase III clinical trial of BDNF failed to demonstrate a significant effect for treating ALS. Although there has been research directed at a possible role for BDNF in the treatment of other neurodegenerative diseases, there is now significant interest in the role BDNF may have in the treatment of major depressive disorder [►Major & Minor & Mixed Anxiety-Depressive Disorders]. Antidepressants increase BDNF expression in the adult rodent hippocampus and considerable evidence indicates that BDNF is required for the therapeutic action of these agents.

All antidepressant drugs acutely increase the levels of monoamine neurotransmitters in the CNS. One class of antidepressants, the ►Monoamine Oxidase Inhibitors, blocks catabolism of norepinephrine, serotonin, and dopamine. Other classes of antidepressant drugs inhibit the transporters required for the reuptake of monoamines from synaptic cleft. These drugs can be classified as serotonin-specific reuptake inhibitors (SSRIs [►SSRIs and Related Compounds]) or norepinephrine reuptake inhibitors [►NARI Antidepressants]. Some antidepressant drugs inhibit the reuptake of several of the monoamine neurotransmitters. Notably, there is a delay, on the order of days to weeks, in the therapeutic effect following the start of chronic treatment with antidepressant drugs. This delayed action gives rise to at least two distinct hypotheses for the cellular basis of antidepressant drug action. These drugs may induce changes in synaptic efficacy and synaptogenesis, or the antidepressants may induce hippocampal neurogenesis. BDNF has a putative role in both of these physiological processes.

The neurotrophic hypothesis for depression. It is proposed that deficits in BDNF expression underlie major depression disorder [►Major & Minor & Mixed Anxiety-Depressive Disorders], and, moreover, that chronic antidepressant treatment increase BDNF levels in the hippocampus. The initial finding that implied a role for BDNF in depression was that antidepressants increase the expression of BDNF, both mRNA and protein, in the adult hippocampus (Nibuya et al. 1995). Additional findings supporting the neurotrophic hypothesis include the demonstration that BDNF mRNA expression is decreased by stress and glucocorticoids in the hippocampus. Both

stress and increased cortisol levels are thought to have a causal role in major depression.

A few key experiments suggest an actual requirement for BDNF in antidepressant action. BDNF infusion directly into the midbrain of rats produces an antidepressant-like effect. Furthermore, heterozygous BDNF knockout mice do not respond to antidepressants in the forced-swim test (Saarelainen et al. 2003), which is a model used to test for antidepressant activity. The implication is that antidepressant drugs increase BDNF levels, which leads to changes in neuronal circuitry underlying an antidepressant effect.

Evidence suggesting that neurogenesis may be required for antidepressant drug action. An ingenious experiment implied a role for hippocampal neurogenesis in the action of antidepressant drugs. Because neurogenesis is acutely sensitive to radiation, it was used to block neurogenesis. Radiation treatment also blocked the action of antidepressant drugs (Saarelainen et al. 2003). Consistent with this finding, antidepressant drugs also induce hippocampal neurogenesis in the adult rat hippocampus (Sairanen et al. 2005). In addition, exercise also induces neurogenesis, which correlates well with the established antidepressant effect of exercise. Taken together, the data suggest increases in neurogenesis may underlie some of the antidepressant effects of these drugs. There may well be other effects of antidepressant drugs such as changes in synaptogenesis or synaptic efficacy.

A role for BDNF in hippocampal neurogenesis. Evidence is growing that BDNF has a direct role in hippocampal neurogenesis. In knockout mice with heterozygous BDNF expression, hippocampal neurogenesis was decreased compared to wild-type BDNF mice. Neurogenesis was decreased in both heterozygous BDNF mice and mice expressing a dominant negative TrkB receptor (TkB.T1) (Sairanen et al. 2005). These studies point to a role for BDNF promoting both increased mitogenesis and survival of newborn neurons.

To get at the precise role of TrkB in neurogenesis, actual neural precursor cells have been used for experiments (Li et al. 2008). Initially, using Nestin-GFP mice, where neural precursor cells were fluorescently marked, it was demonstrated that hippocampal neural precursor cells do indeed express TrkB. Because TrkB knockout mice die shortly after birth, TrkB conditional knockout mice were then used to show that the ablation of TrkB impairs the normal development of the dentate gyrus granule cell layer (Li et al. 2008). This was correlated with a direct decrease in the number of granule neurons. In these studies, the role of TrkB was shown to be in proliferation rather than survival. Most importantly, TrkB expression is required for neural precursor cell proliferation and neurogenesis induced by antidepressant drugs. In a striking extension of these experiments, it was shown that TrkB is also required for the behavioral effects of antidepressant drugs in the novelty-suppressed feeding test paradigm using the conditional knockout mice (Li et al. 2008). This is a conflict paradigm where latency to feed in a novel environment is an indicator of anxiety level in mice. The extensive groundwork that has now been laid indicating a role for BDNF and TrkB in antidepressant action may lead to novel targets for antidepressant discovery and development.

Developmental differences in antidepressant efficacy. There is a distinct difference in the efficacy of different classes of antidepressant drugs in children and adolescents [► Depressive Disorders in Children] compared to adults (Bylund and Reed 2007). Children and adolescents respond to some SSRIs [SSRIs and Related Compounds], but do not respond to tricyclic antidepressants [► Adolescence and Responses to Drugs]. The reason for this underlying difference in antidepressant drug class efficacy between adolescents and adults is not known. Because the serotonergic neurotransmitter systems mature earlier during development than do the adrenergic neurotransmitter systems, earlier maturation of the serotonergic system may explain why SSRIs are effective in adolescents, whereas noradrenergic selective drugs lack efficacy (Bylund and Reed 2007). In a juvenile rodent model, the SSRI ► escitalopram, but not desipramine (a tricyclic which is highly selective for inhibiting ► norepinephrine as compared to ► serotonin reuptake), increases levels of hippocampal BDNF and TrkB (Kozisek et al. 2008). The failure of desipramine to increase BDNF and TrkB levels in juvenile rats is consistent with the lack of efficacy of desipramine in children and adolescents.

This is a truly exciting era in psychotropic drug research. There remains a tremendous need for both more effective treatments and a reduction in the adverse effects of treatment for most mental disorders, including major depression. The delineation of the mechanism of action of fascinating psychotropic drugs, such as the antidepressant drugs with their delayed action, continues at a brisk pace. Further delineation of the precise role BDNF has in hippocampal neurogenesis and the cellular signaling pathways activated by BDNF that are required for antidepressant action may well identify novel targets for antidepressant drug discovery. The role BDNF signaling has in the physiological process underlying the antidepressant effect of drugs could well lead to strategies for novel therapies. This offers the prospect of more effective

antidepressant drugs or perhaps effective cell-based antidepressant therapies.

Definition

Caffeine is a natural xanthinic alkaloid consumed worldwide for its ability in exerting psychostimulant effects of a mild extent usually devoid of severe unwanted consequences.

Pharmacological Properties

History and Sources

Caffeine is contained in several vegetal species, the most famous being *Coffea arabica, Thea sinensis*, and *Theobroma cacao*. The most ancient documentation on the consumption of caffeine-containing plants and their derivatives dates back to the China of the third century, where caffeine was consumed as tea. However, it is believed that consumption of caffeine-containing plants began far earlier, perhaps even during the Stone Age.

Coffee as a beverage was first imported in Europe by the Venetian Prospero Alpino in 1570, while in 1573 Léonard Rauwolf, a German physician and botanist was the first European to describe the preparation and drinking of coffee and in 1819 Friedrich Runge first isolated caffeine. Social appreciation of caffeine dates to the seventeenth century when "coffee houses" were established in Costantinople and Venice. Nowadays, caffeine can be found in dietary products like coffee, tea, mate, and

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

chocolate as well as an additive to soft drinks, particularly in the so called "energy drinks." Moreover, caffeine is a component of certain over the counter medications and of several dietary supplements.

Biological Effects: General Overview

Caffeine is capable of targeting several body organs and of influencing complex physiopathological phenomena (Table 1). Although psychostimulation is envisioned as "the" effect of caffeine, other effects may be associated with caffeine intake whose nature and intensity considerably vary among consumers. This depends, on one hand, on the existence of a different inter-individual responsiveness to caffeine and, on the other, on the rate and duration of caffeine consumption. Some of caffeine effects are manifested only after its intake at very high doses, while ► tolerance to certain effects may occur after prolonged caffeine consumption. Furthermore, ► effect inversion can take place after either the intake of high doses or prolonged consumption of caffeine.

Biological Effects: Central Effects

As mentioned earlier, psychostimulation is the most popular among the central effects exerted by caffeine. Caffeine-induced psychostimulant effects include increased wakefulness, delayed need for sleep, reduced fatigue perception, and augmented alertness. Caffeine also elicits rewarding effects associated with a beneficial influence on mood, and interferes with the perception of stimuli bearing, in addition, discriminative properties (► drug discrimination) towards other psychostimulants. Furthermore, nootropic properties have been suggested for caffeine based on its beneficial effects in tests measuring memory function. However, it is debated whether this result reflects a genuine effect on memory or rather stems from caffeine-induced increase in alertness. Then, the existence of a neuroprotective potential (► neuroprotection) for caffeine has been observed in experimental animal models of Parkinson's and Alzheimer's disease and suggested in humans based on epidemiological evaluation of ► Parkinson's disease incidence (Fig. 1). Finally, caffeine-mediated psychoactive effects may powerfully influence those of other centrally active substances, leading to either their amplification (► amphetamines) or attenuation (► alcohol).

Mechanisms of Action: General Overview

A wealth of experimental evidence indicates that the most commonly manifested biological effects of caffeine arise from its action on ► adenosine receptors. Such receptors are the only ones among the known biological targets of caffeine to be sensitive to the plasmatic concentrations of the substance attained upon its recreational consumption (Table 2). One cup of coffee may contain from 60 to 100 mg of caffeine (~ 5 μM plasma levels); up to 10 cups of coffee, caffeine acts as an antagonist of adenosine A1/A2A receptors. At higher concentrations (100 μM) caffeine inhibits cyclic nucleotide ► phosphodiesterases, whereas at toxic concentrations (1 mM) it stimulates the release of Ca^{2+} through the ryanodine receptor.

Four subtypes of adenosine receptors, namely A1, A2A, A2B, and A3, have been characterized. Caffeine is an antagonist towards these receptors: in humans it preferentially blocks A2A receptors (KD = 2.4 μM), displays a good affinity towards A1 (KD = 12 μM) and A2B receptors (KD = 13 μM), while A3 receptors are bound with lower affinity (KD = 80 μM). All adenosine receptors are G protein-coupled receptors, and their stimulation leads to modifications involving the activity of adenylyl cyclase, phospholipase C, phospholipase D as well as changes in the gating state of Ca^{2+} and K^{+} channels, eventually triggering the biological effects of adenosine (Fredholm et al. 1999). Caffeine effects can, therefore, be considered as resulting from the counteraction of such neurochemical cascade (Fig. 1). The participation of non-adenosinergic mechanisms in caffeine effects, particularly upon intake of high doses, may however exist.

Mechanisms of Action: Central Effects

The A1 and A2A receptors are those mainly involved in mediating caffeine-induced central effects, since next to bearing a good affinity for caffeine, they are also highly enriched in the brain. In this regard, experimental evidence has suggested that, although caffeine leads to a combined A1/A2A receptor blockade, either receptor subtype may acquire particular importance in mediating a specific effect of caffeine. Caffeine discriminative effects appear mostly dependent on A1 receptors, while A2A receptors seem to govern caffeine-induced arousal, increased alertness, and neuroprotection (Higgins et al. 2007; Schwarzschild and Ascherio 2004). Adenosine receptor subtypes other than A1 and A2A appear scarcely relevant to caffeine central effects, as A3 receptors display a poor affinity for caffeine (see above) and A2B receptors are negligibly stimulated by brain adenosine under physiological conditions.

The existence of profound functional interactions between adenosine and other neurotransmitters appears of paramount importance to the manifestation of the central effects of caffeine. In particular, the cross-talk between adenosine and the dopaminergic transmission, whose

activation is critically involved in promoting psychomotor stimulation, seems crucial to caffeine-elicited psychostimulant effects (Cauli and Morelli 2005). Thus, opposite functional interactions between adenosine receptors and ► dopamine receptors have been demonstrated in both animal and human brain (Fredholm and Svenningsson 2003). Stimulation of adenosine receptors depresses dopaminergic transmission while adenosine receptor blockade amplifies it (Ferré et al. 1997). Caffeine, by antagonizing adenosine receptors, boosts dopaminergic transmission, and rodent studies have substantiated the relevance of such a mechanism to caffeine's neurobehavioral effects. In this regard, an attenuation in caffeine-elicited psychomotor stimulation has been described in mice bearing a genetic deletion of either the D2 receptor or the phosphoprotein ► DARPP-32, a key second messenger in dopamine receptor-mediated signal transduction (Fisone et al. 2004; Zahniser et al. 2000). Interactions between adenosine and neurotransmitters other than dopamine, such as ► glutamate, ► serotonin, ► acetylcholine, and histamine, also exist in the brain which may be important to caffeine-induced central effects. In particular, adenosine–glutamate interactions have been suggested to participate in caffeine-elicited psychostimulant effects and to underlie the neuroprotective effects of caffeine (Schwarzschild and Ascherio 2004).

Experimental Paradigms

Several experimental models exist that are suited to the investigation of the biological effects of caffeine. These may involve either in vitro paradigms, widely used to evaluate the effects of caffeine on cell cycle, or in vivo models, employed to study caffeine-induced effects at both the peripheral and central level. The latter models can address the influence of caffeine on phenomena such as diuresis, metabolic and heart function, and neurotoxicity. The majority of the studies concerned with caffeine, however, use models aimed at investigating its effects on brain function. Such paradigms evaluate the capability of caffeine in modifying the behavioral performance of animals, mainly rodents, and they can be paired with complementary techniques (e.g., ► microdialysis) aimed at elucidating the changes in brain neurochemistry triggered by caffeine.

Thus, the magnitude of caffeine-elicited motor activity, whose increase is an index of psychostimulation, is largely measured as parameter reflecting the gross psychostimulant effects of caffeine. Next to this, caffeine influences ► conditioned place preference and ► intracranial self-stimulation, two paradigms useful to investigate drug-induced positive rewarding effects. Furthermore, caffeine affects animals' performance in different ► drug discrimination and taste preference paradigms, reflecting caffeine's influence on the perception of stimuli. Finally,

the ability of caffeine in influencing the execution of tests aimed at evaluating either memory or attention can be used to study the effects of caffeine on cognitive performance (► rodent models of cognition). Either acute or chronic changes in animals' behavior as measured by means of the above paradigms can also be used to ascertain whether, and to what extent, exposure to caffeine modulates the effects elicited by other psychoactive substances. Finally, the study of the conditions favoring the instatement and maintenance of a caffeine consumption habit (► caffeinism) is also possible in animals. This can be performed in either rodents or primates by means of the ► drug self-administration paradigm (Fredholm et al. 1999).

Human Paradigms

The majority of the investigations dealing with the effects of caffeine in humans are concerned with its ► psychostimulant and rewarding effects. The conditions under which caffeine delays the need for sleep and promotes alertness in sleep-deprived individuals are extensively investigated and so are the effects of caffeine on mood and on the execution of mental tasks. Such investigations usually employ a single administration or a brief multiple exposure to caffeine, and are often paired with electroencephalographic analysis (► electroencephalography) to examine the pattern of caffeine-induced neuronal activation. Moreover, investigations can be conducted to address either the features of ► caffeine withdrawal syndrome (► withdrawal syndromes) or the influence of caffeine intake on the neurobehavioral effects of other centrally active substances. Peripheral effects of caffeine can be evaluated in humans as well, and consumption of caffeine is usually included as a variable in epidemiological studies, in light of the widespread diffusion of this habit (Fredholm et al. 1999).

Pharmacokinetics

Caffeine is rapidly and nearly completely absorbed after oral intake. In adult healthy humans, caffeine reaches its plasmatic concentration peak within 0.5–2 h from ingestion. Plasmatic ► half-life of caffeine is estimated for 2–10 h in young adults and elders, while it is higher in neonates and infants, due to the incomplete development of metabolic pathways in these subjects. As it displays lipophilic properties, caffeine crosses the ► blood–brain barrier and can reach the brain at high concentrations. Furthermore, caffeine penetrates the placenta, thus reaching the fetus. Significant levels of caffeine can be also detected in milk and saliva.

Caffeine is mainly metabolized by the ► cytochrome P-450 hepatic enzymes. Several active caffeine metabolites have been isolated, the major being theophylline, theobromine, and paraxanthine, and interspecies differences in caffeine metabolism exist. Many of caffeine metabolites display a pharmacological profile close to the one of their parent compound, and can participate in caffeine effects. In humans, the main metabolic pathway of caffeine involves its degradation to paraxanthine which is catalyzed by the CYP1A2 subform of the P-450 enzymes.

Conditions influencing the function of P-450 enzymes can profoundly impact the metabolism and, accordingly, the ► pharmacokinetics of caffeine. Caffeine plasmatic half-life is increased by diseases depressing hepatic metabolic activity (e.g., cirrhosis) and by agents that are metabolized by, or that inhibit, the CYP1A2 (e.g., cimetidine, ► disulfiram, estrogens). Conversely, a reduction in caffeine half-life is caused by agents capable of inducing P-450 enzymes (e.g., ► carbamazepine, rifampicin, cigarette smoke) (Fredholm et al. 1999; Magkos and Kavouras 2005).

Toxicological and Adverse Effects

Consumption of caffeine is considered a safe habit, since the lethal dose of the substance is very high (at least 100 mg/kg). Nevertheless, cases of either poisoning or anaphylaxis induced by caffeine have been reported, and adverse effects may be associated with recreational caffeine consumption. Irritability, anxiety, psychotic-like symptoms, and increased susceptibility to seizures have been described in caffeine consumers. These effects are likely manifested in the presence of a pre-existing individual susceptibility; hence, their incidence is negligible though it can increase when caffeine is consumed at high doses. In addition, caffeine elevates blood pressure and can, at times, trigger alterations in heart rhythm (Higdon and Frei 2006). Rodent studies have suggested that caffeine consumption during pregnancy might promote teratogenesis, but this hypothesis has not been proven conclusively in humans. Similarly, neither has caffeine intake been convincingly demonstrated to increase the risk of abortion. However, moderation in caffeine consumption is advisable in pregnant women to prevent the fetus from being reached by caffeine which could exert adverse effects on it.

Caffeine can influence the pharmacological effects of several drugs. This may happen through mechanisms involving metabolism (see above), clearance (e.g., lithium), absorption (e.g., oral iron supplements), or pharmacodynamic amplification of other drugs' effects (e.g., ephedrine). In its recreational use, caffeine is often associated with other psychostimulants, as amphetamine analogs, to increase their effects, or to alcohol, to counteract alcohol depressive effects and hangover. In both cases, use of caffeine may produce severe side effects by raising the toxicity of amphetamine analogs (e.g., ▶ MDMA) or letting the alcohol consumer to increase the assumption of alcohol up to toxic doses.

Use as a Medication

The major uses of caffeine as a medication are as analgesic for the treatment of headache and as a respiratory stimulant for the management of postpartum apnea in premature neonates. Furthermore, due to its lipolitic and thermogenetic properties, caffeine is an adjuvant in topic anti-cellulite preparations and its use has been suggested for the treatment of obesity. The use of caffeine to counteract some aspects of ▶ akinesia and tremor associated with Parkinson's disease has also been proposed.

Use as a Research and Diagnostic Tool

Caffeine is widely employed in biomedical research. Thus, caffeine is a standard molecule in studies investigating the pharmacology of adenosine receptors, due to its reduced cost and good solubility in physiological mediums. Furthermore, activation of the ryanodine receptor, which modulates Ca^{2+} release from intracellular stores, by caffeine is exploited to investigate muscular physiopathology and mechanisms of cellular Ca^{2+} turnover. Caffeine is also used in biopharmaceutical studies evaluating the permeability of the skin and artificial skin-like membranes, due to its well-characterized biophysical properties. Measurement of the clearance of caffeine and/or its metabolites is employed to estimate hepatic and/or renal functionality, while quantification of caffeine degradation to paraxanthine is used as a phenotypic marker for the CYP1A2 enzyme. Moreover, changes in the susceptibility of the skeletal muscle to caffeine-induced contraction are evaluated as a diagnostic parameter for malignant hyperthermia.

Conclusion

Caffeine is one of the most popular psychostimulant substances in the world. Although caffeine consumption is generally not associated with harmful consequences, moderation in caffeine intake is advisable to selected categories of individuals, such as pregnant women or persons particularly susceptible to its adverse effects. Finally, the ability of caffeine in interfering with the effects of centrally active substances, including addictive psychostimulants, may represent a further risk factor associated with its consumption.

Definition

Condition that follows the discontinuation of caffeine intake and that is characterized by symptoms such as fatigue, headache, irritability, depressed mood. Symptoms of caffeine withdrawal syndrome are not necessarily manifested all at the same time and their intensity may considerably vary among different individuals. Caffeine withdrawal syndrome is usually not harmful; it is self-limiting and can be manifested by both moderate and heavy caffeine consumers.

Definition

Caffeinism is a complaint encompassing a variety of unpleasant mental and physical symptoms associated with the consumption of excessive amounts of ► caffeine. Symptoms primarily result from exaggerated stimulation of the central nervous system or other organ systems and are not due to a general medical condition or another mental disorder. Symptoms can cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Symptoms resolve when caffeine ingestion is discontinued, and caffeine is metabolized and eliminated from the body.

Role of Pharmacotherapy

Caffeine is generally accepted as the most widely consumed drug in the world. It is naturally present in coffee and tea, the most popular beverages in the world, and in cocoa, chocolate, and a number of other plants consumed around the world. It is added to a variety of soft drinks, especially "cola" drinks, and is a major component of the growing category of "energy drinks" sold as dietary supplements. Caffeine is also a component of many over-the-counter and prescription drugs. Its consumption and use is so widespread, and caffeine-containing beverages are so much a part of social culture around the world, that caffeine is seldom thought of as a drug. However, it is a drug with widespread effects throughout the body.

In its many forms this drug is most often consumed for its properties as a central nervous system stimulant

(► Psychomotor Stimulants). In moderate doses, it is used to reduce physical fatigue, to prevent drowsiness and sleep, and to maintain and restore mental alertness and wakefulness. However, at higher doses, these stimulatory effects can become excessive and lead to an unpleasant and dysphoric physical and mental state that is labeled caffeinism and is also known colloquially as "coffee nerves" or "caffeine jitters."

Symptoms

The common symptoms of caffeinism are essentially exaggerations of the effects that are sought after by those who ingest caffeine and are similar to the effects of overdose of other stimulant drugs. Caffeine overdose results in a state of central nervous system overstimulation, with symptoms that include restlessness, nervousness, excitement, and irritability. People may report feeling jittery or "wired" with "racing thoughts" and have difficulty falling asleep or returning to sleep if awakened. Physical symptoms can include flushing of the face, increased urination, gastrointestinal disturbances, muscle twitching, and irregular or rapid heart beat. These symptoms can result either from acute overdose or from chronic consumption of high doses over extended periods of time.

The acute form is perhaps best described as "caffeine intoxication," which occurs following consumption of an unusually large caffeine dose within a short period of time. This could occur when an individual who is inexperienced with caffeine ingests several cups of coffee, energy drinks, or caffeine tablets, perhaps in an effort to stay awake and alert and to ward off sleep, or to "get a buzz." Acute intoxication can also occur in habitual caffeine consumers, when the doses of caffeine ingested are much higher than normal. A few extra cups of coffee consumed to meet a deadline can produce symptoms of intoxication even in a regular coffee drinker.

Chronic ingestion over long periods of time can also produce symptoms that are labeled caffeinism. Heavy coffee drinking has been associated with symptoms that were initially diagnosed as generalized anxiety or ► panic attacks (James 1991; Lane 1987). Later examination of the patients' histories indicated that anxiety or panic symptoms began after the patient started drinking 10–12 cups of coffee or more every day. In each case, symptoms disappeared shortly after caffeine intake was discontinued. Another report described long-term low-grade fever accompanied by ► insomnia, anorexia, and irritability in a woman who drank 15–18 cups of coffee every day, whose symptoms disappeared after she severely restricted her caffeine intake. Caffeinism associated with chronic ingestion also includes the symptoms that result from the ► physical dependence on caffeine that develops over time. In the habitual heavy consumer, symptoms of caffeine ► withdrawal, including headache, fatigue and sleepiness, mental fogginess and difficulties concentrating, depression, and irritability can appear when regular patterns of caffeine ingestion are disrupted, in as little as 12 h after the last dose (of caffeine).

Mild or occasional symptoms of caffeine overdose may cause few disruptions to the quality of life for the caffeine consumer. However, the American Psychiatric Association currently recognizes several mental health disorders related to caffeine in the ► Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR), which can be clinically significant to mental health. Of these, "Caffeine Intoxication" is the disorder most closely related to caffeinism as described here. According to the DSM-IV-TR, the essential feature of Caffeine Intoxication is the recent consumption of caffeine. This diagnosis requires the presence of at least five signs or symptoms, from a list of 12, that develop during or shortly after caffeine use. (American Psychiatric Association 2000) The signs and symptoms are divided into one group that can appear after an intake of as little as 100 mg of caffeine (roughly the amount contained in a cup of brewed coffee) and another group of symptoms that appear at higher levels of intake (more than 1 g per day). Low-dose symptoms include "restlessness, nervousness, excitement, insomnia, flushed face, diuresis (increased urination), and gastrointestinal disturbance." Symptoms associated with high doses of caffeine include "muscle twitching, rambling flow of thought and speech, tachycardia and cardiac arrhythmia, periods of inexhaustibility, and psychomotor agitation." In order to meet the diagnosis of caffeine intoxication, these symptoms must cause "clinically significant distress or impairment in social, occupational, or other important areas of functioning." Symptoms cannot be due to a general medical condition or be better explained by another mental disorder. This diagnosis does not distinguish between symptoms of acute overdose and of chronic ingestion.

DSM-IV-TR includes two other caffeine-related diagnoses associated with chronic ingestion of caffeine. The diagnosis of "Caffeine-Induced Anxiety Disorder" recognizes that consumption of large amounts of caffeine over time induces in some individuals symptoms that are indistinguishable from anxiety sufficiently severe to warrant clinical attention. This disorder can take many forms, including generalized anxiety disorder, panic attacks (Panic), obsessive–compulsive symptoms (► Obsessive–Compulsive Anxiety Disorders), and phobic symptoms. The diagnosis of "Caffeine-Induced Sleep Disorder"

recognizes that the sleeplessness associated with caffeine ingestion at high doses over time can produce significant disruptions of sleep (Insomnia). Although insomnia may be the typical complaint, some individuals present with a complaint of excessive daytime sleepiness related to caffeine withdrawal. Here again, symptoms must be associated with recent or ongoing caffeine ingestion and cannot be explained by other medical conditions or mental disorders. The World Health Organization (1993) also recognizes the potential for caffeine-related mental disorders in the ▶ ICD-10, although caffeine is grouped with all stimulants other than cocaine. As a result, no caffeine-specific symptoms are mentioned in the diagnostic criteria. The signs and symptoms that are associated with the diagnosis of "Acute intoxication" include most of those listed in the DSM-IV, but also include many that have not commonly been associated with caffeine ingestion. The ICD-10 does recognize that physical dependence on caffeine and caffeine withdrawal are potential mental disorders that can disrupt daily living. However, the diagnostic criteria are general and do not include the specific symptoms known to be caffeine-related.

Risk Factors

Although many of the symptoms of caffeinism are dose-dependent, the dose of caffeine consumed is not the only factor that determines whether symptoms appear or not. There is no consensus about what constitutes an "overdose" of caffeine, and there is no accepted minimum dose that is certain not to produce symptoms in any individual. As the DSM-IV-TR (American Psychiatric Association 2000) states, some symptoms of caffeine intoxication can appear after acute doses of only 100 mg (one cup of coffee), yet other sources suggest that doses of 300–500 mg are necessary.

Caffeine can be consumed in many beverages, foods, medications, and dietary supplements. These vary widely in the amount of caffeine present in a "standard serving." Not all sources are equally likely to promote the development of caffeinism. Coffee is probably the beverage most often associated with symptoms of acute and chronic caffeine overdose, because it provides the highest dose of all foods and beverages. A typical 8-ounce cup of coffee might contain 125 mg of caffeine, although the dose varies widely. By contrast, a cup of brewed tea contains less than half as much caffeine, and 12-ounce servings of caffeinated soft drinks contain roughly one-third the caffeine. In amounts normally consumed, cocoa and chocolate contain even smaller doses. Coffee is also the most likely cause of caffeinism because of its growing popularity and its place as a primary social beverage in many settings. The fact that serving sizes have increased over the years from 5 or 6 ounces in a cup to 24 ounces or more at neighborhood coffee houses and convenience stores only serves to increase the likelihood that coffee drinking will lead to symptoms of overdose. However, consumption of the so-called "energy drinks" sold as dietary supplements is a growing risk factor, as the popularity of these drinks increases. Unlike soft drinks, the caffeine content of these beverages is not commonly restricted, and some brands contain over 350 mg of caffeine per serving. Manufacturers are not required to put the caffeine dose on the label. This can create special problems for the adolescents targeted by marketing, who often have little prior experience with caffeine.

At least three other factors interact with dose to determine vulnerability to caffeinism. The first is individual sensitivity to caffeine. Chronic ingestion of caffeine leads to the development of tolerance to the drug (▶ Pharmacodynamic Tolerance), as the nervous system and body adapt to the continued presence of the drug. When tolerance develops, the same dose has less effect, which should reduce the risk of caffeine intoxication. However, tolerance provides little protection when caffeine doses are acutely increased. Caffeine sensitivity also varies as a function of how quickly caffeine is eliminated from the body (▶ Pharmacokinetics). For example, genetic differences are known to produce slow and fast eliminators. Concurrent use of some other common medications, including oral contraceptives, has been shown to interfere with caffeine metabolism and slow elimination. Those who eliminate the drug more slowly experience higher drug concentrations for longer periods of time after consuming caffeine , which increases the risk of symptoms. A second factor is the presence of other psychiatric conditions (James 1991). The risk for caffeine intoxication is thought to be much greater in those individuals who are already susceptible to anxiety, panic disorder, or other mood disorders. In these individuals, caffeine appears to aggravate an underlying susceptibility. Finally, exposure to stress may increase the risk of caffeinism (Lane 1987). In some studies, increased stress in daily life was associated with increases in the consumption of caffeine. Furthermore, caffeine has been shown to exaggerate the impact of stress on mood and physiology, which could aggravate the symptoms that define the disorder (Lane et al. 1990).

Epidemiology

Little is known about the prevalence of caffeinism in the general population (Iancu et al. 2007). Although most people are familiar with the disorder, it probably remains underdiagnosed, because patients are rarely questioned

about the use of caffeine. Few surveys have been drafted to determine the proportion of the general population who have experienced caffeinism symptoms. These limited results suggest that 10–20% of the general population met the criteria for Caffeine Intoxication (DSM-IV-TR) in the previous year. Surveys also suggest that those who use caffeine to enhance academic or professional performance or to maintain alertness for extended periods of time will tend to use more of the drug and be at greater risk of caffeinism.

Prevention and Treatment

Both the prevention and treatment of caffeinism depend simply on reducing the levels of caffeine present in the body, either acutely or chronically. This depends on reduction of caffeine ingestion and the passage of sufficient time for metabolic elimination of caffeine in the body.

Control of caffeine intake requires awareness of the caffeine content of caffeinated beverages, over-the-counter drugs, and other sources of caffeine in the diet. Such information is not easy to obtain. The content of brewed beverages such as coffee and tea varies greatly based on the method of preparation (James 1991). There can be no standard value for "a cup of coffee." The caffeine content of soft drinks and energy drinks can be difficult to determine, because the labels do not indicate the dose per serving. Caffeine doses in these beverages range from 20 to 30 mg in some soft drinks, up to 350 mg or more in some energy drinks. Although some Internet web sites report caffeine content for beverages, official lists are not available and the number of brands continually grows.

It is possible to eliminate caffeine from the diet by abruptly quitting all consumption of caffeine-containing products ("going cold turkey"). This approach is not recommended, because the resulting symptoms of caffeine ► withdrawal (► Withdrawal syndromes), including headache, fatigue, and difficulty concentrating, can be so unpleasant that the attempt fails. Gradual reductions in caffeine use are recommended to avoid withdrawal. Because caffeinated beverages are often a regular part of daily life, it is essential to break the habits associated with caffeine ingestion and consciously substitute with uncaffeinated alternatives. Programs based on techniques of behavior management have proved successful, although few clinical trials have been conducted to determine the best procedures (James 1991).

cAMP

Synonyms
Cyclic-adenosine monphosphate

Definition
Cyclic-adenosine monphosphate (cAMP) is a major intracellular second messenger generated by adenylate cyclase. Many GPCRs either stimulate or inhibit adenylate cyclase, depending on the specific G-proteins they interact with. cAMP stimulates activation of protein kinase A and also directly binds to other proteins, including some ionic channels to modulate their function in the cell.

Cannabinoids

Definition
In the strictest sense, ► cannabinoids are alkaloids that are present in the *Cannabis sativa* plant. However, the word cannabinoid is often used to refer to all chemicals (synthetic and natural) that bind to ► cannabinoid receptors. Endocannabinoids are cannabinoid receptor ligands that are present in biological tissues and function as endogenous agonists of the cannabinoid receptors.

Pharmacological Properties

History
The unique pharmacological properties of the preparations of *Cannabis sativa* plant have been recognized for thousands of years. There is evidence that *Cannabis* was cultivated in China as early as 4,000 B.C. for multiple purposes, including its use as a food and medicinal agent. In India, the use of *Cannabis* for medicinal purposes began approximately 1,000 BC. C*annabis* extracts were used by these cultures to reduce pain, seizures, anxiety, mania and muscle spasms, and to stimulate appetite.

The introduction of *Cannabis* to Western medicine occurred in the mid-19th century through the writings of William B. O'Shaughnessy, an Irish physician, who became aware of indigenous use of *Cannabis* plant during his service under the British in India. O'Shaughnessy reported the beneficial therapeutic effects of *Cannabis* for convulsions and muscular spasms caused by rabies and tetanus. Jacques-Joseph Moreau, a French psychiatrist, also discovered *Cannabis* during his travel in the Far East and studied its psychological effects in himself and his students. Moreau published his observations regarding the use of *Cannabis* as an experimental psychotomimetic in Du Hachisch et de l'Alientation Mentale: Etudes Psychologiques (1840).

The beginning of the modern era of cannabinoid pharmacology is ascribed to the 1964 publication by Gaoni and Mechoulam of the structure of the psychoactive chemical in *Cannabis*, Δ^9-tetrahydrocannabinol (THC), together with a method for its isolation from the plant. A body of scientific literature was published between 1965 and 1986 that focused on the pharmacological and cellular effects of THC. Among the important contributions of this era was the codification of a tetrad of THC effects in rodents (analgesia, reduction in body temperature, catalepsy, and spontaneous activity) that was used to characterize the cannabinoid activity of an extensive library of THC structural analogs. Levonantradol was found to mimic the effects of THC, although with higher potency, it was used to provide the first biochemical evidence that THC-like molecules inhibit adenylyl

cyclase activity with characteristics that indicated the involvement of a ► G-protein coupled receptor (GPCR). In 1990, the cloning and sequencing of the cannabinoid receptor was reported, confirming both its membership in the GPCR superfamily of receptors and its identity as a high-affinity binding site for THC. This receptor, now referred to as the CB1 ► cannabinoid receptor (CB1R), is the protein product of the *Cnr1* gene. Biochemical studies of the ability of THC to activate the CB1R indicated that THC had surprisingly low efficacy at the CB1R. In other words, although THC binds to the CB1R with high affinity, the THC-bound receptor has a limited ability to activate signaling. As a consequence, THC functions as an antagonist at CB1R that are activated by endogenous ligands and as an agonist at CB1R that are not endogenously activated.

Devane, Mechoulam, and colleagues isolated and identified *N*-arachidonylethanolamine (AEA, also called anandamide) as an endogenous ligand of the CB1R. Several years later, 2-arachidonoylglycerol (2-AG) was identified as a second endogenous ligand of the CB1R. The term "endocannabinoid" is used to refer to these two endogenous, cannabinoid receptor ligands. AEA is the ethanolamide of arachidonic acid, whereas 2-AG is the glycerol ester of arachidonic acid. Both are found in the brain and in the circulation; both bind and activate the CB1R at a binding site that overlaps with that of THC. AEA is a partial agonist of the CB1R and 2-AG is a full agonist.

Mechanisms of AEA Biosynthesis and Catabolism

AEA is a minor member of a family of ethanolamides of fatty acids (*N*-acylethanolamines; NAEs). The immediate precursor of AEA and other members of the NAE family is *N*-acylphosphatidylethanolamine (NAPE), a low-abundance membrane phospholipid that is most likely synthesized via the actions of a poorly understood transacylase. NAPE is subsequently hydrolyzed to NAE via either a single enzymatic step (NAPE-phospholipase D; NAPE-PLD) or via a two-step process recently described by Simon and Cravatt (2008). Very little is currently known about the regulation of these enzymatic processes. There is evidence that increased intracellular calcium can increase AEA biosynthesis; however, whether this is of biological significance is not clear.

AEA is degraded in the brain by ► fatty acid amide hydrolase (FAAH). FAAH-mediated catabolism is a primary mechanism by which brain AEA concentrations are regulated. FAAH is largely constitutively active; the major mechanism for the regulation of FAAH appears to be at the level of its expression. For example, FAAH expression is increased by progesterone and leptin and decreased by ► estrogen and glucocorticoids. Since FAAH is constitutively active, its inhibition would be expected to increase AEA concentrations and, thus, activate CB1R signaling. FAAH inhibitors would be expected to function as indirect agonists of the CB1R.

Mechanisms of 2-AG Biosynthesis and Catabolism

2-AG is synthesized from diacylglycerol (DAG) by an sn-1-acting DAG lipase (DGLα). DAG is a product of phospholipase C (PLC) hydrolysis of phosphorylated phosphoinositides. All isoforms of PLC produce DAG and, thus, could result in 2-AG synthesis. In particular, mGluR activates PLC$ß_1$ and both mGluR and PLC$ß_1$ are co-localized with DGLα in dendrites in proximity to CB1R-expressing axons. This places 2-AG signaling downstream and under the control of ► glutamate signaling.

The primary mechanism of 2-AG inactivation in the brain is via hydrolysis by monoacylglycerol lipase (MGL). MGL is present in brain regions in which the CB1R is also expressed, supporting the hypothesis that MGL regulates the amount of 2-AG available to activate the CB1R. A selective inhibitor of MGL increases the brain 2-AG content by eightfold and produces cannabinoid-like behavioral effects (Long et al. 2009), supporting the notion that catabolism as well as synthesis regulates 2-AG concentrations and, thus, CB1R function. These data suggest that inhibitors of MGL function as indirect agonists of the CB1R.

Localization of CB1 Receptors in the Nervous System

The CB1R is present in the CNS but exhibits a heterogeneous expression pattern. The CB1R is present at extremely high density in the cingulate gyrus, frontal cortex, ► hippocampus, cerebellum, and the basal ganglia. Moderate receptor densities are found in the basal forebrain, ► amygdala, ► nucleus accumbens, periaqueductal gray, and ► hypothalamus; low density is seen in the midbrain, pons, and medulla. Relatively little receptor is found in primary motor cortex or thalamus. Comparison of the expression profiles for CB1R protein and CB1R mRNA reveals several important distributional characteristics that have functional consequences. In the forebrain, CB1Rs are expressed at very high density in restricted number of neurons. These CB1R-expressing neurons project widely, resulting in a dense network of CB1R-positive processes. Double-labeling studies demonstrate that these highly expressing cells are GABAergic interneurons that also express the neuropeptide ► cholecystokinin (CCK). Other neurons express the CB1R at lower densities; these neurons are more heterogeneous and consist of non-CCK, GABAergic interneurons, and glutamatergic terminals.

Functional or anatomical evidence demonstrates that CB1R are also expressed by neurons in other regions of the nervous system. Within the spinal cord, CB1R are expressed by interneurons within the dorsal horn and on axon terminals of descending inputs into the dorsal horn. Primary sensory afferents express the CB1R at their terminals in the spinal cord and in the innervated tissues. CB1R are distributed throughout the enteric nervous system and their activation inhibits both intestinal motility and secretion – effects that are consistent with reports stating that *Cannabis* use reduces some of the signs and symptoms of irritable bowel disorder. CB1R agonists inhibit neurotransmitter release from neurons in the ileum and vas deferens through a presynaptic mechanism.

The CB1R is also expressed by non-neuronal cells in the CNS, including astrocytes, oligodendrocytes, and by endothelial and smooth muscle cells of the cerebral circulation.

CB1R Signaling

Activation of the CB1R results in the inhibition of adenylyl cyclase activity in most tissues and cells via activation of Gi-mediated signaling. In addition, CB1R activation is coupled with the activation of p42/p44 and p38 mitogen-activated kinases and Jun N-terminal kinase. CB1R activation has also been linked to the activation of PLC and Akt signaling in some cells; through these pathways, CB1R activation can influence intracellular calcium concentrations, protein kinase activities, and other signaling cascades that regulate cell growth and differentiation.

Pertinent to its role in psychopharmacology, CB1R activity regulates short-term signaling in the brain. Activation of CB1R present on axonal terminals results in an inhibition of the opening of voltage-operated calcium channels. This results in a reduction in calcium influx in response to an action potential or other depolarization and underlies the role of ► endocannabinoid signaling in the regulation of synaptic strength. This property of the CB1R underlies an important role for endocannabinoid/CB1R signaling in the retrograde regulation of synaptic transmission. Sustained glutamate release results in the mobilization of endocannabinoids from postsynaptic neurons, through increased intracellular calcium or activation of mGluR. The released endocannabinoids act on presynaptic CB1R leading to short-term inhibition of neurotransmitter release. There are two versions of this type of synaptic inhibition: depolarization-induced suppression of excitation (DSE), which is characterized by a reduction in the release of glutamate and DSI, which is the reduced release of GABA. Though endocannabinoid-mediated DSI and DSE are transient, endocannabinoid signaling also underlies more persistent forms of synaptic plasticity. For example, long-term depression of inhibition is mediated by endocannabinoid mobilization and activation of CB1R; it most likely involves a kinase signaling cascade, as CB1R activation results in long-lasting changes in neurotransmitter release.

CB1R Pharmacology

There are currently two preparations of CB1R agonists available in the US and a third preparation is in Phase III clinical trials. Marinol® is a synthetically prepared THC (also called ► dronabinol) that is used as an oral formulation. Nabilone, which is marketed in North America under the trade name Cesamet®, is structurally very similar to THC, but binds to the CB1R with higher affinity and efficacy than THC. In the USA, dronabinol and nabilone have been approved to treat chemotherapy-induced nausea and vomiting and to stimulate appetite in AIDS-related anorexia and weight loss. In addition, nabilone is often prescribed off-label as a treatment for chronic pain, particularly neuropathic pain. A third preparation, Sativex®, is a 1:1 combination of plant-derived THC and a second plant-derived cannabinoid, cannabidiol (CBD). There is good evidence that the presence of CBD in this preparation results in a reduction of adverse effects, particularly anxiety that can occur with the use of THC alone. Sativex is formulated as an oral spray and is currently approved in Canada and rapidly approaching approval the UK for the treatment of pain and spasticity of multiple sclerosis and for cancer pain. Sativex is currently in Phase III trials in the US for the same indications.

Several antagonists of the CB1R have been developed; the prototype is ► rimonabant (previously named SR141716 and SR141716A). Rimonabant is a reversible, competitive antagonist of the CB1R; it also has some ► inverse agonist efficacy. Until late-2008, rimonabant was approved in Europe and the UK for the treatment of obesity, diabetes, and metabolic disorder under the trade name Acomplia®. In November 2008, Acomplia was withdrawn from the market because its use resulted in an unacceptable number of adverse psychiatric events. These events included depression, anxiety, and sleep disturbances. Rimonabant has not received US FDA approval, largely because of its profile of adverse effects.

Potential Therapeutic Uses of Cannabinoids in Psychiatry

Preclinical and human data support a possible therapeutic role for cannabinoid receptor ligands in the treatment of ► anxiety, ► mood disorders, ► schizophrenia, and addictive behaviors. In addition, evidence has accumulated that dysregulation of endocannabinoid/CB1R signaling

could contribute to the risk of the development of psychiatric disorders. The therapeutic promise of cannabinoid-based therapeutics is hampered by adverse psychiatric effects; for ▶ agonists, these are cognitive impairment and for ▶ antagonists, the effects are depression and anxiety. Unfortunately, most of the adverse effects of CB1R agonists and antagonists result from the activation or inhibition of CB1R signaling, not from an off-target mechanism. The CB1R does not exhibit subtypes that would be amenable to the development of drugs selective for the desired over-adverse effects. Although not currently available for use in humans, indirect agonists, including inhibitors of FAAH and MGL, will be arguably more selective as they will only enhance signaling through CB1R that are engaged by endocannabinoids. Preclinical studies with inhibitors of FAAH support this hypothesis.

Anxiety

There is considerable evidence that the activation of CB1R results in decreased ▶ anxiety in humans. This evidence includes the data that the most commonly cited reasons for recreational *Cannabis* use are relaxation and reduction in tension. Although *Cannabis* can also induce anxiety and panic in some individuals, anxiety reactions are more common in stressful environments, with high doses and in inexperienced users. A recent meta-analysis of four large clinical trials indicated that patients taking rimonabant had a significantly greater increase in anxiety symptoms while taking the drug than patients taking placebo (Christensen et al. 2007). Therefore, human experience with a cannabinoid receptor agonist (THC) and antagonist (rimonabant) support the hypothesis that endocannabinoid signaling regulates anxiety in humans and suggest that activation of the CB1 receptor by endocannabinoids could produce anxiolytic effects. A functional single nucleotide polymorphism (SNP) in FAAH (C385A; rs 324420) is associated with reduced FAAH stability and, therefore, has been hypothesized to result in increased AEA-mediated CB1R activation. Individuals who are homozygous for this SNP, exhibited decreased threat-related activation of the amygdala in a recent imaging genetics study (Hariri et al. 2008). This study suggests that genetic variation in endocannabinoid signaling could underlie individual risk for the development of anxiety-related disorders.

Data from animal models of unconditioned anxiety support the hypothesis that activation or enhancement of endocannabinoid/CB1R signaling can produce a reduction in anxiety. This aspect of endocannabinoid signaling appears to be tonically "on" or easily activated since treatment of rodents in mildly aversive environments with CB1R antagonists enhances anxiety behaviors, whereas FAAH inhibition is anxiolytic. ▶ Conditioned fear is a model for certain types of anxiety disorders including post-traumatic stress disorder (PTSD). It has been conclusively demonstrated that inhibition of CB1R signaling impairs the extinction of conditioned fear responses, whereas activation of CB1R signaling enhances extinction of fear responses (Lafenetre et al. 2007). Taken together, these preclinical studies suggest that activation of CB1R signaling could be very useful in the treatment of disorders in which recurrent, fearful memories occur, such as PTSD.

Drug Addiction

Current understanding of drug addiction strongly suggests that drugs with abuse liability share an interaction with brain circuits involved in motivated behavior and reward. In particular, drug-induced plasticity in the mesocorticolimbic circuit contributes to addiction by consolidating reward-driven behavior. CB1R are abundant in the reward circuit and endocannabinoids contribute to ▶ synaptic plasticity in these regions through the mechanisms described above. While the CB1R in these regions certainly contribute to the rewarding effects of THC itself, there is also strong evidence that endocannabinoid signaling is involved in the rewarding and addictive properties of all abused substances (Maldonado et al. 2006). In particular, data suggest that endocannabinoids are released within the ▶ ventral tegmental area (VTA) and that they enhance the activation of dopamine neurons, resulting in potentiation of drug seeking behavior. In agreement with this mechanism, clinical trials with CB1R antagonists show modest efficacy in smoking cessation, particularly when combined with nicotine replacement therapy.

Schizophrenia

Epidemiological evidence indicates that *Cannabis* use can induce psychotic states in healthy individuals, worsen psychotic symptoms of schizophrenic patients, and precipitate ▶ schizophrenia in otherwise susceptible individuals (Ujike and Morita 2004). Examination of CB1R density postmortem reveals that the density of CB1R is higher in the ▶ prefrontal cortex of schizophrenic patients than controls; AEA is also increased in the cerebrospinal fluid of schizophrenic patients. Genetic studies have found that individuals with a repeat polymorphism in the *Cnr1* gene have a 2.3-fold higher risk for the development of schizophrenia than those without this sequence. Taken together, these results suggest that hyperactive CB1R signaling, particularly in the prefrontal cortex, is involved in the pathogenesis of schizophrenia. This hypothesis is supported by preclinical studies as well.

The hypothesis that hyperactive CB1R signaling contributes to the symptoms of schizophrenia led to a limited trial of rimonabant in schizophrenics. The results of this trial were not remarkable; rimonabant did not provide efficacy over that of placebo. While these findings indicate that reduced CB1R activation is not globally effective as a treatment for schizophrenia, it is possible that it would be effective in a subpopulation of patients.

Depression

Elevation of mood is a commonly cited motivation for the use of *Cannabis*. Several clinical trials in the 1970s designed to determine the anti-depressant efficacy of THC found that it failed to improve the symptoms of depression and produced unacceptable adverse effects. A similar hypothesis, that depressed individuals self-administer *Cannabis* because it elevates mood, predicts that depressed people use *Cannabis* to elevate mood more frequently than nondepressed users. This prediction was not upheld in a recent study (Arendt et al. 2007); in fact, depressed subjects experienced more depression, aggression, and sadness when intoxicated with *Cannabis* than when they are not intoxicated.

Cannabis dependence and depression are co-morbid diagnoses more than being expected by chance and available evidence suggests that a common factor or factors predispose individuals to both depression and *Cannabis* dependence. There is evidence that common genetic and environmental factors contribute to both diagnoses.

Bipolar Disorder

People with ▶ bipolar disorder have a 30–61% life-time likelihood for abusing *Cannabis*, compared with 6% in the general population. It is very likely that the co-occurrence of bipolar disorder and *Cannabis* use results from a combination of patients in whom bipolar disorder initiates *Cannabis* abuse and others in whom *Cannabis* abuse initiates bipolar disorder. The first subgroup of patients includes those who use *Cannabis* either in an attempt of self-medication or as a direct result of the mania, which evokes excessive involvement in pleasurable activities such as substance abuse. Evidence supporting this type of relationship between bipolar disorder and *Cannabis* abuse is sparse. In fact, the available data suggest the opposite, that many patients initiate *Cannabis* use prior to the onset of bipolar symptoms. A third option, which has not been studied at all in detail, is that bipolar disorder and substance abuse are both triggered by a common mechanism. An interesting possibility is that early life stress is a precipitating factor for both substance abuse and mood disorders.

Conclusion

Endocannabinoid activation of CB1R in the brain is involved in the modulation of limbic circuitry. It is not surprising that changes in endocannabinoid signaling, either as a result of *Cannabis* use or treatment with CB1R antagonist, affect mood, motivated behavior, learning, and fear responses. These data lead to the possibility that therapeutic agents that target endocannabinoid signaling for the treatment of psychiatric disorders, could be developed. However, current literature leads to the conclusion that this could be a difficult, although possible, goal. The most possible goals are the treatment of anxiety with indirect CB1R agonists, particularly inhibitors of FAAH, and substance abuse with CB1R antagonists.

Definition

Cannabis abuse and dependence are disorders similar to the other ►substance abuse and ►dependence disorders. Problems related to misuse or overuse of cannabis can include social, psychological, and medical consequences. A subset of cannabis users meet the DSM or ICD diagnostic criteria for abuse or dependence which reflect an impairment of daily functioning, repeated use that puts them at risk of harm, failed attempts to cut down or quit, loss of controlled use, or development of tolerance or withdrawal.

Role of Pharmacotherapy

Controversy Over Cannabis Dependence

Controversy regarding the addictive potential of cannabis has propagated since the early 1900s. Advances in the clinical, neurobiological, and behavioral sciences over the last 20 years have provided an empirical base to resolve the major aspects of this enduring controversy. Epidemiological, laboratory, and clinical studies have demonstrated that cannabis dependence occurs, is relatively common, is clinically significant, causes harm, and is difficult to treat. As with other drugs, the majority of people who have tried cannabis do not develop a problem with addiction. However, in the USA, approximately 4% of those older than 12 years, at some time in their lives, have met criteria for cannabis dependence disorder, as defined in the *Diagnostic and Statistical Manual of Mental Disorders* (►*DSM*). This prevalence rate is more than double the lifetime dependence rate for any other illicit drug, reflecting the widespread use of cannabis. ►Conditional dependence rates, that is, the percentage of persons who have ever used a drug who go on to become dependent, suggest that cannabis use is less likely to lead to dependence relative to use of most other illicit drugs. In the USA, approximately 9% of those who try cannabis become dependent compared with lifetime dependence rates of 15% for people who try cocaine and 24% for those who try heroin. Although lower in relative terms, the fact that 9% of cannabis users become dependent is cause for concern given the large number of users. Indeed, the number of people who seek treatment for cannabis abuse and dependence has been steadily increasing in the USA, Europe, and Australia, and is now comparable to the number seeking treatment for cocaine or opiates in some countries.

Two related areas of scientific discovery have provided additional evidence for the addictive potential of cannabis. First, a neurobiological basis for dependence was uncovered with the discovery of the endogenous cannabinoid system in the central nervous system. Specifically, scientists have identified ►cannabinoids that occur naturally in the brain (anandamide, 2AG) and localization of cannabinoid receptors that serve as the sites of action for the direct effects of cannabis and other cannabinoids. Second, human and nonhuman research has established the reliability, validity, time course, and pharmacological mechanism for a true cannabis ►withdrawal syndrome that appears similar to tobacco withdrawal in magnitude and severity (Budney and Hughes 2006; Lichtman and Martin 2002). Prior to these findings, the existence of a clinically significant cannabis withdrawal syndrome was questioned as evidenced by its omission from the DSM. This growing body of research will prompt strong consideration for the inclusion of cannabis withdrawal in the upcoming revision of the DSM.

Epidemiological and controlled treatment evaluation research indicates that the Cannabis Dependence syndrome shares most of the same phenomenology as other types of substance dependence, and the DSM-IV dependence criteria items appear to capture all aspects of the syndrome (cf. Budney 2006). Though the phenomenology of

cannabis dependence is similar, there appear to be some differences in severity relative to dependence typically associated with substances like alcohol, cocaine, or opiates. On average, individuals with cannabis dependence do not meet as many DSM dependence criteria, the withdrawal experience causes discomfort but is not associated with major health risks, and the associated health and psychosocial consequences, although substantial, are typically not as severe. Despite this milder dependence syndrome, quitting cannabis once addicted does not appear any easier than trying to quit other substances. Many of those dependent on cannabis typically use it multiple times per day; they may be ambivalent about its negative effects; they acknowledge multiple perceived positive effects; and the cost is relatively low. All these factors make quitting difficult. Note that the same types of behavioral treatments that are efficacious for other substances (cognitive-behavioral, motivational, and contingency management) have proven effective for cannabis dependence, but the majority of cannabis users who enroll in treatment fail to achieve sustained abstinence (Budney et al. 2007; Roffman et al. 2006).

This body of research suggests that continued debate over whether or not cannabis use can lead to dependence or addiction is obsolete. Cannabis misuse and addiction are relatively common and are associated with significant negative consequences. Moreover, cannabis-related problems reflect a significant public health issue that requires continued attention and action towards developing more effective treatment and prevention interventions.

Neurobiology of Cannabis and the Potential Role of Pharmacotherapy

The increased recognition of the need for effective treatments for cannabis dependence, and the important advances in the understanding of the neurobiology of its actions, has recently led researchers to develop and evaluate potential pharmacotherapies. Delta-9-tetrahydrocannabinol (THC), the primary psychoactive component of cannabis, is a ▶ partial agonist of the CB1 receptor, a G-protein-coupled receptor that is expressed in the brain at the highest concentrations in the basal ganglia (motor control), cerebellum (sensorimotor coordination), hippocampus (memory), and cortex (higher-order cognition) (Cooper and Haney 2009). In addition to direct action on the CB1 receptor, cannabis alters the functioning of several other neurotransmitter systems including those associated with dependence on other drugs such as ▶ alcohol, ▶ cocaine, and ▶ opiates. Specifically, THC and other CB1 receptor agonists have been shown to increase dopamine (DA) release in the mesolimbic-dopamine reward pathway and enhance electrical ▶ brain-stimulation reward. These effects are associated with appetitive drug-seeking and drug-taking behaviors. Also, abrupt cessation of chronic cannabinoid exposure increases ▶ corticotropin releasing factor and decreases dopamine in the ▶ mesolimbic-dopamine reward pathway. These neurobiological changes have been linked to the dysphoric effects associated with ▶ withdrawal from addictive drugs and are thought to contribute to ▶ relapse.

Because chronic cannabis use is associated with neurobiological features similar to those observed with dependence on other drugs, pharmacological approaches successfully applied in the treatment of other drug-use disorders might be similarly effective in the treatment of cannabis-use disorders. One such approach is the use of agonist medications, compounds that have a similar mechanism of action as the abused drug or involve administration of a key component of the abused drug via a different route (e.g., ▶ methadone for opiate dependence, nicotine patch for tobacco dependence). Agonist pharmacotherapies are attractive because they typically attenuate symptoms of withdrawal, are generally well tolerated, and may blunt the reinforcing effects of the abused substance in the case of relapse. Clinical laboratory studies have demonstrated that dronabinol (orally administered THC) reliably and dose-dependently attenuates cannabis withdrawal symptoms and the subjective reinforcing effects of smoked cannabis, but to date there is no evidence that it reduces rates of self-administration. Published case reports and anecdotal reports suggest that dronabinol, when combined with psychosocial counseling, might be an effective ▶ pharmacotherapy for the treatment of cannabis-use disorders. Placebo-controlled clinical trials are currently testing this possibility.

Another pharmacological approach to drug dependence is the use of medications that suppress the reinforcing effects of the abused drug. Examples of this include use of receptor ▶ antagonists (e.g., ▶ naltrexone for opiate dependence) or ▶ vaccines (e.g., nicotine conjugate vaccine for tobacco dependence), which prevent/reduce binding to target receptors in the CNS. Several compounds have been synthesized that exhibit antagonist-like (inverse agonist) effects at the CB1 receptor in non-human species (e.g., suppress self-administration of cannabinoids or precipitate withdrawal). One of these compounds, rimonabant (SR141617A), has been shown to partially attenuate the subjective reinforcing effects of smoked cannabis in humans. In a small open-label clinical trial, administration of rimonabant was associated with a

reduction in cannabis use. While these results indicate some degree of clinical utility, present concerns regarding the safety of rimonabant have resulted in the medication being pulled off the market in most countries. Other neutral CB_1 antagonists that do not inhibit agonist-independent activity of CB_1 receptors and are therefore hypothesized to have a more acceptable side-effect profile compared to CB_1 inverse agonists like rimonabant are under development and may show promise in future studies. To our knowledge, no vaccine for THC or other cannabinoids has been developed.

A third pharmacotherapy approach is to identify medications with pharmacological mechanisms that are different from that of the abused drug, but that may provide clinically desirable effects (e.g., alleviate specific withdrawal symptoms or reduce desire for or liking of the substance). A number of medications typically used to treat affective disorders or other substance use disorders have been investigated as potential adjunct treatments for cannabis use disorders with very limited positive findings (Benyamina et al. 2008; Vandrey and Haney, 2009). ▶ Bupropion and divalproex significantly worsened mood compared with placebo during periods of cannabis abstinence. Nefazodone significantly decreased ratings of anxiety and muscle pain during abstinence, but did not alter other prominent features of cannabis withdrawal. ▶ Lofexidine significantly reduced several symptoms of withdrawal and improved sleep during periods of abstinence, but was associated with significantly increased sedation during the day. The combination of lofexidine and dronabinol significantly reduced withdrawal, improved multiple measures of sleep, and reduced cannabis self-administration during a laboratory relapse test. The combination of dronabinol and lofexidine also increased sedation and drug effect ratings during the day, but it is uncertain whether these effects occurred at a magnitude that would warrant concern in clinical use. A low dose of the opioid naltrexone decreased the intoxicating effects of 20 mg but not 40 mg of dronabinol, whereas higher doses either failed to attenuate or enhanced the subjective effects of dronabinol and smoked cannabis. Another laboratory study showed that pre-dosing with clonidine, a medication used to treat symptoms of opioid withdrawal, reduced cannabis-induced tachycardia, but did not reduce subjective effects.

Several small clinical studies of other commonly used psychiatric medications have recently been tested as treatments for cannabis dependence with few positive findings. ▶ Atomoxetine did not significantly reduce cannabis use and was associated with a high rate of adverse events. An initial trial with ▶ buspirone reported decreased cannabis use, craving, and irritability, but these effects were not replicated in a larger placebo-controlled trial. Two open-label studies of ▶ lithium suggested that it may have some positive effect on withdrawal and cannabis use, but side effects were frequent and the positive effects have not been replicated in controlled studies. The atypical antipsychotic ▶ quetiapine reduced cannabis use in a small study of cannabis-dependent patients with a diagnosis of either ▶ schizophrenia or ▶ bipolar disorder, but this effect has not been replicated in a controlled study and quetiapine has not been assessed in a more general population of cannabis users. Maintenance on the antidepressant ▶ mirtazapine improved subjective measures of sleep compared to placebo, but did not improve other clinical outcomes, including cannabis use, in a controlled clinical trial. Finally, one clinical trial of ▶ fluoxetine for the treatment of alcohol dependence and depression reported that cannabis-dependent participants in that study reported using less cannabis, and using cannabis on fewer days; however, prospective tests examining the effect of fluoxetine on cannabis use have not been reported. A summary of pharmacotherapy research is provided in Table 1.

Summary

Cannabis abuse and dependence pose a significant public health problem. Relatively large numbers of adolescents and adults enroll in treatment programs with cannabis as the primary substance of concern. Unfortunately treatment response rates for cannabis dependence are not substantially better than those observed for most other substance-dependence disorders. ▶ Empirically based behavioral treatments have been identified. Most recently, significant research efforts have focused on the development of pharmacological adjuncts to improve treatment outcomes. To this end, laboratory studies that target the CB1 receptor have demonstrated the most clinically desirable and promising effects (suppressed withdrawal, reduced effects of cannabis). However, results of controlled clinical trials of agonist or antagonist medications have yet to be completed, and there are significant concerns about side effects of each. The medications with pharmacological mechanisms other than the cannabinoid receptor system have thus far exhibited limited clinical benefit, but there is recent laboratory evidence that combinations of these medications and CB1-receptor-specific medications may hold promise. Ongoing research efforts include expanded medication assessments in humans (controlled clinical trials; laboratory studies of hypnotic and anticonvulsant medications), and preclinical development of new

Cannabis Abuse and Dependence. Table 1. Summary of medications tested for potential therapeutic benefit in cannabis users.

Medication tested	Current indication	Mechanism of action	Outcome
Atomoxetine	ADHD	Norepinephrine reuptake inhibitor	No effect on cannabis use, concerning side effects (GI)
Bupropion	Depression, smoking cessation	Norepinephrine and dopamine reuptake inhibitor	Reduced effects of smoked cannabis, but exacerbated cannabis withdrawal symptoms
Buspirone	Anxiety	Serotonin $5HT_{1A}$ receptor partial agonist	Reduced cannabis use, craving, and irritability in pilot study; effects not replicated in placebo-controlled clinical trial
Clonidine	Hypertension, opiate dependence	α_2 adrenergic agonist	Reduced tachycardia, but not subjective effects
Divalproex	Bipolar disorder, epilepsy, migraines	Unknown	No effect on cannabis use; increased withdrawal and effects of smoked cannabis
Dronabinol	Nausea/vomiting, excessive weight loss associated with AIDS wasting	Cannabinoid CB1 receptor agonist	Reduced cannabis withdrawal and subjective effects of smoked cannabis, but had no effect on reinforcement of cannabis and did not prevent relapse in laboratory studies, aided long-term cannabis cessation in 2 case studies
Fluoxetine	Depression, OCD, eating disorders, panic disorder	Selective serotonin reuptake inhibitor	Reduced self-reported cannabis use among a treatment sample of depressed alcoholics
Lithium	Bipolar disorder	Unknown	2 open-label studies suggest reduced withdrawal and cannabis use
Lofexedine	Opiate dependence	α_2 adrenergic agonist	Reduced withdrawal and relapse alone and in combination with dronabinol
Mirtazapine	Depression	α_2 adrenergic antagonist, $5HT_2$ and $5HT_3$ antagonist	Improved subjective sleep during abstinence, no effect of cannabis use outcomes
Naltrexone	Alcohol and opiate dependence	Mu-opioid receptor antagonist	Low dose (12 mg) decreased subjective effects of 20 mg, but not 40 mg oral THC; high doses ($\geq$50 mg) increased or had no effect on the subjective effects of oral THC or smoked cannabis
Nefazodone	Depression	Norepinephrine and serotonin reuptake inhibitor, $5HT_2$ receptor antagonist	Reduced select withdrawal effects but had no effect on total withdrawal severity or the subjective effects of smoked cannabis
Quetiapine	Schizophrenia and bipolar disorder	Antagonism of $5HT_2$ D_2 α_1 α_2 and H_1 receptors	Reduced cannabis use in small sample with schizophrenia or bipolar disorder
Rimonabant	Obesity	Cannabinoid CB1 receptor antagonist	Attenuated subjective and physiological effects of cannabis in laboratory studies. Reduced cannabis use in small open-label clinical study. Side-effect concerns.

medications that target the CB1 receptor system (e.g., second-generation agonists and antagonists, inverse agonists, and FAAH inhibitors) (Janero et al. 2009).

CANTAB

Synonyms

Cambridge neuropsychological test automated battery

Definition

A battery of tests for human cognition that are partly derived from tests of cognition in animals. The battery includes tests of spatial working memory, paired visuospatial associate learning (PAL), recognition memory, set-shifting, and a human analogue of the five-choice serial reaction time (http://www.cantab.com/camcog/default.asp). There is also a CANTAB battery for nonhuman primates.

Capacitation Function of Spermatozoa

Definition

The process that enables spermatozoa to undergo the acrosomal reaction, whose endpoints consist in the hyperactivated motility and the exocytotic release of enzymes, which are considered of major importance for the fertilization of the oocyte.

► Delusional Disorder

Carbamazepine

Definition

Carbamazepine is an antiepileptic drug that is also used in treating bipolar disorder, although clinically it has been extensively used in various patient populations since it has been in clinical use for over 50 years. Although its mechanism of action is not fully understood, its main action is at sodium channels leading to reduced excitability in nerve cells.

Carbidopa

Synonyms

MK486; S-alpha-hydrazino-3,4-dihydroxy-α-methyl-bensemonopropanoic acid monohydrate

Definition

Carbidopa is a peripherally acting aromatic L-amino acid decarboxylase or DOPA decarboxylase inhibitor. Carbidopa does not cross the blood–brain barrier, but increases the plasma half-life of ► L-DOPA, the dopamine precursor, thus increasing brain dopamine concentrations while reducing peripheral dopamine side effects, such as cardiac arrhythmias. Like other DOPA decarboxylase inhibitors, carbidopa is always used in combination with L-DOPA in the management of ► Parkinson's disease. It can also be combined with entacapone and L-DOPA in a triple combination.

Carbon-Fiber Amperometry

Definition
Carbon-fiber amperometry is used to study the exocytosis of certain hormones and neurotransmitters from target tissues and cells. It measures the concentration of such substances by the measurement of the electrochemical current caused by the transfer of electrons after oxidation (or reduction). Detailed analysis of the shape of the amperometric spike can provide valuable information regarding the events surrounding exocytosis.

Carpipramine

Definition
Carpipramine is a first-generation (typical) antipsychotic drug that belongs to the iminodibenzyl class indicated for the treatment of schizophrenia, particularly for negative symptoms. It has been found that carpipramine, and its pharmaceutically acceptable salts, possess antagonist properties with respect to D_2 and 5-HT_2 receptors, and are also useful in the treatment of depression, anxiety, and sleep disorders. It can induce insomnia, agitation, and extrapyramidal motor side effects, but it displays generally low toxicity.

Caspases

Definition
Caspases are cysteine proteases that play an essential role in apoptosis by cleaving key cellular proteins. They are synthesized as inactive pro-caspases that become sequentially activated upon cleavage by upstream caspases in a cascade-like manner. Caspases that cleave other caspases are referred to as "initiator" or "apical" caspases; caspases that cleave other cellular proteins are known as "effector" or "executioner" caspases.

Catatonia

Definition
Catatonia includes both psychic and motor disturbances and is classically associated with psychiatric conditions (such as ► schizophrenia, ► bipolar disorder, ► posttraumatic stress disorder, and ► depression). It can also be caused by dissociative agents, abuse of other drugs, and many medical conditions including encephalitis, autoimmune disorders, strokes, metabolic disturbances, and benzodiazepine withdrawal.

The DSM-IV criteria for catatonia include at least two of the following: motor immobility as evidenced by catalepsy and waxy flexibility or stupor; excessive and purposeless motor activity not influenced by external stimuli; extreme negativism (motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism; peculiarities of voluntary movement as evidenced by posturing, stereotyped movements, prominent mannerisms, or prominent grimacing;

echolalia (repetition of the words or phrases of another person) or echopraxia (involuntary repetition or imitation of the observed movements of another person).

► Cerebral Perfusion

Cerebral Perfusion

Synonyms

BOLD; CBF; CBV; Cerebral blood flow; Cerebral blood volume

Definition

Cerebral perfusion describes the amount of blood passing the brain capillary bed in a certain time period to deliver, that is, oxygen and glucose. Brain perfusion is defined by three quantities: cerebral blood flow (CBF), cerebral blood volume (CBV), and mean transit time (MTT). Brain activity is accompanied with an increase in cerebral energy consumption and consequently prompts changes in cerebral perfusion, thus changes in CBF, CBV, and concentration changes of oxy- and deoxygenated hemoglobin. To assess these processes, different functional MRI methods such as CBF-fMRI, CBV-fMRI, or BOLD-fMRI are applied as indirect measure for brain activity.

Chemical Modifications of Antisense Oligonucleotides

Definition

In order to increase efficiency, the cellular uptake and intracellular stability can be improved by chemical modification of antisense oligonucleotides. The most common chemical

modifications of antisense oligonucleotides are replacing an oxygen group of the phosphate-diester backbone with either a methyl group (methyl phosphonate oligonucleotide) or a sulfur group (phosphorothioate oligonucleotide). Methylphosphanates have high intracellular stability, the absence of charge, however, reduce their solubility and intracellular uptake. The phosphorothioates are the most widely used oligonucleotides, because of their relatively high nuclease stability, relative ease of synthesis, good solubility, and superior antisense properties. Importantly, phosphorothioated antisense oligonucleotides activate RNase H activity both in tissue culture and *in vivo*. Disadvantages include sequence-independent effects making well-designed controls essential. In order to increase specificity as well as efficacy of phosphorothioates, chimeric oligonucleotides are developed in which the RNase H-competent segment (the phosphorothioate moiety) is bounded on both termini by a higher-affinity region of modified RNA.

Other chemical modifications include 2′-OH modifications, locked nucleic acids (LNAs), peptide nucleic acids, morpholino compounds, or hexitol nucleic acids. Although high RNA affinity and high stability have been reported, they do not support RNase H activation. Nevertheless, they can exert their antisense activity via translational arrest or modulation of splicing.

Chlorazepate

Synonyms
Tranxene

Definition
Chlorazepate is a benzodiazepine-derived anxiolytic with anticonvulsant, sedative-hypnotic, and skeletal muscle-relaxant action. It is used for short-term relief of more severe forms of anxiety as well as adjunctive therapy in the management of partial seizures and alcohol withdrawal. The most common side effect is drowsiness while other, less-commonly reported effects include dizziness, blurred vision, headache, confusion, insomnia, irritability, depression, and tremor. As with other antiepileptic drugs, chlorazepate increases the risk of suicidal thoughts or behavior, thus patients receiving this therapy need to be monitored closely by their physicians and family. Like other ► benzodiazepines, it has a significant potential for abuse and dependence and abrupt cessation after prolonged use causes withdrawal symptoms which include anxiety, insomnia, dizziness, nausea and vomiting, tremor, irritability, tachycardia and postural hypotension, memory impairment and, in extreme cases, convulsions and delirium. It was withdrawn from the U.K. market in 2006.

Chlordiazepoxide

Definition
Chlordiazepoxide is ► benzodiazepine with anxiolytic, anticonvulsant, hypnotic, amnestic, and muscle-relaxant properties. Its medium to long ► half-life is exceeded by that of its active metabolite. The metabolites are largely responsible for its pharmacological activity. Clinical indications for chlordiazepoxide include the short-term treatment of severe ► anxiety and the management of acute ► alcohol withdrawal syndrome. Cholecystokinins

Jaanus Harro
Department of Psychology, University of Tartu, Estonian Centre of Behavioural and Health Sciences, Tartu, Estonia

Definition
Cholecystokinins (CCKs) are a group of peptides that possess a common C-terminal sequence and elicit various biological effects after binding to specific G protein coupled receptors termed CCK receptors. CCKs are defined as peptides that elicit gallbladder contraction and have the C-terminal sequence Tyr-Met-X-Trp-Met-Asp-Phe-NH_2,

where X is glycine in most mammals. CCKs can act as a hormone, growth factor or neurotransmitter.

Pharmacological Properties

Physiology

CCK peptides belong to a family of neuroendocrine peptides. CCK was discovered in extracts of the small intestine as a substance that elicits the hormonal gallbladder contracting effect and that can stimulate pancreatic secretion. That these two effects are mediated by the same substance was revealed in 1961 by Viktor Mutt, who also identified its chemical identity (Reeve et al. 1994). CCK also acts as a growth factor for the pancreas and as a neurotransmitter.

Only one CCK mRNA molecule is produced from the CCK gene, and its translational product, preproCCK, consists of 115 amino acid residues. This product is the source of all CCKs. The bioactive CCK peptides include those with 83, 58, 39, 33, 22, and 8 amino acid residues and these are produced in a cell-specific manner. CCK peptides share a common C-terminal sequence with another peptide, gastrin, which has recently also been found in multiple molecular forms (Rehfeld et al. 2007). Modification of this tetrapeptide amide sequence strongly reduces biological activity.

CCK peptides bind to CCK_A and CCK_B (alternatively, CCK_1 and CCK_2, respectively) receptors that are both coupled to G proteins. As ligands, CCK_A receptors require CCKs that are amidated at the C-terminal, and sulfated on a tyrosine in the seventh position from the terminal. These receptors mediate contraction of gallbladder and relaxation of the sphincter of Oddi, and pancreatic growth and enzyme secretion. These receptors are also expressed in the peripheral nervous system and in the anterior pituitary; expression in the brain is less prevalent than of the CCK_B receptors. The latter are identical to the gastrin receptor, and besides brain, are abundantly expressed on gastric ECL-cells and parietal cells, and in the pancreas. CCK_B receptors also bind non-sulfated CCK, CCK-5, and CCK-4 with high affinity. Importantly, the peripheral physiological responses mediated via CCK_B receptors are elicited by gastrin, because the plasma levels of gastrin are much higher than those of CCK (Rehfeld et al. 2007). In brain, CCK_B receptors are expressed with the highest density in the striatum, cerebral cortex, and the olfactory nuclei; moderate levels have been found in the ► hippocampus, substantia nigra, periaqueductal grey matter, and pontine nuclei.

CCK in circulation originates mainly from the intestinal endocrine cells that release the peptide in response to food rich in protein and fat. Since the satiety-inducing ability of CCK was discovered in 1973, many studies on animals and humans have shown it to serve as an endogenous satiety factor (Reeve et al. 1994). This satiety signal appears to be mainly mediated by the vagus nerve and subsequently the nucleus tractus solitarius and area postrema to the hypothalamus. CCK also inhibits gastric acid secretion, directly via CCK_B receptors and indirectly via CCK_A receptors stimulating ► somatostatin release.

Neuronal CCK

Neurons mainly synthesize and release CCK-8. At variance with many ► neuropeptides, expression of CCK is highest in the neocortex. Other brain regions enriched with CCK are caudate-putamen, hippocampus, and ► amygdala, and significant levels are present in thalamus, hypothalamus, olfactory bulb, ventral tegmental area and periaqueductal grey matter. CCK-8 release is, characteristically to neurotransmitters, evoked by potassium-induced depolarization and dependent upon calcium. CCK has been shown to elicit both excitatory and inhibitory postsynaptic potentials. CCK interacts with several other neurotransmitter systems, most notably ► dopamine, ► GABA, ► endogenous opioids and endocannabinoids (Harro 2006).

For both CCK receptors, a plethora of selective ligands of distinct chemical classes have been synthesized (Berna et al. 2007). This has strongly facilitated detailed studies on physiology of the CCK systems. Several of the drugs are chemically not peptides and are active when administered via enteral route.

Panicogenic Properties

Intravenous administration of CCK C-terminal tetrapeptide (CCK-4) or pentapeptide (CCK-5 or pentagastrin) elicits ► panic attacks in patients with panic disorder and in healthy volunteers. This effect is dose dependent. The most common symptoms in response to a bolus injection of CCK-4 are dyspnea, palpitations, chest pain or discomfort, faintness, dizziness, paresthesia, hot flushes or cold chills, nausea or abdominal distress, anxiety or fear or apprehension, and fear of losing control. In panic disorder patients the attacks are not distinguishable to them from their spontaneous panic attacks. The panic disorder patients are more sensitive to the CCK-4 challenge than healthy subjects, but patients with other anxiety disorders do not differ in this regard from healthy volunteers. In panic disorder patients, a few alterations in CCK levels or cellular responses to CCK have been reported, but all findings remain waiting for independent replication. CCK-4-induced anxiety is accompanied by a robust activation in a broad cerebral network including anterior cingulate cortex, middle and superior frontal gyrus, precuneus, middle and superior temporal gyrus,

occipital lobe, sublobar areas, cerebellum and brainstem (Dieler et al. 2008).

The panicogenic effect of administered CCK-4 can be prevented by treatment with ▶ benzodiazepines or CCK_B receptor antagonists, or chronic administration of tricyclics. However, attempts to cure panic disorder or generalized anxiety disorder with non-peptide CCK_B antagonists of different chemical classes have been unsuccessful. It has been proposed that the failure of attempts to prevent panic attacks in panic disorder with CCK_B antagonists used in published studies is due to limitations of these treatments (poor bioavailability and/or insufficient brain penetration of the compounds), but while such a suggestion is not entirely in contradiction with the efficacy of these drugs against CCK-induced panic in humans, it is certainly weakened by this evidence (Harro 2006).

CCK Receptor Agonists and Antagonists in Animal Models of Anxiety

Both systemic and intracerebral administration of CCK peptides has been found to elicit anxiogenic-like effects in ▶ animal models of anxiety, including ▶ elevated plus-maze and ▶ open field test, and several others. These effects are usually antagonized by CCK_B but not CCK_A receptor antagonists. It should be noted that the efficacy of low, non-sedating doses of CCK peptides is not universally reproduced across laboratories and may require presence of unknown environmental factors. CCK_B receptor antagonists as a single treatment have been reported to possess anxiolytic properties, but several thorough studies have not supported such a claim and it seems possible that the anxiolytic-like effect is mimicked by enhancement of locomotor activation by these drugs (Harro 2006).

Behavioral tests that are most sensitive to anxiety-related effects of CCK receptor ligands include potentiated startle, and particularly those that are based on exploratory activity. Effects of CCK receptor ligands on defensive behavior are weak and on social behavior rather contradictory. Conflict tests based on ▶ punishment procedures are not sensitive to CCK, and when exploratory behavior is punished as in the four plate test, CCK antagonists fail to show anxiolytic-like action.

Neurobiology of CCK in Animal and Human Anxiety

Studies that have examined levels of CCK or CCK receptors in anxiety have not found consistent alterations in CCK expression, but increases in CCK_B ▶ receptor binding have been described in animal models of anxiety and in human postmortem studies. CCK_B receptor binding sites are upregulated in cerebral cortex and cerebellum of persistently anxious or stressed rats, and in transgenic mice that overexpress CCK_B receptors anxiety levels are higher, this increase being sensitive to ▶ benzodiazepine anxiolytics. CCK receptor binding has been found increased in frontal and cingulate cortex of human ▶ suicide victims, and by measuring mRNA levels with quantitative PCR this has been confirmed and attributed to CCK_B subtype.

Brain regions in which neuronal CCK appears to play a role in anxiety-related behavior include cortex, amygdala (particularly basolateral), periaqueductal grey matter, cerebellum, septum, hippocampus (particularly areas CA1 and CA2), and paraventricular thalamus (Harro 2006). In some brain regions the anxiety-related effects of CCK are known to occur with some specificity: CCK in amygdala prevents ▶ extinction learning, and CCK-mediated activation of periaqueductal grey by anticipatory anxiety elicits hyperalgesia. In several brain regions such as cortex, hippocampus and amygdala, anxiety-related effects of CCK may interact with changes in GABA-ergic activity. In several brain regions ▶ GABA and CCK coexist in a population of interneurons that also express ▶ endocannabinoid CB_1 receptors. Serotonin, noradrenaline, and opioids also modulate the anxiety-related effects of CCK. The anxiogenic effect of CCK-4 can be blocked with a ▶ CRF receptor antagonist. This suggests that CCK-elicited anxiety is dependent upon the activation of the HPA stress axis.

Stressful events have been associated with changes in CCK levels and CCK mRNA expression. Direct examination of extracellular levels of CCK after a stressful event as measured using in vivo ▶ microdialysis has suggested increased release of the peptide in the frontal cortex (Becker et al. 2001). Importantly, such an increase was observed in rats that had repeatedly been submitted to social defeat in the form of being placed first into a protected smaller environment within an aggressive resident's cage and subsequently allowed a physical contact, but not in animals that could after initial protected exposure explore the whole cage as the resident had been removed. Because ▶ microdialysis was conducted after protected exposure to the resident, the findings suggest that either in frontal cortex CCK is released only after sensitization by severe stressors or that learning of safety can prevent cortical CCK release. Adaptive or maladaptive changes in brain that underlie such differential reactions to threat may also cause the individual to react to drugs dependent upon stressfulness of the situation, as this has been reported for the effects of administered CCK peptides (▶ *Stress: Influence on drug action*). Several other studies also suggest that the role of CCK release in adapting with environmental signals depends upon the previous experiences of the subject, and these may determine whether the net effect of CCK release is anxiety, panic, or instead, perceived safety (Harro 2006).

Implications to Other Psychiatric Symptoms and Disorders

CCK is found in mesetelencephalic dopaminergic neurons that are implicated in ▶ schizophrenia. CCK inhibits dopaminergic activity, changes in the number of CCK expressing neurons have been reported in patients, and thus CCK peptides have been tested in clinical studies as adjuncts to standard antipsychotic treatment (Reeve et al. 1994). It is now known that the interaction between CCK and dopamine neurons takes place at several sites in the brain, involves both CCK receptor subtypes, and is thus very complex, which together with the differences in design in clinical studies may explain why unequivocal results have not been obtained. Alteration in cortical expression of CCK mRNA in schizophrenia could be specific to GABA-ergic circuits and relevant to working memory dysfunction in schizophrenia (Hashimoto et al. 2008).

CCK plays a significant role in cognition (Hebb et al. 2005). The ability of CCK to enhance fear-potentiated startle may be related to its anxiogenic properties, but also to an additional increase in vigilance or memory retention. CCK_B receptor deficient mice have increased locomotor activity and an impairment of spontaneous alternation behavior suggestive of deficiency of ▶ attention or memory. There appears to be a double dissociation between the anxiogenic and pro-cognitive effects of CCK: while many anxiogenic drugs can enhance learning and memory, CCK can be pro-cognitive even when no effect on emotion is observed, and yet in other paradigms reduce memory both in non-anxious and anxious subjects. Decreases in CCK levels that accompany aging have been associated with age-related memory loss.

CCK receptor antagonists modulate effects of ▶ psychomotor stimulants. Low doses of CCK_A antagonists reduce the locomotor enhancing effects of ▶ amphetamine, and such a coadministration prevents amphetamine sensitization from developing. Conversely, CCK_B receptor blockade enhances the psychomotor stimulant effect of amphetamine, and further increase sensitization. Thus, release of CCK occurs during the amphetamine-induced psychomotor response, and this release has opposite effects that are mediated simultaneously via CCK_A and CCK_B receptors and physiologically cancel each other out. Interference with this balance may be important in drug addiction. It seems that to be expressed in full, especially the synergistic effects of psychostimulants and CCK_B receptor antagonists require drug administration to be contingent with exposure to the testing environment.

CCK affects opioid-dependent pain perception (Berna et al. 2007; Hebb et al. 2005). Both CCK_A and CCK_B antagonists potentiate μ- and ∂-opioid receptor dependent analgesia. Disrupting CCK_B mediated neurotransmission by administration of antisense oligonucleotides or knocking the receptor out in mice also potentiates the effects of ▶ morphine and endogenous opioids. CCK acts as a mediator in the periaqueductal grey matter serving both as a positive feedback loop between spinal cord and brainstem that potentiates spinal transmission of nociceptive afferent input, and a suppressor of the opioid-driven anti-nociceptive descending pathway (Lovick 2008). Because ovarian hormones modulate the response of periaqueductal grey neurons to CCK, physiological fluctuations in pain sensitivity and responsiveness to opiates in females could involve changes in sensitivity to CCK. Whether drugs acting at CCK receptors could have a major effect on ▶ opiate dependence is less clear, but CCK_A antagonists have been reported to prevent the development of tolerance to morphine analgesia. Interestingly, CCK antagonists enhance the analgesic ▶ placebo effect and attenuate anxiety-induced ▶ hyperalgesia (Colloca and Benedetti 2007).

CCK is an obvious target in studies on obesity and eating disorders, and impaired CCK response to a meal has been reported to occur in bulimia nervosa patients. CCK receptors undergo complex regulation and can be rapidly desensitized and also resensitized. Continuous minipump infusion of CCK loses its behavioral, including anorectic efficacy in animal models, suggesting that CCK_A agonists may in principle not be sufficient as monotherapy. However, subchronic once daily administration of a peptide CCK_A receptor agonist has been found not to lead to tolerance in an operant feeding test. Nevertheless, in clinical studies CCK_A agonist monotherapy has so far failed to show any beneficial effect in obese subjects (Berna et al. 2007).

Therapeutic Potential

Many subtype-selective CCK receptor agonists and antagonists of different chemical classes are available, but there is no established therapeutic use (Berna et al. 2007). Regarding the CNS disorders of the few trials that have failed to show superiority of these drugs over placebo, the schizophrenia studies have been methodologically too limited to draw conclusions. Selective CCK_B antagonists have not been effective in ▶ panic disorder. However, animal research suggests that CCK ligands deserve investigation as adjunctive medications in anxiety and addictive disorders if applied together with appropriate behavioral therapies. CCK receptor antagonism may also prove beneficial when combined with other neurochemical actions.

Choline Acetyltransferase

Synonyms

ChAT

Definition

Choline acetyltransferase (ChAT) is an enzyme that is synthesized within the body of a neuron. It is then transferred to the nerve terminal via axoplasmic flow. The role of choline acetyltransferase is to join acetyl-CoA to choline, resulting in the formation of the neurotransmitter ► acetylcholine.

Cholinergic

Definition

Cholinergic means related to the neurotransmitter ► acetylcholine. The parasympathetic nervous system is entirely cholinergic. Neuromuscular junctions, preganglionic neurons of the sympathetic nervous system, the basal forebrain, and brain stem complexes are also cholinergic. There are also significant numbers of cholinergic nuclei in the mammalian brain.

Cholinesterase Inhibitors

Definition

Cholinesterase inhibitors are a group of medications used in the treatment of ► Alzheimer's disease. They inhibit CNS acetylcholinesterase in the synaptic cleft, thus preventing the degradation of endogenously released acetylcholine. There are three cholinesterase inhibitors that are marketed for treatment of the cognitive symptoms of Alzheimer's disease including ► donepezil, ► galantamine, and ► rivastigmine.

Chromatin

Definition

The major components of chromatin are DNA and histone proteins, although many other chromosomal proteins have prominent roles too. The functions of chromatin are to package DNA into a smaller volume to fit in the cell, to strengthen the DNA to allow mitosis and

meiosis, and to serve as a mechanism to control expression and DNA replication. The structure of chromatin (whether it is open or closed) around a gene determines the rate at which that gene is transcribed.

Chromatin Immunoprecipitation

Synonyms
ChIP

Definition
Chromatin immunoprecipitation (ChIP) is a method used to determine the location of DNA binding sites on the genome for a particular protein of interest. This technique gives a picture of the protein–DNA interactions that occur inside the nucleus of living cells or tissues. The principle underpinning this assay is that DNA-binding proteins (including transcription factors) in living cells can be cross-linked (often using formaldehyde) to the DNA to which they are binding. By using an antibody that is specific to a putative DNA binding protein, one can immunoprecipitate the protein-DNA complex out of cellular lysates.

Epigenetics

Definition
Changes in the structure of chromatin due to posttranslational modifications, such as histone acetylation, methylation, phosphorylation, and DNA methylation may lead to chromatin remodeling. These changes are also referred as epigenetic modifications that are responsible for changes in gene activity and expression without altering the DNA sequence.

Chronic Disappointment Reaction

Synonyms
Demoralization syndrome

Definition
A syndrome involving lowered or dysphoric mood that occurs in response to a perceived unpleasant situation or set of experiences that is repetitive or enduring. The offending experience typically represents an assault on the individual's self-concept or self-esteem. The person experiencing a chronic disappointment reaction may feel overmatched by the circumstances and may feel helpless and/or hopeless in terms of prospects for improving the situation. Such a person may engage in any of a number of attitudes or behaviors to protect his or her feeling state from further adverse impact – such as avoidance, disinterest, or psychosocial withdrawal. The person having the chronic disappointment reaction may or may not be fully aware of, or fully able to explain, the issue or issues to which the reaction is in response. A chronic disappointment reaction can continue with an open-ended duration.

Introduction: The Biological Clock

Living organisms are continuously influenced by external stimuli, many of which have rhythmic patterns. Environmental rhythms in daily and seasonal patterns of light, food availability, and temperature are predictable, and animals – including humans – have the ability to anticipate these environmental events with periodically and predictably changing internal conditions. These rhythmic patterns of anticipation have clear advantages and survival value. Thus, rhythmicity is the most ubiquitous feature of nature. Rhythms are found from unicellular to complex multicellular organisms in both plants, animals, and men. The frequencies of rhythms in nature cover nearly every division of time. There are rhythms that oscillate once per second (e.g., in the electroencephalogram), once per several seconds (respiratory rhythm, heart rate), up to rhythms that oscillate once per year (circannual rhythm).

The most evident environmental change that results from the regular spin of the earth around its central axis and resulting in the alternation between day and night seems to have induced the predominant oscillation, the circadian rhythm (the about-24-h rhythm; circa = about, dies = day, as proposed by Halberg (1959). There is sound evidence that living systems including humans are not only organized in space but are also highly organized in time.

Circadian rhythms have been documented throughout the plant and animal kingdoms at every level of eukaryotic organization. Circadian rhythms by definition are endogenous in nature, driven by oscillators or clocks (Aschoff 1965), and persist under free-running conditions. In various species (*Drosophila melanogaster, Neurospora, Mouse, Golden hamster*), the genes controlling circadian rhythms have been identified (genes: *per, frq, clock, tau*). In 1971, Konopka and Benzer (1971) were able to identify on the X chromosome of *Drosophila* a region, which controlled the period in the eclosion rhythm of three mutants (*per* clock gene). This data provided the first evidence that the biological clock is genetically determined and can even be transplanted from one animal into another, thereby inducing the rhythmicity of the donor into the recipient.

Circadian clocks are believed to have evolved in parallel with the geological history of the earth, and have undergone selection pressures imposed by cyclic factors in the environment. These clocks regulate a wide variety of behavioral and metabolic processes in many life forms. They enhance the fitness of organisms by improving their ability to efficiently anticipate periodic events in their external environments, especially periodic changes in light, temperature, and humidity.

The mammalian circadian clock, located in the neurons of suprachiasmatic nuclei (SCN) in the brain and in the cells of peripheral tissues, is driven by a self-sustained molecular oscillator, which generates rhythmic gene expression with a periodicity of about 24 h. This molecular oscillator is composed of interacting positive and negative transcription/translation feedback loops as

well as clock-controlled output genes. It is interesting to note that clock genes have been also found in single cells of human skin and mucosa (Bjarnason et al. 2001), furthermore, it has been shown that about 8–10% of all genes are regulated in a circadian fashion.

In general, the human endogenous clock does not run at a frequency of exactly 24 h, but tends to be somewhat slower. The rhythm in human body temperature, which is timed by the biological clock has a period of about 25-h under free-running conditions, i.e., without environmental time-cues or Zeitgebers (e.g., light, temperature). The term "Zeitgeber" introduced by Jürgen Aschoff (1954), is now part of the international scientific language. Mammals such as rodents or humans can entrain their activity to regular light cycles not shorter than 22 but not longer than 26 h. Zeitgebers entrain the circadian rhythm to a precise 24-h period. Zeitgebers are, therefore, necessary to entrain a living subject to a "normal" period of 24 h!

In experimental animals and in humans, however, most rhythmic fluctuations still cannot be studied under free-running conditions, leaving the answer open to what degree they are really "circadian." Purely exogenous rhythms are better termed as "24-h" or "daily" rhythms. Thus, an overt 24-h rhythm in a given parameter can be endogenous or predominately exogenous in nature. Within the published clinical literature, however, the term "circadian" is not always used in the above mentioned correct sense (as used by chronobiologists).

Circadian Rhythms in Man

It is a common paradigm in clinical pharmacology that pharmacokinetic parameters are considered not to be influenced by the time of day of drug administration. Concerning drug concentrations-versus-time profiles, "*the flatter the better*" is also a common aim in drug targeting. However, there is convincing evidence that this paradigm cannot be held any longer. The reason is that it is now well established that nearly all functions of the body, including those influencing ▶ pharmacokinetic parameters, display significant daily variations. Circadian or 24-h rhythms exist in heart rate, body temperature, blood pressure, blood flow, stroke volume, peripheral resistance, parameters of ECG recordings, in the plasma concentrations of hormones, neurotransmitters, and second messengers (e.g., cortisol, melatonin, insulin, prolactin, atrial natriuretic hormone, noradrenaline, cAMP), in the renin-angiotensin-aldosterone-system, in blood viscosity, aggregability and fibrinolytic activity, in the plasma concentrations of glucose, electrolytes, plasma proteins, enzymes, in the number of circulating red and white blood cells and blood platelets, etc. Moreover, various functions of the lung such as minute volume, peak flow, FEV_1, dynamic compliance, functions of the liver (metabolism, estimated hepatic blood flow, first-pass effect) and of the kidneys (glomerular filtration, renal plasma flow, pH, urine volume, electrolyte excretion) vary with time of day. Also gastric acid secretion, gastrointestinal motility, gastric emptying time, and GI-tract perfusion exhibit pronounced circadian variation (see Lemmer 1989, 2005, 2006; Reinberg and Smolensky 1983).

Chronoepidemiology

In man, the organization in time can also be seen in certain states of disease in which the onset and symptoms do not occur at random within 24 h of a day: Asthma attacks are more frequent at nightly hours than at other times of day as already observed about 300 years ago by John Floyer (1698) when stating "I have observed the fit always to happen after sleep in the night…."

Similarly, the occurrences of coronary infarction as well as of angina pectoris attacks and of pathologic ECG-recordings are unevenly distributed over the 24 h span of a day with a predominant peak in the early morning hours. Moreover, subtypes of a disease entity such as forms of vasospastic and stable angina pectoris

or of primary and secondary hypertensions may exhibit pronouncedly different 24-h patterns in their symptoms. The occurrence of stroke, fatal pulmonary embolism, the onset of gastrointestinal bleeding, etc., does also not occur at random within 24 h of a day.

Current Concepts and State of Knowledge

Chronopharmacology

Having in mind the organization in time of living systems including man, it is easy to conceive that not only must the *right* amount of the *right* substance be at the *right* place, but also this must occur at the *right* time. This is even more important when an organism or individual itself has to act or react in favorable biotic or environmental conditions, which by themselves are highly periodic. Thus, it is easy to understand that exogenous compounds, including drugs, may differently challenge the individual depending on the *time* of exposition.

Chronopharmacokinetics and Chronopharmacodynamics

In the last decade, numerous studies in animals as well as clinical studies, have provided convincing evidence that

the ▶ pharmacokinetics (Lemmer and Bruguerolle 1994) and/or the drugs' effects/side effects can be modified by the circadian time and/or the timing of drug application within 24 h of a day (see Lemmer 1989, 2005, 2006; Redfern and Lemmer 1997; Reinberg and Smolensky 1983).

Functions involved in the pharmacokinetic steps – from drug absorption to drug elimination – can be circadian phase dependent (Table 1). Thus, gastric emptying time of solids is faster in the morning than in the afternoon. Also, the perfusion of the gastrointestinal tract varies with time of day, being more pronounced at midnight and early morning hours than around noon and in the late afternoon. These observations would nicely explain that – in general – drugs are more rapidly absorbed and do more rapidly reach the systemic perfusion when taken in the morning. Accordingly, clinical studies showed – mainly for lipophilic drugs – that Tmax (time to peak drug concentration) can be shorter and/or Cmax (peak drug concentration) can be higher after morning drug dosing than evening drug dosing.

In Tables 2 and 3, drugs are compiled for which the pharmacokinetics and –dynamics were studied "around the clock" in order to get information whether a circadian time-dependent effect is present. This observation was corroborated for a number of compounds resulting in recommendations for a time-specified drug dosing. These findings have greatly contributed to the fact that now "*time-of-day*" plays an increasing role in drug treatment (see Lemmer 1989, 2006; Redfern and Lemmer 1997; Reinberg and Smolensky 1983). Unfortunately, psychotropic drugs were only scarcely studied in this respect (see Tables 2 and 3).

Conclusion

The chronopharmacological studies published in recent years gave evidence that both the pharmacokinetics and the effects of drugs can be circadian phase dependent. In the light of the circadian organization of the onset and 24-h pattern of various diseases, the knowledge about possible chronokinetics and a circadian phase dependency in the dose response relationship are of utmost importance for increasing drug efficacy and/or reducing side effects.

Citalopram

Definition

Citalopram is a selective serotonin reuptake inhibitor (SSRI). It is commonly used in the treatment of depression and some of the more severe anxiety disorders (e.g., obsessive–compulsive disorder, panic disorder, social anxiety disorder). As with other SSRIs, the most troublesome side effect of citalopram is sexual dysfunction (dysorgasmia and erectile dysfunction); mild side effects include drowsiness, headache, and nausea. Escitalopram, the *S*-enantiomer of racemic citalopram, is also marketed as an antidepressant.

Classical Conditioning

Synonyms

Pavlovian conditioning

Definition

Classical conditioning results when a stimulus that initially does not elicit a response comes to do so by association with a stimulus that does elicit a response. For example, a drug can serve as the unconditional stimulus (US) and produces an unconditional response (UR). Pairing of an initially neutral stimulus with the drug leads to acquisition by that stimulus (the conditional stimulus or CS) of the ability to produce a response like the US, termed the conditioned response (CR). The new property of the CS is conditional by its association with an established stimulus–response relationship of US–UR.

Classical (Pavlovian) Conditioning

John A. Harvey
Department of Pharmacology and Physiology, Drexel University College of Medicine, Philadelphia, PA, USA

Associative learning; Respondent conditioning

Definition

Pavlovian conditioning is a form of learning in which an association is formed between two stimuli. The Russian physiologist Ivan P. Pavlov (1849–1936) was the first to describe and codify this form of learning (Pavlov 1927). In its most basic form this requires the presentation of a novel stimulus (conditioned stimulus, CS) just prior to a second, biologically significant stimulus (unconditioned stimulus, US) that is capable of eliciting a reflexive response. As a result of this stimulus pairing, the CS acquires the ability to elicit a conditioned response (CR) that is identical to the reflexive response (unconditioned response, UR) elicited by the US. The CS also acquires the aversive or appetitive properties of the US. There are a number of related forms of Pavlovian conditioning that are used to examine drug effects (see ▶ Pavlovian fear conditioning; ▶ Conditioned drug effects; ▶ Conditioned taste aversion).

Impact of Psychoactive Drugs

Examination of drug effects on Pavlovian conditioning has employed only a limited number of target responses with the conditioned eyeblink response being the most widely used. Eyeblink conditioning is carried out by presenting a tone or light CS just prior to delivery of an airpuff US to the cornea or a shock US to the cheek. These USs elicit a spectrum of responses but the eyeblink UR elicited by the airpuff or shock is the identified target response. Various components of the eyeblink can be measured including external eyelid closure in humans, rabbits, and rodents; retraction of the eyeball and the associated passive extension of the nictitating membrane in the rabbit; and the electrical signal generated by the muscles involved in the eyeblink. Three other target responses have also been employed. Acquisition of the conditioned skin conductance CR in humans is accomplished by the pairing of a tone CS and an aversive white noise US. Appetitive conditioning of the rabbit's jaw movement response involves the pairing of a tone or light CS with presentation of an appetitive US such as water to a thirsty animal or a highly palatable solution of sucrose to a nondeprived animal. The US is delivered directly into the oral cavity and jaw movements as the animal swallows are recorded by direct measurement. Drugs have also been examined for their effects on the acquisition of a conditioned heart rate response (bradycardia) resulting from the pairing of a tone CS with delivery of a shock US. The popularity of the eyeblink response is due to several factors. Eyeblink conditioning is abnormal in various neuropathologies that impair associative processes in humans such as ▶ schizophrenia, ▶ Alzheimer's dementia, amnesic ▶ Korsakoff syndrome, ▶ fetal alcohol syndrome, ▶ autism, and ▶ obsessive–compulsive disorder (Steinmetz et al. 2001), and this provides the opportunity to employ both humans and experimental animals to examine the potential therapeutic effects of drugs in these disorders (see ▶ Dementias: animal models; ▶ Schizophrenia Animal Models). This comparison has been shown to be valid since the eyeblink response in nonhuman subjects, such as the rabbit, has been extensively characterized with respect to parametric variations in stimulus scheduling, and has been shown to demonstrate all of the associative phenomena seen in humans (Gormezano et al. 1983). The effects of drugs on learning have been measured during acquisition of CRs to a single stimulus, experimental extinction, acquisition or reversal of a discrimination, and serial compound conditioning. Drug effects have been measured after acute or chronic drug administration, after parenteral or central injection, in progeny after prenatal drug exposure, and during early postnatal development. Drugs employed have been hormones, toxins, and the major classes of pharmaceutical agents including ▶ hallucinogens, ▶ antipsychotics, ▶ antidepressants, ▶ opioids, ▶ benzodiazepines, cognition enhancers, and ▶ psychostimulants (Schindler and Harvey 1990).

Two basic schedules are employed in Pavlovian conditioning, delay and trace. In delay conditioning the CS is presented in close contiguity with the presentation of the US either by simultaneous offset of CS with onset of US or by an overlap of CS and US. In trace conditioning, the offset of the CS is followed by a period of time (the trace interval) before US onset. Learning during delay and trace conditioning is mediated by different neuronal circuits. In both rabbits and humans, trace conditioning requires the integrity of the limbic cortex while delay conditioning depends on the integrity of brain stem circuits. Human subjects are aware of the relationship between CS and US during trace conditioning, while delay conditioning proceeds without awareness (Clark and Squire 1998; LaBar and Disterhoft 1998). These schedules of Pavlovian conditioning also generate different rates of learning depending on the CS–US interval defined as the time between onset of the CS and US and/or the duration of the trace interval defined as the time between CS offset and US onset. For both delay and trace conditioning the rate of acquisition and final asymptotic performance of CRs decreases with increasing CS–US intervals, and within a fixed CS–US interval, increases in the trace interval also decrease rates of learning and asymptotic performance. As would be expected, the highest rates of acquisition occur with short delay intervals. The percentage enhancement or retardation of associative learning by drugs is an inverse function of the rate of CR acquisition in vehicle controls. Consequently, the ▶ ED_{50} for the effects of a drug on learning can vary by more than tenfold depending on the schedule employed. There are several control procedures used to determine the behavioral process through which a drug may be affecting CR acquisition. For example, one can distinguish between associative learning that results from the explicit pairing of CS and US, and nonassociative learning often referred to as pseudo conditioning or sensitization that can occur when the CS and US are presented at temporal intervals that do not support learning in normal controls (Gormezano et al. 1983). Using explicitly unpaired presentations of CS and US, one can determine whether a drug enhances the production of CRs to the CS and/or URs to the US. The increase in CRs might be due to an enhanced baseline rate of responding and this can be determined by measuring the response during the interval prior to the presentation

of the US, the period when a CS would have been presented during paired trials. One can also determine whether the drug had altered motoric function by examining the topography of the CR and UR in terms of their onset latencies, peak amplitude, and rise time (time between the onset of a response and its achievement of peak amplitude). Finally, if the drug has produced its effects by altering the rate of associative learning, one can further determine whether the effect is due to a change in sensory processing of the CS or US by measuring the percentage of CRs as a function of CS intensity and URs as a function of US intensity in animals that had reached asymptotic performance of CRs.

One of the characteristics of Pavlovian conditioning is its precise temporal resolution. For example, in eyeblink conditioning there is no evidence of conditioning at CS–US intervals at or below 75 ms. With increasingly longer intervals there is a proportionate increase in conditioning that reaches its peak sometime between 200 and 400 ms. At longer intervals conditioning declines and is totally absent at intervals of approximately 1–2 s. Similar CS–US functions are generated in other organisms from aplysia to humans. Thus, this CS–US function has been highly conserved during evolution and represents two constraints on associative learning. First, an association cannot be formed if the CS cannot elicit a CR before the occurrence of the US, an interval of approximately 75 ms. Second, the probability that a CS is predictive of the delivery of a US, becomes increasingly less likely as the CS–US interval becomes longer. Drugs have a differential effect on learning depending on the CS–US interval employed (Harvey et al. 1985). Both the enhancement of learning produced by LSD and the retardation of learning produced by scopolamine are the greatest at short and long ISIs and are barely detectable at the optimal ISI of 200 ms.

The use of Pavlovian eyeblink conditioning has revealed the involvement of a number of drug classes and their receptors in learning (Schindler and Harvey 1990). Hallucinogens enhance the rate of associative learning as agonists at the 5-HT_{2A} receptor at doses comparable to those that elicit hallucinations in humans (Table 1) (see ► Hallucinogens). The enhancement of associative learning by d-lysergic acid diethylamide occurs during aversive Pavlovian conditioning of the eyeblink response and the appetitive jaw movement response. Antipsychotics act as ► inverse agonists at the 5-HT_{2A} receptor to retard the rate of learning and thus block the effects of hallucinogens (see ► Antipsychotic drugs; ► Inverse Agonists). Finally, ► antagonists such as d-bromolysergic acid and ketanserin have no effect on learning but do block the effects of ► agonists and ► inverse agonists. The existence of antagonists and inverse agonists at the 5-HT_{2A} receptor indicates that this receptor is ► constitutively active (Harvey 2003). The cholinergic system has been of special interest as a target for drugs effective in Alzheimer's and other forms of dementia. Since eyeblink conditioning has been shown to be impaired in Alzheimer's dementia, a number of studies have examined the effects of putative cognitive enhancers on acquisition of the eyeblink response in humans and experimental animals. Muscarinic and nicotinic agonists as well as ► cholinesterase inhibitors enhance the rate of learning (Li et al. 2008; Weiss et al. 2000) while antagonists at these two receptors retard learning (Harvey et al. 1985) (see ► Acetylcholinesterase inhibitors as cognitive enhancers; ► Muscarinic agonists and antagonists). Both μ- and κ-opiod receptor agonists retard learning during eyeblink conditioning. The opioid antagonist ► naloxone has no effect on learning when given alone, but does block the retardation of learning produced by opioid agonists. A more detailed summary of these results has been published (Schindler and Harvey 1990) (see ► Opioids). Inhibitors of neuronal nitric oxide synthase enhance learning while peripheral or central administration of nitric oxide donors retards learning (Du et al. 2000). Finally, NMDA channel blockers (dizocilpine, ketanserin) retard learning (Du and Harvey 1997).

Definition

Psychopharmacology may be defined as the study of drugs that affect the mental state.

Current Concepts and State of Knowledge

Introduction

By convention, the term psychopharmacology is applied to drugs that are used to treat psychiatric disorders. Such drugs are termed psychotropic drugs. Psychopharmacology is usually grouped with the discipline of neuropharmacology which is concerned with the application of drugs for the treatment of neurologically based disorders. In reality, these areas often overlap. For example, several antiepileptic drugs are used in the treatment of bipolar disorder. Perhaps a more general term should be used to cover all pharmacologically active substances that directly influence brain function.

What is the historical basis for the classification of psychotropic drugs? The link between psychotropic drugs and modern psychiatry can be traced back to the father of European psychiatry, Emil Kraepelin who, in 1882, undertook a research program in the University of Leipzig with Wilhelm Wundt "On the influence of some medicinal drugs on single mental processes." In the publication that arose from this research, Kraepelin and Wundt surveyed the effects of the ► Hypnotics paraldehyde, chloral hydrate, ether, chloroform, the stimulant caffeine and the opiate morphine (Kraepelin 1899). Together with alcohol, these substances were the main components of the pharmacopeia at that time. In the publication, Kraepelin and Wundt established methods for measuring the reaction time and tests of memory function. In addition evaluating the effects of the different psychoactive drugs on these behavioral parameters, the placebo effects were also recognized. Such research led to one of the first attempts to classify psychoactive drugs, according to their clinical effects, under three headings: Narcotics that were medicaments with a calming action comprising opium (for anxiety and manic states), morphine, hyoscine/scopolamine (for inducing a rapid and deep sleep in manic patients) and hashish (a hypnotic with an unreliable action according to Kraepelin). Hypnotics included chloral hydrate, paraldehyde, sulphonal and trional, alcohol (to treat hysteria), and chloroform (for very excited states) The third category of psychoactive drugs comprised the bromides and were used in epilepsy, neurasthenia, and insomnia; bromism was recognized as a serious side effect. Eugen Bleuler, also an important founder of European psychiatry, published a similar classification to Kraepelin but added a barbiturate to the list of hypnotics (Bleuler 1916). It is worthy of note that the pharmacopeias that were available until the 1950s did not contain any drugs for the treatment of depression and schizophrenia. Non drug therapies available in the 1920s and 1930s included the shock therapies (insulin- and leptazol-induced

seizures) and ► electroconvulsive shock (ECT). Amphetamine was first synthesized in 1927 but its use was confined to the treatment of narcolepsy. It was noted that ► amphetamine was ineffective in the treatment of major depression! As is apparent from this group of drugs, until the latter part of the twentieth century the psychoactive drugs that were available to the psychiatrist were extremely limited and mainly used to calm or sedate disturbed patients.

The Revolution in Pharmacopsychiatry

There is a commonly held view that coincidence and chance have played the major role in the discovery of the first therapeutically effective drugs for the treatment of the major psychiatric disorders. This view is only partly true. Take, for example, the discovery of the first effective neuroleptic, ► chlorpromazine. The discoverers, Delay and Deniker. had long been interested in discovering drugs for the treatment of psychotic disorders and their studies of chlorpromazine followed a series of studies of different types of sympatholytic and anticholinergic compounds (see Swazey 1974). In Australia at approximately the same time, John Cade was trying to find a treatment for mania. Having discovered that the urine of manic patients contained a high concentration of uric acid and that lithium carbonate (which formed a lithium salt with uric acid) could protect guinea pigs from the toxic effects of uric acid. Subsequently Cade found that, despite its toxicity, lithium carbonate had an antimanic effect.

The discovery that the major psychiatric disorders were amenable to drug treatment gave a stimulus to the pharmaceutical industry to extend the research to produce new therapeutically active drugs. Thus ► imipramine, a tricyclic compound related to chlorpromazine, showed little benefit in the treatment of schizophrenia. Roland Kuhn, in Switzerland, did show that imipramine was the first effective tricyclic antidepressant. Thus imipramine was added to the first ► monoamine oxidase inhibitor antidepressant iproniazid, a drug that was a spin-off from a series of hydrazide derivatives used to treat tuberculosis. Readers are referred to an excellent history of psychopharmacology by Ban et al. (2000).

The last major breakthrough in psychotropic drug development came with the discovery of ► meprobamate for the treatment of generalized anxiety disorder (GAD). Meprobamate was a "central" muscle relaxant and based on the structure of the antispasmodic mephenesin. It was soon realized that the efficacy of meprobamate was limited and, in addition, could cause dependence. This discovery occurred at a time that the anxiolytic activity of ► chlordiazepoxide, the first benzodiazepine in therapeutic use, was discovered thereby leading to the introduction of a large range of benzodiazepines that were used for the treatment of anxiety, insomnia, epilepsy, and also as anesthetic agents (► midazolam). The term "serendipity" is used to describe the discovery of modern psychotropic drugs and implies that the drugs were discovered by chance. However, this does not take into account the background to the research, the "prepared mind," that recognizes the importance of the unexpected discovery when it occurs (see Jeste et al. 1979).

Thus the developments in different areas of neuroscience (neurochemistry, neurophysiology, neuroanatomy and neuropharmacology) at the time of the discovery of the first effective psychotropic drugs influenced the way psychiatrists and psychologists viewed brain function. If aberrant behavior was somehow based on disrupted neurotransmitter function then mental disorders could be considered from a biological perspective. Drugs could therefore be used to treat mental disorders in the same way that they are used to treat any other disease.

However, despite the progress that has been made in psychopharmacology since the 1950s, progress in the past decade has been limited with very few genuinely novel compounds (rather than "me-too" drugs with marginally improved profiles to those already available!) being discovered. Perhaps a better understanding of the pathophysiological basis of the major psychiatric disorders is required before the next advance in the development of more effective psychotropic drugs can take place.

Classification of Psychotropic Drugs

Psychotropic drugs may be classified (1) according to their chemical structure, (2) by their pharmacological actions on specific biological processes such as receptors, transporter, or ion channels, or (3) by their therapeutic actions. Theoretically, all three approaches form a continuity, as the chemical structure should indicate how the drug affects a specific biological process that is dysfunctional in the disease under consideration. However, as the pathophysiological basis of the psychiatric disorders is unknown, it is currently impossible to predict what the therapeutic profile of a novel compound based on its chemical structure or even on its in vitro and ex-vivo biological activities would be. For this reason, psychoactive drugs are largely classified according to their therapeutic actions into seven major classes:

1. ► Antipsychotics for the symptomatic treatment of schizophrenia, psychotic states that may have a psychiatric or neurological basis and severe agitation associated with acute mania. Such drugs are

sometimes called "neuroleptics" or, in the older literature, "major tranquilizers" (see Table 1).

2. ► Antidepressants for the symptomatic treatment of depression. In the older literature, antidepressants were called "thymoleptics" (Table 2).
3. ► Anxiolytics, sometimes called "minor tranquillers," for the treatment of GAD. Hypnotics are essentially sedative anxiolytics used for the treatment of insomnia. The psychopharmacology of the anxiety disorder is complex because of the diverse nature of the disorders that include panic disorder, phobic disorders, post traumatic stress disorder and obsessive compulsive disorder in addition to GAD. True anxiolytics are effective in the treatment of GAD and are of only limited efficacy, or lack efficacy, in the treatment of the other disorders (Table 3).
4. ► Mood Stabilizers are drugs used for the treatment of mania, hypomania and bipolar disorders (mixed mania and depression) (Table 4).
5. ► Psychostimulants are a group of drugs whose therapeutic use is largely confined to the treatment of narcolepsy and attention deficit hyperactive disorder (ADHD). In the older literature, psychostimulants are called "analeptics" (Table 5).
6. ► Nootropics are classified as a group of drugs that may improve cognitive function without having a stimulant profile. Despite the initial therapeutic claims that nootropics improve cognitive impairment in the elderly (evidence for which was partly based on improved cognitive function in rodents) such drugs are seldom used in Europe, North America or Australasia because they lack proven efficacy.

First generation		
Tricyclic antidepressants		
5-HT/NA reuptake inhibitors	Imipramine	Except lofepramine, all are cardiotoxic in overdose
	Amitriptyline	
5-HT<NA reuptake inhibitor	Clomipramine	Anticholinergic
NA<5-HT reuptake inhibitors	Desipramine	
	Nortriptyline	
	Lofepramine	"Atypical" first generation
Nonselective monoamine oxidase inhibitors (MAIO's)		
Block breakdown of NA and 5-HT	Phenelzine	Interact with dietary amines causing hypertension
	Tranylcypromine	
	Pargyline	
Second generation		
Selective serotonin reuptake inhibitors		
Fluoxetine Fluvoxamine Citalopram Escitalopram Paroxetine Sertraline		First line treatment of depression. Also used to treat anxiety disorders and OCD
Serotonin and Noradrenaline reuptake inhibitors (SNRI's)		
Dual action reuptake inhibitors	Venlafaxine	?More potent than SSRI's
5-HT>NA	Desvenlafaxine	
""	Duloxetine	
NA>5-HT	Milnacipran	
Noradrenaline reuptake inhibitors (NRI's)		
Reboxetine		
Reversible inhibitor of MAO		
Moclobemide		Less likely than first generation MAOI's to interact with diet
Noradrenaline and serotonin specific antidepressants		
Increase NA, 5-HT2 antagonist	Mianserin	
	Mirtazepine	Also anxiolytic and sedative
Atypicals	Trazodone	Weak antidepressant, sedative and axiolytic

7. ► Antidementia drugs comprise a series of compounds that show marginal benefit in slowing the mental decline, particularly in memory and some aspects of cognitive function, in patients with Alzheimer's disease and related dementias (Table 5).

In addition to these major groups of drugs that have specific therapeutic properties, there are many psychoactive drugs that affect brain function but whose therapeutic actions are not directed at the symptomatic relief of psychiatric disorders. Such drugs may be used to relieve pain (for example, the opiates) or to treat specific neurological disorders such as the epilepsies. In addition, there are a large number of recreational psychoactive drugs such as alcohol, the cannabinoids, the hallucinogens, cocaine and nicotine that have no or limited therapeutic use because of their dependence liability. Caffeine, a mild psychostimulant, is considered to be such a recreational drug by some psychopharmacologists! The recreational psychoactive drugs are predominantly ► drugs of abuse and their properties will not be further considered. Their basic properties are summarized in Table 6.

Overview of the main classes of psychotropic drugs and their therapeutic uses.

The following account of the properties of psychoactive drugs and their main pharmacological properties is only intended as a brief overview. Readers are referred to standard texts for more complete account. (e.g., Iversen et al. 2009; Leonard 2003; Spiegel 2003).

Antipsychotics

These drugs are used for the symptomatic treatment of schizophrenia and psychotic disorders.

Schizophrenia is characterized by the following symptoms: delusions, hallucinations (visual and aural), disorganized speech, grossly disorganized or catatonic behavior. These symptoms are termed Positive symptoms. The Negative symptoms consist of affective flattening (referring to a reduction in the range and intensity of emotional expression), ► alogia (poverty of speech) and ► avolition (inability to initiate or persist in goal directed behavior). Patients with schizophrenia therefore fail to understand the external world and how to react appropriately to it and consequently lose touch with reality. This summary, and those relating to other major psychiatric disorders mentioned in this presentation, is based on the Statistical manual of mental disorders (2000).

The antipsychotic drugs can be divided into the "Typical" and "Atypical" types, sometimes referred to as the first and second generation antipsychotics respectively.

The typical antipsychotics are subdivided according to their chemical structures into the phenothiazines (such as chlorpromazine, fluphenazine, trifluperazine and thioridazine), the structurally related thioxanthines that have very similar pharmacological properties to the ► phenothiazine analogs (chlorprothixene, clopenthixol, and flupenthixol), the ► butyrophenones (haloperidol, benperidol, trifluperidol and pimozide) and the benzamides (sulpiride).

The atypical antipsychotics consist of a series of chemically unrelated drugs that differ from the typical antipsychotics by their reduced frequency of motor side effects. Thus whereas the use of the typical antipsychotics are often therapeutically limited because of their extrapyramidal side effects (Parkinsonism, akathisia, tardive dyskinesia etc.) due to their blockade of dopamine D2 receptors in the basal ganglia,the atypicals are less likely to have such side effects at normal therapeutic doses. This group consists of the multi-receptor antagonists that are chemically similar (clozapine, olanzapine and quetiapine), so called because they interact with multiple dopamine, serotonin, noradrenaline, acetylcholine and histamine receptors. The 5-HT_2/D2 receptor antagonists form the bulk of the atypical antipsychotics that consist of risperidone and its metabolite paliperone, ziprazidone, sertindole and zotepine. Other drugs in the atypical series include amisulpride (a D2/D3 antagonist that is related to the first generation benzamide, sulpiride) and the "atypical" antipsychotic aripiprazole.

The typical and atypical antipsychotics differ mainly in terms of the severity of their side effects. All antipsychotics in current use are D2 receptor antagonists, a property that is thought to be an essential component for the attenuation of the positive symptoms of schizophrenia. However, the atypicals, with the exception of amisulpride, are also 5-HT_2 receptor antagonists and action that is thought to block the tonic inhibitory effect of serotonin on the dopaminergic system in the prefrontal cortex thereby facilitating the inhibition by cortical dopamine on the overactive mesolimbic dopaminergic system that is thought to be responsible for the positive symptoms of schizophrenia. The atypical antipsychotics therefore specifically target the mesocortical dopaminergic system without having a major inhibitory effect on the striatal dopaminergic system (unlike the typical antipsychotics that lack this selectivity), thereby having a reduced frequency of motor side effects.

Because of their more acceptable side effects, combined with their efficacy in the treatment of positive, and secondary negative symptoms, the World Health Organization has recommended that the atypical antipsychotics be used as the first line treatment of schizophrenia (Sartorius et al. 2002).

Antidepressants

The DSM IV classification of major depressive disorder lists chronically depressed mood, anhedonia (diminished feeling of pleasure) insomnia or hypersomnia, psychomotor agitation or retardation, fatigue, anorexia (weight loss), feelings of worthlessness and inappropriate guilt, recurrent thoughts of death, suicide thoughts and attempted suicide as the characteristic features of the patient with major depression. Five or more of these symptoms must be present during the same 2-week period and must not be associated with drugs of abuse or other medications that can cause depression.

For the past 50 years, depression has been treated (with reasonable success) with different types of antidepressant drugs or with ECT therapy. All of the antidepressants in current use enhance noradrenergic and/or serotonergic function apart from buproprion that has a mild dopamimetic action. Thus antidepressants are thought to improve noradrenergic and/ or serotonergic function that is dysfunction in depression.

As with the antipsychotics, the antidepressants, may be divided into the first (tricyclic antidepressants TCAs, nonselective monoamine oxidase inhibitors MAOIs) and second generation (reversible inhibitors of monoamine oxidase RIMAs, selective serotonin reuptake inhibitors SSRIs, serotonin and noradrenaline reuptake inhibitors SNRI's, noradrenaline and serotonin selective antidepressants NaSSAs and noradrenaline reuptake inhibitors NRIs) drugs.

The main difference between the first- and second-generation antidepressants lies not in their therapeutic efficacy but in the safety in overdose and tolerability due to the reduction in the side effects of the second-generation drugs.

In terms of their therapeutic action, the second-generation antidepressants can be divided into those that are presumed to selectively increase serotonin function (the SSRIs such as fluoxetine, fluvoxamine, citalopram, escitalopram, sertraline and paroxetine), those that selectively increase noradrenergic function (the NRI reboxetine), the dual action antidepressants that enhance both serotonergic and noradrenergic function (venlafaxine, duloxetine and milnacipran) and buproprion that has a dopaminomemetic action. It should be noted that some of the first-generation TCAs also show some selectivity for the serotonergic system (clomipramine) or the noradrenergic system (desipramine, nortriptyline and maprotiline). The TCAs, SSRIs, SNRIs, NRIs are assumed to act by inhibiting the noradrenaline

and or serotonin transporters on the neuronal membrane thereby prolonging the duration of action of the neurotransmitter in the synaptic cleft.

The tetracyclic antidepressant mirtazepine, and its precursor mianserin, enhance noradrenergic function by blocking the inhibitory presynaptic alpha-2 adrenoceptor on noradrenergic terminals. In addition, mirtazepine blocks post synaptic 5-HT_{2A} receptors and indirectly enhances 5-HT_{1A} receptor function.

Of the first-generation antidepressants, the MAOIs (such as phenelzine, pargyline, and tranylcypromine) increase the catecholamine by blocking their intraneuronal metabolism. These drugs have fallen into disuse as the inhibition of MAO in the gastrointestinal tract can lead to a hypertensive crisis should amine rich foods (cheese, beer, wine etc.) be taken concurrently. This has led to the development of RIMAs (such as moclobemide) that, being reversible inhibitors of MAO, are displaced from

the gastrointestinal MAO should high amine containing foods be consumed.

The use of the TCAs has been restricted in most industrialized countries due to their anticholinergic side effects and cardiotoxicity particularly in overdose. The exception is the TCA lofepramine that is less anticholinergic and cardiotoxic than the other members of this series.

Anxiolytics

Anxiety is an unpleasant state accompanied by apprehension, worry, fear, nervousness and heightened arousal. These psychological changes are usually associated with an increase in autonomic sympathetic activity (such as increased blood pressure and heart rate and gastrointestinal distress. While physiological anxiety is usually of short duration, often with rapid onset and abrupt cessation once the aversive event has terminated, pathological anxiety occurs when the response to an anxiety provoking event becomes excessive, prolonged, and affects the ability of the person to lead a normal life. This condition is referred to as Generalized anxiety disorder (GAD). The anxiolytics are drugs of choice for the treatment of GAD.

However, anxiety disorders comprise a number of conditions for which the conventional anxiolytics are of limited efficacy. Thus, panic disorder is effectively treated with SSRI antidepressants, as are the social phobias and obsessive compulsive disorder. This suggests that unlike GAD, in which the noradrenergic, serotonergic and GABAergic systems are thought to be dysfunctional, a malfunctioning serotonergic system plays a key role in the pathology of panic disorder, obsessive compulsive disorder and the phobic states.

For several decades, the treatment of anxiety has been dominated by the benzodiazepines, drugs that are rapidly effective (unlike most of the other psychotropic drugs), safe in overdose. For this reason, they replaced the barbiturates and meprobamate that had limited efficacy and were dependence producing. The benzodiazepines bid to a specific site on the multifunctional $GABA_A$ receptor (called the benzodiazepine binding site) and enhance the inhibitory action of GABA on the $GABA_A$ receptor. Shortly after the discovery of the first benzodiazepine anxiolytics (► chlordiazepoxide and ► diazepam) a wide range of benzodiazepines were developed for the treatment of anxiety, epilepsy, and as hypnotics, central muscle relaxants for spasticity and as anaesthetics. It is well established that most of these properties are present in diazepam and chlordiazepoxide. Thus low therapeutic doses of these drugs are anxiolytic but as the dose is increased sedation followed by an anticonvulsant effect becomes prominent. Such doses are also commonly associated with GABA dependent muscle relaxation. Dependence can occur in some patients who take high therapeutic doses of the benzodiazepines for long periods. This condition has led to the development of a series of novel non-benzodiazepine anxiolytics/hypnotics, such as ► zolpidem and ► zopiclone. However, these drugs also owe their therapeutic actions to the activation of the benzodiazepine site on the GABA receptor!

Buspirone, a partial 5-HT_{1A} receptor agonist that does not affect the GABA receptor was developed in the hope that, because of its unique action, it could replace the benzodiazepine type of drug. Despite its initial promise, buspirone has had a very limited clinical impact due to the delay in its onset of action, its minimal efficacy, and serotonin-linked side effects (nausea, headache). Nevertheless, the discovery of ► buspirone stimulated the use of the SSRI antidepressants and venlafaxine in the treatment of GAD and other anxiety disorders and, despite their delayed onset of action, the SSRIs are often considered as the first choice for treatment.

Mood Stabilizers

Bipolar disorder is characterized by episodes of mania or hypomania that alternates with periods of depression. The manic symptoms are characterized by an expansive, elated or irritable mood, pressured speech, flight of ideas, easy distractibility and a preoccupation with socially unacceptable, and potentially dangerous, activities. Such symptoms may persist for many days and may require hospitalization. The manic phase of bipolar disorder is usually followed by a euthymic phase or by depression. The depressive phase is often very severe leading to suicide in 10–25% of bipolar patients. The DSM IV classification divides bipolar disorder into bipolar1 disorder (a patient showing both mania and depression) and bipolar 2 (in which mania occurs in a less severe form, hypomania, that alternates with depression). In bipolar 2 disorder, the patient may show predominantly the manic or depressed state and only very occasionally switch to the opposite mental state. An uncommon type of bipolar disorder is the rapid cycling state in which the patient switches from one state to another in frequent succession.

Of the drugs available to treat bipolar disorder, ► lithium is still one of the most widely used. Like most of the psychotropic drugs used in the treatment of the major psychiatric disorders, lithium usually takes several weeks to produce its optimal therapeutic effect. Lithium is used prophylactically and lengthens the euthymic period between the phases of the illness. The pharmacology of lithium is very complex as its mode of action is based on the replacement of Na+ ions in the numerous transporters, ion channels and receptors throughout the body. This not only accounts for its therapeutic effects but also for its numerous side effects that often limit its clinical

use. This has resulted in lithium being replaced by more conventional drugs that are primarily used in other areas such as psychiatry and neurology. Of these, the anticonvulsants (such as ▶ carbamazepine, oxcarbamazepine, sodium ▶ valproate, ▶ topiramate, ▶ gabapentin, and ▶ lamotrigine) are the most widely used. The atypical antipsychotics clozapine and olanzapine have now been added to the list of effective antimanic agents. Conventional antidepressants such as the TCAs and SSRIs are limited efficacy in treated the depressed phase of bipolar disorder. This suggests that the etiology of depression in bipolar disorder differs from that of major depression.

Nootropics and Antidementia Drugs

Nootropic agents are defined as centrally acting drugs that improve higher integrative brain functions, such as memory and cognitive impairment, in the early stages of Alzheimer's disease and in dyslexia .These nonstimulant drugs that are available in some European countries include the central vasodilator co-ergocrine and the pyrrolidinone derivatives piracetam, amiracetam, aniracetam and levetiracetam. Despite the many years of research into the possible mechanisms of action of nootropic agents, their actions are unclear and their clinical efficacy is doubtful.

In contrast to the nootropic agents, the antidementia drugs have proven benefit when administered in the early stage of ▶ Alzheimer's disease. These drugs fall into one of two categories, namely the anticholinesterases and the glutamate *N*-methyl-D-aspartate (NMDA) receptor antagonists. The anticholinesterases (▶ donepezil, ▶ rivastigmine, ▶ galantamine), increase central cholinergic function, a mechanism that is assumed to be responsible for the drug induced reduction in the cognitive decline in the early stage of Alzheimer's disease. This view correlated with the pathological finding that there is severe damage to the nucleus basalis magnus-hippocampal cholinergic pathway in patients with Alzheimer's disease.

In contrast to the anticholinesterases, the partial NMDA receptor antagonist ▶ memantine is thought to protect central neurons from the neurodegenerative effect of excess glutmate that is released in the brain of the Alzheimer patient. Memantine has been shown to be effective in moderate to severe cases of Alzheimer's disease.

Psychostimulants

Psychomotor stimulants, such as D-amphetamine, methylphenidate, and atomoxetine, are most widely used to treat ADHD but are also known to counteract fatigue in normal adults. However, the effects on vigilance, verbal learning and memory are relatively small even though they may be sufficient to permit the individual to continue cognitively demanding tasks for long periods of time.

The ▶ psychostimulants enhance both noradrenergic and dopaminergic function particularly in the frontal cortex and thereby improve working memory. Such effects differ from the actions of the psychostimulants on the subcortical reward system where it is thought that the enhancement of the dopaminergic system results in dependence.

The most recent drug to be developed to improve cognitive function particularly in cases of fatigue is ▶ modafinil. This drug has been shown to improve cognitive function, verbal working memory, visual recognition and planning performance in those suffering from excessive daytime sleepiness often associated with narcolepsy and sleep apnea. Despite its proven therapeutic effects, the mode of action of modafinil is uncertain. It is nonstimulant, does not affect catecholamine function, but there is a suggestion that it modulates the orexinergic system that regulates the sleep-wake cycle.

Conclusion

Because the relationship between the chemical structure of psychotropic drugs and their pharmacological and therapeutic effects remains an enigma, the drugs have been classified according to their therapeutic uses. It is widely recognized that psychotropic drugs treat the symptoms or syndromes of specific psychiatric disorders and do not appreciably change the underlying psychopathology. As many of the symptoms of the different psychiatric disorders overlap, it is not surprising that their uses also overlap different disorders. Thus, anticonvulsants are not only used to treat the epilepsies but also bipolar disorder. The SSRI and SNRI antidepressants are widely used to treat a variety of anxiety disorders in addition to the affective disorders. Hopefully, with an ever increasing knowledge of psychogenetics and the underlying psychopathology of psychiatric disorders, a time will come when psychotropic drugs will target the underlying pathology and therefore revolutionize the psychiatric treatment.

Clearance

Synonyms

CL; Excretion

Definition

Clearance is the fraction of a theoretical volume completely purified (i.e., no longer containing any of the drug concerned) per unit of time. Plasma clearance is the apparent volume of plasma purified per unit of time. Total clearance (CL t) is the fraction of the volume of distribution, V_D, which is completely purified per unit of time. The total clearance depends on the constant of elimination and thus on $t½$ and on V_D. Clearance is a constant in linear kinetics.

Clinical Antipsychotic Trials of Intervention Effectiveness Study

Synonyms

CATIE

Definition

The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study was the largest, longest, and most comprehensive independent, three-phase, clinical trial ever conducted to examine existing pharmacotherapies for schizophrenia. The trial was funded by NIMH and intended to be "pragmatic," involving a representative sample of 1,493 schizophrenic patients from various real-life outpatient settings. The primary outcome measure was time to all-cause drug discontinuation that captured both efficacy and tolerability. Subjects in the CATIE trial were randomized in a double-blind fashion to treatment with olanzapine, quetiapine, risperidone, ziprasidone, or the mid-potency first-generation antipsychotic perphenazine for up to 18 months of treatment.

Clinical Global Impression Scales

Synonyms
CGI

Definition
The clinical global impression (CGI) rating scales (Guy 1976) are commonly used clinician-rated measures of global symptom severity and treatment response for patients with mental disorders. Many researchers, while recognizing the validity of the scales, consider them to be subjective as they require the clinician to compare the subjects under examination to typical patients from their clinical experience.

The Clinical Global Impression – Severity scale (CGI-S) is a seven-point scale that requires the clinician to rate the severity of the patient's illness at the time of assessment, relative to the clinician's past experience with patients who have the same diagnosis. Considering total clinical experience, a patient is assessed on severity of mental illness at the time of rating.

1 = Normal, not at all ill
2 = Borderline mentally ill
3 = Mildly ill
4 = Moderately ill
5 = Markedly ill
6 = Severely ill
7 = Extremely ill

The Clinical Global Impression – Improvement scale (CGI-I) is a seven-point scale that requires the clinician to assess how much the patient's illness has improved or worsened relative to a baseline state at the beginning of the intervention.

1 = Very much improved
2 = Much improved
3 = Minimally improved
4 = No change
5 = Minimally worse
6 = Much worse
7 = Very much worse

Clobazam

Definition
Clobazam is a high-potency, medium-acting anxiolytic benzodiazepine medication used in the treatment of anxiety, panic, and phobic disorders. It has some useful anticonvulsant effects. It is not antidepressant. It is sometimes used in conjunction with antipsychotic medication in acute psychotic episodes. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Long-term use may induce dependence with withdrawal reactions. Recreational use and abuse can occur: alprazolam is a scheduled substance.

Clocapramine

Definition
Clocapramine is a first-generation (typical) antipsychotic drug that belongs to the iminodibenzyl class approved in Japan for the treatment of schizophrenia. It shows higher affinity for 5-HT_{2A}- than for D_2-receptors, but has more potent dopamine antagonist activity than carpipramine that belongs to the same class. Clocapramine can induce extrapyramidal motor side effects and insomnia, but it displays generally low toxicity.

Clock-Speed Effect

Definition
Clock-speed effect refers to the immediate effect of a drug to speed up or slow down the subjective experience. In the PI procedure, a clock effect is observed by an immediate horizontal shift in the response function in peak trials following drug administration that is proportional to the estimated duration.

Chlormethiazole

Definition
Clomethiazole is a sedative medication with a medium duration of action used in the symptomatic treatment of anxiety and insomnia, and in the management of alcohol withdrawal. Unwanted effects include excessive sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Interaction with alcohol can be hazardous. It depresses respiration and is highly toxic in overdose. Long-term use induces dependence with severe withdrawal reactions, including fits. Recreational use and abuse can occur: it is a scheduled substance.

Clomipramine

Definition
Clomipramine, the 3-chloro derivative of imipramine, is a tricyclic antidepressant with a tertiary amine chemical structure. It is a potent, but not selective, serotonin reuptake inhibitor; its primary active metabolite, desmethylclomipramine, inhibits reuptake of norepinephrine. Although originally introduced for the treatment of depression, clomipramine is now used more frequently for the treatment of obsessive–compulsive disorder. Even for this indication, it is usually employed only after nonresponse to a selective serotonin reuptake inhibitor (SSRI); while clomipramine may have slightly greater efficacy than the SSRIs, it also has a less-favorable side-effect profile. Side effects include marked sedation, cardiovascular effects, and anticholinergic effects (e.g., constipation, dry mouth, blurred vision, urinary retention). Clomipramine is dose dependently associated with a higher risk of seizures than other tricyclics; like other tricyclics, it has a high potential for lethality in overdose.

Clozapine

Definition

Clozapine was the first of the second generation of antipsychotic drugs. It has weak D_2 receptor antagonist activity and also blocks D_1 and D_4 receptors as well as α-adrenoceptors, 5-HT_2 receptors and muscarinic acetylcholine receptors. It is an effective anti-schizophrenia drug with little tendency to cause extrapyramidal motor disorders. Its main advantage is that it is effective in a substantial proportion of chronic schizophrenic patients who fail to respond to conventional antipsychotic medication. Its main disadvantage is its tendency to cause agranulocytosis in about 1% of patients and weekly monitoring of the white blood-cell count is mandatory. It has therefore become a third line antipsychotic.

Definition

Cocaine is a naturally occurring substance that is extracted from the leaves of the coca plant (*Erythroxylon coca*), which is traditionally found in South American countries such as Bolivia and Columbia. Its use by the native inhabitants was noted by the Spaniards who invaded South America, and the earliest descriptions of cocaine's effects were given by them. There was continued interest in the plant and its active substances, and cocaine was isolated from the plant in 1855 by the German chemist Fredrich Gaedcke. Its structure was elucidated and its synthesis achieved in 1898 by Richard Willstatter. Cocaine is a member of the ► psychostimulant class of drugs.

Pharmacological Properties

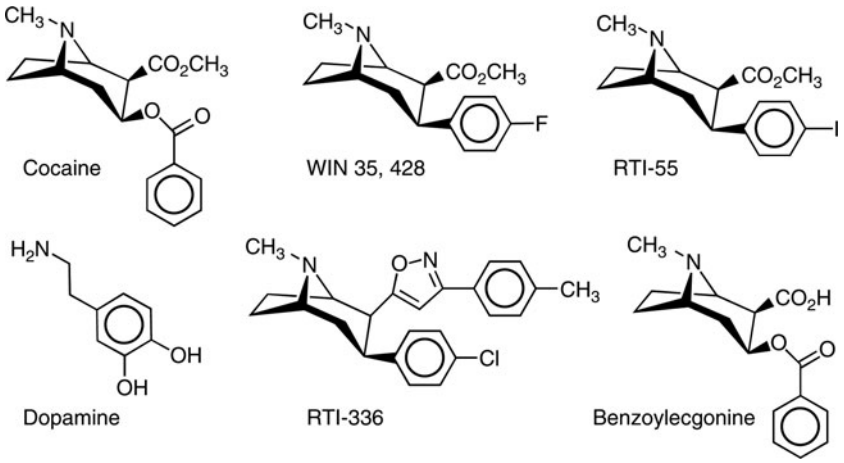
Briefly, the physiological effects of cocaine administration include increased heart rate and blood pressure, increased arousal, and a sense of well-being. Euphoria can occur with higher doses, and agitation and paranoia may occur with repeated doses. Cocaine is also a local anesthetic, and it was this property that intrigued and attracted many early investigators. Toxicities include cardiovascular problems and seizures. Users of cocaine often have a co-occurring psychiatric diagnosis such as ► depression or ► anxiety. ► Tolerance occurs with repeated use.

A serious result of chronic use of cocaine is addiction, and withdrawal from cocaine use in ► addicted individuals can result in craving, fatigue, dysphoria, depression, and sleepiness. Medications for treating cocaine abusers are in clinical trials; but till date, none has been approved for this use. Treatments are mainly behavioral, with management of various physiological symptoms as they occur.

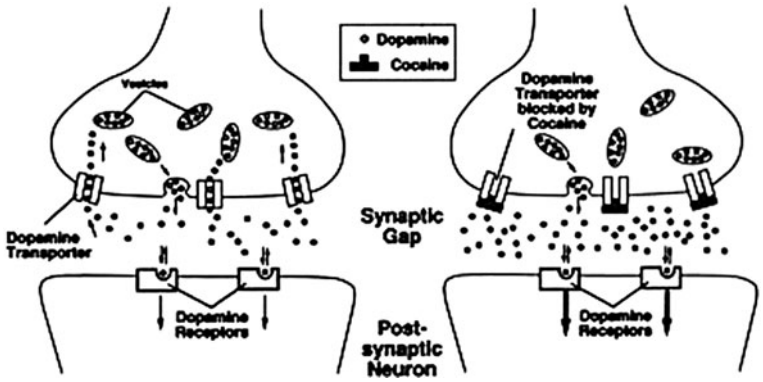
Cocaine has legitimate uses in current clinical medicine. It is used as a local anesthetic and as a powerful vasoconstrictor in the upper respiratory tract. It is swabbed onto the tissues in solutions whose concentrations vary from 1 to 10%. As shown in the chemical structure for cocaine (Fig. 1), there are two ester groups, which are susceptible to metabolism. Benzoylecgonine is produced by loss of the methyl group and is the major urinary metabolite of the drug. It is interesting and important that the ► half-life of benzoylecgonine is a few days (rather than approximately an hour for cocaine), and is therefore a more reliable indicator of recent cocaine use, and is, in fact, the target for urine test for cocaine use.

The Mechanism of Action of Cocaine in the Brain

The articles on ► neurotransmitters and ► transporters reveal that amine neurotransmitters (► dopamine, ► serotonin, and ► norepinephrine) are removed from the synapse by ► transport or reuptake into the synaptic terminal that released them (see Fig. 2). As noted in those articles, this uptake mechanism (the ► neurotransmitter transporter) is very important for turning off the signal created by the neurotransmitters interacting with



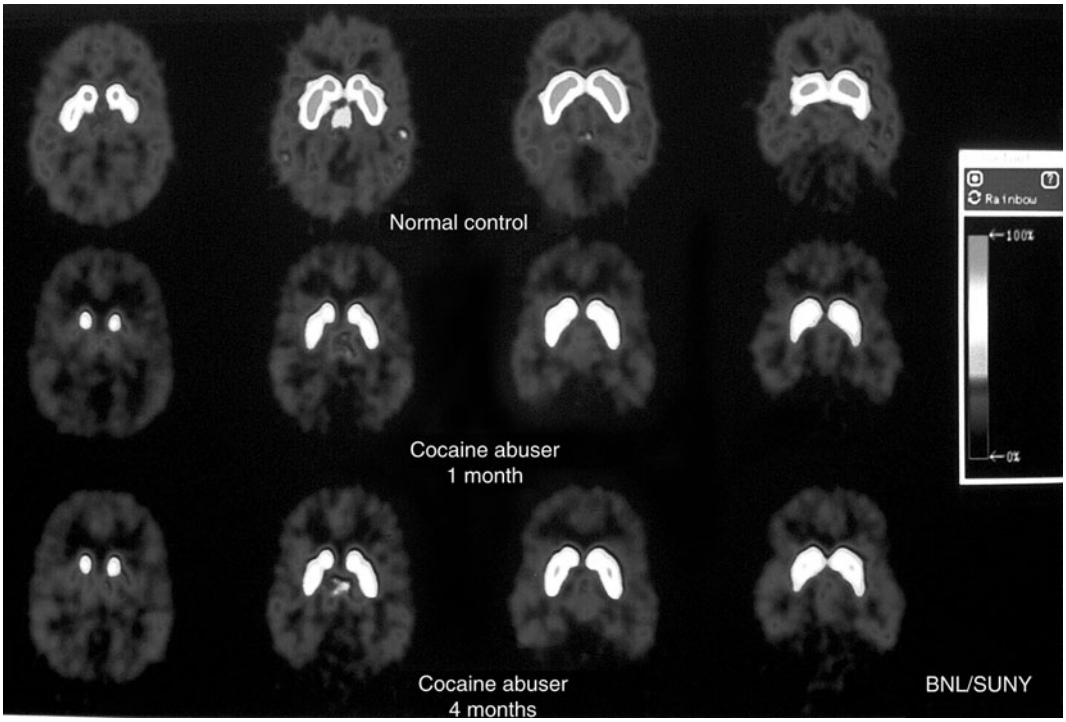
Cocaine. Fig. 1. Chemical structures of cocaine and related compounds. WIN 35,428, RTI-55, and RTI-336 are very similar to cocaine, but have somewhat different pharmacological properties. While cocaine is equipotent in inhibiting the uptake of norepinephrine, dopamine, and serotonin, WIN 35,428 and RTI 55 are more selective for the serotonin and DATs; and RTI-336 is more selective for DAT alone. Both WIN 35,428 and RTI-55, in their radiolabeled forms, are important tools for studying and imaging the DAT. RTI-336 is currently being tested as a medication for cocaine abusers. Benzoylecgonine, which lacks the methyl ester found in cocaine, is a longer half-life metabolite of cocaine and is the target of urine tests for cocaine ingestion. The figure was supplied by Dr Ivy Carroll with permission.



Cocaine. Fig. 2. The dopamine hypothesis of cocaine reinforcement. A variety of binding, behavioral, and neurochemical studies indicate that inhibition of DAT, rather than the norepinephrine or serotonin transporters, is responsible for the reinforcing (addicting) properties of cocaine. Thus, DAT is the initial molecular site of action of cocaine in regard to its addicting properties. (Reproduced from Kuhar et al. 1991.)

their receptors. Being able to turn off the signal is just as important as being able to turn it on; otherwise, there is no discrete signal, just a constant background. These transporters are the initial molecular sites of action of cocaine. The rewarding properties of the drug are due to cocaine's blockade of the ► dopamine transporter (DAT) (Kuhar et al. 1991), and not the serotonin or norepinephrine transporters.

The blockade of the transporters by cocaine results in a buildup of the neurotransmitter in the synaptic cleft and an increased signaling of the neurotransmitter at its receptors. This increased signaling is how cocaine imparts its actions. The brain has evolved hand in hand with neurotransmitters and has developed mechanisms to handle them. For example, dopamine is discretely released by action potentials at nerve terminals onto receptors, and then removed from receptors by reuptake. This occurs at a rapid time scale and, in a sense, in an orderly fashion. However, the brain is not equipped to "handle" cocaine in



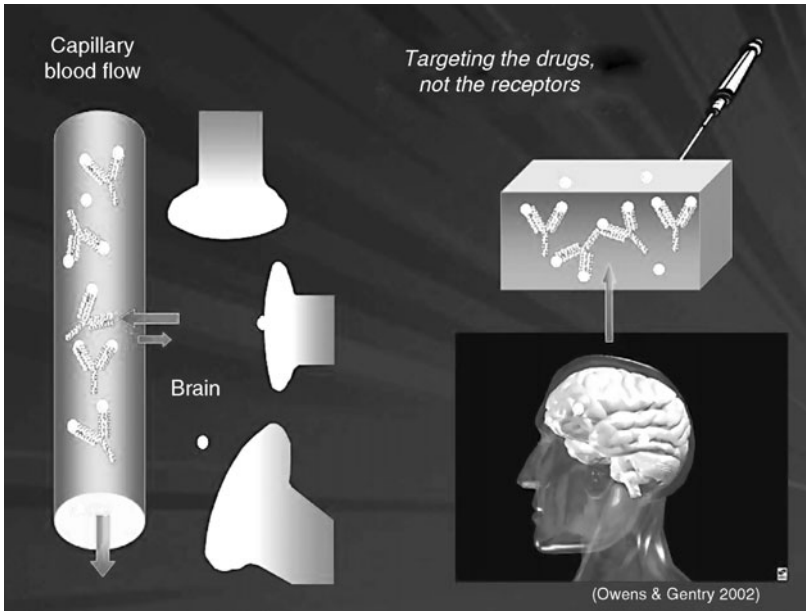
Cocaine. Fig. 3. Long-lasting changes in PET scans of dopamine receptors in cocaine-abstinent individuals. In each row, there are four "slices" of brain at different levels that show D_2 dopamine receptors in color-coded densities. The receptors are grouped together in the basal ganglia, which receives a very dense dopaminergic input. After 1 month of abstinence (middle figures), and after 4 months of abstinence (bottom figures), the receptors are increasing but are still not back to normal levels. Thus, changes in the brain are long-lasting, and likely have important implications for the duration of treatment. This figure shows changes only in D_2 receptors, but there are many additional documented changes of various types, and the challenge is to identify which of these changes are the most important. The changes in the levels of dopamine receptors imply a dysregulation of the reward/reinforcement system in chronic cocaine users. (Reproduced from Volkow et al. 1993.)

that there is no mechanism to control either its access to transporters or its removal from transporters. Thus cocaine's effects on signaling are controlled by external factors (dose, frequency of administration) and are not "normal or expected" by the brain. This must be one of the fundamental reasons why the effects of cocaine are so different and striking, and so powerful.

As noted above, cocaine also potentiates neurotransmission by serotonin and norepinephrine. Although inhibition of uptake of norepinephrine and serotonin are not mainly responsible for the rewarding properties of the drug, these actions do have effects. For example, inhibition of norepinephrine uptake contributes to the cardiovascular effects of cocaine. Inhibition of serotonin uptake has complicated effects; and serotonin, at some receptors, inhibits the rewarding effects of cocaine and dopamine. In any case, we are mainly concerned with the ▶ rewarding/reinforcing/addicting properties of cocaine which occurs by its action at the DAT.

Involvement of Specific Brain Regions

Cocaine can alter the metabolic activity (which reflects neuronal activity) of many brain regions (Everitt and Robbins 2005; Schmidt et al. 2005). When cocaine is taken the first few times, the ▶ nucleus accumbens and parts of the ▶ prefrontal cortex exhibit metabolic changes. But as more cocaine is taken repeatedly over a long time, more regions in the brain are affected as well (Porrino et al. 2007). These include the striatum, ▶ amygdala, ▶ hippocampus, and cortical areas. The progression from casual drug use to ▶ dependence is accompanied by and likely due to this enlargement of the pattern of activity in the brain. These changes in activity are accompanied by changes in proteins, and some of them are



Cocaine. Fig. 4. Antibodies can bind drugs before they enter the brain. The *right side* of the figure shows a brain capillary and brain drug receptors in close proximity. If the drug (shown by a small filled circle) cannot get out of the circulation because it is bound to an antibody ("Y" shaped structure), then the drug cannot have any effect in the brain. related to dopaminergic neurotransmission. This shift in activity and changes in protein levels likely have implications for treatment. Preventing or blunting the shifts, perhaps by using medications or behavioral treatments or both, could reduce or prevent dependence.

A striking finding is that the changes in brain found in cocaine addicts are long-lasting! It takes many months, perhaps more than a year, for the drug-related changes to revert to normality (Fig. 3). The persistence of these changes in brain over many months likely underlies one of the most striking features of addiction – that it is chronic and relapsing. The drive to take drugs persists over many months, and attempts to stop seeking and taking drugs often meet with failure because the duration and power of the brain changes are sometimes underestimated. This has very important implications for treatment. It seems reasonable to consider that treatments in some form should persist as long as the brain changes persist. This means that treatment in many cases will be a long-term process.

Attempts to Develop Medications for Cocaine Abusers: Small Molecules

A significant effort has been made toward developing medications for cocaine addicts (Vocci and Elkashef 2005). As of this writing (February 2009), no compound has been approved specifically for this purpose, although some existing compounds seem useful in this regard. There are different kinds of medications. When we talk of small molecule medications, we can divide them in roughly two classes – substitutes and blockers. "Substitute" medications tend to be similar to the drug itself but may also have some different or additional properties that make the medication especially helpful. Blockers simply block the action of the drug but cannot produce its effects.

Substitution therapy has worked reasonably well for opiate abuse (e.g., ▶ methadone) or ▶ nicotine abuse (nicotine patch). Hence, a major direction for medications for cocaine use is the development of substitutions. Because DAT is the target of cocaine as described above, many possible substitution medications also target this transporter. While no substitute has yet been approved, there are several possible compounds under consideration. One is RTI-336 (Fig. 1), which is more selective for DAT than cocaine. In other words, it has much less of an effect on serotonin and norepinephrine uptake than it does on dopamine uptake. It also likely enters the brain more slowly than cocaine and has a longer half-life than cocaine. If it passes clinical trials, it will be a new medication for cocaine abuse.

Other dopamine-related compounds under consideration include dopamine D_3 receptor partial agonists, and

► disulfuram, an inhibitor of dopamine beta hydroxylase. Aside from DAT inhibitors, which are basically cocaine-substitution medications, there are other neurotransmitter-targeted compounds that are very promising. Compounds that enhance ► GABA's actions, such as ► tiagabine, ► toperimate, and baclofen, have been tested and are being pursued. Compounds that have multiple actions such as dual dopamine and serotonin releasers are being studied as well. A stimulant, ► modafinil, may also be promising.

Antibodies as Therapeutic Agents

Antibody therapy for cocaine abusers is an interesting approach. Antibodies (already formed) against cocaine could be injected (passive immunization) to bind to cocaine and prevent it from entering the brain. Alternatively, specially prepared large molecules with many cocaine molecules attached to it could be used as a vaccine (active immunization). In the latter case, antibodies usually take some weeks to reach useful levels in the serum. In both cases, cocaine is bound by antibodies in the serum so that it cannot enter the brain (Fig. 4). An advantage of that approach is that we need not block the action of neurotransmitters such as dopamine in the brain. Many physiological functions depend on dopamine, and blocking dopamine as a drug abuse therapy would affect all of those physiological functions, and therefore have many side effects. But preventing cocaine from entering the brain with an antibody avoids those problems. This approach has been proven in animal studies where the behavioral effects of cocaine are reduced by the injection of antibodies (Orson et al. 2008).

The utilization of catalytic antibodies is possible in passive immunization procedures. Catalytic antibodies are those that can metabolize and break down cocaine rather than simply bind the cocaine molecule. This is obviously desirable and some progress has been made in this area as well.

This is an experimental approach and no vaccine or antibody preparation has been approved for use in humans yet. However, progress in clinical trials is being made by several companies. But there are still some issues that need to be addressed (Orson et al. 2008). A major issue is being able to induce higher more effective levels of antibodies more reliably.

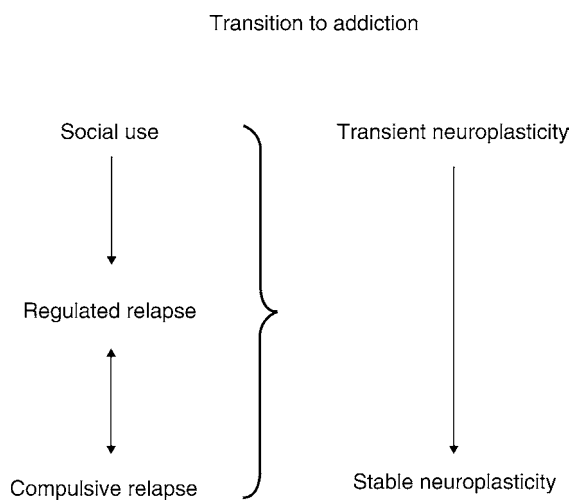
Definition

Cocaine dependence can be characterized as an increasingly difficult urge to resist cocaine whenever it is available. When problematic use is accompanied by tolerance, ► withdrawal, and an increase in the compulsion, or near-compulsion, to seek out and use cocaine, a diagnosis of cocaine dependence should be considered.

This is in contrast to cocaine abuse, where administration is less intense and frequent (American Psychiatric Association 2000).

Pharmacological Properties

According to the 2007 results from the National Survey on Drug Use and Health, 1.6 million Americans abused or were dependent on cocaine during the previous year, underscoring the need for treatment of cocaine dependence. The hallmark of cocaine dependence, and perhaps its most problematic aspect, is the propensity to ► relapse. Cocaine dependent individuals undergo treatment and abstinence from drug use and yet still face considerable desire to consume the drug (craving) and there are high rates of return to drug use (relapse). Clearly, the brains of such individuals have been altered by the repeated drug use such that the individuals have diminished control over their behavior. In addition, drug-seeking will take priority over the pursuit of natural rewards, i.e., reduced drive to obtain natural rewards. The transition from cocaine use to cocaine dependence takes place in different stages. The initial stage is characterized by repetitive, social use of the drug and changes in neural chemistry are largely due to the pharmacological action of the drug itself (Fig. 1). The second stage is defined by persistent changes in the brain circuits that regulate cognitive and emotional responses to environmental stimuli.



Cocaine Dependence. Fig. 1. The transition from cocaine use to cocaine dependence and the relationship with neuroplasticity. Social use can lead to regulated relapse, which can progress into compulsive relapse. This is typified by stable cocaine-induced neuroplasticity and the individual has "learned" to become addicted.

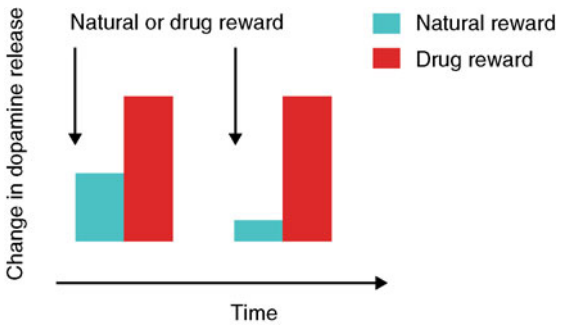
This is accompanied by regulated relapse where the individual consciously decides to relapse. It is therefore a declarative decision-making process to engage in cocaine-taking behavior. Eventually, regulated relapse can progress into compulsive relapse which is a procedural decision-making process and the individual relapses with relatively less consideration of environmental contingencies. Compulsive relapse can be triggered by environmental cues or stressors that were previously associated with drug use (Kalivas and O'Brien 2008). At this stage the cocaine-dependent brain exhibits stable cocaine-induced ► neuroplasticity and the individual has "learned" to become addicted. Accordingly, over the past two decades, a shift has occurred, in which drug addiction is now viewed as a disorder of learning and memory and motivation (Hyman 2005).

Cocaine can be insufflated (intranasal), inhaled (smoked, "freebased," "crack"), or injected. Smoked (freebase, crack) cocaine is derived from cocaine hydrochloride (HCl) using ammonia or sodium bicarbonate. This converts cocaine HCl into freebase cocaine, since most of the HCl form is destroyed by heat. Users report a greater "high" for smoked cocaine versus intranasal cocaine and a faster subjective "peak" versus intravenous and intranasal cocaine. Both the "high" and "feel of drug" peak faster for smoked (1–2 min) compared to intravenous (3–4 min) and intranasal cocaine (10–15 min). By contrast, intravenous cocaine provides the highest blood levels, but it has been suggested that smoked cocaine reaches sooner in the brain. The user initially experiences a euphoric state which is soon followed by cocaine-induced dysphoria. This dysphoric feeling contributes to the repeated use of cocaine, since the user wants to re-experience the initial euphoric rewarding state. Even though cocaine withdrawal lacks overt physical manifestations compared to some other drugs of abuse, the user is subjected to severe psychological withdrawal symptoms. Cocaine dependence often shares comorbidity with other psychiatric disorders (Vocci and Ling 2005). The self-medication hypothesis has been proposed as a possible explanation for cocaine dependence and depression comorbidity, but it does not explain the majority of cocaine dependence.

Different routes of administration are associated with specific side effects. For instance, intranasal cocaine administration could lead to septal necrosis and palatal perforation. Smoking freebase cocaine volatizes the drug and exposes the lungs directly to the smoked mixture, thereby increasing the risk of adverse pulmonary effects and complications. These include interstitial pneumonitis, fibrosis, pulmonary hypertension, alveolar hemorrhage, asthma exacerbation, barotrauma, thermal

airway injury, hilar lymphadenopathies, and bullous emphysema either directly due to the drug itself or associated cutting substances such as talc, silica, and lactose. Intravenous cocaine administration could lead to HIV, hepatitis, and systemic infections such as abscesses and bacteremia due to needle sharing and lack of sterile injection techniques.

After acute administration, there is an increase in dopaminergic neurotransmission in the mesolimbic ▶ dopamine pathway of the ventral tegmental area (VTA) and the ▶ nucleus accumbens (NAc), which is followed by the release of dopamine in the NAc, a reward-related brain structure. In addition, cocaine also inhibits the ▶ dopamine transporter (DAT), by blocking reuptake and thereby increasing extracellular dopamine. The VTA–NAc pathway also mediates the effects of natural rewards such as food and sex. Chronic cocaine use leads to an impaired dopamine system and the baseline levels of dopamine are reduced. Over time, repeated cocaine administration will lead to a sensitized dopaminergic response to the drug or to drug-associated cues from the VTA–NAc, while natural rewards will become less effective in increasing dopaminergic transmission (Koob and Le Moal 2008). In addition, the amplitude and duration of the dopamine release is greater after cocaine administration compared to natural rewards (Fig. 2). Furthermore, there is an increase in dopaminergic neurotransmission from the VTA to the ▶ prefrontal cortex (PFC) and basolateral ▶ amygdala (BLA). At a molecular level, D_1 and D_2 receptors exert opposite effects: D_2 receptors respond to numerous environmental stimuli while D_1 receptors only respond to the strongest stimuli. Chronic cocaine administration promotes a shift toward a D_1-like state. This is accomplished in part through an induction of AGS3 (activator of G protein signaling-3), a protein which is a negative regulator of Gi and therefore of D_2 signaling.



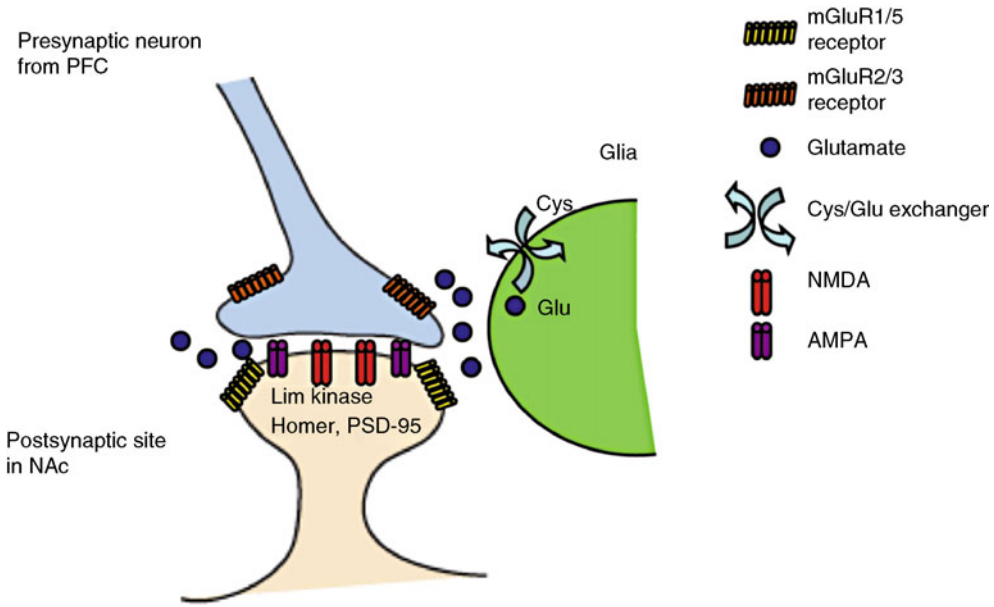
Cocaine Dependence. Fig. 2. Hypothetical histogram illustrating the changes in dopamine release to biological and cocaine reward. Repeated cocaine administration will lead to a sensitized dopaminergic response to the drug or to drug-associated cues, while natural rewards will become less effective in increasing dopaminergic transmission. Furthermore, the amplitude and duration of the dopamine release is greater after cocaine administration compared to natural rewards.

In addition to having effects on the dopaminergic system, chronic cocaine use also causes reduced basal activity in the glutamatergic pathway from several areas of the PFC to the NAc. These areas include the anterior cingulate and orbitofrontal cortices and contribute to executive functions, such as working memory, attention, and behavioral inhibition. The PFC–NAc pathway also mediates the impulsivity and compulsivity to engage in drug taking. Cortical neurons show a decrease in basal glutamatergic neurotransmission, while being hypersensitive to cocaine and cocaine-associated cues. The increase in glutamatergic neurotransmission from the PFC to the NAc corresponds to the increase in dopaminergic neurotransmission from the VTA to the PFC, BLA, and NAc. Human neuroimaging data have confirmed that there is a general reduction in cortical cellular metabolism and blood flow (Goldstein and Volkow 2002). Given the importance of the anterior cingulate cortex in regulating biologically motivated behaviors, and activation of the ventral orbital cortex, this hypofrontality has been characterized as a strong indicator of the reduced ability of addicts to regulate drug-seeking. Presentation of a cue previously associated with cocaine use activates the PFC, including the anterior cingulate and ventral orbital cortices. This activity is positively correlated with the intensity of the cue-induced desire for the drug and is larger than the activation of the PFC in control subjects after presentation of natural reward-related cues. By contrast, presentation of the same natural reward-related cues to cocaine addicts results in reduced PFC activity compared to controls. This is in accordance with the dogma that addicts show an impaired response to natural rewards.

On a cellular level, dysregulation of glutamatergic neurotransmission due to downregulation of the cystine–glutamate exchanger (system xc-) and presynaptic ▶ metabotropic glutamate receptors (mGluR's) has been established in preclinical models of cocaine dependence. Cells use cystine to synthesize the intracellular antioxidant glutathione by exchanging the uptake of one cystine for the release of one molecule of intracellular ▶ glutamate into the extracellular space. The nonsynaptic glutamate in the extracellular space stimulates inhibitory presynaptic

mGluR's and decreases synaptic glutamate release. Therefore, downregulation of xc- will lead to less extrasynaptic glutamate, a reduction in inhibitory tone and ultimately in enhanced synaptic glutamate release probability upon cocaine administration (Fig. 3). These presynaptic effects lead to long-term postsynaptic adaptations. Changes in dendritic spine density and morphology have been well established, which could be a result of an underlying increase in actin cycling. A reduction in Lim kinase which regulates F-actin depolymerization and spine maturation may contribute to the cocaine-induced increase in actin cycling. In addition, there is a decrease in Homer 1b/c and 2a/b scaffold proteins in the NA, which colocalizes with F-actin/Shank/PSD-95/GKAP/NMDA complexes. Additional postsynaptic effects include the membrane insertion of AMPA glutamate receptors and an inability to induce long-term depression (LTD). Controversy remains, since the inability to induce LTD is normally associated with a decrease in AMPA receptors.

As mentioned earlier the emerging view that cocaine dependence is a learning and memory disorder could lead to pharmacotherapy development related to reverting compulsive relapse to regulated relapse. These include normalizing glutamatergic neurotransmission either by altering glutamate levels in the PFC or glutamate receptor activity in the striatum. For example, ► N-acetylcysteine which is a cysteine pro-drug used in treating acetaminophen overdose, has been examined for its potential in affecting relapse, as it appears to increase cystine–glutamate exchange activity and thereby restore inhibitory tone on presynaptic metabotropic glutamate receptors. In fact, recent clinical trials have supported a role for *N*-acetylcysteine in the treatment of drug addiction. In 23 treatment-seeking cocaine-dependent patients, doses of 1,200, 2,400, or 3,600 mg/day were well tolerated. The majority of subjects either stopped using cocaine or significantly reduced their use of cocaine during treatment. Furthermore, in a crossover, double-blind, placebo-controlled inpatient trial, 15 cocaine-dependent participants received four doses of 600 mg *N*-acetylcysteine or placebo. After the final dose, participants completed a cue-reactivity procedure that involved presentations of four categories of slides (cocaine, neutral, pleasant, and unpleasant). Each participant rated how



Cocaine Dependence. Fig. 3. Molecular changes associated with glutamate synapses after chronic cocaine use. In a drug-naïve state, extrasynaptic glutamate provides inhibitory tone via the mGluR's on the presynaptic inputs from the PFC, thus preventing an increase in glutamate levels when cocaine is administered. Chronic cocaine use leads to the downregulation of system xc- and therefore less extrasynaptic glutamate. This decrease in glutamate results in a reduction in inhibitory tone (from the presynaptic mGluR's) and ultimately in enhanced synaptic glutamate release probability upon cocaine administration. In addition, there is a reduction in Lim kinase, Homer 1b/c and 2a/b scaffold proteins in the NA, which colocalizes with F-actin/Shank/PSD-95/GKAP/NMDA complexes and AMPA receptors are inserted into the membrane.

much craving, desire to use cocaine, and interest was evoked by each slide on a 21-point Likert scale. *N*-acetylcysteine significantly reduced the desire to use cocaine, interest in cocaine, and cue viewing time in these patients. Other potential new treatment strategies based on regulating glutamate transmission include the modulation of mGluR's. These include the mGluR2/3 agonist LY379268 ((−)-2-oxa-4-aminobicyclo[3.1.0]hexane-4,6-dicarboxylic acid), which is effective in inhibiting cocaine seeking in preclinical animal models and could decrease stress-induced relapse due to its anxiolytic effects. Similarly, the mGluR1/5 antagonists, 2-methyl-6-(phenylethynyl) pyridine (MPEP) and its analog 3-[(2-methyl-4-thiazolyl)ethynyl]pyridine (MTEP) have shown to be effective in preclinical models of cocaine addiction.

Methylmorphine

Definition

Codeine is an opiate used for its analgesic, antitussive, and antidiarrheal properties. It is an alkaloid, derived from opium, an O-methylated derivative of morphine that is not directly active on the μ-opioid receptors. It is a prodrug that is metabolized to morphine and codeine-6-glucuronide when taken orally. Like most ► opioids, it is a drug of abuse and its continued use induces ► physical dependence and addiction. It is found in some cough syrups that are subject to abuse.

Cognitive Behavioral Therapy

Synonyms

CBT; ERP; Exposure and response prevention

Definition

A therapeutic technique designed for the treatment of anxiety disorders, especially obsessive–compulsive disorder. The therapeutic effect is achieved when the patient

is able to confront his/her fear (e.g., the anxiety caused by the obsession) without performing the escape response (e.g., the compulsion). Therapists traditionally used well-thought out exposure situations in controlled environment to provoke the obsessions and engage in a contract with the patient not to perform the anxiety-relieving compulsion. The initial anxiety of the obsession typically attenuates with success exposures if the compulsion is not performed.

Definition

Pharmacological substances that induce improvement of various facets of cognition, such as attention and memory, are known as pharmacological cognitive enhancers (PCEs). Many pharmacological interventions are aimed at improving cognition in specific neuropsychiatric disorders where cognitive impairment is a prominent symptom, such as attention-deficit hyperactivity disorder (► ADHD), ► schizophrenia, mild cognitive impairment (MCI), and ► Alzheimer's disease (AD). Enhanced cognition would, in turn, lead to improved functional outcome and quality of life. Pharmacological enhancement of cognition is increasingly being considered in both the young and old healthy populations and seems set to become even more popular, extending from dietary supplements and caffeine to drugs specifically targeted at improving cognition.

Current Concepts and State of Knowledge

Cognitive enhancing drugs, also known as smart drugs, are needed to treat cognitive disabilities and improve the functional outcome, wellbeing, and quality of life for patients with neuropsychiatric disorders and brain injury (Sahakian and Morein-Zamir 2007). Cognitive enhancing drugs are used in treating cognitive impairment in disorders such as AD, schizophrenia, and ADHD. In neurodegenerative diseases, such as AD, cognitive enhancing drugs are used to slow down or compensate for the decline in cognitive and behavioral functioning that characterizes such disorders. There are currently 700,000 people with dementia in the United Kingdom, most of whom have AD. Each year, 39,400 new cases are diagnosed in England and Wales, translating to a new case every 14 min. Current costs of long-term care for dementia in the United Kingdom are estimated at £4.6 billion, and with an increasing aging population, this estimate is expected to rise to £10.9 billion by the year 2031. Likewise, the number of people placed in institutions is expected to rise from 224,000 in 1998 to 365,000 in 2031. Cognitive enhancing drugs are important in this context as it has been suggested that a treatment that would reduce severe cognitive impairment in older people by just 1% a year, would cancel out all estimated increases in the long-term-care costs due to the aging population in the United Kingdom.

Cognitive enhancers may be beneficial not only in neurodegenerative disorders but also in neuropsychiatric disorders for which they are not yet routinely prescribed. For instance, though it is common knowledge that people with schizophrenia typically suffer from hallucinations and delusions, it is the long-term cognitive impairments that often impede everyday function and quality of life for many patients. Twenty-four million people world wide suffer from schizophrenia. In the United States, direct and indirect costs were estimated at over $60 billion in the year 2000. It has been suggested that even small improvements in cognitive functions could help patients make the transition to independent living.

It is noteworthy that not only adults suffering from neuropsychiatric disorders can benefit from cognitive enhancing drugs. ADHD affects 3–7% of all children worldwide, and is the most prevalent neuropsychiatric disorder of childhood. ADHD is a highly heritable and disabling condition characterized by core cognitive and behavioral symptoms of impulsivity, hyperactivity, and/or

inattention. It has important implications for education provision, long-term social outcomes, and economic impact. For example, long-term studies indicate that it is associated with poorer long-term outcomes, including increased educational dropout, job dismissal, criminal activities, substance abuse, other mental illness, and increased accident rates. The annual excess cost of ADHD in the United States in 2000 was estimated to be $42.5 billion.

Importantly, in addition to pharmacological cognitive enhancers (PCEs), there are many other methods of enhancement such as education, physical exercise, and neurocognitive activation or cognitive training that are commonly being used (Beddington et al. 2008). However, with the popularization of the notion of cognitive enhancement, pharmacological interventions are being seen as a means not only to improve existing deficits, but also to prevent decline before its onset, and even to enhance normal functioning.

The effects of pharmacological substances on cognition are complex, as cognition is a multifaceted, construct-encompassing attention, executive function, and spatial and verbal learning and memory. Most cognitive enhancing drugs improve only specific aspects of cognition such as forms of executive functions or memory, which are mediated by different systems in the brain. The sizes of the effects to date range from small to moderate, but as pointed out by a recent report by the U.K. Academy of Medical Sciences, even small percentage increments in performance can lead to significant improvements. While the extension of enhancement from the controlled laboratory environment to daily life is controversial, several factors are contributing to the advent of increasingly effective approaches. These include the development of sophisticated neuropsychological tests and the routine inclusion of multiple, converging behavioral and brain-imaging measures. With the development of human pharmacogenetics, uncovering human genetic ► polymorphisms relating to cognition, cognitive enhancers may be matched to those that might benefit from them the most while reducing side effects. For example, the catecholamine-O-methyltrasferase (COMT) gene has been linked to the degree of effectiveness of COMT inhibitors and to the ► working-memory performance, such that the Val158Met polymorphism may also modify the effect of dopaminergic drugs (e.g., the COMT enzyme inhibitor ► tolcapone) in the prefrontal cortex.

Despite the fact that much research has been dedicated to the development and understanding of various cognitive enhancers, we still have limited knowledge of how specific cognitive functions are modulated by neurotransmitters. For example, while we know that ► methylphenidate improves symptoms of ADHD and also improves performance on objective behavioral tasks, such as spatial working memory and stop signal, we are yet to determine conclusively whether dopamine, noradrenaline, or both neurotransmitters are required for these effects on cognition. Some of the most notable PCEs being explored to assist individuals with neurological or neuropsychiatric disorders with executive function and attention difficulties include methylphenidate, ► atomoxetine and ► modafinil. Methylphenidate, also commonly known as Ritalin, increases the synaptic concentration of dopamine and noradrenaline by blocking their reuptake. Atomoxetine on the other hand, is a relatively selective noradrenaline reuptake inhibitor (SNRI). In the case of modafinil, despite considerable research, its precise mechanism of action is unclear, though it has been found to exhibit a multitude of effects including potentiation of noradrenaline and to a degree, dopamine neurotransmission; and elevation of extracellular glutamate, serotonin and histamine levels, and decreased extracellular GABA. Recent evidence suggests that some of its cognitive effects may be modulated primarily by noradrenaline transporter inhibition.

There are many additional considerations in examining the cognitive enhancing effects of various pharmacological agents. Neurotransmitter functions, at times, following an inverted U-shaped curve, with deviations from optimal level in either direction impairing performance. Moreover, different neurotransmitter levels can be found across brain regions, suggesting a complex interplay between baseline levels and drug administration. While some cognitive functions may improve following drug administration, others may worsen, as they depend on different optimum neurotransmitter levels. Drug-induced neurotransmitter increases may improve functioning in some groups but have no effect or even impair performance in others, already at optimum. Namely, the baseline abilities of the individual can limit the effectiveness of certain PCEs, and their effect will be more pronounced in those with an initial below-average level of performance.

An effective method of testing the effects of cognitive enhancers on cognition is by using double–blind placebo control studies where participants undergo a battery of objective cognitive tasks targeted at measuring various facets of cognition, including memory, attention, and executive functions. For instance, in the ► CANTAB Spatial Working Memory (SWM) task, a number of colored boxes are shown on the screen. The aim of this task is that, by touching the boxes and using a process of elimination, the subject should find one blue "token" in each of a

number of boxes. The number of boxes is gradually increased, until it is necessary to search a total of eight boxes. SWM is a test of the subject's ability to retain spatial information and to manipulate remembered items in working memory. It is a self-ordered task, which also assesses heuristic strategy. This test is sensitive to frontal lobe and "executive" dysfunction and is impaired in childhood and adulthood ADHD.

It has been demonstrated that methylphenidate improves SWM task performance in young volunteers and in children and adult patients with ADHD, whereby patients make less task-related errors when on methylphenidate. The neural substrates mediating SWM task performance have been examined using imaging techniques such as positron emission topography (► PET) and indicate that the dorsolateral- and mid-ventrolateral prefrontal cortex are particularly recruited. Studies using PET and contrasting [(11)C] raclopride binding on methylphenidate versus placebo have further indicated that methylphenidate influences dopaminergic function, particularly in the striatum. Methylphenidate has been found to improve both performance and efficiency in the spatial working memory neural network involving the dorsolateral prefrontal cortex and posterior parietal cortex in healthy volunteers. Similar studies using the double-blind, randomized, placebo-controlled methodology have reported that additional drugs such as modafinil and atomoxetine can improve performance in some tasks of executive functioning. Thus, modafinil has been found to improve spatial planning and response inhibition in ADHD patients, as measured by a variant of the Tower of London task and the stop-signal task, respectively. It has been further demonstrated that modafinil produces improvements in performance in a group of healthy volunteers on tests of spatial planning, response inhibition, visual recognition, and short-term memory. Likewise, administration of an acute dose of atomoxetine has been found not only to improve response inhibition in ADHD patients, but also in healthy adults. Using functional magnetic resonance imaging (► fMRI), the brain mechanisms by which atomoxetine exerts its effects in healthy volunteers has been examined in a double-blind placebo-controlled study. Atomoxetine led to increased activation in the right inferior frontal gyrus when participants attempted to inhibit their responses in the stop-signal task. Inhibitory motor control has been shown previously to depend, at least in part, on the function of this brain region.

There is a clear trend in many Western countries toward increasing prescriptions of methylphenidate. With the advent of psychiatric medications with greater tolerability and fewer side effects, these trends are set to continue. However, it is not only those who suffer from neuropsychiatric disorders and brain injury who are appearing to use pharmacological cognitive enhancers (Sahakian and Morein-Zamir in press); but the use of stimulants, including methylphenidate and ► amphetamines by students has been rising as well. Trends suggest that between 1993 and 2001 there was a clear increase in the life-time and 12-month prevalence rates of nonmedical use of prescription drugs in college students. In the United States, studies indicate that up to 16% of students on some college campuses use stimulants, while 8% of university undergraduates report having illegally used prescription stimulants. Surveys on students indicate that most illicit use of prescription stimulants reported in the past year involve amphetamine–dextroamphetamine combination agent, with higher use among Caucasians and Hispanics when compared with African-Americans and Asians and considerable variations between colleges. The most commonly reported motives for use were to aid concentration, help study, and increase alertness. There is also a trend for increasingly younger students to use such drugs with one report indicating 2.5% of eighth grades (13–14 years), abused methylphenidate; as did 3.4% tenth graders and 5.1% twelfth graders. The trends are also not reserved for North America alone, as prescriptions rates in England of stimulants have been rising steadily from 220,000 in 1998 to 418,300 in 2004. Although drugs such as modafinil are prescribed off-label in North America, they can be freely obtained without a prescription via the internet from multiple websites in various countries. In fact, a recent survey identified 159 sites offering drugs for sale, of which only 2 were regulated and 85% not requiring a physician's prescription from the patient. Another cognitive domain of great interest is memory.

These trends of growing use are likely set to increase as presently there are also novel cognitive enhancers under development, many of which are aimed at improving memory and learning. Given the aging population in the United Kingdom and elsewhere, and the fact that the lifespan of individuals is being extended, it is highly likely that cognitive enhancing drugs that can improve memory in healthy elderly will prove to be in demand.

For example, ► Ampakines, which work by enhancing the AMPA receptor's response to glutamate, improve cognition in healthy aged volunteers. Novel compounds such as nicotinic alpha-7 receptor agonists are now in Phase 2 of clinical trials in AD and schizophrenia (e.g., MEM 3454, Memory Pharmaceuticals/Roche).

The popular media has reported extensively both on studies finding improved performance in healthy individuals and on the rising use of PCEs in healthy individuals

(see also Maher 2008). For example, the results from the authors' laboratory on modafinil were reported in the media, including newspapers, magazines, and radio. Publications ranging from *The Guardian newspaper* (London) to *The New Yorker* and *Nature*, as well as the BBC, have discussed their potential for wide-spread use. Maintaining an optimum level of alertness, arousal, and attention might be expected to prove valuable in a range of work and leisure activities. Indeed, the use of PCEs is not restricted to academic use, and American sprinter Kelli White received a two-year ban in 2004 for using modafinil when competing in the world championships and other US national events.

The study of cognitive enhancing drugs, and their influence both on patients with neuropsychiatric and neurological disorders and healthy adults, raises numerous neuroethical issues. In the area of ▶ neuroethics, there are several important considerations in regard to the use of cognitive enhancing drugs, particularly in children and adolescents where the brain is still in development (Marcus 2002). For example, certain drugs such as the stimulants have abuse potential and we do not even know what side effects may emerge with long-term use in healthy people. There are also many other issues, including possible direct and indirect coercion and greater societal disparity, which will impact on the individual and on society.

As pharmacological cognitive enhancement appears set to become increasingly widespread, the profile of cognitive effects of each drug on specific populations should be mapped, along with its potential for harms. This will facilitate ethical and regulatory discussion about each pharmacological substance. At present, regulatory bodies (e.g., FDA, MHRA, EMEA) are concerned with treatments for disorders or diseases, but this may change in future with the increasing use of cognitive enhancing drugs by healthy people (Greely et al. 2008). The development of tailored, cognitive enhancing treatments for a wide range of neuropsychiatric disorders, as well as for normal function, holds much future promise. As ▶ pharmacogenomics and individualized medicine continues to develop, cognitive enhancing drugs may prove of great benefit to society in terms of improving wellbeing and quality of life for people with neuropsychiatric disorders, brain injury, and age-related memory impairment.

Cognitive Enhancers: Role of the Glutamate System

Nootropics

Definition

Cognitive enhancers are drugs that are used to treat problems of memory, attention and inhibitory control.

Pharmacological Properties

Cognitive problems exist in a variety of psychiatric and neurological disorders. Current nootropics, the ▶ acetylcholinesterase inhibitors, are used primarily to treat

► Alzheimer's disease. These drugs have limited efficacy and cannot be used ubiquitously across all disorders where cognitive enhancement might be beneficial (for example, they are inappropriate for the use in patients with ► Parkinson's disease as they can aggravate the motor disability). Therefore, the future development of a range of drugs with different mechanisms of action is likely to occur.

Ionotrophic Glutamate Receptors

Ionotrophic ► glutamate receptors as a target for cognition enhancement have been of interest since the 1980s following the discovery of their involvement in ► Long-term potentiation (LTP; a persistent strengthening of synapses). This form of synaptic plasticity requires the activation of *N*-methyl-D-aspartate (NMDA)-receptors for its induction. Alpha-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA)-receptors can also promote the induction of LTP, and they play an important role in the expression of the potentiated response (Cooke and Bliss 2005). It has been presumed that LTP underlies some forms of learning and memory for two reasons. First, because the induction of LTP at any particular synapse requires coincident activity, it fulfils the criterion for a Hebb Synapse, predicted in 1949 to be necessary for the formation of associations. Second, compounds that act as antagonists at NMDA-receptors both impair the induction of LTP and produce clear cognitive deficits in animals and humans (see Robbins and Murphy 2006). Not surprisingly then, the enhancement of cognition with ligands that positively modulate NMDA- and AMPA-receptors has been a goal for some time. While it is not possible to use agonists that act by stimulating these receptors via the glutamate binding site, due to the risk of causing neurodegeneration or inducing seizures, in recent years, ligands that act through other binding sites to modulate receptor activity and which have pro-cognitive effects have emerged.

Drugs Acting at NMDA Receptors

► NMDA-receptors are comprised of four protein subunits clustered around an ion channel. The channel is normally occupied by magnesium, but when the neuronal membrane is sufficiently depolarised, magnesium dissociates and calcium influx into the cell is permitted. Each heteromeric NMDA-receptor is believed to consist of two protein NR1 subunits plus two NR2 subunits. There are four variants of the NR2 subunit, denoted A,B,C, and D. While glutamate itself binds to sites on the NR2 subunits, there are a number of other binding sites located at different parts of the receptor, including those for the endogenous "co-agonists," glycine and D-serine which bind to the NR1 subunits, at $Glycine_B$ sites (see Fig. 1). Although glutamate and $Glycine_B$ sites are located on different subunits of the NMDA-receptor, both glycine and D-serine can enhance the action of glutamate. In turn, the effectiveness of glycine and D-serine at $Glycine_B$ sites is determined by the variant of NR2 subunit(s) present in the receptor (Millan 2005). In terms of putative nootropics acting at NMDA-receptors, compounds acting on receptors containing NR1 plus NR2A/NR2B subunits are of interest, as these subunits are distributed in brain areas such as the ► hippocampus and the frontal cortex. Ideas about enhancement of cognition via these particular NMDA-receptors have also been encouraged by the seminal publication of Tang et al. (1999), indicating that mice that are genetically engineered to over express receptors containing NR2B subunits showed superior performance in several tests of learning and memory. Although the $Glycine_B$ site was once thought to be saturated by its endogenous ligands, it is now recognized that it is, which opens up the possibility that this site might be targeted by drugs to produce procognitive actions via the NMDA-receptor.

Agonists at the $Glycine_B$ Site

Agonists acting directly at the $Glycine_B$ site of the NMDA-receptor include the amino acids glycine, D-serine, and the synthetic ► partial agonist D-cycloserine. In preclinical studies, the full agonists such as glycine and D-serine have been investigated as cognition enhancers. Large doses are required for efficacy, but they do reverse deficits in ► novel object recognition tests and the impairment seen in a developmental model of sensorimotor gating deficits. Human studies have also investigated the effects of full agonists such as glycine, D-serine, and D-alanine. In healthy humans, many studies report that glycine is ineffective in a variety of tests and that high doses may

even impair some aspects of cognition. One study employing a very low dose, however, has reported retrieval improvements in a test of word recall. The effects of the full agonists have also been investigated in ► schizophrenia where they appear to produce some improvement in negative symptoms. Their cognitive benefits appear less clear though.

The effects of the partial agonist D-cycloserine have been more studied than those of the full agonists. Preclinical experiments in rats have shown that it can enhance ► spatial memory, such as that measured in radial and water mazes, in addition to visuospatial memory and visual recognition in primates. Reversal of decrements in cognition can also be seen in ageing animals. In rats, some elegant studies by Davies and colleagues have demonstrated the ability of D-cycloserine to facilitate fear extinction. Fear extinction refers to the process of reducing a response to a cue previously paired with a fear-evoking event, by exposure to the cue in the absence of the associated event. This is the basis of exposure therapy, where a patient is repeatedly exposed to a feared object or situation, with support and without any adverse consequences. Importantly, extinction of the fear response occurs through new learning which inhibits the original fear, rather than by simple forgetting. As with some other forms of learning, extinction is a process that can be prevented by antagonists acting at NMDA-receptors. Davis and colleagues therefore predicted that ligands that positively modulate the NMDA-receptor should facilitate fear extinction and in preclinical studies they went on to show that D-cycloserine could do exactly that. These and later studies led to clinical trials of D-cycloserine in humans as an adjunct to improve exposure therapy for acrophobia (fear of heights). During these trials that were carried out in a virtual reality environment, patients were given D-cycloserine (or placebo) before two therapy sessions and retested 1 week and 3 months later. At the retests, patients who had received D-cycloserine during therapy sessions, showed enhanced fear reduction in the virtual reality environment (Davis et al. 2006). Therefore, by potentiating the action of glutamate through the $Glycine_B$-site, extinction learning can be accelerated in both animals and humans.

In other studies, D-cycloserine has been found to improve different aspects of learning, memory and also performance in tests of cognitive flexibility in both healthy humans and in patients with schizophrenia or Alzheimer's disease. As in the fear extinction studies, these procognitive actions of D-cycloserine have invariably been seen at small doses only, perhaps because its efficacy as an agonist may be lost at larger doses (Priestley et al. 1995).

Glycine Reuptake Inhibitors

Another way to enhance the activity of NMDA-receptors via the $Glycine_B$-site is to elevate the synaptic levels of endogenous glycine itself. Normally, the action of glycine would be terminated by its removal from the synapse by specialized transporters located on neuronal membranes and on the surrounding glial cell membranes. Although there are multiple subtypes of transporter, glycine-1 transporters (GLYT-1) located on the glial cells play a major role in the removal of glycine from the synapse and it is the activity of these transporters that is thought to be the reason why $Glycine_B$-sites are not saturated in vivo. Drugs that prevent the activity of GLYT-1, glycine reuptake inhibitors (GRIs) should therefore increase glutamate action at NMDA-receptors.

The first generation of GRIs were based on sarcosine (*N*-methyl-glycine), a selective inhibitor of glycine uptake at GLYT-1 and include NFPS (*N*-[3-(4′-Fluorophenyl)-3-(4′-phenylphenoxy)propyl]sarcosine) and Org24461/24598. Second generation GRIs are non-aminoacid-based compounds, such as SSR504734. Accompanying the rise of the glutamatergic hypothesis of schizophrenia, our knowledge of the procognitive actions of GRIs comes mostly from preclinical studies aimed at modeling aspects of cognition that are impaired in the disorder. Pre-pulse inhibition, or PPI, describes the ability of a small pre-stimulus to inhibit the startle response to a larger stimulus. In animal models, deficits in PPI arise spontaneously in the DBA/2 strain of mouse or can be seen to develop in adult rats, following neonatal treatment with phencyclidine. These are thought to model a schizophrenic abnormality in filtering information and studies in animals have consequently shown that GRIs can reverse these deficits. Other studies have shown their effectiveness at improving object recognition or reference memory, in tests where deficits have been pharmacologically induced with NMDA-receptor antagonists. In human schizophrenia patients, sarcosine and other GRIs can improve "cognitive symptoms" but the nature of these improvements is not yet well described.

Overall, drugs targeting the $Glycine_B$-site of the NMDA-receptor do appear to have procognitive effects on several aspects of learning and memory. There is little evidence for improvements in attention and their effectiveness for enhancing other cognitive domains remains to be fully investigated.

Drugs Acting at AMPA-Receptors

Most of the fast glutamatergic neurotransmission in the brain is mediated by ► AMPA-receptors. In addition, changes in synaptic plasticity are associated with

AMPA-receptor insertion and removal from the neuronal membrane (receptor trafficking). They are composed of four protein subunits (tetramers) clustered around an ion channel and which are denoted by GluR1-4. These subunits can also exist as "flip" and "flop" variants. There is therefore AMPA-receptor subtype diversity throughout the brain. The calcium permeability of the receptors depends on the subunit composition – those containing GluR2 subunits are impermeable. The ►hippocampus and the ►amygdala are areas of the brain containing receptors that lack the GluR2 subunit and as a consequence, they have high calcium permeability.

There are two ways in which glutamate neurotransmission at AMPA-receptors is terminated. In the first case, deactivation, glutamate dissociates from the binding site and the ion channel closes. In the second, desensitization, glutamate remains bound, but a conformational change in the receptor causes a closing of the ion channel with the ligand trapped (see Fig. 2). The subunit constitution of the receptor can alter the rate at which it desensitizes. In principle then, any compound that prevents the deactivation or the desensitization of the receptor should prolong the receptor response to glutamate. Such drugs are termed AMPAkines or AMPA-receptor potentiators and most act by preventing desensitization.

Four main classes of AMPA-receptor potentiators have been developed to date (see Table 1).

The exact pharmacology of each compound varies due to receptor diversity, but all can enhance glutamatergic neurotransmission at AMPA-receptors and this has a number of consequences. First, because AMPA-receptors play a key role in LTP, potentiation of their activity can remove the magnesium block on NMDA-receptors resulting in the enhancement of synaptic plasticity. Second, their activation can also increase the expression of the neurotrophin ►brain derived neurotrophic factor (BDNF); the result of this is to increase neurogenesis. It is therefore not surprising that AMPA-receptor potentiators should be of interest in regard to cognition enhancement.

The preclinical profile of the AMPA-receptor potentiators, with respect to therapeutic potential, including as cognition enhancers was reviewed by Black (2005). Several studies have shown that they can have beneficial effects on new learning. These procognitive actions have been reported in rodent maze tasks tapping spatial memory and in conditioning tests, such as passive avoidance or conditioned fear. In primate studies, they can also reverse pharmacologically-induced deficits in new learning. Also, there is evidence for positive benefits on ►working memory in both rodents (using models such as ►delayed matching to sample tests) and primates (►delayed non-matching to sample) and for improved performance in object recognition tests. Enhanced impulse control has been reported in rat studies. This latter finding, however, rests solely on the effect of aniracetam, and it is not yet

clear whether this is a class effect of the AMPA-receptor potentiators.

Preclinically then, the cognitive effects of the AMPA-receptor potentiators are in many ways similar to those of drugs aimed at positively modulating the NMDA-receptor, perhaps because of their ability to enhance LTP, although this picture is likely to be biased by the use of animal models designed to detect specific pharmacological effects believed to be therapeutically useful in particular disorders.

Very few studies on the effects of AMPA-receptor potentiators have been carried out in humans. An early study found some evidence for improved free recall of nonsense syllables in elderly volunteers and a small clinical trial in younger adults was also able to detect enhanced performance in four different memory tasks (Lynch 2004). There is also some evidence for alerting effects in sleep deprived volunteers. In schizophrenic patients, equivocal results have been obtained, with CX516 as an add-on treatment to current antipsychotic medication. Results have also been disappointing with LY451395 in a trial in patients with Alzheimer's disease, where the measure of cognitive assessment was the cognitive subscale of the Alzheimer's disease assessment scale. Lastly, no improvement was seen in a variety of cognitive measures in a trial of CX516 in patients with ▶ Fragile X Syndrome. Fragile X Syndrome is an inherited disorder characterized by intellectual and emotional disabilities and where there may be abnormalities of AMPA-receptor trafficking. The reason for the negative results in patients is unclear, although some of the AMPA-receptor potentiators are not particularly potent drugs and the difficulty of achieving adequate concentrations has been debated.

Overall, the preclinical studies indicate that AMPA-receptor potentiators can promote learning and memory. However, there is room for investigation of their effects across more cognitive domains. There is a paucity of clinical studies, although those carried out in healthy volunteers are suggestive of some of the preclinical findings being translatable to humans.

Cognition Enhancers as Investigational Tools

For the most part, drugs such as the GRIs and the AMPA-receptor potentiators have been developed in attempts to provide new medicines for specific psychiatric disorders, most notably for schizophrenia. While this hopefully proves fruitful, many of the positive modulators of ionotrophic-receptor activity can also be used effectively as tools to investigate the role of ▶ glutamate in a broader range of cognitive functions and aspects of other mental health disorders. One obvious area for their use as tools is in addiction studies. This is partly because a role for glutamate-mediated neuroadaptations in addiction has been known for some time (see Kauer and Malenka 2007) partly as many drugs of abuse induce glutamate release in reward-related areas of the brain and also because the cognitive aspects of addictions, such as inhibitory control over drug-seeking behavior, are increasingly being recognized.

With the possible exception of the compounds that may require large doses, many of the drugs mentioned above could be used as tools in addiction research, in both animal and human studies. In using them as tools, one important factor needs to be taken into account. A common property of the $Glycine_B$-site agonists, GRIs and the AMPA-receptor potentiators is that they do not directly activate receptors themselves. Instead, as they modulate the action of glutamate, it may be presumed that some level of endogenous activity would be required for their effects to emerge. In the case of the $Glycine_B$-site agonists and the GRIs, the endogenous levels of glycine and D-serine are also likely to be a factor. It might be possible to predict however, certain situations where a level of endogenous activity is to be expected. First, where new learning occurs during the extinction of drug-taking behavior, thus in an analogy with the studies on fear extinction, these drugs would be expected to facilitate the process. Second, in line with much evidence from studies using NMDA-antagonists which indicates a role for glutamate in inhibitory control, it could be predicted that the $Glycine_B$-site agonists and GRIs would aid active inhibition of impulsive behavior.

D-cycloserine, the partial agonist at the $Glycine_B$-site, is well tolerated in humans and therefore being used increasingly as an investigative tool. As D-cycloserine is a partial agonist, it has the ability not only to potentiate glutamate-receptor function, but for a given dose, it can also block the action of glycine through its antagonist property. Like any partial agonist then, the "direction" of its behavioural effect depends on levels of endogenous activity. As a pure cognitive enhancer the effects of D-cycloserine therefore, may only be useful under particular conditions, but for the purposes of investigating the role of glutamate in cognition and behavior it may be a uniquely useful tool. A recent study by Jackson and colleagues illustrates how it can be used.

As there is a considerable amount of preclinical evidence implicating a role for glutamate in the effects of nicotine, D-cycloserine was used to investigate the role of glutamate in the cognitive and subjective effects of smoking in humans. Figure 3 illustrates the theoretical approach that was used for the study. Volunteers were asked

to "partially smoke" a cigarette after taking 50 mg of D-cycloserine (or placebo). They then completed a series of cognitive and subjective tests. Volunteers who had received D-cycloserine reported less subjective effects after smoking, compared with those given placebo. In contrast, the same dose of D-cycloserine *enhanced* inhibitory control after smoking compared with those given placebo. Thus by using the bidirectional pharmacological property of D-cycloserine, a role for glutamate in some of the cognitive and subjective effects of smoking was confirmed in humans.

Ultimately, it is not possible to know what the level of endogenous glutamate activity was during the smoking study. Although the results with D-cycloserine indicated a role for glutamate in the effects of smoking, the interpretation of that role is made in the light of numerous other studies that have employed the use of NMDA-antagonists. Similarly, if the AMPA-receptor potentiators are to be used as effective tools, it might first be important to understand the consequences of reduced AMPA-receptor function, as a null result with these drugs might simply be a reflection of preexisting conditions of high endogenous activity. However, provided that their pharmacological mode of action as modulators of glutamate activity (as opposed to direct activators of receptors) is taken into account during the design of studies and in the interpretation of results, their use as investigational tools is possible and should provide valuable further information about the processes involved in cognition.

Cognitive Impairment

Synonyms

Cognitive deficit; Neurocognitive dysfunction

Definition

Cognitive impairment is considered a core feature of *schizophrenia* that is related to the daily functioning of patients. On average, *cognitive impairment* in schizophrenia is severe to moderately severe compared with healthy controls. *Cognitive impairment* is not state-related and is not specific to subtypes of the illness. It includes problems in speed of processing, attention/vigilance, working memory, verbal learning, visual learning, reasoning and problem solving, and social cognition. These deficits can also serve as an endophenotype for the illness and are

considered a reasonable treatment target in individuals with schizophrenia.

Cognitive Neuroscience

Definition
The field of cognitive neuroscience is concerned with the study of the brain basis of mental processes in humans – or how the brain enables the mind. It seeks to understand how specific mental abilities and their behavioral correlates are supported by brain systems (regions, networks) both in healthy and disordered populations. Cognitive neuroscience integrates the theoretical background and experimental practices of cognitive science, cognitive psychology, neuroscience, and psychophysiology. The advent of functional neuroimaging techniques, in particular fMRI, has had a major influence on the growth of this field.

Cognitive Subtraction

Synonyms
Pure insertion; Subtraction method

Definition
In functional neuroimaging studies, cognitive subtraction refers to an aspect of experimental design involving the comparison of two conditions or brain states that are presumed to differ in only one discrete feature (the independent variable). Cognitive subtraction designs rely on the assumption of "pure insertion" – the notion that a single cognitive process can be inserted into a task without affecting the remaining processes, or that there are no interactions among the cognitive components of a task.

Comprehensive Drug Abuse Prevention and Control Act of 1970

Definition

Enacted into law by the U.S. Congress, the Comprehensive Drug Abuse Prevention and Control Act of 1970, also known as the Controlled Substances Act, outlines the policies for the manufacture, importation, possession, use, and distribution of certain chemical substances. The Controlled Substances Act divides these substances into five schedules (classifications) and the decisions for classification are based upon the potential for abuse and current medical uses by the Drug Enforcement Administration and the Food and Drug Administration.

Compulsions

Synonyms

Compulsive acts; Compulsive rituals

Definition

Compulsions are repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) the goal of which is to prevent or reduce anxiety or distress, not to provide pleasure or gratification. The person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly. The behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation. However, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive. At some point during the course of the disorder, the person recognizes that the obsessions or compulsions are excessive or unreasonable. The compulsions cause marked distress, are time consuming (>1 h/day), or significantly interfere with the person's normal routine, occupational or academic functioning, or usual social activities or relationships.

Definition
The following essay will examine the historical and more recent scientific contributions in the field of conditioned drug effects. The focus will remain on drugs as the unconditioned stimuli. The aim is to provide an outline of the present state of knowledge and also present a framework on how to examine the direct and indirect influence of many experimental and clinically used psychoactive compounds and their conditioned effects.

Impact of Psychoactive Drugs
Drugs can produce physiological changes (e.g., salivation, hypothermia) or behavioral changes (e.g., locomotor stimulation). Cues that are repeatedly associated with drug administration can acquire the ability to elicit similar physiological changes or in some cases, opposite responses to those elicited by the drug itself. Collectively, responses elicited by cues associated with drugs are termed conditioned responses (CRs) or conditioned drug effects. The following chapter is organized into two parts: Part 1 is concerned with conditioned physiological responses to drugs and Part 2 is concerned with conditioned behavioral responses to drugs.

Part 1: Conditioned Physiological Responses to Drugs
The Nobel Prize-winning Russian physiologist IP Pavlov showed that the responses produced by a drug can be

evoked by cues associated with drug administration even in the absence of the drug. Pavlov described this phenomenon as ▶ classical conditioning. The drug serves as the unconditioned stimulus (US) and produces an unconditioned response (UR). Pairing of an initially neutral stimulus with the drug leads to acquisition by that stimulus (the conditioned stimulus or CS) of the ability to produce a response like the US, termed the conditioned response (CR).

The earliest studies examining physiological responses to drugs tested morphine effects on salivation. Pavlov showed that injection of ▶ morphine (the US) evoked salivation (the UR) in dogs; after a number of morphine injections, the cues associated with drug administration (the CS) were able to elicit the response (the CR) produced by morphine. Pavlov showed further that injection of atropine inhibited salivation; perhaps surprisingly, after a number of atropine injections, cues associated with its administration elicited salivation, a CR opposite to the UR.

In Pavlovian conditioning, it is essential to identify the US and the UR when drugs are used to induce physiological changes. Eikelboom and Stewart (1982) argued that the unconditional stimulus is a "...physical event that results in neuronal consequences...what is crucial in this definition is that the (unconditioned) response is an outcome of neural activity" (p. 509). Learning and conditioning are activities of the central nervous system (CNS); hence, stimuli need to be viewed as inputs to and responses as outputs from the CNS. Only when a drug acts on the input side of the CNS should its action be considered an US and only those observed drug effects that are CNS-mediated physiological reactions to unconditioned stimuli should qualify as a UR. Drug-manipulated thermoregulation provides an example. Two widely studied drugs are morphine that causes hyperthermia and ethanol that causes hypothermia. Morphine has been shown to act directly through the CNS to produce effects on the thermoregulatory system. The CR to morphine mimics the drug effect, hyperthermia. On the other hand, ethanol acts peripherally to produce increased cutaneous blood flow leading to heat loss and a decrease in body temperature that is detected by the CNS that then mounts a compensatory hyperthermic response. When the drug-associated cues (the CS) are subsequently presented alone, only the (CNS-mediated) hyperthermic response (the CR) is observed. The CR in this case is opposite to the drug effect (the UR).

The classic study by Zubkov and Zilov (see Bespalov et al. 2001) reveals some further complexities for identifying the true UR. They examined the CR to epinephrine-associated cues on heart rate in dogs. Epinephrine produced heart rate acceleration upon initial injection. However, the effect was substantially attenuated after several injections and complete ▶ tolerance was reported by the sixth injection. When the dogs with a history of epinephrine administration were injected with saline the heart rate was significantly decelerated. This phenomenon was termed associative tolerance: CRs elicited by environmental stimuli paired with epinephrine injection were opposite in direction to the initial UR produced by the drug.

The aforementioned observations conflict with Pavlovian conditioning where the CR is the same as the UR evoked by the US. In defense to their findings, Zubkov and Zilov argued that the CR need not mimic the UR and under certain circumstances, it may actually counteract the effects of the US. However, a related study by Androsova (see Bespalov et al. 2001) did not support this compensatory CR explanation of associative tolerance – instead, it was shown that epinephrine has dual actions on heart rate. The direct effect is seen as tachycardia and the indirect effect is a result of increased blood pressure via the baroreflex mechanism. Thus, during acute treatment with epinephrine, the cardiac increase effects overshadow the indirect vagal stimulation. It was argued that the indirect vagal reflex effect that was evident during the drug-free test was the true UR that became conditioned to stimuli that accompanied repeated epinephrine injection (Bespalov et al. 2001).

Morphine has been known to produce dose-dependent, biphasic, physiological and behavioral responses. When a naïve rat is injected with a large dose of morphine, it initially shows hypothermia, followed by hyperthermia. Similarly in behavior analysis, a dose of morphine will evoke initial hypokinesia followed by later-onset hyperkinesias. Therefore, it is essential to identify each UR that occurs throughout the action period of the drug. These opposite effects may acquire associations with different conditioned stimuli that elicit a number of CRs across time.

There is some debate concerning associative tolerance of morphine analgesia. Siegel (1975) first demonstrated that the tolerance observed to the analgesic effect of morphine is context- or environment-specific. Rats previously injected with morphine and then tested with saline (in the environment previously associated with morphine) showed increased sensitivity to pain; this effect was not observed when the rats were tested in a novel environment. Siegel subsequently proposed a conditioning model of tolerance to explain his findings, suggesting that conditioned hyperalgesic responses to morphine develop as an adaptive homeostatic mechanism in response to

predictable changes caused by the drug. Therefore, this conditioned opponent response that counteracts the analgesic action of morphine is elicited by the environment in which morphine was administered.

In associative tolerance, the CR elicited by environmental stimuli paired with morphine injection is reported to be opposite in direction to the UR produced by the drug. This observation conflicts with Pavlovian associative learning, yet it follows the same rules of conditioning. Firstly, like Pavlovian CRs, associative tolerance to morphine can be extinguished with repeated presentation of environmental cues that were previously associated with morphine but without morphine injection. Secondly, like Pavlovian CRs, associative tolerance to morphine is subject to latent inhibition. Exposure to conditioning stimuli prior to pairing with the drug inhibits the acquisition of tolerance. Lastly, like Pavlovian CRs, tolerance is not seen when the drug cues are absent. Based on this evidence the question remains: Why is the CR opposite to the observed drug effect? A parsimonious explanation would argue that it is possible that morphine may have a dual effect on pain sensitivity. Siegel (1975) reported that rats had shorter paw-lick latencies on the hot plate on the last six out of eight test trials following administration of morphine, when compared with saline controls. Therefore, following morphine administration rats appeared hyperalgesic. Perhaps, hyperalgesia is an observed drug effect, i.e., an UR that can become conditioned and is evoked as a CR.

In accordance with this idea, Celerier et al. (2001) reported that acute administration of heroin induces delayed hyperalgesia in rats and that this increased sensitivity to pain may serve as the UR during the CS–US pairings. Furthermore, this effect was seen initially for 4–5 h following each treatment, and sensitized upon repeated heroin treatments shifting the curve to the left; hence, increasingly counteracting the opioid-induced analgesia. Therefore, hyperalgesia following morphine treatment may be masked by morphine's initial analgesic activity.

Both analgesia and hyperalgesia are direct effects of morphine on the CNS, but they appear at different times after injection. However, only hyperalgesia is expressed as a CR when rats are exposed to the test environment. The reason for this may be that different drug effects can be paired with different cues and the strength of conditioning to a particular cue is affected by that cue's salience. The environment previously paired with morphine injections consists of many cues of variable relevance, where each is competing to gain the most associative weight. It was reported that from a number of stimuli conditioned to morphine, only the morphine-associated gustatory stimulus showed an analgesic CR. Thus, different drug effects may be conditioned at different times to a variety of stimuli within different modalities. This was addressed by Eikelboom and Stewart (1982), where temporal and environmental cues were found to play a different role during conditioned hypothermia and hyperthermia based on morphine.

Morphine acts directly through the CNS on the thermoregulatory system and acts as an US to produce hyperthermia. In studies where saline was injected in a distinctive conditioning environment that was paired previously with morphine, robust-conditioned hyperthermia was observed. Subsequently, a second-conditioning component of the experiment was reported. It was observed that rats consistently showed hypothermia 1 h before each expected morphine injection (given at 24 h intervals), although their body temperatures were normal 2 h prior to the injection. It was hypothesized that the temporal cues became predictive of the next morphine injection and elicited conditioned hypothermia. However, if rats were given injections at irregular temporal intervals and temperatures were taken throughout the 24 h period, the rats exhibited hypothermia at all hours of the day relative to controls. Therefore, only when injections were given at the same time each day, making temporal cues predictive of the next morphine injection, did the hypothermia become locked into the time of day (i.e., a true conditioned compensatory response). Thus, two conditioned temperature responses were evoked by two different CSs: conditioned hyperthermia by contextual environmental cues and conditioned hypothermia by temporal cues. If both CRs had been elicited by the same cues, only the net effect would be evident. When animals were tested in the presence of both types of conditioned stimuli (temporal and environmental), no temperature changes were evident.

In summary, physiological effects of drugs such as changes in body temperature or changes in pain sensitivity can become associated with cues that signal the administration of these drugs. In some cases, the physiological responses produced by conditioned stimuli mimic the URs produced by the drug. In other cases, the physiological responses produced by conditioned stimuli are opposite in direction to those produced by the drug. A consideration of the locus of action of the drug and the point where the drug itself or its somatic effects influence the CNS provides a framework for predicting the direction of CRs. Consideration also needs to be given to the acute versus chronic unconditional effects of drugs and which of these are being associated with conditioned stimuli. When these elements have been identified and

understood, most conditioned physiological responses to drugs can be seen to conform to the conditioning paradigm developed by Pavlov.

Part 2: Conditioned Behaviors

A useful paradigm for the behavioral evaluation of conditioned drug effects is ▶ conditioned activity. Pickens and Crowder (1967) were among the first to report that environmental stimuli paired with the psychomotor-stimulant drug ▶ amphetamine produced conditioned locomotor activity in rats. In this paradigm, the CR is not a specific operant but rather a general increase in locomotion, rearing, and other related behaviors in the drug-associated environment.

The procedure involves injecting animals with a drug and then placing them into a distinct environment for a period of time (e.g., 1 h). After several drug-environment pairings, experimental animals are injected with saline and again placed into the test environment. The animals that received drug-environment pairings are observed to be more active than control animals with a similar history of placement in the environment and a similar history of drug injections but without having received the drug in the test environment (Fig. 1). Therefore, the effect of increased activity in rats having received environment–drug pairings can be attributed to the association of environmental stimuli with the effects of the drug rather than a previous history of drug treatment. Conditioned activity has been demonstrated with a number of drugs including amphetamine, ▶ cocaine, ▶ nomifensine, (+)-4-propyl-9-hydroxynaphthoxazine (PHNO), quinpirole, ▶ apomorphine, morphine, and etorphine.

Locomotor activity (count per 60 min) typically observed during conditioning based on cocaine (10 mg/kg; *left side*) and test of conditioned activity (*right side*). Three groups ($n = 18$ per group): *saline controlled, unpaired* (saline in conditioning environment; cocaine in homecage), *paired* (cocaine in conditioning environment; saline in homecage). *Significantly greater than unpaired and saline groups by analysis of variance followed by pairwise comparisons, $p < 0.05$.

The conditioning procedure used in this paradigm is often referred to as Pavlovian, where the drug is the US, the distinctive environment is the CS, and the increased activity in response to the drug is the UR. Increased activity during the CS alone is the CR. In spite of this apparent similarity, some research has shown that the CR does not strongly resemble the UR as is usually assumed in Pavlovian conditioning. In particular, behaviors not manifested during the drug-conditioning phase have been reported on the drug-free test day. For example, rats that received the dopamine reuptake inhibitor nomifensine on conditioning days were observed to gnaw on the drug-free test day, but gnawing was never produced by the nomifensine. In another study, the pattern of cocaine-induced turning during the drug-free test day did not resemble the pattern of turning observed on conditioning days. Based on these reports, Martin-Iverson and Fawcett (1996) examined whether behaviors of rats placed in an environment previously paired with amphetamine or the direct dopamine D_2-like receptor agonist PHNO, looked like the drug-induced behaviors. The authors found that out of the 11 behavioral measures increased by amphetamine on conditioning days, only four were increased on the drug-free test day. The total duration of sniff, head movement, snout contact, and stand were significantly greater than that of control animals. Furthermore, rearing behavior was increased on the drug-free test day but this was not so during conditioning. The authors argued that some of the behaviors observed during the test session represented an increase in scanning of the test environment as a result of a change in that environment due to the absence of the drug cue. The drug-free day may alter the affective state of the animal by removing an anticipated rewarding stimulus; this in turn, might lead to a frustrative affective state that is behaviorally activating. Similar differences in behaviors observed during conditioning and test sessions were seen when PHNO was the drug used for conditioning. Out of 19 behaviors increased by PHNO during conditioning only three were significantly increased when compared with control rats in the test. Thus, behaviors evoked by an environment previously paired with either amphetamine or PHNO are not always the same as those produced by the drugs used for conditioning.

Ahmed et al. (1998) tested whether three variables known to affect the acquisition of Pavlovian conditioning would interfere with conditioned activity using amphetamine. The authors examined sensitivity to CS–US temporal order, to unsignaled occurrences of the drug US between CS–US pairing trials and CS-alone test, and to the US preexposure effect. With respect to the first, the acquisition of a Pavlovian CR is abolished if the US is presented simultaneously or before the CS. In the case of conditioned activity however, a 25 or 50 min drug US–CS delay during the six pairing sessions had no significant effect. Second, in Pavlovian conditioning, unpaired presentations of a US alone between CS–US pairings lead to a diminished CR in the test. Conditioned activity was not influenced by the number of unsignaled amphetamine injections given between the pairings of the CS and the drug US. Third, according to Pavlovian conditioning, preexposing the animal to the US alone usually has a detrimental effect on the acquisition of a CR. However, the acquisition of conditioned activity was not influenced by 10 days of preexposure to amphetamine prior to CS–US conditioning. Therefore, research argues that conditioned activity based on drug stimuli is not controlled by the same variables that control Pavlovian conditioning.

It has been suggested that conditioned activity can be understood as involving ▶ reward-related incentive learning (Beninger 1983; Beninger and Olmstead 2000). In this view, the environment paired with the rewarding properties of the drug acquires an increased ability to elicit approach and other responses during conditioning that manifests as a conditioned activity during testing. All drugs that elicit conditioned activity share a common feature: they all exhibit facilitative effect on the ▶ mesotelencephalic dopamine reward system especially in the striatal regions of the mammalian brain. Further, it has been shown consistently that conditioned activity does not develop if dopamine function is blocked during conditioning. Drugs that block dopamine transmission at D_1- and/or D_2-like receptors block the acquisition of conditioned activity. Classical Pavlovian learning has been shown to be relatively independent of dopamine; e.g., animals are able to learn CS–US associations under the influence of dopamine receptor blocking drugs. When the dopamine receptor blocker ▶ pimozide was administered during tone–food pairings, learning of the stimulus–stimulus associations was not blocked but the tone failed to acquire incentive motivational properties and consequently, could not be used as a conditioned reinforcer to control instrumental responding.

Another conditioned behavioral phenomenon that involves reward-related incentive learning, although in the opposite direction, is ▶ context-dependent catalepsy. Unlike conditioned activity that depends on enhanced dopamine transmission in the striatum, conditioned catalepsy depends on the lack of dopamine transmission in striatal regions. In one version of this paradigm rats were treated with a low dose of ▶ haloperidol, a dopamine D_2-like receptor blocker, for 8 days. Paired rats were injected with haloperidol 1 h before being tested for catalepsy and were injected with saline 30 min after the test. Unpaired rats were injected with saline 1 h before the catalepsy test and then with haloperidol 30 min post test. Control rats received saline 1 h before and 30 min after the test. The dose of haloperidol did not produce catalepsy on the first session; however, a day-to-day increase in catalepsy was observed from day 1 to day 8. On day 9, paired rats were administered saline only and showed context-induced catalepsy in the environment previously paired with haloperidol. The unpaired group did not differ from saline control rats, thus history of haloperidol injections alone could not account for this effect. Conditioned catalepsy shares a number of characteristics with conditioned activity; however, the net effect is not an enhanced activity in the conditioned environment but a decrease in the locomotor output (Schmidt and Beninger 2006).

In the conditioned catalepsy studies, a day-to-day ▶ sensitization to haloperidol was also seen. This is similar but opposite in direction to the augmentation of behavior observed with repeated administration of psychostimulant or opiate drugs. The context in which the drug is expected facilitates the expression of sensitization to the effects of both haloperidol and stimulant drugs. Normally, this context-dependency is extinguishable by repeated exposure to the test environment without the drug. However, retesting animals with haloperidol following extinction resulted in a slight but significant cataleptic response in the paired group and not in the unpaired group. This suggested that haloperidol itself may act as an interoceptive cue that was conditioned along with the environment. Thus, sensitization might involve two separate learning components: first, a context-conditioned component that is not expressed following extinction and second, an interoceptive cue-related component that had become associated with the conditioning environment and was not weakened by exposures to that environment while in a drug-free state.

The development of sensitization has been shown to depend on the dopamine activity in the ▶ ventral tegmental area (VTA) and ▶ nucleus accumbens. This enhancement is also glutamate dependent. Studies using the glutamate *N*-methyl-D-aspartate receptor antagonist MK-801 have shown that glutamatergic input to the

dopamine system is vital for context-induced sensitization. Environment-dependent sensitization may also be considered to result from dopamine-mediated incentive learning. In the case of psychostimulants or opiate drugs, dopamine released in the striatum may lead to enhanced motor responses to stimuli associated with that drug. This is observed as enhanced behavioral responses to these drugs over repeated conditioning days. In the case of dopamine deficiency produced by haloperidol an antireward signal may lead to attenuated future responding in the presence of stimuli associated with that drug. This would produce a decline in motor responses to the drug with repeated testing. Dopamine can be viewed as a modulator where too much dopamine produces a test-to-test increase in behavior and too little dopamine produces a test-to-test decrease in behavior.

In summary, some drugs produce reliable increases or decreases in general locomotor activity. and research has shown that the stimuli associated with the drug state acquire the ability themselves to elicit increases or decreases in general locomotor activity similar to those elicited by the drugs. This phenomenon of conditioned activity or conditioned catalepsy has the appearance of Pavlovian conditioning, the drug being the US, the change in locomotor activity the UR, the environment associated with the drug the CS, and the motor response in that environment in the absence of the drug the CR. However, Pavlovian conditioning originally involved physiological reflexes that were shown to be affected in predictable ways by parametric manipulations. Studies have shown that when instrumental-type responses are conditioned they are not similarly affected by these manipulations. In addition, conditional responses to drug-related stimuli were shown to differ from the URs produced by those stimuli. The ability of many drugs to produce conditioned behaviors depends on mesotelencephalic dopamine reward systems, and likewise, conditioned activity can be understood as an example of reward-related incentive learning. Thus, stimuli associated with activation of dopamine neurons acquire the ability to elicit approach and other responses manifested as a conditioned activity.

General Conclusion

- Drugs can produce physiological or behavioral effects. Physiological effects can result from a direct action of the drugs on the CNS or from direct actions of the drug on a peripheral effector. In the latter case, the response of the effector may influence the CNS. The effects of drugs on the CNS can become conditioned to stimuli associated with the drug state so that those stimuli can elicit the drug-like effect in the absence of the drug stimulus. In the case of drugs that act directly on the CNS, the CR will mimic the unconditioned effect of the drug; in the case of drugs that act indirectly on the CNS, the CR may be opposite in direction to the UR. Conditioned physiological effects or reflexes conform to the Pavlovian conditioning paradigm.
- Drugs can also produce changes in instrumental-type behaviors such as locomotor activity. Stimuli associated with the drug state acquire the ability to elicit behaviors like those produced by the drug. Although the phenomena resembles Pavlovian conditioning, studies have shown that conditioned activity changes do not conform to a number of parametric manipulations that reliably affect conditioned physiological effects or reflexes. Conditioned activity may be better understood as an example of reward-related incentive learning.
- Drug placebo effects may provide a common example of conditioned drug effects. For example, in ► Parkinson's disease placebo effects are well documented. When a patient believes she is receiving medication even though she is not, there is a notable benefit. This can be understood as a conditioned drug effect where the stimuli associated with anti-Parkinson's medication acquire the ability to produce a response like that produced by the drug itself. From observation like these it has been suggested that nondrug placebo administration may be used periodically to good effect in some treatment regiments.
- The study of conditioned drug effects remains an active area of research in behavioral neuroscience. As the mechanisms of ► neuronal plasticity underlying learning and memory continue to be unveiled, they will be recruited to the further understanding of the mechanisms underlying conditioned drug effects. This knowledge will enhance our ability to maximize the therapeutic use of drugs with a more complete understanding of their combined unconditioned and conditioned effects.

Conditioned Fear

Fear conditioning

Definition

Conditioned fear is a state of fear (or anxiety) that occurs in animals after a few pairings of a threatening stimulus with a formally neutral stimulus using a classical (Pavlovian) conditioning procedure. For example, in experimental animals, when a tone (i.e., the conditioned stimulus) is paired with the occurrence of a mild footshock (i.e., the unconditioned stimulus), after a few pairing, the presentation of the tone alone is sufficient to elicit a state of fear (i.e., the conditioned response). Sometimes, the fear response is conditioned to specific features of the setting or the context in which the stimulus was presented (i.e., the contextual stimuli). Conditioned fear provides a critical survival function, which activates a range of defensive behaviors that protect the animal against potentially dangerous environmental threats.

The classic example of Pavlovian (classical) conditioning is that of one stimulus such as a buzzer signaling the occurrence of some other stimulus like meat powder (i.e., unconditioned stimulus or US). With repeated parings, the buzzer or conditioned stimulus (CS) in this situation acquires the ability to excite a response (e.g., salivation) and, hence, is sometimes referred to as a conditioned excitor. In contrast, a CS can also signal the absence or nonoccurrence of the US. In this case, the CS may be called a conditioned inhibitor. Conditioned inhibition is often conceptualized as a directly opposing process to conditioned excitation. In fact, the two primary

tests for conditioned inhibition, summation and retardation of acquisition tests, are based on this assumption.

Conditioned Place Preference and Aversion

Definition

Conditioned place preference (CPP)/conditioned place aversion (CPA) is a behavioral paradigm largely based on principles of ► classical (Pavlovian) conditioning. For conditioning, a distinct set of environmental cues is explicitly paired with a particular drug or nondrug treatment, and a distinctly different set of environmental cues is paired with a control treatment. Most commonly, treatment and control pairings are repeated several times, usually once per day. Over the course of conditioning, the rewarding or aversive treatment effects will become associated with the particular set of cues paired with the treatment, such that in a post-conditioning test trial, these cues will elicit approach (when the treatment had rewarding effects) or avoidance (when the treatment had aversive effects), resulting in a conditioned preference or aversion for the treatment-paired environment (or "place") (Fig. 1).

Principles and Role in Psychopharmacology

CPP/CPA is among the most widely used behavioral pharmacological models to assess the rewarding or aversive effects of drugs or nondrug treatments (Tzschentke 1998, 2007). The consideration of drug effects is closely related to the issue of validity of the model, in particular, ► predictive validity, which describes to what extent the effects of a drug seen in an animal model can predict the effect of the drug in healthy humans or in a human disease condition. Under this perspective, the CPP/CPA model is very frequently used in the context of ► abuse liability evaluation of known and novel drugs (Buccafusco

2001; Willner 1991). Over the past decade, place conditioning has also become one of the standard procedures for the behavioral phenotyping of ► genetically modified animals (Tzschentke 2007).

Virtually all classes of psychoactive drugs and drugs acting on the central nervous system have been evaluated in the CPP/CPA paradigm. Overall, the predictive validity of the model has been found to be very good, with some exceptions, as a few false-positive effects (i.e., CPP despite demonstrated lack of abuse potential), as well as false-negative effects (i.e., lack of CPP despite abuse in humans) were found. While these discrepancies may be related to genuine species differences, procedural aspects may also play an important role.

Advantages and Disadvantages of the Model

There are a number of features that make place conditioning a very useful and very versatile model. One of the major advantages, in particular, as compared to ► operant conditioning paradigms, is that drug-induced side effects cannot interfere with the expression of behavior during the test session, since the test session is conducted in the drug-free state. In other words, the effects of a drug (during conditioning) are assessed in the absence of the drug, i.e., sedative, ataxic, stimulatory, or other side effects do not affect the outcome of the test session.

A further advantage, in particular, as compared to operant intravenous self-administration paradigms, is that the outcome is bidirectional, i.e., rewarding as well as aversive effects can be measured within one single experiment, resulting in CPP or CPA, respectively. This feature is particularly useful when new drugs with unknown motivational effects are tested, or when a large dose range of a drug is evaluated (often, low-to-moderate doses can produce rewarding effects, whereas high doses result in aversive effects due to side effects). Another distinguishing advantageous feature of place conditioning is that nondrug rewards or punishers can be studied, such as foods and liquids, social or sexual interaction, electric footshocks, states of pain, states of ► withdrawal, etc.

Finally, the technical requirements to do CPP/CPA studies can be reduced to a minimum. Although most commonly, location and locomotor activity are monitored by computer-controlled infrared light beams or a video-tracking system, a simple wooden or plastic box and a patient observer is all that is needed to run experiments and to generate valid data.

Despite these advantages, there are also a number of disadvantages to the model that can limit its usefulness, or that at least prevents an unreflected use of the model and/or interpretation of data.

More often than not, no clear dose–response relations are observed in place conditioning. Often, an all-or-nothing effect is observed, with a threshold dose above which CPP/CPA is observed, albeit not with a dose-dependent increase in effect magnitude. This also means that effect size is not a good measure of the efficacy of a drug to produce rewarding or aversive effects. In the absence of dose-dependent effects, the potency of a drug can be best determined from the threshold dose for CPP/CPA, and this can be used to compare different drugs. Nevertheless, overall, place conditioning is not a very quantitative model and is not well suited to compare the potency, and, in particular, the efficacy of drugs to produce rewarding or aversive effects. The data generated with this model have a more qualitative than quantitative character.

Furthermore, care has to be taken that the experimental parameters are adjusted to match the particular properties of the drug under investigation. Otherwise, the model is prone to false-negative results. In particular, since conditioning depends on the close temporal pairing of rewarding/aversive drug effects with the environmental cues, it is important that the temporal contingencies of drug-cue pairing are appropriate for the pharmacokinetic properties of the drug under investigation.

Finally, the field of place conditioning is suffering from the fact that there is a very small degree of standardization of experimental parameters across laboratories. The use of biased or unbiased designs (referring to the use of conditioning apparatuses, in which animals do or do not show, respectively, an unconditioned preference for one of the compartments), different numbers and designs of conditioning compartments, number and duration of conditioning sessions, duration of test sessions, number of preconditioning (habituation) sessions, delay between drug administration and conditioning session, and different statistical methods to analyze the data (comparison vs. vehicle compartment or vs. pretest; pairwise *t*-tests vs. analysis of variance (ANOVA) across all groups; raw data vs. transformed data scores), all make comparisons of data across laboratories almost impossible, since at least one of these important parameters is always different between individual studies from different labs.

See Carr et al. (1989) and Bardo et al. (1995) for review of the issues mentioned in this section.

Procedural/Methodological Aspects to Consider

State-dependency: ► State-dependent learning or state-dependent retrieval, refers to the fact that information or a behavioral response that has been learned or acquired while the subject was in a certain (drug-induced) state can only (or at least better) be retrieved or reproduced when

the subject is in that same state, but not when in a different state (e.g., in an undrugged state). The potential influence of state-dependency effects on the outcome of place conditioning experiments is obvious, as animals are conditioned in a certain (drugged) state, but are usually tested for CPP or CPA in an undrugged state. To control this potential caveat, one can include an additional test session in the experimental protocol, during which the animals are tested after administration of the conditioning drug.

Choice of comparator: In by far the most place conditioning studies, the treatment under investigation is compared with an appropriate vehicle treatment (i.e., drug is paired with one compartment, and vehicle is paired with the other compartment), yielding information about a treatment's "absolute" rewarding or aversive effects. However, place conditioning can be more versatile than this. The effects of one drug can be directly compared with those of another drug (by pairing one drug with one compartment and the other drug with the other compartment); likewise, two doses of the same drug can be compared with each other. This approach, which is very rarely used, yields information about the "relative" rewarding or aversive effects of two treatments.

Latent inhibition and within-session extinction: ► Latent inhibition refers to the phenomenon that if a subject is exposed to a to-be-conditioned stimulus in the absence of the unconditioned stimulus, the subsequent formation of an association between unconditioned and conditioned stimulus is impaired. Applied to the CPP/CPA paradigm, this means that exposure of the animal to the conditioning environment without drug administration will impair subsequent formation of CPP/CPA. This issue is of relevance, since a place conditioning experiment almost always involves preconditioning ► habituation exposures of the animals to the conditioning apparatus. The number and duration of these preexposures needs to balance maximal habituation (i.e., long preexposure) and minimal latent inhibition (i.e., short preexposure). Establishing the optimum amount of preexposure should be part of the model establishment and validation procedures.

Classical conditioning depends on the temporal association between the unconditioned and the conditioned stimulus. Applied to the CPP/CPA paradigm, this means that exposure of the animal to the conditioning environment has to coincide with the experience of the drug effect. Thus, the timing and duration of conditioning must be appropriate for the ► pharmacokinetics of the drug under investigation. If a drug has very rapid kinetics (fast onset and short duration of action), the conditioning sessions need to commence directly after drug administration and be of short duration. Otherwise, the animal could experience the conditioning environment in the absence of any drug effect late in the conditioning session, resulting in within-session extinction. On the other hand, if a drug has very slow kinetics (in particular, late onset of action), there needs to be an appropriate delay between drug administration and commencement of conditioning session. Otherwise, the animal would experience the conditioning environment in the absence of any drug effect early in the conditioning session, resulting in a latent inhibition effect, or the experience of drug effect may be missed altogether during the conditioning session.

See Tzschentke (1998) for review of the issues mentioned in this section.

Recent Developments

Place conditioning is most commonly used, past and present, to study the rewarding/aversive effects of a drug (applied systemically or intracranially), or of drug combinations. More recently, the paradigm has become a standard procedure in the characterization of knockout and otherwise genetically modified mice.

However, beside these straightforward uses, the paradigm is also increasingly used to study more complex phenomena. For example, place conditioning can be used to study the development of ► sensitization or tolerance to rewarding effects of drugs upon repeated administration. Besides being an interesting scientific issue in its own right, it bears particular relevance to the question of to what extent early drug exposure (e.g., in childhood or adolescence) would affect the response to drugs later in life. To this end, animals can be treated acutely or repeatedly at one point and subjected to a place conditioning experiment at a later point in their life. This approach has been used, for example, to study the impact of treatment of juvenile or adolescent rats with ► methylphenidate (a psychostimulant drug, used to treat children with ► attention-deficit hyperactivity disorder) on the response to drugs later in life (as there is a continuing concern that methylphenidate treatment in childhood could predispose the individuals to increased risk of addictive behaviors later in life).

Another approach that has been developed and used with increasing frequency in the context of place conditioning is the study of extinction and ► reinstatement phenomena. This has most commonly been studied in operant intravenous self-administration paradigms (Epstein et al. 2006), and only the last decade has seen a strong increase in the number of studies addressing these issues by means of place conditioning. Although the operant behavior may be more robust and more easily

quantifiable, the place conditioning approach also has certain advantages. It is technically much easier – experiments often involve protracted extinction and withdrawal periods prior to the reinstatement sessions, and it can be challenging to keep intravenous catheters patent for such long periods. Furthermore, the classical conditioning approach may have better face validity for human addiction than the operant conditioning approach, since withdrawal, abstinence, and confrontation with drug-predictive cues (that can lead to relapse in abstinent addicts) are normally not contingent upon the addict's behavior, and are more closely matched by classically conditioned cues.

Apart from the issue of reinstatement, extinction, and, in particular, the time to or resistance to extinction may be an additional useful readout in place conditioning studies. As mentioned previously, place conditioning usually is not a very quantitative method, and it is difficult to directly compare the rewarding/aversive efficacy of two or more treatments (either different doses of the same drug or given doses of different drugs). Analyzing the number of test sessions needed until the conditioned effect has undergone extinction may offer an additional, more quantitative readout, in that, within limits, the resistance to extinction is related to the "strength" of conditioning, which, in turn, is related to the magnitude of the unconditioned stimulus, i.e., the drug dose.

Finally, the place conditioning approach is increasingly used to study the emotional component of pain. Pain research is, in large part, focused on the study of evoked pain reactions. While this may be appropriate for certain kinds of pain in humans, spontaneous or continuous pain (i.e., not evoked by a particular external stimulus) cannot be studied by the traditional methods. Likewise, the traditional methods cover only the sensory aspects of pain, but cannot access the adverse emotional dimension of pain, which, for pain patients is often more troublesome than the sensory pain experience. Several interesting findings have been reported, combining pain models with place conditioning. For example, in animals that are in a state of pain (acute or chronic), the dose–response curve of morphine to produce CPP is shifted to the right, i.e., larger doses are needed to produce a rewarding effect. In other words, pain reduces the rewarding effects of an opioid. This finding corresponds well with the clinical observation that abuse of, and addiction to ▶ opioids in patients receiving them for pain relief is only rarely observed.

Like other unpleasant stimuli, acute and chronic pain can produce a conditioned aversion for a pain-associated context, i.e., a CPA. This CPA is likely due to the negative emotional component of pain. Interestingly, opioids are highly potent in abolishing this pain-induced CPA, and they do so at doses that are neither rewarding by themselves nor have an analgesic effect in a standard pain model. This means that the abolition of CPA is not simply due to a summation of an aversive pain effect and a rewarding drug effect, or to a blockade of the sensory pain experience, but is likely due to a selective inhibition of the aversive component of pain. This again corresponds with clinical observations that when pain patients are treated with low doses of an opioid, they may still have the sensory experience of pain, but this experience is no longer aversive, i.e., they feel the pain but they do not care about it anymore.

See Tzschentke (2007) for review of the issues mentioned in this section.

Outlook

Place conditioning is a long and well established model. In most laboratories, it is used in its "basic" form to test for rewarding or aversive effects of drugs or drug combinations. Nevertheless, new and innovative applications of the model, as described in this essay, continue to be explored, and it can be expected that new ideas and applications continue to be developed in the future. Likewise, the more procedural and theoretical aspects of the model are also still being explored (see e.g., Groblewski et al. 2008). This will lead to a better knowledge about the model and its implications and will likely further enhance the usefulness and validity of the model.

Definition
Conditioned taste aversion (CTA) refers to a learning phenomenon in which the pairing of a taste with the effects of a drug results in the subsequent avoidance of that taste. The robust nature of CTA, induced by a variety of drugs belonging to a wide range of pharmacological classes, has made aversion learning a sensitive and widely used index of a drug's aversive effects.

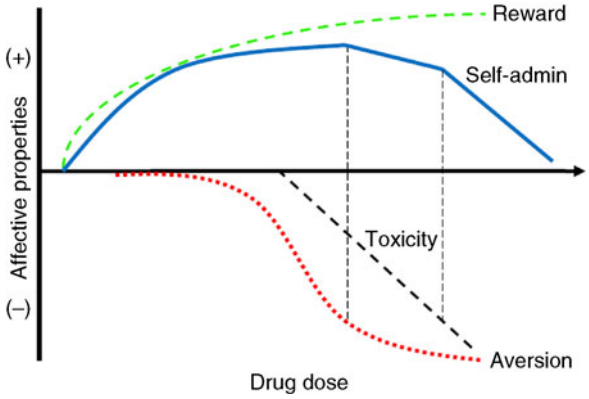
Impact of Psychoactive Drugs
The phenomenon of CTA learning emerged from studies on radiation toxicity when Garcia et al. (1955) presented rats with access to a distinct saccharin solution that was then paired with exposure to radiation (for a historical perspective, see Freeman and Riley 2008). Although the initial preference for saccharin-flavored water was much greater than unflavored water (86% preference for saccharin), pairing the taste with radiation produced a dramatic decrease in saccharin preference relative to the initial baseline and to sham-irradiated controls (or subjects irradiated, but that had not received access to saccharin). This decrease was sufficiently robust enough to persist for almost 30 days post irradiation despite continuous and free access to the radiation-associated solution. Garcia

et al. (1955) went on to suggest that it was the nausea-inducing effects of the radiation that were responsible for the decrease in saccharin consumption. That is, the gastrointestinal disturbance brought on by the radiation had become associated with the taste of the saccharin solution, resulting in the animal's avoidance of the solution on its subsequent presentation (i.e., a ▶ classical conditioned taste aversion). In addition to being robust (and as revealed in follow-up research with radiation and classical emetics), CTA learning is acquired rapidly (usually taking very few pairings, and in some instances, only a single pairing), occurs with ▶ long delays between consumption and the onset of illness, and is established selectively to gustatory stimuli, i.e., non-gustatory cues are only weakly associated with illness. This avoidance has been suggested to be an evolutionarily significant response to ingestion of foods that could be potentially toxic to the animal. Thus, the ability of an animal to quickly (and selectively) ▶ associate ingestion of specific foods or tastes (likely sources of natural toxins) with disruption to its internal milieu could be thought of as a protective factor against accumulating dangerous or fatal amounts of a toxin due to overconsumption. Later studies showed that a wide number of compounds, many of which were considered to be toxins, produced a CTA, and often at doses lower than those shown effective in other measures of ▶ drug toxicity, suggesting that the CTA design may provide a sensitive measure to assess drug toxicity.

Although based on toxicology, CTA learning was not limited to classical emetics (see bibliographic database www.ctalearning.com). In fact, drugs such as ▶ alcohol, ▶ morphine, and ▶ cocaine that are abused by humans are also effective at inducing CTAs, leading some to classify this phenomenon as "▶ paradoxical" in that drugs of abuse are typically considered to be reinforcing stimuli (Hunt and Amit 1987). In this context, the issue becomes how drugs that produce an approach response in maintaining ▶ self-administration also produce the avoidance seen in CTA. Drugs that are abused by humans have been shown to produce multiple stimulus effects in the user. Rather than being reported as only rewarding or aversive, drugs of abuse typically produce an array of effects that combine to produce an overall drug experience. Preclinical, as well as some clinical, evidence provides support for these multiple stimulus effects. For example, animals will bar-press for an injection of a drug, but they will avoid a saccharin solution that is paired with the same self-injection. In a runway model of self-administration, animals will increase the speed with which they run to a goal box for an injection of a drug, but then hesitate prior to entering the goal box, suggesting concurrent rewarding (increased running speed) and aversive (hesitation) drug effects. Finally, individual animals display both an approach and avoidance response to stimuli paired with a drug injection such that they spend more time in an environment that is paired with drug effects, but at the same time avoid a sweet solution paired with that same drug. Interestingly, in humans, both rewarding and aversive effects have been reported for opiates, as first time users report the subjective effect of heroin as a "good sick," while cocaine users indicate a "rush" produced by the anxiogenic effects of the drug. Subjective ratings for specific drugs such as alcohol include not only positive ratings such as euphoria and relaxation, but also include negative ratings such as drowsiness, loss of motor coordination, ▶ withdrawal (or hangover), etc.

Although there is ample evidence that a complex array of effects are produced by drugs of abuse, it is important to view the "aversive" and "rewarding" properties of these drugs, not as a simple dichotomy (Hunt and Amit 1987) of drug effects, but rather as dynamic and interacting sets of effects that determine the abuse liability of a particular drug as well as the abuse potential for any individual. The likelihood of a drug becoming abused by an individual (or ▶ abuse liability) then would be the result of the balance between the rewarding and aversive effects of the drug (see Fig. 1; see also Stolerman and D'Mello 1981). There are many environmental, genetic, individual, and pharmacological factors that can influence this vulnerability to addiction. The individual experience of a given drug will not be the same for all users, which would help to explain why only a small subset of the population which tries a drug continues its use, escalates its pattern of intake, or becomes addicted.

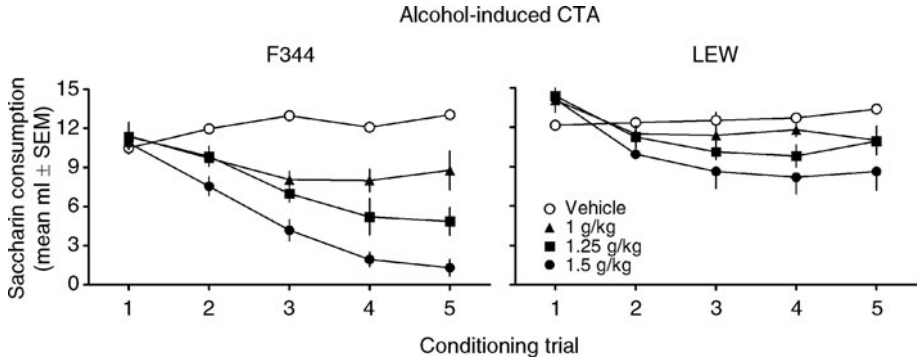
Understanding which factors influence some individuals (but not others) to become addicted has been a central issue in drug addiction research. One factor that seems to be crucial for continued drug-taking is the user's initial response to the drug. In a population of drug addicts, Haertzen et al. (1983) found that the reinforcing quality of an individual's first drug experience was related to its likelihood of subsequent use. This was true for a number of abused drugs, including alcohol, the opiates, and cocaine. Thus, users that reported having a greater euphoric or pleasant experience when taking the drug for the first time were more likely to continue taking that drug, making them more vulnerable to addiction. Conversely, individuals who experienced negative or aversive effects of the drug on this initial exposure were less likely to try the drug again. This work suggests that some individuals may be more sensitive to the aversive effects produced by a drug, which apparently acts as a limiting or



Conditioned Taste Aversions. Fig. 1. The balance between the rewarding and aversive affective properties of a drug influences total drug intake. When a drug of abuse is administered at low doses, the subjective effects are primarily rewarding (green-dashed line), leading to dose-dependent increases in drug intake or self-administration (blue-solid line). However, as the dose of the drug increases, aversive drug effects (red-dotted line) begin to influence the amount of drug self-administered (in their balance with the drug's rewarding effects), leading to lower levels of overall intake. The intensity of the aversive effects experienced during initial drug use impacts the probability of future drug taking. Changes in the aversive effects (resulting from experience with the drug or specific characteristics of the individual) impact a user's likelihood of subsequent use or abuse of the drug. This is based on a conceptualization by Greg Busse (2004).

protecting factor for continued use (Fig. 1). If this is the case, studying the various factors that can influence such aversive effects becomes just as important as studying the factors that can alter drug reward. CTA learning offers such a model in which the drug's aversive effects become paired with a distinctive flavor. In this case, changes in consumption (reductions) index the drug's aversive effects. The procedure also allows one to see how such effects vary with experimental manipulations and subject characteristics.

As noted, a variety of factors affect the likelihood of drug use and abuse. Some are specific manipulations such as dose of the drug and frequency of its use, while other factors are more characteristic of the user. A subject characteristic that is widely considered to be important in drug addiction is genetic predisposition or ► pharmacogenetics. One way that the genetic influence on drug abuse has been studied in the laboratory is through the use of selected or ► inbred rat strains, or mouse lines as ► animal models of particular aspects of the disease. An animal model that has received considerable attention in drug abuse research in recent years is that of the ► Fischer (F344)/Lewis (► LEW) ► inbred rat strains which show diverse drug intake and responsivity patterns across a number of drug classes (a review of genetic effects on CTA in rodents can be found in Riley et al. 2009). One among the drugs for which these strains show marked differences is alcohol. During oral self-administration studies, the LEW strain consumes greater amounts of alcohol than the F344 strain. However, it does not appear to be the case that the alcohol is more rewarding in LEW compared to F344, because both strains show comparable alcohol-induced ► conditioned place preferences, a model of ► conditioned drug effects sensitive to drug reward. Instead, the differences in alcohol consumption appear to be rooted in a differential sensitivity to the aversive effects of the drug. Specifically, F344 rats show greater suppression of saccharin drinking (i.e., a stronger CTA) when saccharin is paired with a dose of alcohol than the LEW strain (see Fig. 2). That alcohol is reinforcing in F344 rats is evidenced by acquisition of alcohol self-administration, yet their failure to exhibit the levels of intake seen in the LEW strain may be due to the aversive effects of the drug serving as a limiting factor in overall intake. The relation of CTA to drug self-administration is also exemplified in correlational analyses of these behaviors in various mouse strains with similar results. Using a number of genetically distinct mouse lines, it has been shown that the degree of alcohol-induced CTA is related to overall levels of alcohol intake such that the mouse lines that consume high levels of alcohol display little or no CTAs when an alcohol injection is paired with saccharin intake. Those mouse lines that drink very little alcohol are the ones that show the greatest levels of alcohol-induced taste aversion conditioning. Interestingly, mice that show the greatest levels of CTA also show greater severity of alcohol withdrawal, suggesting an overall increased sensitivity to the aversive effects produced by alcohol. The oral self-administration of alcohol appears unrelated to the acquisition of alcohol-induced place preferences in these strains, suggesting that the differences in alcohol self-administration are mediated more by differences in alcohol aversion than alcohol reward. While we have chosen to focus on alcohol, parallel effects with the F344/LEW model, in particular, are evident with a diverse range of drug classes and include compounds such as morphine, ► nicotine, and cocaine. Further, a variety of parameters other than strains, for example drug history, dose of the drug, route of administration, age, and sex have been shown to impact taste aversion learning (see Riley and Freeman 2004) as well as drug self-administration (see Schuster and Thompson 1969) in related ways, suggesting



Conditioned Taste Aversions. Fig. 2. Dose effect of alcohol-induced conditioned taste aversions (CTA) in the Fischer (F344) and Lewis (LEW) rat strains. Both strains show dose-dependent reductions (from vehicle-treated rats) in saccharin consumption when alcohol (injected intraperitoneally) followed saccharin. However, the F344 strain displays a greater sensitivity to the aversive effects compared to the LEW strain. Interestingly, LEW rats consume greater amounts of an available alcohol solution (per body weight) than F344 rats, suggesting that the greater sensitivity to the aversive effects limits alcohol intake in the F344 strain. Conversely, the LEW strain, which shows weak CTAs, may be more vulnerable to greater alcohol consumption because of their apparent insensitivity to its aversive effects. (Figure redrawn from Roma et al. 2006.)

that the drug's aversive effects limit drug intake in self-administration studies. More work is needed to further characterize how the avoidance response seen during CTA ultimately impacts drug self-administration.

Although these animal models of genetic predisposition to drug abuse are important in demonstrating the relationship between the aversive effects of drugs and drug intake and how various factors may influence these aversive effects, analogous findings in humans is essential for validation as a true model of the human condition. The clearest example of this comes from high prevalence rates of ► alcohol abuse and dependence in sons of alcoholic fathers. Through a genetic variation in enzymes important for alcohol metabolism, these individuals are thought to be less sensitive (i.e., a biological predisposition for tolerance) to the aversive (or punishing) effects of alcohol (for a review of human CTAs to alcohol, see Baker and Cannon 1982). The decreased sensitivity to the behavioral (ataxia) and physiological (cortisol release, disruption to EEG patterns) responses to alcohol may be among the factors that limit intake in the normal population. Without the experience of the aversive alcohol effects, sons of alcoholics are more likely to exhibit patterns of heavy drinking. In a second example, a genetic enzymatic variation seen in the Asian population, which has a very low incidence of alcoholism, exacerbates the aversive effects of alcohol (via a failure to metabolize ► acetaldehyde), producing greater facial flushing and more reported subjective complaints. Such effects are seldom seen in Caucasians (who have a low frequency of this specific allele and a higher frequency of alcohol abuse).

This relationship between the aversive effects of drugs and a risk for drug use and abuse seems to be important for the human user as it is in our animal models. CTA offers a procedure by which we can assess the aversive effects of a drug and how they might impact overall drug acceptability for an individual or group. Understanding the contribution of a drug's aversive effects to drug intake and addiction vulnerability (as well as how these effects are impacted by the numerous factors known to affect drug self-administration) may give insight into the etiology of drug use and abuse and its potential treatment.

Definition

Conditioned taste preferences refer to ► appetitive responses evoked by tastes associated with the effects of a drug manipulation. Taste preferences are best seen when a drug-paired taste is presented on a drinking test concurrently with a control taste not paired with the same drug manipulation; the conditioned taste preference is evidenced by a relative increase in the consumption of the paired taste. There are conditioned preferences for tastes paired with most self-administered drugs due to the conditioning that takes place during the training for self-administration. Taste preferences can also be produced in experimentally naive rats without extensive training by pairing tastes with an injection of low doses of ► opioid analgesics or with the offset of drugs having acute aversive effects. Conditioned taste preferences help understand the interplay between initially aversive effects of drugs and incentive effects that characterize motivation for drugs in the dependent organism. They also provide an interdisciplinary model of ► drug cues. Taste stimuli and related oral stimulation are important for the intake, enjoyment, and quality of self-administered drugs that are drunk, chewed, or smoked.

Current Concepts and State of Knowledge

Conditioned taste preferences are formed by the pairing of a distinct taste with the motivational effect of a drug with ► abuse liability. This effect is variously referred to as incentive, reinforcer, or reward. It is generally believed that the preferences are due to the activity of the drugs in the reinforcement system in the brain (see ► Reinforcement Disorders) and that they underlie the ► self-Administration of drugs. It is further understood that these effects can also be transferred through the pairing to the paired stimulus such that the stimulus comes to elicit some of the effects of the reinforcers.

The protocols used for studying conditioned taste preferences fall within the general literature on ► conditioned drug effects. They constitute simple conditioning paradigms, which model features of the motivational processes underlying the addictive properties of drugs (see ► Addictive Disorders: Animal Models). They are similar to the procedures of ► conditioned place preference and aversion and the same as those used to study ► conditioned taste aversions. Moreover, the latter two procedures define the ► paradoxical effects of drugs; the conditioned taste preference phenomenon bridges the outcomes that give rise to this paradox.

Unfortunately, drug-produced conditioned taste preferences do not have a concentrated systematic body of data. The relevant findings are found over a wide range of parametric aspects of the phenomenon (protocols used, degrees of training, methods of applying the taste, nature, and forms of application of drugs used to train, species, age and developmental stage of subjects, purpose of the

studies). Studies on paradigms other than those for taste preference conditioning are also relevant. Taste preferences have often been missed only because the designs and the methods were intended to detect the exact opposite effect. These are relevant for epistemological reasons and serve to indicate the voids and points of emphasis in the literature. Moreover, conditioned taste preferences likely occur for different reasons. Listed below are a few of the issues, which largely serve only to define the phenomenon.

Conceptual Issues of a Taste Conditioning Produced by Drugs

Conditioned taste preferences have been validated in different ways using nondrug reinforcers. They are seen to previously neutral tastes paired on a small number of occasions with electrical brain-stimulation reward, with pleasant foods or with pleasant flavors. More commonly, conditioned preferences are found for flavors of a food and this can be enhanced by the deprivation of the nutrient.

In the area of alcohol and drug dependence, the oral route is a historically old and simple method of drug application, and with few exceptions, oral drug application embodies taste stimuli that will undergo conditioning. Even for smoking, the sensation in the mouth and throat is reported as important for the pleasure derived. The conditioning does not have to be strong, if it is considered that smoke intake occurs at least 10 times per cigarette. A middle-aged smoker on a pack a day for three decades would have in the order of 2 million pairings of oral stimulation and the effects of smoking.

The self-administration procedure often requires extensive and complex training (Meisch 2001; Stolerman and D'Mello 1981) and it is important that cues be available to the organism. Tastes play an important role in the oral self-administration, since the swallowing of drugs is not pharmacologically efficient. The onset of the pharmacological effect after oral drug application is generally slow and variable. Only little drug may reach the brain due to problems of absorption from the gut wall and high metabolism as the blood passes through the liver before being sent to the brain. Therefore, tastes of the drug are particularly important for signaling the reinforcing effects of the drug (Meisch 2001; Stolerman and D'Mello 1981). The paired taste would simply increase the probability that the fluid carrying the taste would be consumed. For example, the taste of a fluid can act as discriminative stimuli for further drinking. It ensures that drinking occurs and that it is the fluid containing the drug and not another fluid that is chosen and swallowed. The paired taste can also act as conditioned stimuli due to the pairing with the drug effects. After the taste is sampled, one could say that the paired taste keeps the organism in its vicinity or "pulls" it back if it does leave. This is the generally the way drug cues are thought to maintain drug intake in drug consumers and to re-initiate high intake in abstinent individuals.

However, it was originally found that the formation of taste preferences after pairing with psychotropic drugs would not occur without long-term exposure to the drug and to the taste. Solutions of drugs needed to produce pharmacological effects usually have disturbing tastes. For example, both alcohol and morphine taste badly, by leaving a burning sensation on the tongue and by being bitter like the rind of a grapefruit, respectively. In addition, the rat is the preferred experimental animal for studying motivational processes and it is an omnivorous eater that does not consume any new foods or fluids without confirming that they are not toxic. Rats will avoid the taste of any newly ingested material associated with perceived changes in internal state, as it could be an indicator that the ingested substance has toxic effects (see ► conditioned taste aversions). As this might suggest, conditioned taste aversion is a very common effect seen on the initial dosing of most psychotropic drugs. Consequently, the conditioning of taste preferences has traditionally received little attention in the drug-naive organism.

The Traditional One-Choice Method for Studying Taste Conditioning

The systematic study of conditioned taste preference in laboratory animals is closely related to the application of special conditioning protocols. In taste conditioning procedures where conditioned aversion is the target of interest, the drug manipulation is usually paired with a single very palatable experimental solution. A high baseline of taste consumption under control conditions makes a condition taste preference difficult to observe and only a few significant effects have been reported (Gaiardi et al. 1991; Mucha 1992). Appropriate would be the application of experimental tastes that do not show maximal consumption, thereby making it easier to demonstrate an increase in its consumption after pairing with a drug-related effect. Aside from some exceptions (e.g., Green and Garcia 1971) this has not been routinely used. Indirect evidence for the existence of a preference effect has also been suggested in the data of the one-taste conditioning model by comparing the pattern of dose-response curves for taste conditioning produced by different drugs and to those of toxins. Thus, Hunt and Amit (1987) compared taste aversions to other acute responses

produced by drugs and concluded that a simple process of conditioned aversion could not account for all of the findings.

A variation of a one-taste model where preferences do emerge involves ► drug taste preference conditioning (see ► Alcohol Preference Tests). In the case of morphine taste preference conditioning, the development of a preference for the solution containing morphine can be made apparent against a baseline comprising a normal rejection of the aversive solution of morphine in subjects that do not have the pairing. However, the gradual consumption of a solution that is unpalatable does not necessarily evidence the development of a preference for several reasons. For example, repeated exposure to tastes lead to habituation, sensitization, contrast effects, changes in food intake, and so on. Thirst develops under conditions of forced drinking of an aversive solution and this would counteract the aversion. These processes and the drinking will also interact with the acute drug effects. The actual treatment drug may produce, for example, general malaise and hyperactivity. Drug effects would also affect taste sensitivity, alter general motivational states, and produce sensory impairment, overshadowing stimuli, etc. In such a one-taste paradigm like these, confounds can only be dealt with by applying additional groups and control conditions (Mucha 1992; Stolerman and D'Mello 1981).

An efficient solution to some of these problems is to offer the same test subject an alternate taste in a choice test. Much work on both conditioned aversion and conditioned preferences involve simply offering the test subjects a choice with water. For example, one can conclude that a preference is present when taste that was previously strongly avoided is now preferred relative to the water (see ► alcohol preference tests). The overall levels of fluid consumption would control for nonspecific effects of the training drug on fluid regulation. Care is nevertheless needed to avoid biases due to the left or right position of the experimental test on choice tests (Stolerman and D'Mello 1981). The use of choice tests with a water choice is still not fully adequate. In the case of drug taste preference conditioning using morphine-containing fluids, the preference produced by morphine could only be interpreted when the morphine solution was substituted for a taste similar to the bitter taste of morphine (Stolerman and D'Mello 1981).

The Two-Taste Test Paradigm and the Study of Experimentally Naive Rats

The two-taste method is a differential two-stimulus classical conditioning procedure. In this procedure, one taste is paired with the drug manipulation and a second taste is paired with a control manipulation. It provides robust within-subject control conditions and can be used to show subtle conditioned changes after only a few drug exposures (Mucha 1992). This method was first used to show a preference for a taste paired with a drug-related effect by Green and Garcia (1971). They paired a taste with the offset of the effect of a high dose of the ► dopamine agonist, ► apomorphine. The direct effect of the dosing induced illness: the same rats showed a taste aversion to a different taste presented just before the same injection. The conditioned preference was referred to as a "medicinal" effect of the offset of the emetic. Such a medicinal effect was also noted when the effects of nicotine infusions were blocked with a nicotine antagonist.

The use of two taste cues for discriminated conditioning procedures was largely developed over the course of work on the aversive effects of psychoactive substances (e.g., ► morphine, ► psychostimulants, and opioid agonists) during neuropharmacological studies at the University of Birmingham (UK) by David Booth, Charles Pilcher, Ian Stolerman, and others. However, the appetitive responses of tastes paired acutely with drugs only became apparent later when the procedure was applied to study low doses of sufentanil and fentanyl, two highly potent opioids (reviewed by Stolerman 1985).

In Fig. 1, there are taste preferences seen with adult rats in a two-taste conditioned preference procedure. There is a biphasic effect of dose with a preference effect seen at lower doses and aversion at higher doses. Thus, after a phase of adaptation to a water-deprivation schedule, rats were allowed to consume a target taste. This taste was paired shortly after using a subcutaneous injection of one of a range of doses of a test drug. The drug comprised one of three opioid analgesics (see Fig. 1). On another occasion, the same rats also received a second taste paired with a control manipulation (saline injection). The experimental and control pairings were repeated each day over 3 days. On a subsequent day each rat was then tested by offering the two tastes simultaneously for 24 h. Morphine shows the biphasic dose effect only with extended pairings (Fig. 1, *open symbols*).

Mechanisms of Conditioned Taste Preferences

Like conditioned place preferences (see ► conditioned place preference and aversion), taste preferences index simple approach or appetitive responses produced by a previously neutral stimulus paired with a drug reinforcer. They extend to gustatory and flavor stimuli experimental work based on environmental or place cues. However, until the 1980s, considerable attention was given to the idea that the initial application of self-administered

substances only produced taste aversions and that taste preferences were not produced in these situations. The fact that low doses of opioids in drug-naive animals also show conditioned taste preferences refute this notion. Some of the paradoxical effects of self-administered drugs are indeed due to the toxicity of high dosing typically used in the study of conditioned taste aversions. However, there are important differences between classes of addictive drugs, such as between opioids and psychostimulants. Indirect dopamine agonists such as ► amphetamine, for example, do not appear to evoke conditioned taste preferences, despite the fact that they act in the same general area of the brain as the opioids (Stolerman 1985). Therefore, conclusions about the opioids in the drug-naive animal probably do not generalize to drugs from other pharmacological classes.

The pattern of conditioned taste preferences in Fig. 1 likely reflects the activity of these training drugs on the mu-opioid receptors, as ► kappa-opioid agonists produced only aversions. The peak increases in intake of the drug-paired taste in the figure also correspond to the known relative activities of the test substances on the mu-opioid receptor. The conditioned taste preference also only occurs with ► stereoisomers active on the mu receptor, suggesting that, indeed, opioid receptors are involved. However, it is still not known whether opioid antagonists block the formation of these preferences (Stolerman 1985). Opioid antagonists used as training drugs also produce conditioned taste aversion in morphine-naive rats and this response is potentiated in animals treated chronically with opioids, (Mucha 1992). The taste aversions produced by opioid antagonists in drug-naive rodents are also limited to the stereoisomer active on the opioid receptors. Therefore, taste preference and taste aversions conditioning appear to be modulated by increases and decreases in activity on the opioid receptors, respectively (Stolerman 1985).

The conditioned taste preferences have not been studied using local brain injections, which would be necessary to show that they occur in the reinforcement system in the brain. The pattern of effects seen for the opioids in Fig. 1 parallel conditioned place preferences produced by these substances, which are known to be centrally mediated. Consistent with this, the potent opioid analgesics, sufentanil and ► fentanyl, which have the strongest effects in Fig. 1, have physicochemical properties allowing them to penetrate into the brain much more readily than morphine. However, there are a number of open questions, particularly regarding other substances active on the reinforcement system that fail to produce conditioned taste preferences under acute treatment conditions (e.g., amphetamine).

An important issue is that opioids give rise to physical dependence and their removal results in ► withdrawal syndromes. These states are highly aversive and can be alleviated by the reapplication of opioids (Mucha 1992). This was a major explanation of the motivation for the oral intake of drugs in the early studies of oral self-administration of drug. Clear evidence for the hypothesis is actually rare partly because incentive effects of a training drug confound tests for conditioned taste preferences produced by withdrawal. The effects in Fig. 1 are also seen at doses that are too low and infrequent to produce dependence. There are data from one-taste conditioning work and on morphine taste preference conditioning where animals were given supplementary injections of morphine independent of the taste preference conditioning. There was a suggestion for a facilitation of the preference conditioning in injected animals; however, the conclusions were still not fully in line with a withdrawal alleviation hypothesis. It was possible that the injections sensitized the incentive effects of the morphine or produced a habituation of the initial aversive effects (Gaiardi et al. 1991; Stolerman and D'Mello 1981). However, this

does not preclude a role for withdrawal alleviation with regard to other drugs, such as in ► alcohol preference tests.

Consumption of food can condition taste preferences and a conditioned taste preference may arise from a drug's nutritional effect. This can be the case for conditioned taste preferences reported for ethanol. This drug provides an organism with calories as well as pharmacological consequences and both of these effects seem to be important in accounting for its conditioned taste preferences (Cunningham and Niehus 1997). However, this cannot be the case for many other drugs that do not have nutritional effects, including the opioid analgesics in the figure.

Regarding other mechanisms, there are special issues of conditioned taste preferences formed in the human during a career of oral drug intake. Because of a paucity of data in the drug area, one needs again to address as models factors important for the development of preferences for and the eventually liking of the taste of foods. For example, Paul Rozin and colleagues have studied the development of preferences for flavors that were initially aversive, such as those that are spicy or bitter (see article by Debra Zellner in Bolles 1991). Peer group pressures or modeling (seeing another individual enjoy a spicy or bitter substance) promotes the liking for an initially aversive substance. Flavors can also be paired with reinforcing effects that do not come from the biological consequence of the ingestion, such as due to a pleasant environment or social interaction. In addition, expectations that a flavor is aversive may actually be seen as a goal for some individuals seeking adventure or thrills; indeed, such individual have a risk for developing alcohol and drug dependence (► risk taking, ► Attention Deficit and Disruptive Behavior Disorders). General anticipatory information about drug effects can also have a role in the formation of taste preferences, as predicted by other ► expectancies and their influence on drug effects. When the consumption of a flavor is found to have fewer negative consequences than originally anticipated, the flavor can thereafter be viewed as more pleasant. Also, experience with predictable negative events may give rise to anticipatory opponent processes that are hedonically positive.

Conditioned Taste Preferences as an Interdisciplinary Probe for Appetitive Effects of Drugs

Taste conditioning is easy to apply. The taste stimuli can be applied as liquids consumed for fluid balance and for nutrition or as fluids applied on to the tongue of experimental subjects. Therefore, unconditioned and conditioned tastes can be examined in many interdisciplinary situations. There is some experimental work on taste preference conditioning produced by drugs in the human. For example, a body of data in healthy coffee drinkers show that previously neutral tastes will evoke taste preferences when paired with ► caffeine intake (Yeomans et al. 2005). It may be important that this effect is not found in persons who are not high caffeine consumers. The methods for producing the taste conditioning are remarkably similar to those in animals and two taste, differential conditioning procedures have also been used. However, most of the preference effects produced by caffeine are based on subjective reports on the test flavors, rather than on actual consumption as used in animals.

Conditioning using tastes and related stimuli can also be seen in the perinatal organism. There are examples of conditioning to tastes delivered *in utero*; effects of drugs of abuse have not been paired with these, however. Gary Beauchamp and colleagues did confirm in the human that tastes taken in by breast-feeding women can be detected in the milk expressed from the mother; the taste of ethanol is one of these. Work with other aversive flavors such as garlic as models has also shown that the experience of such flavors by the young breast-feeding infant can promote a subsequent acceptance of those flavors by the infant itself.

Only neonatal rodents have been routinely used to study conditioned preferences produced by drugs. In 5-day old rat pups, Priscilla Kehoe and Elliot Blass showed with morphine a biphasic dose pattern of taste preference conditioning. A variation of the one-taste method was used. Rats received a single pairing of saccharin prior to a morphine injection. Five days later, the saccharin solution was infused over the tongue for testing. As compared to control animals, those injected with 0.5 mg/kg swallowed more of the solution; animals injected with 2.0 mg/kg swallowed less. The perfusion was carried out with a catheter implanted directly into the tongue of the animal, which may be traumatic and interact with the opioid effects. Therefore, it is important that the same pattern of effects was observed using an odor-conditioning paradigm. Taste is closely associated with olfactory processes; in fact, the flavors of most fluids are comprised of smells as well as tastes. Randall et al. (1992) used a single pairing with morphine in a two-odor conditioning paradigm and confirmed the low-dose preference and a high-dose aversion, as seen in Fig. 1 for the adult rat.

For a focused perspective on reinforcement processes, conditioned taste preferences and aversion are the phenomena of choice. Most investigators remain only interested in appetitive-conditioned effects and avoid any confusion seen with the competing conditioned taste

aversion effects. The conditioned taste preference procedures are often used in the literature to examine the interplay between aversive and incentive effects. For example, the taste conditioning methods are used together with other paradigms (e.g., place preference conditioning) to show different conditioned responses in the same study (e.g., Gaiardi et al. 1991). However, there is growing interest in assessing taste stimuli using the ► taste reactivity test. As systematically explored by Linda Parker and colleagues, this test is similar to the tests of a two-taste preference conditioning paradigm, since it can also evidence motivational responses of both positive and negative valence to a taste. However, this test has the additional feature that it can differentiate between different forms of conditioned aversive effects, such as the aversion produced by a self-administered drug such as morphine and one produced by a toxin. Data from a taste reactivity test were originally used to evidence ► liking and wanting produced by reinforcers.

Conditioned Tolerance

Synonyms

Behavioral tolerance; Learned tolerance

Definition

Conditioned tolerance refers to those instances of tolerance where it is a consequence not only of neuronal adaptations to the effects of a drug, but also involves either (1) associative learning in a classical (Pavlovian) conditioning situation or (2) differential tolerance arising from the impact of contingencies of reinforcement in operant conditioning procedures. Tolerance within a classical conditioning paradigm may be seen as a ► conditioned drug effect and is sometimes called situationally specific tolerance; when results are interpreted according to the concepts of operant conditioning it is called ► behavioral tolerance.

Synonyms

CAM

Definition

The CAM is a nine-item delirium diagnostic scale based on the DSM-III-R criteria for delirium. A unique and helpful feature of the CAM is that it has been simplified into a diagnostic algorithm that includes only four items

of the CAM designed for rapid identification of delirium by nonpsychiatrists. The four-item algorithm requires the presence of: (a) acute onset and fluctuating course, (b) inattention, and either (c) disorganized thinking, or (d) altered level of consciousness. CAM has also been validated in palliative care settings with a sensitivity of 88% and a specificity of 100% when administered by well-trained clinicians.

Congestive Heart Failure

Definition

Heart failure is a global term for the physiological state in which cardiac output is insufficient for the needs of the body. In case the low cardiac output itself is the underlying cause, this is often termed congestive heart failure. Common causes of heart failure include myocardial infarction, hypertension, valvular heart disease, and cardiomyopathy. The PDE3 inhibitor milrinone is used for the treatment of congenital heart failure. However, one of its side effects is ventricular arrhythmias which might be fatal and therefore it is only prescribed when conventional treatment with vasodilators and diuretics has proven to be insufficient.

Consolidation

Definition

The process by which recently acquired information (i.e., labile, short-term memory) is progressively stabilized into a persistent form known as long-term memory.

Consolidation and Reconsolidation

Synonyms

Memory restabilization; Memory stabilization

Definition

Consolidation and reconsolidation refer to transient memory stabilization processes: While consolidation processes stabilize newly acquired memories, reconsolidation processes re-stabilize reactivated, i.e., retrieved, established memories. Although synaptic consolidation and reconsolidation are universal properties of neurons, certain experimental conditions can reduce the probability of reconsolidation. For example, very strong memories are less likely to reconsolidate than weaker ones.

Impact of Psychoactive Drugs

Synaptic consolidation posits that new memories initially exist in an unstable state and are susceptible to amnesic treatments. Once they are resistant to these treatments they are referred to as ► long-term memories (McGaugh 1966). The predominant view of synaptic consolidation posits that new RNA and proteins must be synthesized by neurons to stabilize new memories (Kandel 2001). In addition, at the physiological level changes in the efficacy of synaptic connections (i.e., long-term potentiation; see ► long-term potentiation) are thought to reflect the biological substrate of memory (Martin et al. 2000).

The empirical evidence for the existence of a consolidation period is that new learning induces a time window during which subsequent memory performance can be (1) diminished by impairing neuronal function (e.g., inhibiting protein synthesis), (2) impaired by new learning, and (3) increased by manipulations that improve neuronal function (e.g., ► psychostimulants such as ► amphetamine) (McGaugh 2000).

► Synaptic reconsolidation posits that retrieval can transfer a consolidated memory from an unstable to a stable state. The currently available evidence suggests that new RNA and protein synthesis can be required for restabilization. In addition, there is preliminary evidence that changes in synaptic efficacy, thought to represent the biological substrate of memory, are subject to restabilization processes, i.e., reconsolidation (Nader and Hardt 2009) (see ► Learning & Memory: Molecular Mechanisms).

The existence of a reconsolidation period is deduced from evidence showing that reactivation of a consolidated memory induces a period of time during which subsequent memory performance can be (1) impaired by challenging neuronal function, (2) impaired by new learning, and (3) enhanced by manipulations that facilitate neuronal function (including ▶ psychostimulants (Nader and Hardt 2009)).

Synaptic consolidation and reconsolidation are different from Systems Consolidation. Systems consolidation and reconsolidation refer to the idea that the ▶ hippocampus plays a time-limited role in supporting memory. When found, the time course of systems consolidation in humans ranges from months to years, and in rodent models from weeks to months.

Constraints on Reconsolidation

Memory reconsolidation has been found in many paradigms and for many amnesic agents, but reconsolidation is not ubiquitous. Some memories, such as memories of unreinforced contexts (i.e., pure space), do not seem to undergo reconsolidation. Other memories can undergo reconsolidation when certain paramters or conditions are met. Several parameters that have been found to inhibit memories from undergoing reconsolidation include ▶ extinction consolidation, memory age, predictability of the reactivation stimulus, and training intensity.

Therefore, studies that test for the neuropsychopharmacology of reconsolidation must ensure that the training-parameters allow a memory to undergo reconsolidation. Otherwise, reconsolidaiton may not occur, and a negative effect of a neuropsychopharmacology challenge will be obtained, which might not reflect the inability of the pharmacological treatment to principally affect reconsolidation.

Comparing Reconsolidation and Consolidation

Care must be taken when directly comparing the results obtained from studies testing consolidation and reconsolidation, as often different protocols are used to study the two memory processes. For example, in a Pavlovian paradigm consolidation is studied by presenting both a conditioned (CS) and an unconditioned stimulus (US), whereas reconsolidation is usually induced by presenting the CS alone. Such small changes in protocols can lead to surprising changes in the molecular mechanisms mediating consolidation. For example, the mitogen-activated protein kinase (MAPK) pathway is engaged in the gustatory cortex when a novel, but not a familiar, taste is used in a ▶ conditioned taste aversion paradigm. Consolidation of contextual fear conditioning requires either one or two phases of protein synthesis and protein kinase A (PKA), depending on whether animals received one or two foot shocks. Therefore, reported differences in the neuropsychopharmacoloygy of consolidation and reconsolidation may reflect that a difference in mechanisms mediating the two memory processes exists, or simply that the induction protocols were different.

The neuropsychopharmacology of consolidation has been well described (McGaugh 2000). Although the neuropsychopharmacology of reconsolidation, has been a relatively new field, already many neurotransmitter systems and signaling molecules have been implicated in the mechanisms that underly memory reconsolidation (Diergaarde et al. 2008; Tronson and Taylor 2007). A number of studies have investigated the memory enhancing or disrupting effects of various pharmacological agents, which act on different neurotransmitter systems during the reconsolidation process. In these studies, the pharmacological agents were administered (rodents or humans) just before or after the reactivation of an established memory. Various paradigms have been used, including aversive memory tasks such as ▶ pavlovian fear conditioning and ▶ conditioned taste aversions; appetitive learning paradigms such as conditioned place preference (CPP); and ▶ passive avoidance tasks.

Glutamatergic System

The activation of ▶ NMDA receptors seems to be crucial for memory reconsolidation. The administration of drugs that affect these receptors pre or post retrieval has been shown to interfere with the reconsolidation process in a manner consistent with consolidation (Kandel 2001; Martin et al. 2000).

Several studies have tested the effect of NMDA antagonists on reconsolidation in rodents. When administered systemically, the non-competitive antagonist MK801 impairs the reconsolidation of fear memory, of appetitive memory for food-rewarded spatial discrimination task, of appetitive pavlovian task, and long-term cocaine or amphetamine-associated memories as measured by a conditioned place preference paradigm. With regard to NMDA agonists, there is evidence that d-cycloserine adminstered systemically or into the ▶ amygdala facilitates fear memory reconsolidation in rats.

Adrenergic System

As is the case for conslidation, memory reconsolidation can also be disrupted by ▶ beta-adrenergic antagonists. The antagonist ▶ propanolol impairs reconsolidation of aversive memory and reward-related memories when injected systemically in rodents. Propanolol can also

impair reconsolidation of addictive-drug associative memories such as cocaine and morphine-CPP.

In humans, oral administration of propanolol disrupts the reconsolidation of fear memories, resulting in a loss of the behavioral expression of fear in ► pavlovian fear-conditioned subjects (Kindt et al. 2009); and in patients with post-traumatic stress disorder, propanolol given after memory retrieval reduced the physiological response to the traumatic event.

GABAergic System

Memory reconsolidation can also be disrupted by administration of drugs that act on the GABAergic system. Systemic injection of the ► $GABA_A$ receptor agonist after memory reactivation reduced contextual fear. However, GABA antagonists seem to not have an effect on reconsolidation, as a study suggests in which the ► GABA antagonist bicuculline did not affect the reconsolidation of contextual fear memories.

Glucocorticoids

The ► glucocorticoid receptors, which are important for modulation of consolidation, have also been shown to be a target for the modulation of reconsolidation of aversive memories. Several studies have demonstrated that infusion of the glucocorticoid receptor antagonist RU38486 into the basolateral amygdala (BLA) after reactivation impairs long-term fear memories in rats.

Endocannabinoid System

There is clear evidence from experiments in rats that the ► endocanabinoid system plays an important role in the modulation of the reconsolidation process in various types of memories involving different brain areas. Post-retrieval infusion of the cannabinoid agonist WIN55,212-2 into the insular cortex blocked the expression of conditioned taste aversion memory. Bilateral infusion of WIN55,212-2 or HU210, another canabinoid agonist, into the ► amygdala after memory retrieval disrupted the reconsolidation of fear memory.

Infusions of the canabinoid agonist ► anandamide into the CA1 region of the dorsal hippocampus after memory reactivation impaired the reconsolidation of contextual fear memory whereas the infusion of a canabinoid antagonist AM251 facilitated it (de Oliveira Alvares et al. 2008).

Cannabinoids also play a major role in the reconsolidation of drug-reward-related memory as the antagonist ► rimonabant disrupted the reconsolidation of metamphetamine-conditioned place preference in mice (Yu et al. 2009).

Dopaminergic System

► Dopamine signaling via the D1 receptor is thought to be especially important for consolidation. This receptor is coupled to the cyclic AMP signaling pathways that are thought to be engaged during learning. Drugs that affect the dopaminergic system have shown to interfere with the reconsolidation process in some types of memories. In chicks, the D1 receptor antagonist SCH23390, when administered before retrieval, impaired passive avoidance memory. Drugs that affect dopamine reuptake also influence memory reconsolidation. Cocaine treatments after memory reactivation enhanced active avoidance memory in rats, but amphetamine did not affect reconsolidation of a morphine-related memory in a CPP task.

Cholinergic System

The effects of cholinergic drugs on memory reconsolidation are not as clear as for other neurotransmitter systems. Evidence in favor for ► acetylcholine neurotransmission in reconsolidation stems from studies in which the choline-uptake inhibitor hemicholinium was administered intracerebrally, and blocked consolidation and reconsolidation of an inhibitory avoidance in mice. In addition, there is some evidence that systemic injections of the acetylcholine receptor antagonist ► scopolamine impair reconsolidation of morphine-conditioned place preference in rats. However, administration of scopolamine into the ► amygdala had no effect on the reconsolidation of contextual fear memory.

Protein Kinases

In addition to the pharmacological agents that act directly on neurotransmitter systems, drugs that interfere with activation of some protein kinases (see ► kinase inhibitors) have been shown to affect memory consolidaton and reconsolidation (Tronson and Taylor 2007). For example, in rats, inhibition of PKA in the BLA by administration of Rp-cAMPS after memory retrieval disrupted conditioned fear memories and conditioned taste aversion. Activation of PKA by 6-BNZ-cAMP in the BLA enhanced fear-conditioned memories. However, in *lymnea* the PKA inhibitor KT5720 impairs long-term associative memory only when injected 6 h after, but not shortly after, memory retrieval.

Administration of the mitogen-activated protein kinase (MAPK) inhibitors UO126 impairs reactivated fear memories when inejected into the amygdala, and the reconsolidation of recognition memory when injected intracerebroventricularly. Reconsolidation of cocaine-CPP was also disrupted by infusing UO126 into the core of nucleus accumbens, and by systemic administration of the MAPK inhibitor SL327.

Context-Dependent Catalepsy

Synonyms

Conditioned catalepsy

Definition

Context-dependent catalepsy occurs when a history of pairing the injection of a catalepsy-inducing drug, such as haloperidol, with the testing of catalepsy in a particular

environment results in acquisition by that environment of the ability to elicit catalepsy in the absence of the previously administered drug.

Context-Induced Reinstatement

Definition

In this procedure, laboratory animals are first trained to self-administer a drug or nondrug reinforcer in an environment (typically termed context A) associated with a specific set of "background" stimuli (e.g., operant chamber fan, time of day). During training, these stimuli become associated with the availability and effects of the reinforcer. Lever pressing is then extinguished in a different environment (typically termed context B) with a different set of "background" stimuli. During reinstatement testing under extinction conditions, exposure to the context previously paired with the reinforcer (context A) reliably reinstates operant responding.

Definition

► Contingency management (► CM) is an intervention to change behavior by systematically reinforcing meeting treatment goals and withholding reinforcement or providing punitive consequences for unmet goals. This treatment approach is based on principles of ► operant conditioning, an area of psychology concerning the effects of reinforcement and punishment on the probability of future behavior. ► Reinforcement refers to the behavioral process whereby an environmental consequence increases the probability of a response, and ► punishment refers to a behavioral process where the probability of a response is decreased because of its consequence.

Current Concepts and State of Knowledge

Clinical and Scientific Rationale: CM is designed to increase motivation for behavior change in patients whose motivation to change varies over time. While drugs themselves can serve as positive reinforcers, CM is designed to replace these reinforcers with other healthier positive reinforcers for abstaining from substance use, attending therapy sessions, and taking prescribed medications (Higgins et al. 2008).

Important Features of CM Interventions: CM interventions promote behavior change using positive and negative reinforcement. Positive reinforcement involves the delivery of a reinforcing consequence such as a voucher to purchase retail items contingent on meeting a therapeutic goal such as abstaining from recent drug use. ► Negative reinforcement involves the removal, or a reduction in the intensity of an aversive event such as job suspension contingent on meeting a therapeutic goal such as successful completion of treatment. Positive punishment involves the delivery of an aversive event such as a social

reprimand contingent on a therapeutically undesirable response such as failure to attend therapy sessions. Finally, negative punishment, involves the removal of a positive condition such as forfeiture of clinic privileges contingent on the occurrence of an undesirable response such as resumption of substance use.

While reinforcement and punishment contingencies are effective, punishment is typically disliked by patients and staff, and can inadvertently increase treatment dropout. Nevertheless, judicious use of negative punishment can help to retain patients in treatment, reduce substance use, and improve other therapeutic targets.

Several practical considerations improve outcomes with CM interventions: (1) the details of the intervention should be explained carefully to patients prior to treatment, accompanied by written contracts; (2) the response being targeted by the CM intervention (e.g., drug abstinence) should be defined objectively (e.g., drug-negative urine toxicology results); (3) the methods to be used for verifying that the target response has occurred (e.g., urine toxicology testing) should be identified in advance; (4) the schedule for monitoring progress (e.g., Monday, Wednesday and Friday) should be outlined clearly; (5) progress should be monitored frequently to provide opportunities for patients to experience the programmed consequences; (6) the duration of the intervention should be clearly stipulated in advance; (7) the treatment should focus on a single target (e.g., abstinence from a single substance) rather than targeting multiple behaviors (e.g., abstinence from multiple substances); (8) the consequences of success and failure should be clear; (9) the delay to delivering consequences should be as short as possible. For example, delivering the consequence on the same day that the target response is verified produces larger treatment effects than delivering the consequence at a later time; (10) larger value incentives produce larger treatment effects.

Applications of Contingency Management: CM was first used with substance use disorders (SUDs) in a programmatic manner in the 1980s to reduce unauthorized drug use among patients enrolled in methadone treatment for opioid dependence (Stitzer et al. 1982). These studies showed that illicit drug use, even among severely dependent individuals, could be reduced using reinforcement contingencies, and they showed that medication take-home privileges for patients who otherwise had to report to the clinic daily were an effective incentive for increasing abstinence from unauthorized drug use (Stitzer et al. 1992).

Later in a seminal study, ▶ cocaine dependent outpatients were randomly assigned to 24 weeks of behavior therapy including CM or to standard drug abuse counseling (Higgins et al. 1993). The CM intervention was 12 weeks in duration and explicitly integrated with routine urine toxicology testing. Participants earned points for drug-free urines that were recorded on vouchers. The first negative test results earned 10 points or $2.50 in purchasing power, the number of points earned increased by 5 with each consecutive cocaine-negative test result. Cocaine-positive test or failure to provide a specimen reset the value of the vouchers back to the initial low level. Five consecutive test results following a reset restored voucher value back to where it was prior to the reset. Money was never given to patients. Instead, patients were given vouchers to purchase retail items in the community such as gym memberships, fishing licenses, or gift certificates to local restaurants. Staff counseled patients to use vouchers to support involvement in healthy activities that could serve as attractive alternatives to cocaine use. If a patient earned all the points available across 12 weeks, he/she could earn a total of $997.50 in purchasing power. The CM treatment was combined with an intensive behavioral counseling intervention known as the community reinforcement approach (CRA) that focused on promoting healthy lifestyle changes. In that study, the majority (58%) of patients in the CM+CRA condition remained in treatment for the recommended 24 weeks of treatment compared to only 11% in the comparison treatment using standard drug abuse counseling (Fig. 1, top panel). Regarding cocaine abstinence, 68% of those treated with CM+CRA, achieved two or more months of continuous cocaine abstinence during the recommended treatment period that was verified by urine toxicology testing. By contrast, among those assigned to standard treatment, the majority either dropped out of treatment or resumed cocaine use, with only 11% achieving two or more months of objectively verified abstinence from cocaine use (Fig. 1, bottom panel). Subsequent studies on the treatment of cocaine dependence, replicated the findings described above, showed that voucher-based CM was an active contributor to the positive outcomes achieved with the CM+CRA approach, and also demonstrated continuing benefits for approximately 2 years after the CM program was discontinued.

CM has been applied to different types of SUDs in several different populations. A meta-analysis of controlled studies using voucher-based or related monetary-based CM to treat SUDs from January 1991 and March 2004 (Lussier et al. 2006), identified 63 reports of studies that targeted abstinence from substance use, clinic attendance, or medication compliance. The review supported the efficacy of CM.

(Adapted from Higgins et al. 1993.)

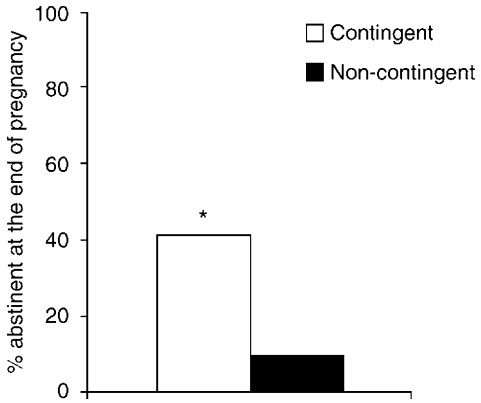
CM has been used with subpopulation, special subpopulation such as pregnant cigarette smokers (Heil et al. 2008). Eighty-two women who were still smoking upon entering prenatal care were randomly assigned to a condition where they received vouchers contingent on abstinence from recent smoking through 12 weeks following delivery of the baby or to a control condition where they received vouchers independent of smoking status (even if they kept smoking). Significantly more women in the condition where vouchers were earned contingent on recent smoking abstinence successfully abstained from smoking during pregnancy (41% vs. 10%; Fig. 2).



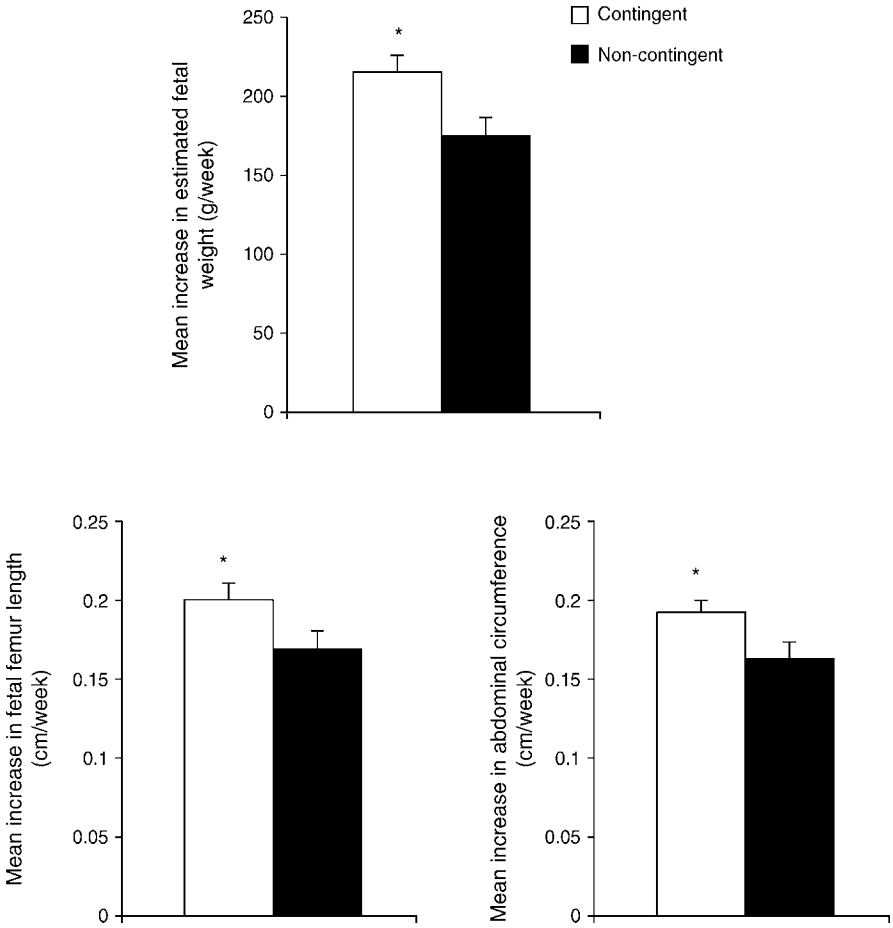
Contingency Management in Drug Dependence. Fig. 2. Point-prevalence smoking abstinence at the end of pregnancy. * indicates a significant difference between conditions ($p < 0.05$). (Adapted from Heil et al. 2008.)

Additionally, fetal growth was significantly greater in the condition where vouchers were earned contingent on smoking abstinence compared to the control condition (Fig. 3). Those outcomes were achieved with average payouts of $\$461 \pm 461$ in vouchers across, approximately 9 months of treatment.

CM has been successful in other applications with pregnant women. For example, it has been used effectively to increase abstinence from cocaine and heroin use among pregnant women (Silverman et al. 2002). CM is also effective at improving the likelihood of taking medication among those with infectious diseases. Improving compliance with antiretroviral medications for HIV/AIDS patients with SUDs is one example in that area (Rounsaville et al. 2008). Another special population with whom there is growing evidence of CM's efficacy is the seriously mentally ill who also have SUDs (Sigmon and Higgins 2006). CM is effective at reducing substance use in that population and reducing other complicating factors such as re-hospitalization rates that often go along with drug abuse among the mentally ill. CM is effective with adolescents with SUDs, with the evidence mostly centering on cigarette smoking and marijuana use. Finally, CM is an essential component in multi-element treatments for homeless crack and other drug abusers (Milby and Schumacher 2008).

Conclusion

CM treatments represent an important part of evidence-based interventions for SUDs. They are effective and sufficiently versatile to be used in different settings and with different population in need of treatment for SUDs.



Contingency Management in Drug Dependence. Fig. 3. Mean (±SEM) rates of growth in estimated fetal weight (top panel), fetal femur length (bottom left panel), and fetal abdominal circumference (bottom right panel) between ultrasound assessments conducted during the third trimester. * Indicates a significant difference between conditions ($p < 0.05$). (Adapted from Heil et al. 2008.)

While very effective, they do not represent a silver bullet. For example, improvements are needed to help the interventions succeed with a larger proportion of the patients treated, to develop methods that will ensure longer-term maintenance of beneficial effects over time, and to continue to develop and refine practical applications that will be used widely in society. The broad success to date should give great confidence in the continuing development and improvement of this approach to help address the adverse individual and societal consequences of SUDs. Moreover, CM interventions are being successfully extended to a wider range of public health problems, including, for example, increasing physical activity levels among the elderly and increasing weight reduction among obese adults. Taken together, CM interventions offer much promise for making important improvements in the public health.

Definition

The Controlled Substances Act (CSA) is the commonly used name for the Title II of the Comprehensive Drug Abuse Prevention and Control Act of 1970 passed by the U.S. Congress. It provides the basis for the current regulation of drugs of abuse in the USA (http://www.usdoj.gov/dea/pubs/csa.html). Drugs controlled under the CSA are assigned to one of five Schedules (I to V) based on their abuse liability. Restrictions on possession, sale, and distribution of drugs differ among the Schedules, with the most severe penalties given for violations involving drugs in Schedule I.

Definition

The major neuropeptide transmitter responsible for orchestrating the endocrine, autonomic, immune, and behavioral responses to stress.

Pharmacological Properties

Introduction

Corticotropin-releasing factor (CRF), also known as corticotropin-releasing hormone (CRH), orchestrates the stress response in the endocrine, autonomic, immune, and behavioral systems through the activation of the hypothalamic–pituitary–adrenal (HPA) axis and extrahypothalamic pathways. The peptide itself is highly conserved between species, and its evolutionary role is to mobilize energy stores and appropriate behavior(s) in response to a stressor. It has since evolved to regulate a variety of responses to stress. CRF was first isolated and characterized by Vale and colleagues in 1981. Due to the similarity in sizes of ACTH and CRF and limits on detection techniques, purification was performed on approximately 490,000 sheep (ovine) hypothalami in order to generate enough samples for isolation. This was part of an ongoing study elucidating a variety of hypothalamic peptides. In the majority of studies, the CRF system has consistently been shown to be dysregulated in many patients suffering from a variety of psychiatric illness including post-traumatic stress disorder (PTSD), early life trauma, and major depressive disorder (MDD) (Nemeroff et al. 1984). In a few studies, the dysregulation of CRF activity has also been implicated in anorexia nervosa and Alzheimer's disease. During pregnancy, CRF plasma levels spike during the third trimester and have been implicated in parturition. The variety of molecular and behavioral responses orchestrated by this single peptide defines it as the central focus of stress research today.

Pharmacological Properties

CRF belongs to a family of ► neuropeptides including sauvagine (a peptide secreted from the skin of a South American frog *Pyllomedusa sauvagei*), the urocortins (endogenous neuropeptides with effects similar to those of CRF), and urotensin (a peptide secreted by the Goby fish). The CRF gene was cloned by Furutani and colleagues 2 years after the isolation and characterization of CRF itself and is expressed in diverse animal species, from zebrafish to all higher mammals. Human CRF is localized to the long arm of chromosome 8 at position q13.

The CRF gene is first activated by transcription factors to produce a 196 amino acid polypeptide. The polypeptide is posttranslationally cleaved at the N-terminus at position 147. The C-terminus is cleaved at amino acids 195–196 and undergoes posttranslational ► amidation. The importance of amidation is not clearly understood; however, sauvagine and urocortin, which also bind and activate CRF receptors, are amidated (Petrusz and Merchenthaler 1992). In vitro receptor binding experiments studying CRF receptors have shown that deamidated CRF has reduced binding affinity for the CRF receptor, clearly demonstrating an important albeit elusive role for amidation. The mature product is a 41 amino acid neuropeptide with a molecular weight of 4,758.4 Da

and an isoelectric point of 5.09. Human, rat, and mouse CRF are identical to each other and display significant sequence homology to ovine CRF (Table 1).

The CRF mature peptide structure was characterized by Lau in 1983 and forms a random coil monomer under physiological conditions. However, in an ► amphiphilic environment such as the cell surface, CRF forms an α-helix and displays an amphiphilic pattern of hydrophobic and hydrophilic surfaces segregated on opposite sides of the α-helix. Upon binding to the CRF receptor at the extracellular domain, the CRF peptide undergoes a conformational change to produce the α-helical secondary structure.

Peripherally administered CRF does not cross the ► blood–brain barrier but exerts effects via peripheral CRF receptors in the gut, on immune cells, or its major endocrine action on corticotropes of the anterior pituitary. Direct central administration of CRF in the ► hypothalamus and/or ► amygdala, as well as the cerebroventricular system, results in a pronounced endocrine and behavioral stress response.

CRF neurons are highly distributed but selectively clustered in the CNS. The densest region of CRF neurons is the parvocellular region of the paraventricular nucleus of the hypothalamus. These neurons project to the median eminence where CRF is released into the portal vessel system supplying the anterior pituitary to initiate the pituitary–adrenal axis endocrine response to stress. A significant number of CRF cell bodies are also localized in the central nucleus of the amygdala, the bed nucleus of the stria terminalis (BNST), and the locus coeruleus where CRF mediates appropriate behavioral and autonomic responses (Owens and Nemeroff 1991). The expression of CRF neurons in these areas, as well as others, infers a role of CRF in modulating monoaminergic systems. CRF neurons innervate noradrenergic cells of the locus coeruleus, the major noradrenergic cell body nucleus. Within the hypothalamus, CRF neurons are innervated by serotonergic, GABAergic, cholinergic and dopaminergic neurons as well as additional CRF neurons. This provides a feedback loop and turns off CRF expression (Petrusz and Merchenthaler 1992). Specific innervation patterns of extrahypothalamic CRF are not known but similar interactions with various transmitter systems are expected.

CRF immunoreactivity has also been localized in diverse areas outside of the brain. CRF is present in the adrenal medulla, pancreas, small intestine, stomach, and testis but a function in these organs is still unclear. It is believed that CRF and CRF receptor expression in lymphocytes and the organs of the GI tract may be involved in inflammation mechanisms in a variety of GI disorders. CRF is also present in the blood plasma to a small extent, although its use as a biomarker for stress has not been supported. During pregnancy, CRF plasma levels spike 6–40-fold during the third trimester of pregnancy but circulating ACTH and cortisol remain level during the entire course of pregnancy due to multiple mechanisms to keep free cortisol in check. Therefore, there is some other non-endocrine function of placental CRF, probably in the process of parturition.

The Hypothalamic–Pituitary–Adrenal Axis

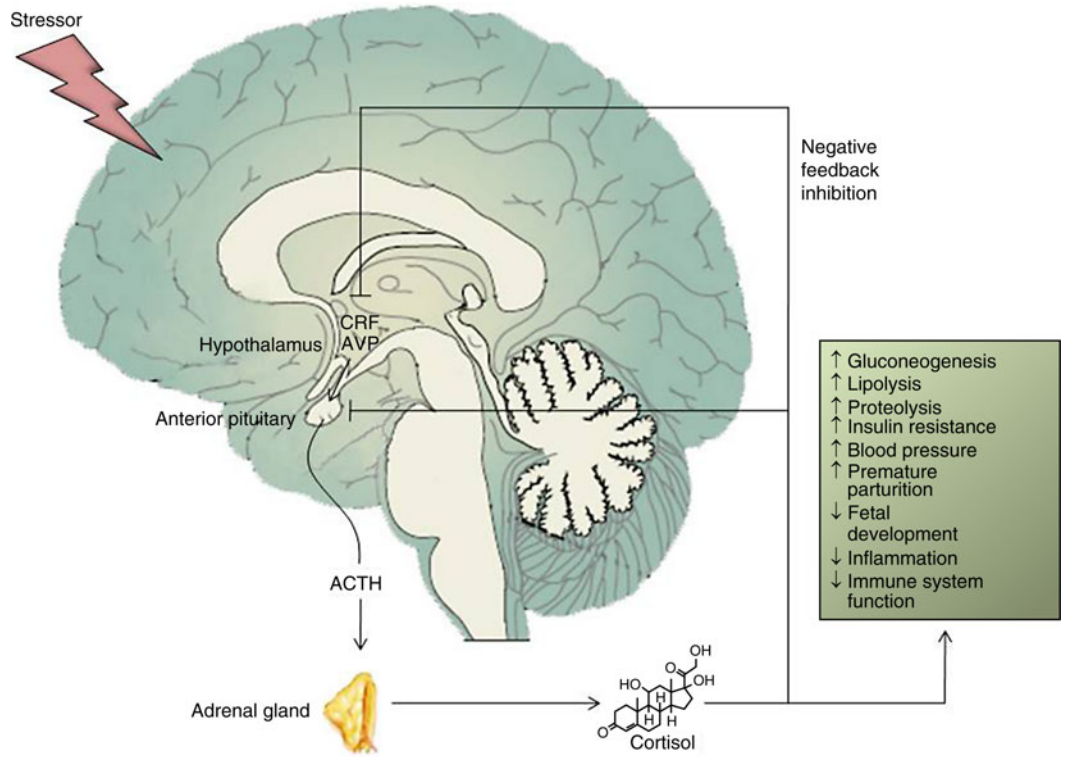
The endocrine response to stress is mediated by the hypothalamic–pituitary–adrenal axis. The HPA axis is activated by a combination of neurons projecting from the amygdala and hippocampus along with the serotonergic and cholinergic (and possibly opioid) neuronal stimulation of CRF neurons in the paraventricular nucleus of the hypothalamus. This stimulates the release of CRF and increases the gene expression of CRF and vasopressin (Fig. 1). The peptide(s) are secreted from nerve terminals in the median eminence through the blood to the anterior pituitary gland via the portal plexus system. On the surface of corticotroph cells in the pituitary, CRF binds to the CRF receptors producing a G protein-coupled receptor (GPCR) signal transduction cascade activating G_s or G_i. The stimulatory G protein (G_s) activates adenylate cyclase, converting ATP into cAMP, which causes PKA activation. PKA activates CREB, a transcription factor, which increases the gene expression of proopiomelanocortin (POMC). As it undergoes intracellular trafficking, proteolytic cleavage processes POMC to produce the mature adrenocorticotropin hormone (ACTH) which is secreted into the peripheral blood circulation. There is a readily releasable pool of ACTH immediately available for release into the bloodstream as well. ACTH travels through the peripheral blood stream until it binds ACTH receptors/melanocortin type-2 receptors located on the zona fasciculata of the adrenal gland. The binding of ACTH causes a similar GPCR signal cascade resulting in PKA activation, which causes cholesterol sequestering and transfer to the mitochondria within steroidogenic cells. There, P450 side-chain cleavage enzyme binds cholesterol and converts it into pregnenolone, which undergoes further enzymatic reactions to form the glucocorticoid cortisol (Minneman and Wecker 2005). Cortisol is important in energy production, inflammation, fetal growth, development, and protein and lipid catabolisms.

The HPA axis is modulated by a negative feedback loop encompassing the hippocampus, hypothalamus, and anterior pituitary. Following cortisol secretion into the peripheral blood circulation, cortisol diffuses through the plasma membrane of cells in the pituitary, hypothalamus,



Corticotropin-Releasing Factor. Fig. 1. The hypothalamic–pituitary–adrenal axis. External stressors cause initiation of the HPA axis by first stimulating CRF neurons in the hypothalamus. and hippocampus where it binds to the ▶ glucocorticoid receptor (GR), a nuclear receptor transcription factor. Upon binding, the GR dissociates from a chaperone complex, which keeps it in an inactive state, and homodimerizes with another cortisol-bound GR. The homodimer translocates into the nucleus and binds to specific glucocorticoid response elements to cause the transcriptional regulation of CRF and POMC related genes, as well as many others, decreasing CRF and POMC production and release.

Metabolism

Unbound CRF is sequestered by a rather unique CRF-binding protein (CRF-BP), a 37 kDa protein characterized by Orth and Mount in 1987. CRF-BP and the CRF receptors bind CRF with similar affinity (0.2 nM). The protein also binds CRF fragments from residues 6–33 (designated as CRF 6–33) and residues 9–33 (CRF 9–33) with high affinity while the receptors bind these fragments with a lower affinity, supporting a role of the binding protein in modulating CRF ▶ bioavailability. Additionally, 40–60% of brain CRF is bound to CRF-BP, further supporting a role for this protein in CRF bioavailability. CRF-BP also binds peptides in the same family as CRF such as urocortin, sauvagine, and urotensin. In the brain, CRF-BP localization coincides with CRF and the CRF receptors in the ▶ amygdala and pituitary but is also distributed in the cerebral cortex and brain stem. Peripheral CRF-BP is highly expressed in only the human and primate placenta and to a lesser extent in the liver. These studies contribute to the theory that CRF-BP regulates CRF levels and acts as a reservoir for CRF when needed (Kemp et al. 1998). During the end of pregnancy, CRF-BP levels fall as placental CRF rises further implicating the protein as a CRF regulator. Novel treatments for mood and ▶ anxiety disorders (*vide infra*) may involve drugs targeting the CRF-BP in order to modulate free CRF concentrations without fully blocking the receptor as an antagonist might.

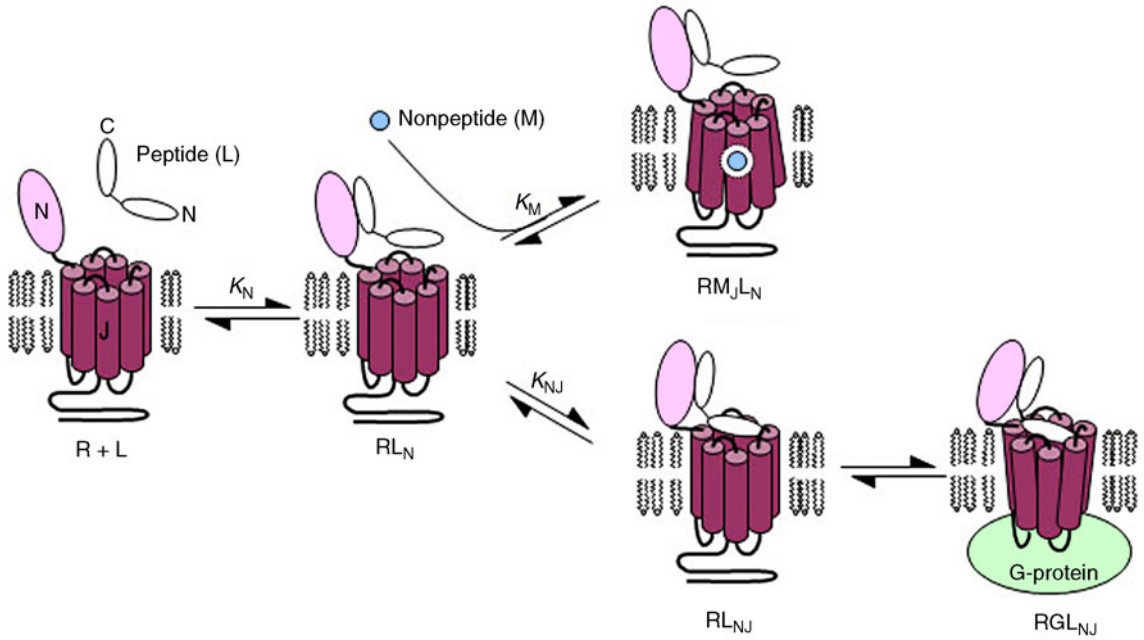
The endogenous enzyme(s) responsible for the degradation of CRF are unknown. However, experiments using purified endogenous ectopeptidases show that CRF is cleaved into smaller fragments. These fragments have reduced activity at CRF receptors.

Mechanism of Action

CRF binds exclusively to CRF_1 and CRF_2 receptors to produce its intracellular effects. Both CRF receptor ▶ subtypes are part of the Class B family of GPCRs, which also includes the calcitonin receptors and the parathyroid hormone receptor (De Souza 1995). Class B receptors contain an N-terminal extracellular ligand binding site (ECD), a seven transmembrane/juxtamembrane domain (JD), and a C-terminal binding site for the G protein (guanine nucleotide exchange protein). CRF binding has been proposed to proceed according to a "Two Domain Model" in which the C-terminus of CRF binds the N-terminus of the receptor (Fig. 2). This initial binding increases the affinity of the N-terminus of CRF for the J-domain of the CRF receptor. The N-terminus of the newly formed α-helical CRF binds the J-domain and initiates the activation of the CRF receptor, which can in turn activate adenylate cyclase via G-protein mediated signal transduction (Hoare 2005). This model explains some of the discrepancies in the loss of binding affinity observed in CRF fragments because the fragments may only be binding to one domain or blocking the binding pocket.

CRF_1 and CRF_2 receptor subtypes display 71% amino acid sequence homology to one another but mediate very different actions. CRF_1 receptors are implicated in the stress response while CRF_2 receptors are associated with feeding behaviors and, arguably, stress-coping behaviors. CRF_1 receptors are highly expressed in the anterior pituitary and mediate the pituitary–adrenal axis response to stress. It is also diversely expressed in the cerebral cortex, hippocampus, amygdala, cerebellum, and hypothalamus. Peripheral CRF_1 receptors are localized within the adrenal glands and the GI tract as well as the testis, ovaries, and immune system where they serve a variety of paracrine roles.

There are three separate ▶ isoforms of CRF_2 receptor delineated as CRF_{2A}, CRF_{2B}, and CRF_{2C}. These are produced from post-transcriptional mRNA processing of the same gene leading to splice variants, which produce different forms of the N-terminus and a single amino acid change at position 41. The exact importance of these changes is not clearly understood. However, binding studies have shown that the isoforms display slight changes in affinity for certain peptides in the CRF family (Dautzenberg and Hauger 2002). CRF_{2A} receptors are localized primarily in the lateral septum, raphe nucleus, and ▶ BNST. Unlike rodents, there is significant CRF_{2A} receptor density within primate cortex. Peptides that are CRF_{2A} selective antagonists have been shown to have some anxiolytic effects following stress conditions although transgenic studies in mice show that CRF_{2A} receptors may be involved in coping responses following stress. CRF_{2B} receptors are localized within ventricles and arterioles of the cerebrovasculature. There are detectable levels of mRNA expression in cardiac and skeletal muscles. Human CRF_{2C}



Corticotropin-Releasing Factor. Fig. 2. CRF receptor binding and activation. Binding of CRF and/or small molecule antagonist to CRF receptor. Non-peptide small molecule antagonist (M) can bind regardless of ligand but if bound, M will block binding of CRF N-terminus resulting in noncompetitive antagonism (Adapted by permission from Grigoriadis et al. 2009).

mRNA is localized in the septum and hippocampus with weak expression in the frontal cortex, amygdala, midbrain, and nucleus accumbens. A clear and significant role for the CRF_{2C} receptor has not been ascribed.

Behavioral and Endocrine Responses to CRF

Central administration of CRF into the CNS produces anxiety and fear-related behaviors in mice and rats nearly identical to those following exposure to a variety of experimental stressors. CRF antagonists also abolish or strongly attenuate stress-induced changes in physiology and behavior. Central administration also disrupts gastric and colonic motor systems, implicating CRF in the pathophysiology of irritable bowel syndrome. Numerous detailed reviews of the behavioral actions of CRF are available. Peripheral administration of CRF in the ▶ CRF stimulation test (with or without dexamethasone) is used to measure HPA axis dysregulation in MDD patients.

CRF is hypothesized to play a major role in many endocrine changes observed in patients suffering from psychiatric disorders. A significant subgroup of patients suffering from MDD exhibit elevated plasma cortisol concentrations as well as elevated cerebrospinal fluid CRF concentrations. Many MDD patients also exhibit a dysregulated glucocorticoid-mediated negative feedback mechanism. Depressed suicide victims show increased CRF mRNA expression in the ▶ hypothalamus as well as decreased CRF_1 receptor binding. There is also evidence that CRF plays a role in early life stress. Evidence suggests that early life trauma increases the sensitivity of the CRF system in adulthood, which may increase the risk of developing depression.

Although the data are limited, the genetic regulation and variation of components in the CRF system are associated with the pathophysiology of ▶ depression and ▶ anxiety. Specifically, single-nucleotide polymorphisms (SNPs) within the CRF_1 gene (CRHR1) support a link between these polymorphisms and the development of depression in patients with a history of child abuse (Bradley et al. 2008). Functional SNPs in the CRHR1 gene are also implicated in the susceptibility to ▶ panic disorder but only in conjunction with SNPs in the vasopressin receptor 1b gene (AVPR1B). Vasopressin receptors in the pituitary synergize with CRF to stimulate ACTH release. Some SNPs in the CRF-BP characterized in a Swedish population are comorbid with major depressive disorder, providing further evidence for the CRF system's role in depression. While there are no known polymorphisms in the CRF gene itself, SNPs in the CRF promoter region are associated with decreased sensitivity to

glucocorticoids and increased consumption of alcohol in Rhesus monkey.

Clinical Applications

Various peptides have been good tools for probing CRF receptor function *in vitro* and in laboratory animals; however, the lack of CNS penetrance renders them of no use for therapeutic applications. Research has focused on the development of non-peptide antagonists of the CRF_1 receptor for the treatment of stress-related disorders including depression and anxiety. High throughput screening and structure–activity relationship driven drug design has produced many small molecule antagonists. CP 316,311 failed in a clinical trial for depression in 2008 and pexacerfont was recently reported as ineffective for irritable bowel syndrome subjects. It should be noted that the extant literature suggests that, at least for major depression, only those individuals with dysregulated (hyperactive) CRF systems would be expected to benefit from CRF antagonists. We believe that this represents only a subgroup of depressed individuals. Therefore, only these individuals should be evaluated for efficacy in future trials. It is not at all clear how to best determine whether an individual has a CRF dysregulation. The use of CRF antagonists as anxiolytic medications might be expected to target a much larger population of individuals.

Craving

Synonyms

Urge

Definition

The description of a strong urge and desire to drink alcohol or to take drugs, and its conceptualization to the construct of "craving" as a central downstream mechanism that initiates drug intake and precedes relapse, has a history of at least 60 years. Concepts of classical conditioning had a major impact on theories of alcohol and drug craving, suggesting that stimuli paired repeatedly with alcohol withdrawal could become conditioned stimuli that elicited conditioned positive and negative reinforcement which, in turn, would generate craving. For clinical use, craving was included in the international classification of diseases (ICD-10; WHO, 2003) as an optional diagnostic criterion for alcohol and drug dependence, defining the term as "a strong desire or sense of compulsion" to take the drug. In line with this, the majority of current conceptualizations of ► substance dependence define subjective craving as a sensory phenomenon that contributes the continuation of drug use.

Critical Flicker Fusion Frequency

Synonyms

CFFF; Flicker fusion rate; Flicker fusion threshold

Definition

Critical flicker fusion frequency (CFFF) is the frequency at which an intermittent light stimulus appears to be completely steady to the observer. This is often measured by exposing the subjects both to a low-frequency flicker, by increasing the frequency to the point the subject has the sensation that the flickering stops, and a

high-frequency flicker that decreases to the point where the flicker is detected. The CFFF is the mean of the two. If the frequency at which frames are displayed in a film falls below the CFFF then the image will be perceived as jerky.

Cross-Dependence

Synonyms
Substitution

Definition
When one drug is able to suppress the withdrawal signs and symptoms resulting from discontinued repeated administration of another drug, cross-dependence is said to occur. For example, methadone can be used to suppress withdrawal in persons physically dependent on heroin. This underlies one of the therapeutic bases for methadone treatment of opiate addiction. Cross-dependence is most readily seen among various opioids and is also seen among the CNS depressants such as the barbiturates, benzodiazepines, and alcohol.

Cross-Tolerance

Definition
Animals and humans who have become tolerant on one drug are often tolerant to related drugs as well. This phenomenon is called cross-tolerance. For example, heroin abusers who are tolerant to heroin would also be tolerant to many other opioids, including methadone. This means that higher does of these other opioids would be needed to produce analgesia or intoxication than would be needed in a non-tolerant individual. Similarly, a patient treated with high doses of methadone would become cross-tolerant to heroin and other opioids, requiring higher doses to achieve intoxication. This serves as one of the pharmacological bases of methadone treatment.

Definition

Cytochrome P450 is a large superfamily of hemoproteins that are essential to the enzymatic catalysis reactions involved in the metabolism of exogenous compounds (e.g., drugs) and endogenous (e.g., steroid hormones) substances. Usually, they form part of multicomponent electron transfer chains, called P450-containing systems. The most common reaction catalyzed by cytochrome P450 is a mono-oxygenase reaction.

Synonyms
Dopamine-and-cyclic-AMP-regulated-32KDa-phosphoprotein

Definition
Phosphoprotein enriched in the cytoplasm of medium-sized spiny neurons located in the caudate nucleus and receiving dopaminergic innervation. DARPP-32 critically influences the manifestation of ► dopamine receptor-mediated effects by regulating the signal cascade of adenylyl cyclase. Two isoforms of DARPP-32 exist that bear a phosphorilation at either of two distinct threonine residues: one of these isoforms is an inhibitor of the adenylyl cyclase cascade, while the other amplifies it. An equilibrium between the two isoforms of DARPP-32 exists under physiological conditions. Several centrally active substances, including ► opiates, addictive ► psychostimulants, and caffeine, can alter such an equilibrium, thus profoundly influencing the functionality of the dopaminergic transmission.

Declarative and Non-Declarative Memory

Consciously accessible and nonconsciously accessible memory; Explicitly and implicitly assessed memory.

Definition

Declarative memory and nondeclarative memory are two major classifications of long-term memory systems. Declarative memory allows us to consciously recollect events and facts. It is generally indexed by our ability to explicitly recall or recognize those events or facts. Nondeclarative memory, in contrast, is accessed without consciousness or implicitly through performance rather than recollection.

Impact of Psychoactive Drugs

Psychopharmacology of Declarative Memory

To embrace findings about the effects of pharmacological agents, it is helpful to distinguish between two key aspects of declarative memory. ▶ Episodic memory allows us to mentally travel back in time to re-experience personal events; it also helps us project into the future to pre-experience and plan for forthcoming events. ▶ Semantic memory, in contrast, stores language, concepts, and facts about the world.

Episodic memory is the most sensitive memory system to pharmacological disruption, and a range of drugs dose-dependently impairs our ability to mentally relive past experience. To date, the vast majority of research has involved single doses of drugs and we know correspondingly less about chronic effects, which are more relevant clinically for individuals who were prescribed repeated doses for treatment or those who addictively self-administer drugs. In terms of differentiating effects on long-term memory systems, the most intensively studied drugs are the ▶ benzodiazepines (BZDs), cholinergic blockers like ▶ scopolamine (SP), NMDA-receptor antagonists like ▶ ketamine, and, particularly in terms of emotional memories, beta-adrenergic antagonists like ▶ propranalol. This essay will provide a brief overview of the psychopharmacology of human declarative and nondeclarative memory, focussing on those compounds, which have been most extensively researched.

Anticholinergics, Benzodiazepines, and Declarative Memory

Interest in the cholinergic modulation of episodic memory was intrinsic to the development of the cholinergic hypothesis of ▶ Alzheimer's Disease (AD). All drug treatments currently available (e.g., tacrine, donepezil, rivastigmine) are designed to ameliorate or moderate this cholinergic depletion. Interest in the effects of BZDs on memory stemmed from anesthetists who value drugs that ensure a sufficient period and depth of anterograde amnesia so that even if the patient regained consciousness during an operation, they would not remember doing so. In this respect, BZDs proved to be ideal drugs. BZDs like ▶ diazepam, ▶ alprazolam, ▶ lorazepam, and 30 or more similar compounds act via specific $GABA_A$-BZD receptors to facilitate the transmission of ▶ GABA (γ-aminobutyric acid). BZD receptors are found throughout the brain, but the highest concentrations are in areas of known importance for memory functions: the cerebral cortex, limbic system, and cerebellar cortex.

Despite their differing pharmacological actions, SP and BZDs produce remarkably similar effects on episodic memory. Episodic impairments are anterograde, not retrograde such that information presented *after* the drug is administered is poorly remembered, whereas information studied *before* the drug is administered is retrieved intact. There is a general agreement that these drugs dose-dependently impair acquisition (encoding/consolidation) of new information and not retrieval. Once learning has been accomplished, the rate of forgetting is normal and there is no increased susceptibility to interference when initial acquisition levels on drug and placebo are matched.

When false recognition paradigms are used, these drugs acutely reduce false as well as veridical memories, a pattern similar to that seen in organic amnesia. Studies of metamemory suggest that people are unaware of having episodic memory deficits when they are intoxicated with a BZD.

Retrieval of material learned before a drug is ingested is not impaired and interestingly, can be improved when retrieval takes place on a BZD. This retrograde facilitation may be due to poor memory for material studied post-drug, which reduces interference on retrieval of material studied pre-drug. It could also reflect disinhibition of retrieval processes that may increase reliance on automatic rather than controlled processing. Retrograde facilitation is the opposite of notions of "► state-dependent retrieval" where performance is meant to be aided when encoding and retrieval taking place in the same drug state. In reality, state-dependent effects in humans are quantitatively very small and do not account for the marked effects of these drugs on acquisition.

The degree and duration of anterograde amnesia depends on the particular drug, its dose, and time curve of absorption and elimination. For example, following one oral dose of the BZD lorazepam, peak memory impairments occur from 1.5 to 5 h, after which effects slowly subside. Memory decrements also vary with task demands, so, for example, recall of information immediately after studying it is less impaired than recall tested several minutes or more after study; free recall deficits are greater than cued recall and recognition deficits. The degree of amnesia observed also varies with the characteristics of the tested individuals. Older healthy adults and Alzheimer patients show SP-induced memory impairments at lower doses of the drug than those needed to induce impairments in younger people. Further, the effects of a single dose of BZD are more pronounced in individuals who have never taken the drug before compared with those who have taken it occasionally or patients who take the drug daily for an ► anxiety or sleep disorder. As one would expect, neuroimaging studies show that BZD-induced dose-related decreases in memory performance are associated with dose-related decreases in activation in areas important for encoding information including the medial temporal lobe and prefrontal cortex.

In Endel Tulving's theory, the essence of episodic memory is the capacity to remember in the sense of re-experiencing events in subjective time. One way of evaluating episodic memory is therefore to tap into people's subjective awareness, which accompanies retrieval of a memory. Experiential approaches using the remember-know paradigm are based on a distinction between "remembering" in the sense of re-experiencing as a participant in an event and "knowing" in the sense of a personally detached observer of an event. BZDs, SP, and alcohol all acutely reduce "remember" responses at the same time as leaving "know" in tact, suggesting that they impair people's ability to mentally re-experience in subjective time (episodic memory) but do not affect semantic memory (reflected by "knowing").

Semantic memory has received less attention than episodic memory in terms of effects of BZDs and SP. Although some studies have assessed retrieval efficiency, acquisition of new semantic knowledge has been largely ignored. On the whole, these drugs do not appear to impede people's ability to *retrieve* items of general knowledge or other well-established memories. Conceptual priming in category generation tasks is intact even though a participant's explicit recall of studied category exemplars shows marked impairment, thus showing a differential effect of the drug on semantic and episodic memory assessed within the same task.

Glutamate, NMDA Blockers, and Declarative Memory

The excitatory amino acids, notably ► glutamate and aspartate, are the most prevalent excitatory neurotransmitters in the brain, and play an important role in cortico−cortical and cortical−subcortical interactions. Extensive research with animals has implicated the importance of glutamate, and especially the glutamatergic N-methyl-d-aspartate (► NMDA) receptor, in memory. Much of this research concerns ► long-term potentiation (LTP), an enduring form of synaptic plasticity that was initially identified in the hippocampus and more recently in the amygdala. LTP has been proposed as a mediator of learning and memory, although, it is not yet clear how LTP at the synaptic level relates to memory at a behavioral level. Drugs that block the NMDA receptor (e.g., ► ketamine) inhibit the induction of LTP in the ► hippocampus and there is considerable evidence that LTP is mediated by the NMDA receptor. In the human brain, NMDA receptors are densely localized in the cerebral cortex and the hippocampus.

Ketamine, like BZDs and ► scopolamine, disrupts acquisition of new information but not its retrieval. Acute ketamine dose-dependently impairs an individual's memory for the source – or contextual details – of information studied, reflecting a true episodic impairment. One study has suggested that interference from previously learned material may be increased acutely by ketamine. Preliminary evidence implies that ketamine may differ from classic amnesic drugs like BZDs and SP by adversely

impacting on semantic memory. Impairment of both episodic and semantic memory was suggested by one study showing that a single dose of ketamine produced similar impairments on both "remembering" and "knowing" states of subjective awareness in recognition. More recently, research using semantic priming tasks suggests that this drug has detrimental effects on aspects of semantic memory, although the degree to which this reflects in impairments from controlled rather than automatic processing are not clear.

Although ketamine is used clinically as an anesthetic, especially in vetinary and pediatric medicine, it is also a street drug, taken for its mood- and consciousness altering effects. Research with ketamine abusers has shown that the drug acutely impairs not only episodic memory but also retrieval from semantic memory on tasks such as semantic priming and sentence verification. Acute or chronic effects in recreational users mimic acute effects in healthy nonusers. There is now evidence that frequent, chronic use of ketamine may be associated with chronic episodic memory impairment, which persists for a period after stopping use of the drug.

Alcohol

Alcohol also produces its major amnesic effect on episodic memory and these range from mild impairment at low doses to total amnesia ("black-out") at high doses. ► Alcohol has NMDA-blocking as well as GABA-ergic properties, so it is not surprising that its effects are qualitatively similar to those of ketamine and BZDs.

Monoamines, Monaminergic Drugs, and Declarative Memory

Monoamines include the catecholamines (► dopamine, ► noradrenaline, adrenaline) and the indolamine, ► serotonin (5-hydroxytriptamine or 5-HT). Compared with SP or BZDs, there is relatively little research on the effects of monoaminergic drugs on memory for neutral information.

Dopaminergic compounds exert their most consistent effect on executive functions. A fairly consistent finding is that these drugs influence short-term or ► working memory (in ways which vary according to an individual's baseline level of functioning) and do not directly affect episodic memory. However, recent research using semantic priming paradigms has suggested dopaminergic modulation.

Our memory for personally experienced emotional events tends to be particularly vivid and durable. The neurobiological basis of enhanced episodic memory for emotional – as compared with neutral – information has been explored in an elegant series of studies by Cahill, McGaugh, and colleagues. They showed that drugs affecting adrenergic systems modulate emotional memory. Thus, the β-adrenergic antagonist, propranalol impairs healthy people's recall of emotionally arousing (but not neutral) elements of a storey, whereas stimulation of noradrenaline (with ► yohimbine) produces some enhancement of memory for emotional elements of the same story. Using the same task with two patients who had bilateral damage in the ► amygdala, they found a similar pattern of memory for the emotional and neutral storey elements. Together with the evidence that noradrenaline is released in the rat amygdala in response to learning to avoid an ► aversive stimulus, Cahill and others argue that adrenergic function in the amygdala mediates memory for emotional material. Within the basolateral amygdala and hippocampus, noradrenaline enhances glutamatergic ► synaptic plasticity, which is thought to underpin learning and memory. The profile of noradrenergic effects differs from that of BZDs, which acutely appear to impair memory similarly for both neutral and emotional elements.

Serotonin has been implicated in learning with some studies showing that rapid depletion of brain ► tryptophan (the amino acid precursor to serotonin) produces impaired learning and memory. However, manipulations that lead to serotonin depletion have not produced a consistent pattern of results. On the contrary, there is clear evidence that the drug "ecstasy" (3, 4-methylenedioxymethamphetamine ► MDMA), which produces marked serotonin *release* acutely impairs performance on tasks tapping episodic memory.

Other Compounds and Declarative Memory

A range of other drugs exert their primary effect on episodic memory. Cannabis and its main active ingredient Δ^9-tetrahydrocannabinol (THC) produce robust deficits for a time period after acute ingestion. However, the chronic effects of ► Cannabis on episodic memory appear more subtle and findings have been inconsistent. Opiates such as ► morphine and ► methadone can also exert detrimental effects on tasks tapping episodic memory, especially at high doses. Although tolerance rapidly develops in daily users, subtle episodic memory impairments have been observed following a daily dose or an increase in the prescribed dose.

Psychopharmacology of Nondeclarative Memory

Nondeclarative memory is an umbrella term, which covers our memory capacities that support skill and habit learning, perceptual priming, and other forms of behavior, which are expressed through performance rather than recollection. ► Procedural memory, such as knowing

how to ride a bicycle, is expressed indirectly through performance in riding a bicycle; perceptual representation memory, which underpins our ability to recognize words and other perceptual skills, is accessed implicitly; conditioning is generally seen as another type of nondeclarative memory.

In contrast to episodic memory, procedural memory is largely, although not always, resistant to drug-induced impairments. Often, though a drug may alter performance on a procedural learning task by disrupting physical coordination or arousal, it does not generally disrupt memory for previously acquired motor skills. Simple procedural learning tasks such as pursuit rotor or mirror reading tasks show very similar effects of BZDs and SP with learning curves on the drug generally being parallel to those for placebo. However, more complex tasks reveal differences. For example, one interesting study used the same sequential reaction time task to compare diazepam-induced amnesia with organic amnesia. Procedural learning in this task was preserved following ► diazepam in the same way as it was preserved in organic amnesia. However, the expression of that knowledge (priming) was impaired in both types of amnesia when contextual support was limited. This impairment of contextual priming was clearly dose-related in the diazepam condition. There is also some evidence from a single study that acutely, ketamine may impair procedural learning on the same task. Overall, findings suggest that whether impaired procedural memory is observed depends on the complexity of the task itself as simpler tasks generally show no drug-induced impairment.

Although conditioning has been traditionally seen as a nondeclarative memory capacity, its categorization varies according to whether successful conditioning occurs with or without conscious awareness. There is evidence that diazepam prevents the acquisition of fear conditioning in humans. However, the locus of this effect seems to be due to impairments in forming associations between the conditioned and unconditioned stimuli rather than the consolidation of fear memory per se. Enhancement of extinction of conditioned learning has been seen with drugs like D-cycloserine, which acts as a partial agonist at central glutamatergic NMDA receptors. This in turn suggests that D-cyloserine may be a useful therapeutic aid to psychological treatments which aim to extinguish conditioned responses (e.g., cue exposure in anxiety disorders). It may also have the potential as an adjunct to exposure treatment of drug dependency, a disorder in which both declarative memory and nondeclarative memory are intrinsically involved.

Perceptual ► priming studies have produced an intriguing finding that one particular BZD (lorazepam) but not others produces impairments on tasks tapping perceptual priming such as word stem, word fragment, or picture completion. Task purity criticisms can be applied to some earlier studies on the grounds that explicit impairments contaminated the performance on the "implicit" task. However, these could not explain findings of several studies, which compared lorazepam with another drug (a different BZD or SP) and found that although each drug produced the same impairment on an explicit task, only lorazepam impaired the perceptual priming. The fact that one BZD and not others suppresses priming supports a distinction between a system mediating perceptual priming (such as Tulving and Schacter's perceptual representational system) and other memory systems. The mechanism of this apparently unique effect of lorazepam is not yet known. One could speculate that there is a second population of BZD receptors, perhaps concentrated in posterior cortical areas, to which lorazepam but not other BZDs bind. Sub-types of BZD receptors have been identified by microbiological studies, but their functional significance is not yet known.

Specificity of Pharmacological Effects on Declarative and Nondeclarative Memory

In terms of neurocognitive specificity, clearly no drug *only* affects memory. Many drugs affect arousal and mood, and many alter aspects of executive functions. Changes in these functions may indirectly produce performance changes on a long-term memory task. Similarly, there is the fuzzy issue of neuropharmacological specificity, as drugs have diffuse effects on the central nervous system and changes in one neurotransmitter system will impinge on others. For example, acetylcholine interacts with other neurotransmitters and especially with the amino acids, ► GABA, and ► glutamate, which control basal forebrain cholinergic neurons. Such neurotransmitter interactions may underpin the similarity of amnesic effects of some of the different pharmacological compounds we have considered here.

There is now substantial evidence that the amnesic effects of benzodiazepines are not simply by-products of their sedative effects. Amnesic and sedative effects are differentially affected by (1) reversal by either a BZD antagonist or a stimulant like ► amphetamine; (2) ► tolerance over repeated dosage; (3) different dosages of BZDs and (4) amnesic effects of BZDs are seen even when their sedative effects are matched with other centrally acting compounds. The ► attentional effects of BZDs are less consistent than their memory effects. There is some evidence from dual task studies that reduced attentional resources cannot account for the amnesic effects of BZDs. With SP, the specificity debate has focussed more

on the attentional effects of the drug. Studies generally suggest that sedation may contribute to SP performance impairments on memory tasks but does not account for amnesia. On the other hand, studies of ▶ acetylcholinesterase inhibitors in patients with AD suggest amelioration of attentional function – rather than memory – may be the main route for cognitive change. Terms like attention, ▶ executive function, and arousal are umbrella concepts, which cover a range of differing systems, processes, or functions. There may be separate mechanisms responsible for different aspects of attention and arousal and these may be mediated by different neurobiological substrates.

Even with relatively specific task manipulations, tasks do not invoke/tap memory systems in isolation, and memory systems themselves are interacting, with considerable overlap in the neural machinery they engage. Acutely, although ketamine, SP, and BZDs do not impair the maintenance of information in working memory, they can all impair the manipulation of information in working memory. This means that elaborative encoding of information into episodic memory will be compromised as a by-product of working memory changes.

Conclusions

To date, the vast majority of research has involved single doses of drugs and we know correspondingly less about chronic effects, which are more relevant clinically for individuals prescribed repeated doses for treatment or those who addictively self-administer drugs. Further, research to date has focused almost exclusively on retrospective memory (memory for the past) and neglected "▶ prospective memory" (PM) – remembering to do something in the future – even though PM failures are the most frequent cause of forgetting in daily life. Some novel work on alcohol suggests that it globally impairs PM regardless of the specific type of PM task. It also suggests that engaging in "episodic future thinking" – mentally projecting oneself into the future to pre-experience an event – may overcome the deficit induced by acute alcohol and even play a role therapeutically in the treatment of alcoholism.

Taken as a whole, psychopharmacological studies support a differentiation between declarative and nondeclarative memory, and within declarative memory, between episodic and semantic systems. However, nondeclarative memory processes, such as perceptual priming, often contribute to the performance on declarative memory tasks such as recognition of words or pictures. Though this framework has clear benefits in describing psychopharmacological findings, one should be cautious of over-emphasizing differences at the expense of commonalities and interactions between different memory systems.

Delayed Match-to-Sample Test

Synonyms
DMTS

Definition
In (variants of) this test, subjects are presented one or more stimuli to remember (spatial location, visual object, letter, etc.). These encoding stimuli are followed by a short delay, during which subjects have to maintain the stimuli "on-line." This delay is followed by a probe period, during which subjects reproduce the encoding stimuli (e.g., point to the spatial location), choose between two probe stimuli, or decide whether the probe stimulus was the same as one of the encoding stimuli. In some variants, intervening distractor stimuli are presented during the delay. In other "stimulus-reordering" versions, subjects

are required to reorder a sequence of letters presented to them during encoding. In these latter variants of the DMTS test, demands for executive components of working memory are increased.

Delayed (Non)Match-to-Sample Task

Definition

Derived from delayed-response principles, the delayed (non)match to sample task is a widely used test of working memory in animals. Typically, the animal is presented with a sample stimulus. After a short delay, the sample stimulus is shown again along with a novel alternative. In the nonmatching paradigm, the animal is rewarded for selecting the novel stimulus. In the matching paradigm, the animal is rewarded for selecting the sample stimulus thereby avoiding the novel stimulus. If different stimuli are used for every trial ("trial unique"), then the test specifically measures visual recognition memory. If the same stimuli are used on every trial ("trial nonunique"), then the test effectively measures the animal's ability to remember the most recent item. Delayed (non)matching tasks are considered tests of working memory because: (a) the information to be remembered on each trial is independent from the next and (b) the response is contingent upon the information that was presented at the beginning of the trial that must be discriminated from subsequently presented stimuli. Both rats and monkeys spontaneously select novel stimuli, thus the nonmatching version is usually preferred.

Delayed onset of action

Definition

According to the theory of delayed onset of action, the effects of antipsychotic or antidepressant drugs occur only after a delay of several weeks.

Current Concepts and State of Knowledge

The Concept

This chapter deals with the "delayed onset of action" hypothesis of ► antipsychotic and ► antidepressant drugs. This old theory states that antipsychotic or antidepressant drugs do not start to improve the symptoms immediately after administration, but that it rather takes several weeks until their effect sets in. It is shown that the "delayed onset of action" hypothesis is a myth and that the onset of action is early if not immediate. This article focuses on the evidence of ► antipsychotic drugs, but similar findings on ► antidepressants are briefly summarized at the end.

Historical Background

This theory probably emerged in the early 1970s, but there is no single author who could be quoted as its inventor and the statements in early textbooks were actually quite vague. For example, in 1969, Klein and Davis wrote in their seminal textbook: "Figs. 2–5 show that improvement takes place over long periods of time. In order to obtain maximum clinical effect, the patient must be treated with an adequate (antipsychotic) drug dose for an adequate time period" (Klein and Davis 1969). It then seems that the explanation of the effects of antipsychotic drugs by the ► depolarization block theory lent support to a delay of onset. The depolarization block theory was based on the studies on rats showing that antidopaminergic treatment leads to inactivation of dopamine firing and that it takes 3 weeks until the inactivation is in effect. This delay in the occurrence of the biological marker was thought to coincide with and explain the delay of onset of antipsychotic drug effects (Agid et al. 2003). Although the delay of onset of antipsychotic drug action had never been validated in clinical trials, it became widely recognized and was codified in many psychiatric textbooks (e.g., Gelder et al. 2000).

Refutation of the Delay of Onset of Action Hypothesis

Although the assumed delay of onset was a key concept in the mechanisms of action of antipsychotic drugs, it has only recently been systematically investigated. Two large, independent meta-analyses clearly refuted the theory (Agid et al. 2003; Leucht et al. 2005). A pivotal ► meta-analysis by Agid et al. (2003), based on 47 ► double-blind studies including 7,450 patients with schizophrenia, showed that the reduction of the overall ► positive

symptoms in the first 2 weeks was greater than that in the subsequent 2 weeks. Leucht et al. (2005) confirmed this finding using 1,708 original patient data from ▶ randomized controlled trials. In addition, they extended the analysis to 1 year and found that the largest part (68%) of the antipsychotic drug effect occurred in the first 4 weeks of treatment. Several subsequent analyses showed that the effects of antipsychotic drugs can be separated from that of placebo as early as within 24 h after the initiation of treatment (e.g., Kapur et al. 2005). In summary, these analyses clearly showed that the "delay of onset" was a myth, but that the onset of antipsychotic drug action rather sets in early.

Why Has the Delay of Onset Hypothesis Prevailed for such a Long Time?

There is an important distinction between a delay of "onset" and a delay of "development of full antipsychotic effects." While the recent studies have clearly refuted the concept of a delay of *onset* of drug action, it is very clear that it usually takes several weeks or even months until an antipsychotic drug develops its *full* effects or until a patient is in remission. It is likely that a confusion of these two concepts fueled the misunderstanding.

Consequences for the Understanding of the Mechanism of Action of Antipsychotic Drugs

The rejection of the delay of onset of action hypothesis has major implications for the explanation of the mechanism of action of antipsychotic drugs. The delay of onset of action suggested that the well-known effects of antipsychotic drugs on ▶ dopamine receptors are not directly responsible for the therapeutic effect, but rather postsynaptic mechanisms. As it is now clear that antipsychotic drugs start working without a delay, it is more likely that the blockade of dopamine receptors is also key in mediating the clinical response.

Does Early Improvement Predict Later Response?

The new "early onset of antipsychotic drug action" hypothesis also has major clinical implications. Due to a belief in the former theory of delay of onset, the treatment guidelines recommended to keep the patients for up to 6–8 weeks on the same drug before it should be considered ineffective and switched. As it is now clear that antipsychotic drugs can exert important effects in the first few weeks, it is possible that the degree of early improvement in 1 or 2 weeks predicts later treatment success. Already in the 1980s and 1990s, several studies showed that the degree of symptom reduction in 1 or 2 weeks strongly correlated with the degree of response after 4–8 weeks (e.g., Bartko et al. 1987). While these studies suggested that the degree of early improvement may be used as a predictor of later response, they were small and only correlational in design, that is, they did not come up with cutoffs of early improvement that could serve as predictors for later response or remission. A reliable measure such as a diagnostic test with high specificity, sensitivity, positive and negative predictive values is needed. Such a test would indicate whether a patient is an early improver or an early nonimprover, and would further predict whether a patient would develop a full response at later stages. Stimulated by the meta-analysis of Agid et al. (2003) several recent investigations have tried to develop such a test and usually based it on a minimum percentage reduction of the Brief Psychiatric Rating Scale (BPRS) or Positive and Negative Syndrome Scale (PANSS) total score in 1 or 2 weeks (e.g., Leucht et al. 2007). Although these analyses differed in populations (e.g., patients in registrational trials versus naturalistic settings), study duration (4–12 weeks), or definition of response (e.g., at least 20 or 50% BPRS/PANSS reduction or remission), they by and large found that minimal improvement (e.g., less than 25% BPRS/PANSS total reduction from baseline) in 1–2 weeks could serve as a predictor nonresponse at later time points (4–12 weeks).

In the Case of Nonresponse – Should Antipsychotic Drugs Be Switched Early On?

The fact that early improvement is a good predictor of later response suggests that the antipsychotic drug of early nonimprovers should be switched. But is this really true? It could also be that early nonimprovers have a poor outcome, irrespective of the antipsychotic drug used. It is necessary to find out whether an early switch to the antipsychotic drug really improves outcome from randomized studies in which early nonresponders are either switched to another antipsychotic or are kept on the same one. The first large double-blind study of this kind has been completed and it indeed showed that those patients who had not responded to 2-week treatment with ▶ risperidone were more likely to respond if they were switched to ▶ olanzapine than if they stayed on risperidone for another 10 weeks (Kinon et al. 2008). However, the gain was relatively small and the early nonimprovers never caught up with the early improvers, even if they were switched to olanzapine. As olanzapine and risperidone are both atypical antipsychotic drugs with similar receptor-binding profiles, studies on drugs with more different receptor-binding

profiles are now needed. Such studies could also investigate other strategies, for example, an early switch to the most efficacious antipsychotic drug ► clozapine, high dose strategies, or augmentation with other psychotropic compounds.

Delay of Onset of Antidepressants

As mentioned in the beginning of this article, the treatment of schizophrenia with antipsychotic drugs was used as an example, but there was also a delay of onset hypothesis in the treatment of depression which has recently been refuted. Taylor et al. (2006) published a meta-analysis of 28 randomized controlled trials including 5,872 participants and found that the effects of ► selective serotonin reuptake inhibitors (SSRIs) separated from those of placebo by the end of the first week of use and the rate of improvement decreased in the following 5 weeks. Szegedi et al. (2009) demonstrated in a large database of 6,562 patients from 41 randomized antidepressant drug trials that early improvement predicted later response with sufficiently good test values (Taylor et al. 2006; Szedegi et al. 2009).

Delay-Independent Deficit

Synonyms

Nonspecific memory impairment

Definition

In tests of working memory, the delay period is typically intermixed with short and long delays (~0–30 s) with long delays serving to increase the memory load of the task. Such tasks generally reveal a decline in performance accuracy as the delay interval between the sample and the choice phase is increased. The slope of the delay-performance curve (i.e., high accuracy at short delays and low accuracy at long delays) provides an index of the animals' rate of forgetting from working memory. Such delay-dependent gradients suggest that the disruptive effect of experimental or pharmacological treatments is attributable to a disturbance in the animal's working memory capacity. By contrast, a change in the slope of the curve that is *independent* of the delay whereby a decline in accurate performance is observed at the short "zero"-second delay as well as the long delays is generally interpreted as a nonspecific effect of attention. Thus, a delay-independent deficit suggests that the animals' failure to attend or encode the stimulus contributes to the overall memory deficit.

Definition

Delirium is a common and often serious neuropsychiatric complication in the management of medically ill patients. It is associated with increased morbidity and mortality, causing distress in patients, family members, and staff (Breitbart and Alici 2008). It is characterized by an abrupt onset of disturbances of consciousness, attention, cognition, and perception that fluctuate over the course of the day. It is a sign of significant physiological disturbance, usually involving multiple medical etiologies, including infection, organ failure, and adverse effects of medication (APA 1999, 2000).

The Diagnostic and Statistical Manual of Mental Disorders (APA 2000) outlines the diagnostic criteria for delirium as follow (► DSM):

1. Disturbance of consciousness with reduced ability to focus, sustain, or shift attention.
2. Change in cognition that is not better accounted by a preexisting, established, or evolving dementia or development of a perceptual disturbance.
3. Development of the disturbance over a short period of time, usually hours to days, and fluctuation of symptoms during the course of the day.
4. Evidence from the history, physical examination, or laboratory tests that delirium is a direct physiological consequence of a general medical condition, substance intoxication or withdrawal, use of a medication, or toxin exposure, or a combination of these factors.

Role of Pharmacotherapy

Delirium is a medical emergency that needs to be prevented, identified, and treated vigorously. It is one of the most prevalent neuropsychiatric disorders in inpatient settings. The prevalence of delirium at hospital admission ranges from 14 to 24%, and the incidence of delirium during hospitalization ranges from 6 to 56% among general hospital populations (APA 1999; Breitbart and Alici 2008). Old age is a well-known risk factor for the development of delirium likely associated with increasing severity of medical comorbidities, dementia, and physical frailty. Postoperative patients and cancer and AIDS patients are also at greater risk for delirium. The highest prevalence and incidence of delirium is reported in terminally ill patients, occurring in up to 85% of patients in the last weeks of life (Breitbart and Alici 2008; Casarett and Inouye 2001).

Delirium is a syndrome of generalized dysfunction in higher cortical cerebral processes. Despite many different etiologies, symptoms of delirium are largely stereotypical, with a set of core symptoms. It appears that this diversity of physiological disturbances translates into a common clinical expression that may relate to dysfunction of a final common neuroanatomical and/or neurochemical pathway (Trzepacz 2000). It has been postulated that the final common pathway involves the ► prefrontal cortex, posterior parietal cortex (PPC), temporo-occipital cortex, anteromedial thalamus, and right basal ganglia with an imbalance in the neurotransmitters ► acetylcholine and ► dopamine (Trzepacz 2000). The acetylcholine–dopamine hypothesis explains the efficacy of dopamine antagonists in the treatment of delirium by regulating the imbalance between cholinergic and dopaminergic activity while the underlying etiology is being treated. Many other neurotransmitter systems including the serotonergic, noradrenergic, opiatergic, glutamatergic, and histaminergic systems, may contribute to delirium as a syndrome (Trzepacz 2000).

The clinical features of delirium are numerous and include a variety of neuropsychiatric symptoms as outlined above. Main features of delirium include prodromal symptoms (e.g., restlessness, anxiety, sleep disturbances, and irritability); rapidly fluctuating course; abrupt onset of symptoms; reduced attention (e.g., distractibility); altered level of alertness; increased or decreased psychomotor activity; disturbance of sleep–wake cycle; affective symptoms (e.g., emotional lability, depressed mood, anger, or euphoria); perceptual disturbances (e.g., misperceptions, illusions, and ► hallucinations); ► delusions; disorganized thinking; incoherent speech; and cognitive impairment (Breitbart and Friedlander 2006). On the basis of the psychomotor behavior and arousal levels, two subtypes of delirium have been described, including the hyperactive (or agitated, or hyperalert) subtype and the hypoactive (or lethargic, hypoalert, or hypoaroused) (► hyperactive

delirium; ▶ hypoactive delirium) subtype. A third subtype, namely the mixed subtype has been proposed with alternating features of each. Both hypoactive and hyperactive subtypes of delirium have been shown to cause distress in patients, family members, clinicians, and staff. There is evidence suggesting that the subtypes of delirium may be related to different causes, and may have different treatment responses. A ▶ randomized controlled trial of ▶ haloperidol and ▶ chlorpromazine found that both medications were equally effective in hypoactive and hyperactive subtypes of delirium. However, in an open label trial, the hypoactive subtype was associated with poorer treatment response to ▶ olanzapine. The hypoactive subtype of delirium is associated with higher mortality risk when compared with hyperactive delirium (APA 1999; Breitbart and Alici 2008; Breitbart and Friedlander 2006).

Many of the clinical features of delirium can also be associated with other psychiatric disorders, such as ▶ depression, ▶ mania, ▶ panic disorder, ▶ psychosis, and ▶ dementia. Acute onset, fluctuating course, disturbances of consciousness, and cognition in the presence of one or more etiological causes are characteristic in the diagnosis of delirium. The most challenging differential diagnostic issue is whether the patient has delirium or dementia. The temporal onset of symptoms in dementia is more subacute and chronically progressive. In delirium superimposed on an underlying dementia, such as in the case of an elderly patient, an AIDS patient, or a patient with a paraneoplastic syndrome, differential diagnosis becomes even more challenging. Delirium, unlike dementia, is by definition reversible, although in terminally ill patients, delirium may be irreversible (APA 1999; Breitbart and Friedlander 2006).

Clinically, the diagnostic gold standard for delirium is the clinician's assessment utilizing the DSM-IV-TR criteria as outlined above (APA 1999, 2000). Several delirium screening and evaluation tools have been developed to maximize diagnostic precision for clinical and research purposes and to assess delirium severity including the ▶ Delirium Rating Scale-Revised 98 (DRS-R-98), the ▶ Confusion Assessment Method (CAM), and the ▶ Memorial Delirium Assessment Scale (MDAS) (Breitbart and Alici 2008).

The standard approach to managing delirium includes a search for underlying causes, correction of those factors, and management of the symptoms of delirium. Treatment of the symptoms of delirium should be initiated before, or in concert with, a diagnostic assessment of the etiologies to minimize distress to patients, staff, and family members (APA 1999).

Nonpharmacologic and supportive therapies play an essential role in the treatment of delirium. Nonpharmacologic interventions have been shown to result in faster improvement of delirium symptoms and slower deterioration in cognition (Casarett and Inouye 2006). However, these interventions have not been found to have any effects on mortality or health-related quality of life when compared with usual care (Breitbart and Alici 2008). Nonpharmacologic interventions include oxygen delivery, fluid and electrolyte administration, ensuring bowel and bladder function, nutrition, mobilization, pain treatment, frequent orientation, use of visual and hearing aids, and environmental modifications (e.g., quiet, well-lit room with familiar objects, a visible clock or calendar) to enhance a sense of familiarity (Casarett and Inouye 2006). One-to-one nursing may be necessary for observation of agitated patients with delirium. Physical restraints should be avoided, when possible. The use of physical restraints has been identified as an independent risk factor for delirium persistence at the time of hospital discharge (Breitbart and Alici 2008).

Nonpharmacologic interventions and supportive measures alone are often not effective in controlling the symptoms of delirium. Symptomatic treatment with psychotropic medications is often essential to control the symptoms of delirium, although no medications have been approved by Food and Drug Administration (FDA) for the treatment of delirium.

Antipsychotic Medications

The American Psychiatric Association (APA) practice guidelines provide directions for the use of ▶ antipsychotics in the treatment of delirium and growing evidence supports their use (APA 1999) (Table 1).

Haloperidol (a "typical" antipsychotic) is often the gold-standard medication for the treatment of delirium, due to its efficacy and safety (e.g., few anticholinergic effects, lack of active metabolites, and availability in different routes of administration). ▶ Haloperidol in low doses (1–3 mg per day) is usually effective in targeting agitation and psychotic symptoms. In general, doses of haloperidol do not exceed 20 mg in a 24-h period; however, some clinicians advocate higher doses in selected cases. In severe agitation related to delirium, clinicians may add lorazepam to haloperidol. This combination may be more effective in rapidly sedating patients and may help minimize any ▶ extrapyramidal adverse effects of haloperidol (APA 1999; Breitbart and Alici 2008).

Oral or intravenous (IV) ▶ chlorpromazine is considered to be an effective alternative to haloperidol (with or without ▶ lorazepam) when increased sedation is required, especially in the intensive care unit (ICU) setting where close blood pressure monitoring is feasible, and for

Delirium. Table 1. Antipsychotic medications in the treatment of delirium.

Medication	Dose range	Routes of administration	Side effects	Comments
Typical antipsychotics				
Haloperidol	0.5–2 mg every 2–12 h	PO, IV, IM, SC	Extrapyramidal adverse effects can occur at higher doses. Monitor QT interval on EKG	Gold-standard treatment for delirium
Chlorpromazine	12.5–50 mg every 4–6 h	PO, IV, IM, SC, PR	More sedating and anticholinergic when compared with haloperidol	May be preferred in agitated patients due to its sedative effect
Atypical antipsychotics				
Olanzapine	2.5–5 mg every 12–24 h	PO*, IM	Sedation is the main dose-limiting side effect in short-term use	Older age, preexisting dementia, and hypoactive subtype of delirium have been associated with poor response
Risperidone	0.25–1 mg every 12–24 h	PO*	Extrapyramidal adverse effects can occur with doses >6 mg/day. Orthostatic hypotension	Clinical experience suggests better results in patients with hypoactive delirium
Quetiapine	12.5–100 mg every 12–24 h	PO	Sedation, orthostatic hypotension	Sedating effects may be helpful in patients with sleep–wake cycle disturbance
Ziprasidone	10–40 mg every 12–24 h	PO, IM	Monitor QT interval on EKG	Evidence is limited to case reports
Aripiprazole	5–30 mg every 24 h	PO*, IM	Monitor for akathisia	Evidence is limited to case reports and case series

*Risperidone, olanzapine, and aripiprazole are available in orally disintegrating tablets.

severe agitation in terminally ill patients to decrease distress for the patient, family, and staff. It is important to monitor chlorpromazine's anticholinergic and hypotensive side effects, particularly in elderly patients (Breitbart and Alici 2008).

A systematic review of the pharmacologic therapies for delirium in the terminally ill concluded that haloperidol was the most suitable medication for the treatment of patients with delirium near the end of life, with chlorpromazine being an acceptable alternative (Jackson and Lipman 2006).

FDA has issued a warning against the risk of QT interval prolongation and torsades de pointes with IV haloperidol, thus monitoring QT intervals daily among medically ill patients receiving IV haloperidol has become the standard clinical practice.

► Atypical antipsychotic agents (i.e., risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole) are increasingly used in the treatment of delirium due to lower risk of extrapyramidal adverse effects (Breitbart and Friedlander 2006).

A Cochrane review, comparing the efficacy and the incidence of adverse effects between haloperidol and atypical antipsychotics, concluded that, like haloperidol, selected newer atypical antipsychotics (risperidone, olanzapine) were effective in managing delirium. Haloperidol doses greater than 4.5 mg/day were more likely to result in increased rates of extrapyramidal symptoms when compared with the atypical antipsychotics, but low-dose haloperidol (i.e., less than 3.5 mg/day) did not result in a greater frequency of extrapyramidal adverse effects (Lonergan et al. 2007).

The APA guidelines for the treatment of delirium recommend use of low-dose haloperidol (i.e., 1–2 mg po every 4 h as needed or 0.25–0.5 mg po every 4 h for the elderly) as the treatment of choice in cases where medications are necessary (APA 1999).

On the basis of the existing literature, ► risperidone may be used in the treatment of delirium, starting at doses ranging from 0.25 to 1 mg and titrated up as necessary with particular attention to the risk EPS, orthostatic hypotension, and sedation at higher doses. ► Olanzapine can be started between 2.5 and 5 mg nightly and titrated up with the sedation being the major limiting factor, which may be favorable in the treatment of hyperactive delirium. The current literature on the use of ► quetiapine suggests a starting dose of 25–50 mg and a titration up to 100–200 mg a day (usually at twice-daily divided doses). Sedation and orthostatic hypotension are the main dose-limiting factors. Case reports suggest a starting dose of 10–15 mg daily for ► aripiprazole, with a maximum dose of 30 mg daily (Breitbart and Alici 2008; Breitbart and Friedlander 2006).

Despite the availability of intramuscular formulations of olanzapine, aripiprazole, and ziprasidone, none of these medications have been studied in the treatment of delirium.

Important considerations in starting treatment with any antipsychotic for delirium may include EPS risk, sedation, ► anticholinergic side effects, cardiac arrhythmias, and possible drug–drug interactions. The FDA has issued a "black box" warning of increased risk of death associated with the use of typical and atypical antipsychotics in elderly patients with dementia-related psychoses (Breitbart and Alici 2008). A retrospective study comparing the mortality risk among elderly patients with delirium who were treated with antipsychotics to those who did not receive antipsychotics did not find an increased risk of mortality with the use of antipsychotics in this patient population (Elie et al. 2009).

Psychostimulants

Some clinicians have suggested that the hypoactive subtype of delirium may respond to ► psychostimulants such as ► methylphenidate, or combinations of antipsychotics and psychostimulants or antipsychotics and wakefulness agents such as modafinil (Breitbart and Alici 2008). However, there have been no randomized controlled trials supporting the use of psychostimulants in the treatment of delirium. The risks of precipitating agitation and exacerbating psychotic symptoms should be carefully evaluated when psychostimulants are considered in the treatment of delirium.

Cholinesterase Inhibitors

Impaired cholinergic function has been implicated as one of the final common pathways in the neuropathogenesis of delirium (Trzepacz 2006). Despite case reports of beneficial effects of ► donepezil and ► rivastigmine in the treatment of delirium, a Cochrane review concluded that there is currently no evidence from controlled trials supporting the use of ► cholinesterase inhibitors in the treatment of delirium (Breitbart and Alici 2008).

Dexmedetomidine

Dexmedetomidine, an alpha-2-adrenergic agonist, is used in the ICUs for its central sedative effects through inhibition of noradrenergic cortex activation (Riker et al. 2009). The use of dexmedetomidine in the treatment of delirium among mechanically ventilated ICU patients has been associated with an increased number of delirium-free days when compared with lorazepam-treated patients in a randomized controlled trial (Lonergan et al. 2009). Dexmedetomidine has also been associated with a lower incidence of delirium when compared with ► midazolam among ICU patients (Riker et al. 2009). However, the expense of dexmedetomidine treatment limits its routine use in ICU patients despite encouraging results with this agent.

Benzodiazepines

Benzodiazepines are commonly used in the treatment and prevention of ► alcohol-withdrawal delirium. A systematic review of the use of ► benzodiazepines in the treatment of nonalcohol-withdrawal delirium has concluded that there are no controlled trials to support the use of benzodiazepines, and a controlled trial comparing the effectiveness of lorazepam, haloperidol, and chlorpromazine has shown increased confusion associated with the use of lorazepam among HIV-patients with delirium.

Prevention of Delirium

Several researchers have studied both pharmacologic and nonpharmacologic interventions in the prevention of delirium among older patient populations, particularly in surgical settings (Breitbart and Alici 2008). Antipsychotic medications (i.e., haloperidol) and cholinesterase inhibitors (donepezil and rivastigmine) have been studied in randomized controlled trials for their effectiveness in the prevention of postoperative delirium. Both groups of medications have failed to reduce the incidence of delirium in patients undergoing elective cardiac or joint replacement surgery (Breitbart and Alici 2008). Geriatric consultations and nonpharmacologic interventions such as a multicomponent intervention program have reported reduced number and duration of episodes of delirium among hospitalized older patients. However, a systematic review of all the existing delirium-prevention studies concluded that the current evidence on effectiveness of

interventions to prevent delirium was limited (Breitbart and Alici 2008).

Conclusion

Clinicians commonly encounter delirium as a major complication of medical illness and its treatments, particularly among hospitalized patients. Proper assessment, diagnosis, and management of delirium are essential in improving quality of life and minimizing morbidity in the medically ill.

Delirium Tremens

Definition

Delirium tremens is the most severe phase of alcohol withdrawal and occurs in individuals with a history of constant, long-term alcohol intake. Five percent of cases of acute ethanol withdrawal progress to delirium tremens. Main symptoms are disorientation, confusion and agitation, and signs of severe autonomic instability (fever, tachycardia, hypertension). It commonly includes intense visual hallucinations. Delirium tremens often also includes symptoms of anxiety and paranoia. If untreated, mortality ranges up to 35%.

Synonyms

DRS

Definition

The DRS is a numerical rating scale that specifically integrates DSM-III-R diagnostic criteria for delirium. It is a 10-item scale, with items scored from 0 to 3 or 0 to 4 in the following domains: (1) temporal onset, (2) perceptual disturbance, (3) hallucinations, (4) delusions, (5) psychomotor behavior, (6) cognitive status, (7) physical disorder, (8) sleep–wake cycle disturbance, (9) lability of mood, and (10) variability of symptoms. A score of 12 or greater is diagnostic of delirium. DRS-R-98 is the revised version of the DRS. The summation of the first 13 item scores allows for a total severity score (range 0–39), while the last three (temporal onset and fluctuation of symptoms, and the presence of a physical disorder) can be exclusively used for diagnostic purposes. It includes more items than the DRS and is designed for phenomenologic and treatment research although it may be used clinically. The DRS-R-98 is a valid, sensitive, and reliable instrument for rating delirium severity.

Delta-Receptor

Definition

The term δ-opioid peptide receptor represents the ▶ G-protein coupled receptor protein that responds

selectively to a group of largely experimental opioid drugs and endogenous opioid peptides. It is usually named the δ-receptor or DOR. It is homologous with the MOR receptor and is expressed in areas of the nervous system that moderately mediate analgesia with a side-effect profile distinct from μ-opioids. The DOR receptor protein is produced by a single gene. When activated, the DOR receptor predominantly transduces cellular actions via inhibitory G-proteins. The electrophysiological consequences of DOR receptor activation are usually inhibitory.

Definition

Paranoia/paranoid psychosis was renamed by Winokur (1977) as delusional disorder. Different forms of the disorder have been well described since the early nineteenth century (Grover et al. 2006). Delusional disorder is characterized by the presence of one or more delusions, which are not bizarre. These delusions may occur in real life and last at least 1 month according to the fourth Edition of the Diagnostic and Statistic Manual (► DSM-IV) of Mental Disorders and at least 3 month according to the Tenth Revision of International Classification of Diseases and Related Health Problems (ICD-10) (American Psychiatric Association 2005). Bizarre and nonbizarre delusions may be difficult to differentiate. However, delusions of control, thought broadcasting, thought insertion, and thought withdrawal are described as bizarre delusions, while persecutory, somatic, grandiose, and religious delusions, as well as most delusions of jealousy are described as nonbizarre. Examples of nonbizarre delusions include false beliefs of being followed or loved, of having special abilities, power or wealth, etc.

Delusional disorder can be diagnosed if diagnostic criteria for ► schizophrenic disorder have never been met and organic mental disorders and psychoactive/drug-induced psychotic disorders can be excluded. Delusions are the leading symptoms of this disorder even if some hallucinations are present. Patients suffering from delusional disorder may have well-preserved social and work functions in spite of complete or almost complete lack of insight.

Role of Pharmacotherapy

Phenomenology of Delusional Disorders

Delusional disorder is a rare condition, the lifetime morbidity risk is estimated to be less than 0.2%, the annual incidence is 1–3 new cases per 100,000 persons. The types of delusional disorder are defined based on the predominant delusional theme (Sadock and Sadock 2003). They are:

Erotomanic Type: having a delusion of a secret lover; the "lover" is often a famous person, a celebrity. The person with this type of delusional disorder may or may not contact the person, who is object of the delusion. The characteristics of this disorder have been excellently described by de Clerambault (1921): "Fundamental postulate: *It is the Object who began it and who loves the most or is the only one to love.* (N.B.: Object usually of high birth, classic notion." Some of the derived themes are: "The Object cannot achieve happiness without the suitor. . . . The Object is free. His marriage is invalid."

Grandiose Type: having delusion/s of one's own extreme greatness, goodness, knowledge, power, and/or wealth, having special relationship to famous persons, having famous ancestors.

Jealous Type: having a delusion of unfaithfulness of the spouse/sexual partner. It includes accusations of infidelity/testing the fidelity, searches for evidence

of infidelity, questioning/interrogation of the partner, and also stalking. As Shakespeare described in his play "Othello," delusions of jealousy can be very dangerous and result in homicide and suicide.

Persecutory Type: having a delusion of persecution – it is one of the most known delusional disorders. Being followed by the police, Mafia, FBI, KGB, etc., are frequent contents of persecutory delusions.

Somatic Type: having a delusion of somatic disorder/pathology, such as Ekbom syndrome (delusional parasitosis), which is characterized by delusions about the skin being infected (e.g., the skin is infected with parasites, "small bugs"). Some patients with Ekbom syndrome may have unusual delusions, which may qualify for bizarre delusions, e.g., claiming that invisible "small houses" are in the skin. Another example is koro, which is characterized by delusions of penis shrinkage and retraction into the body or a delusion that the genitals have been stolen. Koro has been more frequently reported from Asia, but also described internationally for hundreds of years. Somatic defects may lead these patients to plastic surgeons. Some patients claim having a specific disease, e.g., AIDS in spite of the fact having negative laboratory findings. The delusions (e.g., the patient may claim that the laboratory values were falsified) differentiate it from hypochondriasis. Current diagnostic systems classify individuals with dysmorphic delusions into two groups: delusional body dysmorphic disorder and delusional disorder, somatic type. The differentiation may be difficult: a good example is the delusional complaint about ugliness.

Mixed Type: persons have more than one delusional theme.

Religious delusions are not included in the diagnostic systems as a type of delusional disorder, but they are frequent in some parts of the world (e.g., in the city of Jerusalem) and their differential diagnosis may be rather difficult. It can be part of ▶ schizophrenia, manic episode of ▶ bipolar disorder, delusional disorder, or of other psychotic disorder, however it may be a shared belief of a religious community. The consensus of the given community can help in understanding the difference between their religious beliefs, practices, and delusions.

Querulous paranoia has rarely been reported from some parts of the world (e.g., China), which may have been related to the underdetecting and underreporting of this disorder. Querulous paranoia has practically disappeared from the psychiatric literature; however, it seems to be flourishing in modern complaints organizations and the courts (Lester et al. 2004). Thus, social and cultural factors have a major influence on the detection and diagnosis of some forms of delusional disorders.

Delusion of reference is often part of the above mentioned types of delusional disorder. Delusion of reference is characterized by false beliefs about remarks, events, or objects unrelated to the person by giving them person related meaning and significance. Mistrust and hypersensitive personality are typical features of the syndrome.

Cotard delusion or Cotard's syndrome, is also known as nihilistic or negation delusion. Patients may claim having no arms or legs, in severe cases may even deny to exist. This delusion is part of other psychiatric disorders, such as schizophrenia or most often of severe (melancholic) depression.

Genealogical delusions are characterized by false beliefs about the descent of a person through an aristocratic or famous ancestral line. Genealogical delusions are part of other psychiatric disorders and interestingly the theme of the delusions changes over time, e.g., nowadays no patient claims being related to the Habsburg emperors.

Shared paranoid disorder (also known as shared psychotic disorder, induced psychotic disorder, folie á deux, and double insanity) is characterized by the transfer of delusions from one person to the other. They "share" the same false beliefs. Persons involved are close to each other, mostly have lived together for a long time. Shared paranoid disorder is considered to be a separate psychiatric disorder; it is not included in the group of delusional disorders.

The aetiology of delusional disorder is not known. Most probably it includes different conditions which share the presence of nonbizarre delusions; however, the available literature indicates substantial heterogeneity of this diagnostic category. Neurobiological and neuropsychological correlates of delusions suggest dysfunctions of the prefrontal, limbic, and subcortical regions, however further studies are needed (Kunert et al. 2007). Toxic and organic origin of the disorder has been repeatedly described in the literature. Delusions of patients with ▶ organic brain syndromes are looser and simpler, and often temporary. Patients with complex and systematized delusions showed only slight cognitive impairment, which may indicate that largely intact cognitive functions are an important prerequisite for elaborate delusional processing (Kunert et al. 2007).

The female:male ratio in delusional disorder is around 3:1. Recent studies found only a slightly increased prevalence in females, and could not confirm the 3:1 ratio. The grandiose type affects almost only men, while the erotomanic type is more frequent in women. The most frequently encountered type is the persecutory type, followed by the somatic type and jealous type. The age at onset is around 40 years, however, there are differences described according

to the type of delusional disorder, the oldest age at onset being associated with the persecutory type, and the youngest with the somatic type (Yamada et al. 1998). The onset is often insidious. Key experiences may facilitate the development of this disorder. Delusions may have an interpretative character related to the key experience – in this case the disorder starts with a real event/sensation followed by delusional interpretation and an uncontrollable drive to relate everything to himself. Other delusions, (e.g., most erotomanic delusions) are autonomous, not related to any experience.

Treatment

Delusional disorders are difficult to treat; to our knowledge no drug has been approved for its treatment until April 2009, when this chapter was written. Publications about the pharmacological treatment of delusional disorders are focusing on the use, actually on the ► off-label use, of ► antipsychotic drugs. The off-label status of antipsychotics in delusional disorders is a very severe limitation in prescribing them with this indication. Before considering pharmacotherapy the diagnosis has to be confirmed, other disorders and conditions that may cause delusions have to be excluded, such as schizophrenic disorder and organic brain syndromes. It may be difficult to differentiate between delusions/paranoid development and inappropriately rigid, unwavering demands to receive that which is due to us, whether such action is practical or not and leads to catastrophic consequences or not (e.g., the case of Michael Kohlhaas as described in the novel of Heinrich von Kleist).

The treating personnel need some training in psychiatry. Two major problems may arise with untrained staff members: (1) arguing with the patient about the delusions, trying to convince him about the unreality and senselessness of his delusions; (2) submission to the delusions, deal with delusions as with part of reality. In the first case the patient may leave the treatment immediately, in the second case the patient sooner or later will realize that the physician (or other staff member) is lying. While most patients with delusional disorder are treated as outpatients, in case of danger to himself or to others (see Othello syndrome above) urgent and even involuntary hospitalization is indicated. Due to lack of insight, which is a core feature of delusional disorder, patients do not seek psychiatric treatment. With somatic type of delusional disorder patients may turn to other specialists, such as dermatologists in the case of Ekbom syndrome, which gives the opportunity to provide these patients with appropriate treatment. Well-organized consultation – liaison psychiatric services could improve psychiatric treatment, including the treatment of these patients.

Since we are dealing with a rare disorder, which even if diagnosed is still rarely treated and difficult to treat and there is no approved drug for its treatment, it is not surprising that there is a dearth of strong evidence-based data. However, the available data support the usefulness of both first and second generation antipsychotic drugs (Smith and Buckley 2006) antipsychotic drugs, ► first-generation antipsychotics, and ► second and third generation antipsychotics. Early publications on antipsychotic treatment of delusional disorders focused on the efficacy of ► pimozide, a first generation antipsychotic drug. This finding supported the ► dopamine hypothesis of delusions. The use of pimozide significantly decreased partly because of the increasing use of second generation antipsychotics and partly because of safety concerns (ECG changes) with pimozide. Among the second generation antipsychotics, most experience in the treatment of delusional disorders is with ► risperidone and ► olanzapine (Freudenmann and Lepping 2008). The reported full or partial remission rates were high, around 70%. It is important to note that the doses used were lower than those used in schizophrenia. To our knowledge there are no dose-response data for any antipsychotic drug in the treatment of delusional disorder. Treatment data on one type of delusional disorder – such as delusional parasitosis – may not be generalized to other types of delusional disorders. Lack of treatment compliance is a major obstacle in the treatment of delusional disorders. Adherence to treatment in schizophrenia seems to be higher with second generation antipsychotics. Long acting intramuscular injection formulations of first generation antipsychotics and the availability of choices and formulations (liquid, dissolvable, acute intramuscular, and long-acting intramuscular) with second generation antipsychotics may offer an opportunity to improve treatment adherence in patients with delusional disorder. The efficacy, safety, and tolerability, as well as the advantages and the limitations of antipsychotic drugs are described in the other chapters of this book on ► antipsychotic drugs, ► first generation antipsychotics, and ► second and third generation antipsychotics.

Pharmacotherapy of delusional disorders needs major development, since the available options have very limited value.

Delusions

Definition

Delusions are false beliefs that are held with complete conviction, unaffected by clear evidence to the contrary and implausible or bizarre. For a belief to be considered a delusion, it should additionally not be shared by other members of the culture from which the individual who holds it originates.

Dementia

Definition

Dementia is the significant loss of intellectual abilities such as memory capacity, severe enough to interfere with social or occupational functioning. Criteria for the diagnosis of dementia include impairment of attention, orientation, memory, judgment, language, motor and spatial skills, and function. It often includes disturbances in many cognitive domains including executive function (decision making), language, object recognition, and spatial navigation. By definition, dementia is not due to major depression or schizophrenia.

Definition

Amnestic disorders in general are characterized by memory impairment based on the inability to learn new information or recall previously learned information or past events, which causes marked impairment in social or occupational functioning. Dementia (from Latin, de- "apart, away" + mens- "mind") is a syndrome in which multiple cognitive deficits develop that include memory impairment, as well as impairment of attention, orientation, judgment, language, motor and spatial skills, or executive functioning. In addition to cognitive deficits, patients present behavioral and psychological signs and symptoms of dementia (► BPSD), as well as impairments of functional, instrumental, and social activities of daily living. Patients clearly display a decline from a previous higher level of functioning.

Role of Pharmacotherapy

Dementia may be due to the direct physiological effects of a general medical condition, the persisting effects of a certain substance or may have multiple etiologies (Table 1).

Dementia of the ► Alzheimer's type (DAT) is the most frequent type of dementia, accounting for 60% of cases. The prevalence of DAT has been estimated at about 10% among people aged 65 years or more, and 40% among people aged 85 or more. DAT is by its prevalence and nature an important burden on the life of patients, their immediate family, and caretakers. This essay will, therefore, mainly focus on the pharmacological treatment options for DAT.

Currently, several symptomatic treatment options are available for DAT in routine clinical practice. While not healing the disease, symptomatic treatment may contribute during a limited time period to slowing down the evolution of the symptoms. The mode of action is mainly based on ► neurotransmitter (Neurotransmitter synthesis, turnover, and uptake) replacement therapy. Given the cholinergic deficit typical of DAT, current drugs are based on acetylcholine replacement by inhibition of the catalytic enzyme ► acetylcholinesterase (AChE) (► Acetylcholinesterase inhibitors as cognitive enhancers). Though mainly aiming at improvement of cognitive function, these compounds were also shown to positively affect activities of daily living and BPSD. Until now, five cholinesterase inhibitors (Acetylcholinesterase inhibitors as cognitive enhancers) have been marketed: tacrine, metrifonate, donepezil, rivastigmine and galantamine. Currently, four are still available (not metrifonate), and tacrine sees its use steadily decreasing because of important cholinergic side effects, mainly of gastrointestinal origin, and the complex multiple daily dosing. ► Donepezil, ► rivastigmine, and ► galantamine currently form the cornerstone of

symptomatic treatment of DAT. Donepezil was the second cholinesterase inhibitor which became available for the symptomatic treatment of DAT. It is a noncompetitive, reversible AChE inhibitor (► Acetylcholinesterase inhibitors as cognitive enhancers) with a high central versus peripheral cholinomimetic specificity and a long duration of inhibitory action. In large-scale clinical studies it was shown to be a well-tolerated drug that causes improvement of cognitive and global function in mild to moderate DAT. Rivastigmine is a noncompetitive, pseudoirreversible AChE and butyrylcholinesterase inhibitor indicated for treatment of mild to moderately severe DAT. It has a long-lasting inhibitory effect, and besides being brain-selective, rivastigmine acts brain region-specific being most effective in hippocampus and cortex, which are in the main associated with cholinergic dysfunction in DAT. Rivastigmine significantly ameliorates cognitive function, activities of daily living and disease severity. Galantamine enhances central cholinergic activity through a dual mode of action. Besides its action as a brain-selective, competitive, reversible AChE inhibitor, galantamine is an ► allosteric potentiating ligand of the nicotinic acetylcholine receptor (nAChR). Clinical efficacy if this compound is based on improvement of cognitive function, as well as functional and behavioral symptoms of mild to moderate DAT.

Although the second-generation AChE inhibitors have a better safety and tolerability profile compared with the first-generation compounds, e.g., tacrine, on an average, approximately 75% of participants randomized to active AChE inhibitor treatment reported at least one adverse effect. The most frequently reported adverse events are of gastrointestinal origin, including nausea, diarrhea, vomiting, weight loss, as well as dizziness. For memantine, the most frequently reported adverse events in placebo-controlled trials included agitation, falls, dizziness, accidental injury, influenza-like symptoms, headache and diarrhea.

Although a substantial relation has not been established between sex and responsiveness to the second-generation cholinesterase inhibitors, some indications toward sexual dimorphism in response to these agents warrant further investigation, especially in regard to its role in the development of novel DAT therapies.

In focusing on DAT, it is useful to note that conclusions drawn from DAT studies, will frequently apply to other dementia entities. Cerebrovascular dementia consists mainly of patients with DAT and notable concomitant cerebrovascular disease (mixed dementia or DAT with cerebrovascular disease). Cerebrovascular disease is now believed to represent a continuum of relevance for DAT as well as cerebrovascular dementia. Lewy body dementia is frequently noted to be accompanied by DAT neuropathology and is sometimes seen to be a Lewy body variant of DAT. These latter clinical entities have also been shown to benefit – at least to a certain degree – from treatment with AChE inhibitors as has also been demonstrated for Parkinson's disease dementia. Nevertheless, additional clinical evidence is required since studies have reported contradictory efficacy levels. Cholinesterase inhibitors and memantine produce (although sometimes limited) benefits in cognition, including executive functioning, but often not in activities of daily living, as is the case in DAT.

Besides neurotransmitter replacement therapy, several routinely available treatment strategies for DAT are based on knowledge of underlying pathophysiological mechanisms. Their potential disease modifying efficacy is, however, in many cases still a matter of debate.

The therapeutic use of enzyme inhibitors in treatment of neurodegenerative diseases has its origin in the anti-Parkinson action of the selective, irreversible monoamine oxidase (MAO) B inhibitor, ► selegiline, thus preventing the breakdown of monoamine neurotransmitters and thereby increasing their availability. Clinical evidence for therapeutic efficacy in DAT is controversial with few studies showing improvement of cognitive function, mood, and behavior. Recently, selegiline was demonstrated to have a synergistic cognition-improving effect with donepezil, whereby selegiline potentiates the effect of donepezil on the cognitive impairment presumably through both the cholinergic and dopaminergic systems.

Dysfunction of the excitatory glutamatergic neurotransmitter system has been implicated in neurodegenerative disorders, including DAT. Under physiological conditions, *N*-methyl-D-aspartic acid ► (NMDA) receptors are blocked by Mg^{2+} in the absence of their ligand, glutamate. Excitatory toxicity is based on the permanent activation of NMDA receptors by continuous presynaptic release of low glutamate levels, and subsequent toxic Ca^{2+} influx. ► Memantine is a noncompetitive, voltage-dependent NMDA receptor antagonist that blocks the ion channel in the presence of sustained release of low glutamate quanta, thereby inhibiting a toxic Ca^{2+} influx. Symptomatic efficacy of memantine treatment is presumably based on the brief removal of memantine from the channel in case of transient high glutamate release into the synaptic cleft during learning and memory processes. Memantine is indicated for treatment of moderate-to-severe DAT, where it improves cognitive, functional and behavioral parameters. Given the fact that based on its mode-of-action, memantine may prevent glutamatergic excitotoxicity, it has been proposed as a neuroprotective agent with disease-modifying potential.

Although originally developed as symptomatic treatment agents, neuroprotective effects have been allotted to the cholinesterase inhibitors as well. For donepezil this is presumably based on the inhibition of AChE-induced ► amyloid-β (Aβ) aggregation and fibrillogenesis, since it is the only AChE inhibitor currently marketed that targets both the catalytic site of the enzyme and the peripheral anionic site, with latter triggering amyloid-β fibril formation. Galantamine's dual mode of action is supposed to underlie its neuroprotective capacities. Galantamine distinctively operates upon the α4β2 nAChR subtype, which upon stimulation inflicts neuroprotective effects. In addition, neuroprotective efficacy of both donepezil and galantamine seems to be linked to the α7 nAChR. Rivastigmine favorably modulates the human cellular response to injury through potentiating of heat–shock transcriptor factor-1, which elevates heat–shock protein 70 levels leading to cell protection. Advanced studies are required to further scrutinize action mechanisms underlying presumed neuroprotective mechanisms of cholinesterase inhibitors.

Based on the cholinergic hypothesis of DAT, the use of nicotinic agonists has incited a large research endeavor. There are significant numbers of nicotinic receptors within the brain, both pre- and postsynaptically, that are known to be important in learning and memory. DAT patients exhibit a loss of some subtypes of nicotinic receptors and the degree of loss correlates with the severity of the symptoms. There is a large body of evidence to indicate that nicotinic drugs indeed affect learning and memory. ► Nicotine and other ► nicotinic agonists can improve cognitive and psychomotor function, whereas nicotinic antagonists lead to cognitive impairment. Nicotine is reported to improve attention and information processing in DAT patients and small short-term studies have been carried out looking at the use of nicotine skin patches. Nicotine or nicotinic agonists are likely to have marked vascular effects and this may limit their use. In addition, direct stimulation by nicotinic agonists may induce desensitization of nicotinic receptors reducing the efficacy of such compounds in the longer term. Receptor modulation, as is the case for the allosteric potentiating ligand galantamine, may therefore be a better approach to overcome this hurdle.

The main drug target of commercially available neuroprotectants is oxidative stress by oxygenized free radicals. *Ginko biloba* extract has been used for treatment of memory problems for many years despite the lack of proven clinical efficacy. Its presumed mode of action is based on the presence of flavonoids, terpenoids and organic acids in the extract acting as free radical scavengers. A recent randomized controlled clinical trial found that it was not effective in reducing either the overall incidence rate of dementia or DAT incidence in elderly individuals with normal cognition or those with MCI. Vitamin E or α-tocopherol is another free radical scavenger used for treatment of DAT, despite of insufficiently proven clinical efficacy.

Given the central role of amyloid-β pathology in the DAT disease process, future treatment strategies should mainly focus on the prevention or reversal of amyloid-β peptide deposition. Several experimental strategies focusing on amyloid-β are presently under intense preclinical and clinical investigation, including interventions modulating proteolytic amyloid precursor protein processing with e.g., secretase inhibitors, passive or active immunization against amyloid-β, and treatments blocking amyloid-β aggregation. Data from animal models suggests that antibodies raised against the amyloid-β can decrease Aβ deposition through several mechanisms, as well as decrease amyloid-β associated damage such as dystrophic neurite formation, and improve behavioral performance. Data from human studies suggests that active immunization can result in plaque clearance and that passive immunotherapy might result in slowing of cognitive decline. Despite this, a recent analysis from a phase I trial evaluating active immunization with $A\beta_{1-42}$, while not powered to determine efficacy, suggested no large effect of active immunization despite the fact that plaque clearance was very prominent in some subjects. An important issue to consider is when active or passive immunization targeting amyloid-β has the chance to be most effective. Pathological and biomarker studies have shown that amyloid-β deposition probably begins about 10–15 years prior to DAT symptom onset. By the time the earliest clinical signs of DAT emerge, amyloid-β deposition may be close to reaching its peak and tangle formation and neuronal cell loss is substantial, though still not at its maximal extent. Since immunization targeting amyloid-β does not appear to have major effects on tangle pathology, for immunization to have the most chance for success, performing clinical trials in individuals who are cognitively only very mildly impaired or even in those with preclinical DAT would likely offer a much better chance for success. Current work with DAT biomarkers suggests that such individuals can now be identified and it seems likely that targeting this population with antiAβ immunization strategies is likely to be successful.

Epidemiological data collected between the mid 1980s–late 1990s suggested that prolonged exposure to ► nonsteroidal antiinflammatory drugs (NSAIDs) in conditions like arthritis entailed a reduced risk and delayed onset of

DAT. NSAIDs exert antiinflammatory, analgesic and antipyretic activities and are involved in the suppression of prostaglandin synthesis by inhibiting cyclo-oxygenase, a key mediator of the inflammatory cascade. Initially, the diminishing effect of prolonged usage of NSAIDs on the risk of DAT was attributed to a reduction of inflammation. Several subsequent clinical trials testing NSAIDs in DAT patients based on this rationale, however, yielded negative results. In recent years, several studies have proven that a subset of NSAIDs (e.g., ibuprofen, indomethacin, flurbiprofen) reduce $A\beta_{1-42}$ production in cultured cells and mouse brain, whereas other NSAIDs do not affect Aβ metabolism (e.g., aspirin, sulindac, ketoprofen), and others (e.g., celecoxib) even increase $A\beta_{1-42}$ production. The use of NSAIDs may prove efficacious in other protein-misfolding disorders besides DAT, given the fact that some of these compounds may exhibit antifibrillogenic and fibril-destabilizing activities for other proteins that can aggregate and form amyloid-like fibrils besides amyloid-β, including alpha-synuclein in Lewy body dementia. Nevertheless, a large body of preclinical and clinical research is required to underpin these presumed disease-modifying effects of certain NSAIDs.

Until a therapy is developed that can prevent or reverse the disease, the optimal goal for effective DAT management is to develop a treatment regimen that will yield maximum benefits for individual patients across multiple domains, including cognition, daily functioning, and behavior, and to provide realistic expectations for patients and caregivers throughout the course of the disease.

Besides focusing on cognitive symptomatology, treatment of DAT should also include managing BPSD and related behavioral alterations, especially given their major impact on patients, caretakers, and society at large. Behavioral symptoms, particularly aggression, agitation and circadian rhythm disturbances, or sundowning behavior, have been described as the primary predictor of caregiver burden and often motivate institutionalization in specialized care facilities. In addition, the presence of BPSD in DAT is associated with more rapid cognitive deterioration.

A variety of pharmacological agents has been evaluated for the treatment of BPSD, including cholinomimetics, antidepressants, anticonvulsants, anxiolytics, hormonal preparations and antipsychotic (neuroleptic) drugs. Unfortunately, clinical evidence is rather anecdotal or based on open-label clinical trials for most of these substances. In addition, although the categories of BPSD are superficially similar to symptoms in, for example, the psychosis of schizophrenia or depression in major affective disorders, the specific nature of these symptoms in DAT and related disorders may be different based on DAT-specific neurochemical alterations and the interaction with psychological, cognitive and functional factors.

Neuroleptics are implemented most frequently, although the use of classic neuroleptics in an elderly population implicates the risk of irreversible movement disorders, extrapyramidal side effects, anticholinergic effects and adverse drug interactions. Novel (atypical) antipsychotic agents should be screened in placebo-controlled randomized double-blind clinical trials assessing efficacy and safety profile. Two atypical antipsychotic agents, ▶ risperidone and ▶ olanzapine, are presently the most optimal treatment options for BPSD and have been evaluated in a series of placebo-controlled randomized clinical trials, albeit with rather variable results. Nevertheless, the increased risk of cerebrovascular accident in patients taking risperidone or olanzapine may limit their use in demented subjects. Risperidone is a strong dopamine antagonist with high affinity for D_2 dopaminergic receptors, as well as serotonin ($5\text{-}HT_2$) receptors. It is well absorbed after oral administration and peak plasma levels are reached in 1 h. Olanzapine has a higher affinity for $5\text{-}HT_2$ serotonin receptors than D_2 dopamine receptors. Peak plasma levels are reached within 5–8 h following oral administration. Taking into account the rather limited efficacy and the importance of side effects observed with psychotropic agents overall in this indication, the majority of existing guidelines underline the importance of nonpharmacological strategies.

The proportion of dementia patients experiencing major or minor depression is estimated to be around 25%, and 20–50% in patients diagnosed with DAT. The etiology of depression in DAT is heterogeneous as indicated by the four subtypes identified: adjustment disorder, recurrence of earlier depressive episode, vascular depression and depression associated with neurodegeneration. Given the symptom overlap between nondepressed DAT patients and depression associated with dementia, including psychomotor retardation and difficulty thinking and concentrating, as well as depression-like symptoms in case of DAT-associated apathy, diagnosing depression in DAT may be complex. Beyond the inherent burden on patients and caretakers, comorbid depression may cause a decline in quality of life, impairment in functionalities of daily living and has been linked to greater and faster cognitive decline. In addition, controlled pharmacological treatment trials of depression in DAT yielded conflicting results. DAT-associated depression has been treated with ▶ tricyclic antidepressants (TCAs) (e.g., imipramine, clomipramine) or ▶ selective serotonin reuptake inhibitors (e.g., setraline, citalopram). SSRIs increase the extracellular level of serotonin by inhibiting its reuptake into the presynaptic cell,

increasing the level of serotonin available to bind to the postsynaptic receptor. SSRIs are currently the first choice for treatment of comorbid depression in dementia because of a superior safety and tolerability profile compared to TCAs, as well as the fact that worsening of cognitive impairment with TCAs has been observed. Interestingly, some DAT patients experienced significant improvement of cognitive and emotional functioning with ► citalopram compared to placebo (<*individual items on the Gottfries–Bråne–Steen Dementia rating scale*).

Treatment goals clearly change with the severity of DAT. In patients with mild to moderate disease, goals are to improve or maintain baseline performance through the administration of disease-modifying drugs targeting crucial etiological processes that thereby are neuroprotective. As the disease progresses, the goal of treatment is to slow the rate of decline in performance, mainly through highly efficacious symptomatic therapeutics improving cognitive and behavioral deficits that impair the well being of patients and caregivers. Symptomatic therapies, however, do not address the cause of the disease. If predisposition for the development of DAT should become predictable in the future, for example based on biomarker profiling in patients with mild cognitive impairment, the development of truly preventive therapies will become mandatory.

A laboratory animal that has undergone a manipulation, for example a pharmacological challenge, surgical procedure or genetic modification(s) so that it models aspects of human dementia.

Current Concepts and State of Knowledge

There are over 50 described causes of dementia but the most common among these are ► Alzheimer's disease, vascular dementia, Lewy body dementia, frontotemporal dementia, and HIV-associated dementia. Dementia is also associated with diseases such as Parkinson's, Huntington's, progressive supranuclear palsy, Creutzfeldt–Jakob disease, Gerstmann–Sträussler–Scheinker syndrome, other prion disorders and ► dementias and other amnestic disorders but for the sake of brevity, this essay will focus on animal models of dementia caused by Alzheimer's disease (AD).

AD is characterized by a progressive, age-dependent decline in cognitive functioning including, but not restricted to gross impairments in memory, speech, visuospatial skills, and behavior. The clinical symptoms of AD are the result of significant neuronal and synaptic loss in selected brain regions, including the temporal and parietal lobes and restricted regions within the frontal cortex and cingulate gyrus. In addition to neurodegeneration, the two main histopathological hallmarks of AD are

extracellular plaques comprising predominately of ► β-amyloid derived from the amyloid precursor protein (APP), and intraneuronal ► neurofibrillary tangles (NFT's), comprising of a hyperphosphorylated form of the microtubule associated protein Tau. β-amyloid and ► Tau show distinct regional distribution throughout the brain with amyloid plaques predominately found in the neocortex, temporal and entorhinal cortices, ► amygdala, and ► hippocampus, while Tau NFT's are primarily localized to the entorhinal and limbic cortices but also the CA1 region of the hippocampus.

During the mid-1970s, a detailed biochemical analysis of brains from Alzheimer's patients demonstrated that there were significant neocortical reductions in the enzyme responsible for the synthesis of the neurotransmitter ► acetylcholine (ACh). Later studies then went on to show reduced uptake of choline, ACh release, and significant cell loss in the primary cholinergic cell body that projects to the neocortex (nucleus basalis of Meynert). In addition to the pronounced deficits of the cholinergic system, more subtle deficits to other neurotransmitter systems including the noradrenergic, serotonergic systems and neuropeptides such as substance P and somatostatin were also reported, whereas the dopaminergic system and several other neuropeptides appeared to be unaffected. Degeneration of the primary noradrenergic cell body (locus coeruleus) is perhaps the best documented with studies reporting up to 68% cell loss.

It was from these seminal histological and biochemical studies and the subsequent connection between emerging data demonstrating a role for ACh in learning and memory, that the "Cholinergic Hypothesis of AD" was formed (for review see Bartus 2000). Essentially this hypothesis states that the degeneration of cholinergic neurons in the basal forebrain and associated loss of cholinergic transmission in the cerebral cortex and other areas associated with cognition are responsible for the decline in cognitive functioning observed in AD. While providing the first starting point for AD animal model development, the cholinergic hypothesis also forms the theoretical basis for cholinergic therapy with ► acetylcholinesterase and cognitive enhancement, which are still the most effective in the treatments for AD.

Primarily driven by the cholinergic hypothesis, a variety of experimental approaches were developed that aimed to establish dysfunctional cholinergic systems in animals. The most commonly utilized of these is the ► scopolamine challenge model. Scopolamine and atropine are naturally occurring compounds found in the nightshade (Solanaceae) plant family. When administered to animals, including man, they potently block both central and peripheral cholinergic muscarinic receptors, ► muscarinic agonists and antagonists. The resulting cholinergic dysfunction causes pronounced, albeit reversible cognitive impairments. The first studies that determined the effects of scopolamine on normal human cognitive functioning were performed in the early 1970s. When administered to healthy human volunteers, scopolamine was shown to cause reversible learning and memory deficits similar to those observed in elderly and dementia patients. Due to its procedural simplicity and distinct lack of safety concerns, the human scopolamine challenge model is still occasionally used today for the evaluation of novel drugs postulated to improve cognitive functioning of ► cognitive enhancers: novel approaches.

In addition to the human studies, the effects of scopolamine in pre-clinical species were first reported in the 1950s. While these studies focused primarily on the general impairing effects of scopolamine on operant test responding ► operant behavior in animals, considerable efforts over the last 50 years have led to a comprehensive characterization of scopolamine's effects on most aspects of animal cognition. Although a review of this work is beyond the scope of this article (for review see Blokland 2005), it is worth mentioning that while there is irrefutable evidence for scopolamine-induced amnesia in animals, there has also been some considerable debate as to whether the impairments are specifically learning- and memory- related. This is because scopolamine also elicits multiple effects on other non-cognitive related processes including gross animal behavior (i.e., locomotor activity), pupil diameter, salivation, perception, and anxiety responses. These effects are caused by the lack of selectivity that scopolamine displays across all the muscarinic receptor subtypes (m1–m5) located in the body.

While most of the confounding effects of scopolamine are typically associated with higher doses of scopolamine, it can be still extremely difficult to experimentally separate scopolamine effects on cognition from its non-specific effects (Blokland 2005). Moreover, there is now considerable evidence suggesting that scopolamine effects on learning and memory are likely to be secondary to its effects on attentional processes. Even with these caveats, there is no doubt that the scopolamine challenge model is an important tool for both the pre-clinical and clinical assessments of novel cognitive enhancing compounds and is perhaps one of the clearest examples of a CNS translational model for ► translational research.

As a direct parallel to the scopolamine model, alternative approaches were developed that aimed to address the selectivity issues mentioned earlier, but also to establish

more permanent cholinergic deficits similar to that observed in AD. Both of these objectives were partially achieved by lesioning discrete cholinergic brain nuclei and/or pathways. The basal forebrain contains two groups of cholinergic neurons: (1) the medial septal nuclei (medial septal nucleus and vertical diagonal band) that project to the ▶ hippocampus and parahippocampal gyrus (2) the nucleus basalis nuclei (nucleus basalis, substantia innominata and horizontal diagonal band) that project to the neocortex, limbic cortex, and ▶ amygdala. The nucleus basalis magnocellularis (nbm) is the rodent equivalent to the human nucleus basalis of Meynert that undergoes degeneration in AD.

Early brain lesioning techniques were limited by available technology, and therefore relied upon either electrolytic probes or direct injection of ▶ excitotoxins. Electrolytic-induced lesions are generated by stereotaxically placing an anodal electrode into the brain region of interest. A small electrical current is then passed through the electrode and cells that are in close proximity to the electrode undergo degeneration. Although far from precise, lesion size can be manipulated by altering either the current amplitude and/or length of current application. Electrolytic lesioning techniques are now rarely used because they have been shown to cause considerable damage to adjacent fiber tracts which can cause neuronal degeneration at sites distal to the lesion.

The use of excitotoxins to cause brain lesions was a considerable improvement on the electrolytic approach. Excitotoxins are receptor ligands that directly act on the glutamatergic system (e.g., NMDA, ibotenic acid, and quisqualic acid). These ligands once directly infused into the brain region of interest bind to their appropriate receptor and open calcium channels. The resulting calcium influx leads to hyperpolarization and ultimately, cell death. Excitotoxic lesions are generally thought to spare axons (fibers) that run adjacent to the injection site and thus avoid the issues associated with electrolytic lesions.

Further improvements in lesion specificity was achieved when a monoclonal antibody raised to the nerve growth factor (NGF) receptor "192IgG" was coupled to the cytotoxin, "saporin," forming a "192 IgG-saporin" complex. When administered intracranially, the 192 IgG-S complex binds to the low-affinity neurotrophin receptor ($p75^{NTR}$) on cholinergic cells and the receptor complex is internalized. Once in the cell, ▶ saporin enzymatically disables ribosomes and shuts down protein synthesis, resulting in the selective death of cholinergic neurons. This widespread, yet selective degeneration of cholinergic neurons including those in the nucleus basalis of Meynert and septum causes pronounced learning and memory deficits.

There is no doubt that animals with lesions in the forebrain cholinergic nuclei have proved useful as a model of cholinergic hypofunction. They have provided information on cortical cholinergic innervations and how changes to this system can affect neuronal functioning and cognitive processes. They have also proved useful in determining the effects of novel compounds designed to restore/preserve cholinergic functioning, for example acetylcholine esterase inhibitors. However, as a model of AD, they show a number of serious limitations. The main concern is that the resulting cholinergic hypofunction is not associated with amyloid ▶ plaques or NFT's, and there is no progressive worsening of the hypofunction but on the contrary some recovery may take place (for review see Toledano and Alvarez 2004).

As briefly mentioned earlier, AD is also associated with significant degeneration of the primary noradrenergic cell body (locus coeruleus) with resulting downstream alterations in noradrenergic receptor expression. DSP-4 is a potent and selective neurotoxin of noradrenergic neurons and when injected systemically, produces long-lasting reductions in basal noradrenaline levels and uptake capacity in the brain and spinal cord. The most consistent effects of DSP-4 lesions are disruptions in behavioral tasks designed to measure attention-related processes (for review see Sara 2009). Interestingly, most studies have shown no effect of noradrenaline depletion on learning and memory tests that are otherwise dramatically altered by either cholinergic blockade or aging. Due to these caveats, the time and associated costs in generating lesioned animal models, but primarily the concern that these models fail to predict for clinical efficacy, they are very rarely used in the modern drug discovery process.

Aged animals have been and are still occasionally used for investigating drugs postulated to be active in treating AD. While aged rodents (mice and rats) are the most frequently used since they are relatively easy and cheap to obtain, occasionally old primates are used and may form the last preclinical step before evaluation in humans. There are two main limitations of the aging animal model. First, aged animals do not develop the neuropathological picture of AD. While extremely rare, plaques have been described in the primate, but none of the histopathological alterations typical of AD occur in aging rodents. Second, in aged animals, it is relatively easy to improve the cholinergic hypofunction and associated cognitive deficits with drugs whose efficacy has proved difficult to demonstrate in clinical trials.

Studies of amyloid plaques in the 1980s showed that they predominantly consisted of a long peptide with

40–42 amino acids that is formed into a beta-pleated structure. The subsequent sequencing of the isolated β-amyloid peptide identified a 90 Kd single transmembrane protein termed the APP, whose cleavage leads to the production of β-amyloid peptides. The amyloid cascade hypothesis postulates that the aberrant accumulation of β-amyloid is the primary abnormality in AD and that its deposition leads to disturbed axonal transport and neuronal cell death, ultimately causing deficits in synaptic plasticity and cognition, ► long-term potentiation and memory. The supporting evidence for the amyloid cascade hypothesis derives from a number of observations (for review see Tanzi and Bertram 2005), but can be broadly classified into three strands: (1) an association of AD with Down's syndrome, (2) APP mutations on chromosome 21, and (3) experiments demonstrating that β-amyloid is neurotoxic both in-vitro and in-vivo.

Animal models based on the amyloid cascade hypothesis of AD can be simply divided into two groups: transgenic models ► genetically modified animals and non-transgenic models. The non-transgenic amyloid animal model involves acutely injecting or continuously perfusing β-amyloid peptide directly into the brains of normal animals. The first in-vivo data showing that injection of β-amyloid into the frontal cortex of rats causes neurodegeneration and cell loss was reported in 1991 (Kowall et al. 2001). Since then there have been a large number of in-vitro and in-vivo studies clearly showing that β-amyloid peptides are neurotoxic and can lead to learning and memory impairments in rodents and primates (for review see Harkany et al. 1999).

With respect to transgenic models, the first APP transgenic mouse that deposited β-amyloid similar to that observed in AD patients was generated in the mid 1990s. As a platelet-derived growth factor promoter was used to express the mutant human APP gene, this transgenic mouse is referred to as the "PDAPP" mouse (Games et al. 1995). Shortly after, a variety of novel APP transgenic mice were developed including the Tg2576 mouse (Hsiao et al. 1996) and the APP23 mouse (Sturchler-Pierrat et al. 1997). The Tg2576 and APP23 mice both express human APP with the AD Swedish mutation, whilst the PDAPP mice express human APP with the Indiana AD mutation.

Simply because the Tg2576 strain was made freely available to both profit and non-profit research organizations, the Tg2576 mouse is the most widely investigated of the APP transgenic lines. The histopathogical characteristics of Tg2576 mice are similar to that seen in AD in that they show amyloid plaques, dystrophic neurites, astrogliosis, microgliosis, increased oxidative stress and inflammatory ► cytokines. β-amyloid levels generally begin to increase in Tg2576 mice at approximately 6 months of age and plagues begin to develop at around 9–12 months (Hsiao et al. 1996).

In the same year that the PDAPP transgenic mouse was described, mutations in the presenilin (PS1) gene were found to be responsible for some cases of familial AD (Sherrington et al. 1995). Soon after a mouse line overexpressing the mutated PS1 gene was generated and when later crossbred with the APP mouse, the new strain showed pronounced increases in amyloid levels with earlier onset of plaque deposition. Within a short period, numerous mouse lines were created that carried either single or multiple mutations in the APP and presenilin genes. Whilst APP and PS1 transgenic mice showed elevated levels of β-amyloid and increased amyloid plaque deposition, the lack of robust neuronal loss and NFT's pathology raised serious debate on the validity of the amyloid hypothesis as a model for AD (for review see McGowan et al. 2006).

In 1998, mutations of the Tau gene on chromosome 17 was linked to frontotemporal dementia with Parkinson's disease confirming that Tau dysfunction is linked to neurodegeneration (Hutton et al. 1998). Subsequent phenotyping of the rapidly generated Tau transgenic mice revealed age-dependent expression of insoluble hyperphosphorylated Tau and intraneuronal NFT inclusions. Whilst some NFT's were present in the brain, greater expression was seen in spinal cord neurons. The spinal cord also showed considerable axonal degeneration ultimately leading to paralysis of the hind limbs. Whilst slightly more problematic, the Tau transgenic mice were crossed with APP mice to determine if there was synergy between β-amyloid and Tau pathogenesis. The double transgenic mouse line showed considerably more neuropathology than the Tau mutation alone, but because these mice were extremely poor breeders and developed severe motor deficits, long term studies were not feasible.

A relatively recent development in the AD transgenic mouse field has been the generation of the triple transgenic mouse line. To avoid potential issues associated with the cross breeding of APP, PS1, and Tau lines, the two transgenes encoding APP and Tau were injected into single cell embryo's harvested from a PS1 mouse line. The resulting 3X TG-AD mouse shows: age-dependent increases in β-amyloid levels, amyloid and Tau pathology, reduced long-term potentiation and significant deficits in both spatial and contextual learning (for reviews see McGowan et al. 2006; Sankaranaarayanan 2006). Whilst cognitive analysis of AD transgenic animals has certainly yielded fascinating results, cautious interpretation is always recommended as cognitive testing in mice is not as straight

forward as the rat and the published reports on the mice have certainly caused some controversy (Routtenberg 1997).

Bearing in mind the above caveats, the transgenic and non-transgenic models described above have proved useful in reproducing the pathological phenotype associated with amyloid and Tau expression, and to a lesser extent the neurodegeneration and synaptic deficits found in AD. As a consequence, a number of late stage therapeutic compounds designed to lower β-amyloid load have been tested in these models and some look promising ► neuroprotectants: novel approaches for dementias. As these molecules progress through clinical trials, the amyloid hypothesis of AD will be tested. This should hopefully lead to a clear conclusion that reducing β-amyloid in the CNS will lead to either stabilization or more preferably an attenuation of the cognitive decline in AD.

Although cognition tests are discussed in more detail within other essays, for example see, operant behavior in animals, ► rodent models of cognition and ► short-term and working memory in animals, it is worth briefly mentioning some of the classical rodent cognition tests that have been used in the characterisation of AD animal models. Due to the pronounced hippocampal abnormalities in AD patients, rodent cognition tests that are hippocampal-dependent have been the tests of choice. The most popular of these has been the ► Morris water maze which was developed nearly 30 years ago to measure ► spatial learning and memory capabilities in rodents. The water maze consists of a large circular water filled tank with a submerged escape platform. The animals are required to learn and remember the location of a hidden platform using spatial cues positioned within the testing room. Aged, lesioned, pharmacologically challenged and AD transgenic animals have all shown performance deficits, sometimes reversible in the water maze.

Another widely used test for rodent cognition involves the acquisition and retention of ► passive avoidance behavior. Here a rodent is punished when it engages in a spontaneous behavior, typically receiving a mild foot shock when it enters a dark compartment from a brightly lit holding chamber. Later, the animal is tested for its "memory" of the aversive event by determining the latency to reenter the compartment where the shock was delivered. Taken at face value, changes in entry latencies can be interpreted as measures of the animal's memory for the aversive event. However, there are considerable confounding factors that must be taken into account when interpreting data from passive avoidance studies. For example, treatments that cause motor impairments, changes in anxiety responses, pain sensitivity, and motivation can all impact entry latencies and potentially be misconstrued as cognitive effects. Perhaps the most significant concern with passive avoidance has to be its lack of predictive validity as numerous novel cognitive enhancers which have shown efficacy in this test have failed to deliver in the clinic. In addition to these tests, other examples of cognition tests that have been used to characterize AD animal models and assess potential efficacy of AD therapies include cued/contextual learning, operant-based (lever pressing) tasks, object recognition tests and the five choice serial reaction time test.

To conclude, animal models and appropriate tests have been and still will be pivotal in our attempts to understand the complex biology found in AD and other related dementias. Furthermore, they also serve as indispensable tools in the drug discovery and development process. Data generated in these models not only provides additional confidence in the likely therapeutic utility of novel compounds, but also confirms whether the identified molecular target is linked to the disease process and whether its modulation will lead to beneficial effects. Whilst there is no single animal model that can fully recapitulate all of the cognitive, biochemical and histopathological abnormalities observed in AD patients, partial reproduction of AD neuropathology and cognitive deficits have been achieved with the AD models described above. AD and other dementia research will continue to depend on the use of thoroughly validated animal models but to increase clinical success researchers are now combining new technologies such as biomarker and genetic profiling so that improved treatments may be identified and hopefully delivered to the patients.

Dendritic Spine

Definition

A protrusion in neuronal dendrites that contains the postsynaptic part of a neuronal synapse. The vast majority of dendritic spines is found in glutamatergic neurons and form asymmetrical synapses.

Deoxyglucose

Synonyms

2-deoxyglucose; 2-DG

Definition

A glucose molecule where the 2-hydroxyl group is replaced by a hydrogen, preventing further glycolysis following cellular uptake and hence accumulation in the cell. Deoxyglucose can be administered to living organisms where it competes with glucose uptake into the cell. Consequently, cells with higher glucose uptake, such as activated neurons, have a higher uptake of deoxyglucose. Deoxyglucose can be radiolabeled with tritium [^{3}H], carbon-14 [^{14}C], or fluorine-18 [^{18}F] and used as a ligand to measure brain activation in animals or man, either by autoradiography, mPET, or PET.

Dependence

Definition

Synonymous with addiction. The World Health Organization defined it as a state, psychic and sometimes also physical, resulting from the interaction between a living organism and a drug, characterized by behavioral and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to

experience its psychic effects, and sometimes to avoid the discomfort of its absence. Tolerance may or may not be present. A person may be dependent on more than one drug because a range of withdrawal symptoms are experienced. Other definitions are also in use.

Depolarization Block Theory

Definition

A theory based on studies in rats showing that antidopaminergic treatment leads to inactivation of dopamine firing which was thought to be the mechanism of antipsychotic drug action. As it took 3 weeks until this inactivation was in effect, it was believed that this delay explained the delay of onset of antipsychotic drug effects.

Depression

Synonyms

Major and minor and mixed anxiety-depressive disorders

Definition

An emotional state characterized by persistent feelings of sadness, loss of energy and interest, thoughts of death or suicide.

Depression: Animal Models

Definition

Animal models for ▶ depression refer to experimental procedures or animal preparations which model the aspects of Major Depressive Disorder (MDD) in humans. These animal models are broadly subdivided into screening models, used primarily for identifying potential therapeutic effects of established and novel compounds, and simulation models, where the emphasis is on understanding the theoretical basis for MDD. General reviews of animal models of depression are available (Cryan et al. 2002; Nestler et al. 2002; Willner and Mitchell 2002a,b) and specific models are described in a special issue of *Neuroscience & Biobehavioral Reviews* (2005, vol. 29, No. 4–5).

Current Concepts and State of Knowledge

Symptoms of MDD

The clinical symptoms required for diagnosis of an episode of MDD are depressed mood, markedly diminished interest or pleasure in activities, significant weight loss or weight gain, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue, or loss of energy, feelings of worthlessness or excessive or inappropriate guilt, diminished ability to think or concentrate, and recurrent thoughts of death or suicide (DSM IV) (American Psychiatric Association 1994). The symptoms must be persistent, at least 2 weeks in duration. Some of the clinical symptoms can be modeled directly by behavioral studies in rodents and are marked in the italicized rows of Table 1. These behaviors form the basis for some of the tests and animal models of the predisposition or treatment of mood disorders.

Symptoms outside of the DSM IV criteria, such as anxiety, loss of control, and irritability, may also form the basis for animal models of depressive behavior because they are part of a dimension of similar behavior clusters described for MDD. Symptoms of depressed mood and recurrent thoughts of death and suicide cannot be modeled in rodents because they are internal or private states experienced by the patients.

Behavioral Screening Tests for Antidepressant Treatments

The most common use of animal screening tests for depressive behaviors (Table 2) is to predict the therapeutic

effects of novel drugs. The rationale for the prediction is to reproduce the pattern of response of antidepressant drugs that have already been shown to be clinically effective, a criterion of success defined as ► predictive validity. Predictive validity for antidepressant treatments has grown more complex with the introduction of compounds and somatic treatments with a wide array of pharmacological and physiological effects. Initially, ► TCAs and ► MAOIs were the principal classes of antidepressant drugs. Subsequently, other classes of antidepressant drugs were introduced, including ► SSRIs, NRIs, ► SNRIs, and atypical antidepressants. In addition, some effective somatic treatments for depression are in widespread use, including ► electroconvulsive shock, exercise, ► transcranial magnetic stimulation, and stimulation of the vagus nerve. Different antidepressant treatments (SSRIs, SNRIs, novel compounds) may produce similar behavioral effects, though they may produce their effects through different mechanisms.

Pharmacological screening tests may be based on a particular theoretical rationale, but the particular theoretical rationale used in the screen may also limit the range of compounds that can be detected with the test. For example, reversal of the effects of ► reserpine or ► tetrabenazine ptosis, motor activity or hypothermia is based on the catecholamine hypothesis of affective disorders, because reserpine and tetrabenazine deplete catecholamines and the clinical use of reserpine was reported to cause depression. However, these screening tests cannot be used to detect SSRIs or other compounds that do not involve catecholamine mechanisms. Behavioral screening tests may differ from pharmacological tests because they are not limited to identifying drugs from a particular class. Thus, the forced swim test, based on a theoretical rationale involving ► learned helplessness (LH) as a contributor to the development of depression, can detect all of the major pharmacological and somatic classes of antidepressant treatments.

Behavioral tests of depressive behavior are not true animal models of MDD. They do not attempt to reproduce multiple components of depression and they do not induce symptoms for a prolonged duration. Screening tests are usually a behavioral characteristic, or an ► endophenotype, that can be measured quantitatively and is associated with a single dimension of emotional behavior related to depression. Tests of ► behavioral despair involve the reaction of animals to inescapable stress and the loss of control, hyponeophagia involves anxiety associated with novelty, and DRL or waiting behavior are tests of impulse control.

Another important dimension is whether screening tests or models respond to acute or chronic

antidepressant treatment. There is a temporal delay between the initiation of clinical treatment and the appearance of full or even partial recovery. Some behavioral and pharmacological effects require chronic treatment to develop and may bear a closer temporal correlation with the time course of clinical treatments. Tests such as the forced swim test, tail suspension test, DRL behavior, and waiting behavior can respond to acute treatment with antidepressants, particularly at high doses. However, these tests may respond or demonstrate sensitization upon chronic treatment, particular if lower doses are used that produce plasma levels of drug that are similar to those in humans. Some behaviors, such as reduction of hyponeophagia, are produced only following chronic treatment and are associated with increases in ►brain-derived neurotrophic factor and hippocampal neurogenesis.

Depression Models Based on Environmental Adversity

A number of animal models of depression use environmental stress to produce long-term changes in behaviors associated with depression. The models of environmental adversity are based on the rationale that exposure to stress is a known precipitate of MDD (Table 3).

Learned Helplessness

►Learned Helplessness (LH) is based on an influential theory that exposure to uncontrollable stress leads animals to learn that voluntary actions will not be effective in coping with stress. LH produces changes in affective, cognitive, and motor functions, although controversy has centered on whether the effects of LH represent cognitive impairment or motoric inactivity. In LH, animals that are exposed to inescapable stress will subsequently fail to escape from a situation where escape is possible. Usually, rodents are tested for escape from electric shock in a shuttle box. Animals are compared to several control groups, including yoked control animals that receive the same amount of shock but are allowed to terminate the shock through a response. Differences are then attributable to control over shock termination.

LH animals show several neurovegetative changes that are similar to depression, such as rapid eye movement sleep alterations, reduced body weight, diminished sexual behavior, and elevated levels of corticotropin releasing factor and corticosterone. Repeated treatment with antidepressants reduces the latency to escape and decreases the number of animals that develop LH.

It remains unclear whether LH is a better model of posttraumatic stress disorder and other conditions where acute stress is a clear etiological factor than of depression. Since there is variability in the susceptibility of different animals to LH, some studies have used the variability to segment vulnerable populations from resilient populations. The effects of LH training depend on genetic background, and lines of rodents have been bred with increased vulnerability that may amplify its effects (Table 4). Nevertheless, the effects of LH training are usually not long-lasting.

Chronic Mild Stress

The ► chronic mild stress procedure causes behavioral changes in rodents that parallel the symptoms of depression by continuous exposure to a variety of mild stressors, such as periods of food and water deprivation, cold, changes of cage mates or isolation, and alterations of the light cycle (Willner 2005). An assortment of heterogenous stressors is used to avoid adaptation to repeated exposure to a single stressor. Over weeks of chronic exposure, rodents gradually reduce their consumption of a preferred dilute sucrose solution. The deficit of sucrose consumption persists for weeks until the cessation of the stress. These effects appear to reflect a generalized insensitivity to reward, as also shown by reduced ► brain stimulation reward or place preference conditioning. Other behavioral signs of chronic stress include reduction of body weight, altered sleep patterns, decreased sexual and aggressive behavior, and abnormal grooming behavior.

Chronic treatment of rodents with antidepressant drugs restores the normal preferential intake of sucrose and other indices of stressed behavior, such as abnormal grooming or place conditioning. Chronic treatment is required for behavioral effects, and nonantidepressants are ineffective. Giving antidepressant drugs chronically to unstressed animals did not alter these behaviors. The chronic mild stress procedure has been used to measure the potential antidepressant activity of a number of novel targets. The major disadvantage of this model has been its variable outcome across laboratories.

Social Dominance Models

There are parallels between the symptoms of MDD and behaviors of animals of low social rank. Such comparable behaviors form the basis for attempts to model MDD using species-specific subordinate behaviors evoked by social conflict. The rationale for these models generates from the greater pathology risk of individuals in subordinate roles or those who have lost social status as a result of defeat in social conflict. One of the attractive features of models using ► social stress is that they employ naturalistic and ethologically relevant situations to evoke and measure depressive behavior. Many models involve rodents but these have been extended to nonhuman primates.

In chronic social defeat, a rodent is exposed briefly but repeatedly to an aggressive and dominant animal. In continuous subordination stress, rodents are exposed to defeat and then held in close contact with the dominant animal from a protected enclosure on a daily basis. Modified procedures expose dominant pair-housed rats to defeat by an intruder from a more aggressive strain, resulting in the loss of their dominant status. Rodents exposed to chronic social defeat show reduced body weight, reduced sucrose drinking, increased corticosterone levels, increased immobility in the forced swim test, and suppression of BDNF activity in the VTA. Rodents exposed to social defeat will demonstrate avoidance of other rodents in a social choice situation that will persist for weeks after the cessation of social contact. Chronic administration of antidepressant drugs has been shown to restore social approach behavior and the other behavioral effects of chronic social defeat. Subordinate rats or tree shrews often need to be rescued, however, because they will not maintain subordinate status without morbidity.

Social Hierarchy

A way to measure social status is to house rats in closed social groups of 2 or 3 animals per cage to develop a stable social hierarchy. Their relative social rank can be assessed by tests of competitive behavior, usually involving food consumption. The hierarchy can be disrupted by treating the subdominant animal chronically with antidepressant drugs, where the subdominant animal demonstrates increased assertiveness during social encounters.

A similar competitive situation has been used to examine social competition between stable pairs of rodents contesting over access to food. Chronic administration of antidepressant drugs to the subordinate member of the pair has been shown to increase their competitiveness for food to the extent where the hierarchy is no longer maintained. There is a great deal of variation in the behavior of rodents involved in daily social competition, and a stable hierarchy must be maintained over many weeks for antidepressant drug testing. In laboratory rodents, winning or losing in a competitive situation is limited to the specific test and does not readily transfer to other competitive situations. A separate control group (treated with vehicle) is needed to assess whether drug treatments change the behavior significantly beyond the level expected from normal variation.

Social Separation

The loss of important social support, either loved ones or peers, contributes to the development of depression. A number of animal models are based on the separation of social groups, either infants separated from parents, juveniles separated from a peer group, or two life-long mates in the case of voles. One of the most well-known primate models is the development of depressive behaviors by separating infants from parents, decreased activity, appetite, failure to play, and sad facial expressions, that are strikingly similar to human depression. Maternal

separation in rodents also produces life-long vulnerability to changes in depressive and anxiety behaviors.

Models of Genetic Predisposition to Stress

MDD is a highly heritable disorder with genetic factors estimated to comprise at least 50% of the risk for developing the disorder. Genetic factors also determine an animal's biological and behavioral responses to stress that are reflected in vulnerability to tests of depressive behavior. Different inbred strains of rats and mice show variations in responses to stress, along with sets of behaviors that comprise models of exaggerated depression-related behaviors similar to humans (see Table 4). Understanding the genetic factors underlying these behavioral differences using techniques such as quantitative trait locus analysis could facilitate human genetic studies by suggesting individual genes and gene maps that may contribute to mood disorders in humans. Inbred strains also display variations in the response to antidepressant drugs that can be used to model factors contributing to treatment resistance (Crowley and Lucki 2005).

Despite acknowledgement of a genetic etiology, no specific genetic abnormalities that confer risk have been identified. Targeted genetic mutations can be produced by removing or replacing a selected sequence of DNA within the genome with a different sequence. When genetic factors for MDD are identified or hypothesized, rodent models of depression may be developed to study the effects of homologous genetic mutations. Until that time, many lines of rodent mutations have been studied using depression-related behaviors, mostly using the mouse forced swim test. Some mouse lines have been identified that show exaggerated depressive behaviors associated with genetic deficiency of endocrine function (aromatase, CRF-R2), neurotrophic factors (BDNF), or neurotransmitter function (5-HT transporter). Other lines of rodents have been identified as genetic models of depression because they demonstrate a consistent pattern of exaggerated depressive-like behaviors, although the genetic mechanisms underlying these changes have not been identified.

Aside from genetic predisposition, developmental and lesion models have also been used to produce long-lasting predispositions to depressive behavior. Rodents as neonates given antidepressants develop exaggerated signs of depressive-like behavior when tested as adults. Rodents exposed to higher levels of stress prenatally also demonstrate behavioral abnormalities associated with depression and anxiety when tested as adults. Lesions of the olfactory bulb produce a complex of abnormal emotional behaviors, not due to anosmia, that are normalized by the chronic administration of antidepressant drugs.

Medical Comorbidity

MDD has frequently been reported to occur coincidentally with the development of medical illness, such as cardiovascular illness, diabetes, or stroke (see Table 5). When MDD develops, it has been shown to worsen the trajectory of recovery from medical illness. Pre-existing depression also increases the vulnerability for developing serious consequences of medical illnesses, such as myocardial infarction or stroke. Insufficient secretion of major gonadal hormones developed through progressive aging has been associated with increased incidence of MDD. Pre-existing addictions, principally to psychomotor stimulants or nicotine, can convey residual vulnerability to MDD after clinical treatment for substance abuse. Rodent models of depression have been developed for studying these comorbid conditions. Altered vulnerability to stress or immunological factors could convey comorbidity between depression and medical illness. Comorbid illness may also respond to different sets of antidepressant medications than other depression models.

Depressive Disorder and Schizophrenia

Definition

Schizophrenic patients frequently suffer from ► comorbid depressive syndromes. These can either be part of the acute manifestation of the illness or occur during the prodromal period, or as post-psychotic depression. The latter is diagnosed after the symptoms of acute psychosis have subsided and is sometimes interpreted as an adjustment disorder related to the disabilities caused by schizophrenia. Lastly, depression and ► schizophrenia can occur in parallel in patients suffering from schizoaffective disorder.

Definition

Depressive disorders in children and adolescents include major depressive disorder (MDD), depressive disorder not otherwise specified (► depressive disorder nos) and ► dysthymic disorder. Discussion in this essay will be limited to major depressive disorder because there are no controlled trials for the treatment of dysthymic disorder or depressive disorder nos. However, in clinical practice, treatment recommendations for MDD are successfully used in the management of dysthymic disorder and depressive disorder nos.

MDD in children and adolescents is characterized by one or more major depressive episodes, defined as at least 2 weeks of persistent change in mood manifested by either depressed or irritable mood or loss of interest or pleasure and at least four additional symptoms of depression, including changes in appetite or weight, sleep, psychomotor activity, decreased energy, feelings of worthlessness or guilt, difficulty thinking or concentrating, or recurrent thoughts of death or suicidal ideation, plans, or attempts. The symptoms must persist for most of the day nearly every day, must be associated with an impairment in functioning (social, academic or other), must not represent the direct physiologic effect of a substance or a general medical condition and must not be better accounted for by bereavement (American Psychiatric Association 1994).

Role of Pharmacotherapy

Depressive disorders in children are common, recurrent, and impairing. Depression is prevalent in 1–2% of children and 3–8% of adolescents. By the end of adolescence, approximately 1 in 5 adolescents will have experienced at least one depressive episode. After the onset of puberty, girls have twice the risk of developing depression that boys do, and risk is closely correlated with levels of testosterone, estradiol, and follicular stimulating hormone (Lewinsohn et al. 1998). Depression is a recurrent condition in children and adolescents, with 40% of patients experiencing a second episode within 2 years, and nearly 75% within 5 years. Almost all will experience another episode in their adult life. Untreated depression is associated with substantial impairment both during and after the episode, with difficulties in school, interpersonal relationships, and occupational adjustment, tobacco and ► substance abuse, suicide attempts, and a 30-fold increased risk of completed suicide.

When depression presents with psychotic symptoms, especially in adolescents with family history of bipolar

disorder, it is usually resistant to treatment and is associated with increased risk for bipolar disorder. Atypical depression presents with atypical symptoms such as lethargy (► leaden Paralysis), increased appetite, ► hypersomnia and increased sensitivity to rejection. While the major symptoms of depression persist across all ages, manifestations of depression may vary with age. Preschoolers may exhibit irritability, withdrawal, or regression as symptoms of depression (Luby et al. 2003). School-age children may display irritable or depressed mood, crying spells, or somatic complaints such as headaches and stomachaches. Adolescents often present with extreme irritability or atypical depressive symptoms such as increased appetite, hypersomnia, and excessive fatigue.

Clinical guidelines for the acute management of child and adolescent depression recommend the prescribing of antidepressant medications, psychotherapy, or both, with the best-studied psychotherapy being cognitive behavioral therapy (CBT) (Birmaher et al. 2007).

Antidepressants

It is important to personalize the selection of a specific medication to each patient by taking into consideration the relative safety for the particular patient, comorbid psychiatric diagnoses, side-effect profiles, and the patient's other medical conditions. Physicians need to discuss risks and benefits of the medication and available alternative treatments, and obtain informed consent prior to starting treatment.

The ► selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed class of antidepressants. They work by inhibiting reuptake of serotonin by presynaptic neurons, with at least 70% reuptake inhibition required to result in clinical improvement. They include ► fluoxetine (Prozac), ► sertraline (Zoloft), ► paroxetine (Paxil), ► fluvoxamine (Luvox), ► citalopram (Celexa), and ► escitalopram (Lexapro). Currently, fluoxetine and escitalopram are the only antidepressants approved by the U.S. Food and Drug Administration for the treatment of depression in patients under the age of 18, although other SSRIs are often prescribed based on factors such as side-effect profile or personal or family history of response to a specific medication. Depressed patients treated with SSRIs have a relatively good response rate (40–70%), but placebo response rate in ► randomized controlled trials of pediatric depression is also high (30–60%), resulting in an overall ► number needed to treat (► NNT) of 10 (Bridge et al. 2009). Baseline depression severity was an inverse predictor of treatment response in these studies (i.e., less severely ill children were more likely to respond) (Curry et al. 2006). Antidepressants are more efficacious in adolescents than in children (NNT of 7 vs. 15), except for studies of fluoxetine, in which the effects are equal in children and in adolescents and are stronger than in most other studies of pediatric depression (NNT = 5). The half-lives of paroxetine, sertraline, citalopram, and ► venlafaxine are shorter in children and adolescents than in adults, which may explain the superior efficacy of fluoxetine vs. these other agents in prepubertal youth. While response and sustained improvement occurs in well over half of treatment-naive depressed adolescents, complete symptomatic ► remission rates are considerably lower, on the order of 20–37% after 12 weeks of treatment.

To date, no non-SSRI medication – except for venlafaxine in treating resistant depression – has demonstrated clear efficacy in treating pediatric depression, but a number of newer non-SSRI antidepressants are available (Brent et al. 2008). These agents preferentially affect a variety of different receptor sites, and they include ► bupropion (Wellbutrin, Zyban), a primarily noradrenergic agent with some dopaminergic effect; ► trazodone (Desyrel) and nefazodone (serzone), serotonin receptor blockers; ► mirtazapine (Remeron), a serotonergic and adrenergic receptor blocker; venlafaxine (Effexor) and ► duloxetine (Cymbalta), serotonin and norepinephrine reuptake inhibitors; and ► atomoxetine (Strattera), a selective norepinephrine reuptake inhibitor (which is marketed for ► attention deficit hyperactivity disorder [ADHD], but not as an antidepressant). These are in addition to the older ► tricyclic antidepressants (TCAs), mixed serotonergic and noradrenergic agents that include ► amitriptyline (Elavil), ► clomipramine (Anafranil), desipramine (Norpramin), ► imipramine (Tofranil), ► nortriptyline (Pamelor, Aventyl), and protriptyline (Vivactil).

► Randomized control trials (RCTs) conducted with nefazodone are contradictory, with one trial demonstrating positive efficacy on some measures while the other was negative. Trials conducted with mirtazapine were negative. Conversely, in a study comparing response to an alternative SSRI or venlafaxine in adolescents who had failed to respond to an adequate trial of an SSRI, both classes of antidepressants were equally effective in reducing depressive symptoms, although venlafaxine has resulted in more side effects. Small open-label studies have suggested bupropion's efficacy in treating adolescent MDD with and without ADHD but no RCTs have been conducted. In a study of adolescents with ADHD and comorbid MDD, atomoxetine was shown to improve ADHD symptoms but not depression compared to placebo. RCTs, as well as a ► meta-analysis, have shown that TCAs are no more efficacious than placebo for the

treatment of child and adolescent depression and should not be used as a first-line medication. Moreover, they are associated with more side effects than the SSRIs and are potentially lethal in overdose.

Side Effects

Suicidal Ideation/Attempts

Antidepressants increase the risk of spontaneously reported suicidal adverse events by about twofold, with estimates of the risk difference ranging between 9 to 2% (Bridge et al. 2007). Most of these suicidal adverse events were increases in suicidal ideation, with relatively few attempts and no completions. Twelve times more depressed youths show a clinical response than experience a suicidal event. Those depressed youth with high suicidal ideation, irritability or anger, family conflict, and drug and alcohol use have been reported to be at higher risk for a suicidal adverse event. While disinhibition, switch to ► mania, onset of ► akathisia, increased irritability, and non-adherence followed by withdrawal from medication have all been posited to be related to suicidal adverse events, none of these hypotheses have been tested in pediatric samples. The ability to identify those who are most likely to respond and least likely to have adverse events is critical given the current level of concern about the associated risk of suicidality (Brent and Maalouf 2009).

Other Side Effects

SSRIs and other newer antidepressants are associated with side effects that are dose dependent and that may subside with time. The most common side effects include gastrointestinal symptoms, sleep changes (e.g., insomnia, somnolence or nightmares), restlessness, headaches, changes in appetite, and ► sexual dysfunction. Approximately 5% of youths, mainly young children, may have behavioral activation characterized by increased agitation and irritability or silliness. It is clinically important to differentiate these symptoms from mania or hypomania that may be induced by the antidepressant in children and adolescents with bipolar disorder or a family history of bipolar disorder. Other rare side effects include ► serotonin syndrome, ► extrapyramidal syndrome and increased bleeding time.

Side effects that are specific to some newer antidepressants include elevated blood pressure and tachycardia with venlafaxine; increased appetite, weight gain and somnolence with mirtazapine; risk of priapism in males taking trazodone; risk of fulminant hepatitis with nefazodone (which has led to its removal from some markets as a result); and risk of seizure with immediate-release formulations of bupropion, especially in doses higher than 400 mg/day and in patients with a history of eating disorders.

Treatment of Resistant Depression

Issues to consider in treating a child or adolescent who is not responding to treatment include misdiagnosis, undetected bipolar disorder, untreated comorbid medical or psychiatric disorder and non-adherence to treatment. Evidence shows that for the treatment of depressed adolescents who have not responded to an initial adequate trial with an SSRI, a switch to another SSRI is just as efficacious as a switch to venlafaxine, with fewer side effects (Brent et al. 2008). Small studies using ► lithium augmentation in resistant depression in adolescents have shown contradictory results. Studies in adult depression suggest that augmentation with atypical antipsychotics (such as ► aripiprazole), lithium, or thyroid hormone (T3) is efficacious and well-tolerated, but such studies have not been conducted in younger populations. Finally, some reports have suggested that ► electroconvulsive therapy (ECT) may be efficacious in treating resistant depression in adolescents, especially those with bipolar depression, although further research in this area is needed.

Diamorphine

Synonyms

Diacetylmorphine; Heroin

Definition

Diamorphine is more commonly known as heroin. It is a semisynthetic opioid drug synthesized from morphine, obtained from the opium poppy. It reaches the brain rapidly, where it is deacetylated into 6-monoacetylmorphine (6-MAM) and then into morphine, which binds to μ-opioid receptors to produce the drug's euphoric, analgesic, and anxiolytic effects. Diacetylmorphine itself exhibits relatively low affinity for the μ receptor. It has an extremely high potential for abuse and only limited medical uses, due to the wide range of other substances available. Frequent and regular administration is associated with tolerance, physical dependence, and severe psychological dependence.

Diazepam

Definition

Diazepam is a classical benzodiazepine drug with sedative, hypnotic, anxiolytic, amnestic, muscle-relaxant and anticonvulsant activity. It produces these effects by potentiating the effects of ► GABA at $GABA_A$ receptors. Diazepam, like other ► benzodiazepines, binds to a distinct site within the $GABA_A$ receptor ion channel complex causing a conformational change in the receptor ion channel that potentiates the effects of GABA. Thus, the channel passes more current in a given time and produces greater neural inhibition. Diazepam itself has a ► half-life of approximately 30 h but there are several active metabolites that considerably increase the active half-life (range 20–100 h). It is used widely for sedation and as an anxiolytic, in particular, as a premedication before surgery, and sometimes for inducing brief anesthesia during minor investigative or surgical procedures. It is also used as an adjunct treatment for the relief of skeletal muscle spasm, for

convulsive disorders especially *Status epilepticus*, and for the treatment of alcohol withdrawal. Diazepam is also used recreationally either alone as a sedative or to enhance the effects of alcohol or opioids, for example, diazepam reportedly produces an augmented high when administered with methadone. Diazepam is also used by cocaine users to reduce the risk of seizures and by heroin users to enhance the effects of heroin. In addition, it is often used by cocaine and heroin users and alcoholics to reduce withdrawal symptoms between doses. The main adverse effect associated with the long-term clinical administration of diazepam is tolerance and dependence.

Digital EEG Nomenclature

Synonyms

Electroencephalography; qEEG; Spectrograms

Definition

Digitization is carried out at sampling rates that are often called "sampling frequency." To avoid confusion with frequencies in EEG signals, this will be expressed in samples/s units. High-pass section is mostly carried out by digital filters and expressed in Hertz, normally set at 0.3–0.5 Hz. In the old literature, this section was determined by RC-circuits, and its characteristics are expressed in time constants t s, the shorter its value, the faster the relaxation is dampened. A t of 0.6 corresponds roughly with 0.3 Hz high pass. EEG frequency bands are also expressed in Hertz, but one can still find the expression cycles-per-second, cycles/s or cps.

Dihydrocodeine

Synonyms

DHC; DF-118; Paracodeine

Definition

Dihydrocodeine is a semisynthetic opioid analgesic developed in Germany in 1908 and released on the market in 1911. Dihydrocodeine is a powerful cough suppressant like all other members of the immediate codeine family and their cousins hydrocodone and oxycodone. It is also an analgesic, but the antitussive dose tends to be less than the analgesic dose. It is prescribed either alone or compounded with aspirin or paracetamol. In some countries, controlled-release dihydrocodeine is used as an alternative to methadone in treatment of opioid dependency and addiction.

Discontinuation Symptoms

Definition

Symptoms that emerge or worsen markedly, following either the withdrawal or a reduction in prescribed dosage of medication, seen with most classes of psychotropic drug but perhaps most visibly with benzodiazepines and some SSRIs. Symptoms are typically at their worst within the first week, although some patients report symptoms persisting over longer periods.

Discrete-Cue-Induced Reinstatement

Definition

In this procedure, laboratory animals are first trained to self-administer a drug or nondrug reinforcer; each reinforcer delivery is temporally paired with a discrete cue (e.g., tone, light). Lever pressing is then extinguished in the absence of the reinforcer and the cue. During reinstatement testing, exposure to the cue, which is earned contingently during testing, reliably reinstates responding.

Discriminative-Cue-Induced Reinstatement

Definition

In this procedure, rats are trained to self-administer a reinforcer in the presence of distinct discriminative stimuli; one set of stimuli signals reinforcer availability (S+) and the other signals unavailability (S−). Lever pressing is then extinguished in the absence of the discriminative stimuli. During the reinstatement test, re-exposure to the S+ reinstates lever responding.

Discriminative Stimulus

Synonyms

Cue (in psychology); Discriminative cue

Definition

A discriminative stimulus is an environmental event that sets (signals) occasions during which a behavioral response has a significant consequence such as the presentation or withholding of a reinforcer. Discriminative stimuli may be present either in the external environment (exteroceptive stimuli) or the internal environment (interoceptive stimuli).

Definition

Dissociative anesthesia is a form of anesthesia characterized by ► catalepsy, ► catatonia, analgesia, and amnesia. It does not necessarily involve loss of consciousness, and thus does not always imply a state of ► general anesthesia. Dissociative anesthetics probably produce this state by interfering with the transmission of incoming sensory signals to the cerebral cortex and by interfering with communication between different parts of the central nervous system.

Pharmacological Properties

History

Most dissociative anesthetics are members of the phenyl cyclohexamine group of chemicals. Agents from this group were first used in clinical practice in the 1950s. Early experience with agents from this group, such as ► phencyclidine and cyclohexamine hydrochloride, showed an unacceptably high incidence of inadequate anesthesia, convulsions, and psychotic symptoms (Pender 1971). These agents never entered routine clinical practice, but phencyclidine (phenylcyclohexylpiperidine, commonly referred to as PCP or "angel dust") has remained as drug of abuse in many societies. In clinical testing in the 1960s, ► ketamine (2-(2-chlorophenyl)-2-(methylamino)-cyclohexanone) was shown not to cause convulsions, but was still associated with anesthetic emergence phenomena, such as ► hallucinations and agitation, albeit of shorter duration. It became commercially available in 1970. There

are two optical isomers of ketamine: S(+) ketamine and R(−) ketamine. The S(+)-isomer is approximately three to four times as potent as the R(−)-isomer, probably because of higher affinity of the S(+)-isomer to the phencyclidine binding sites on NMDA receptors (see subsequent text). The S(+) enantiomer may have more pschotomimetic properties (although it is not clear whether this simply reflects its increased potency). Conversely, R(−) ketamine may preferentially bind to opioid receptors (see subsequent text). Although a clinical preparation of the S(+)-isomer is available in some countries, the most common preparation in clinical use is a racemic mixture of the two isomers.

The only other agents with dissociative features still commonly used in clinical practice are ► nitrous oxide, first used clinically in the 1840s as an inhalational anesthetic, and dextromethorphan, an agent used as an antitussive in cough syrups since 1958. Muscimol (a potent $GABA_A$ agonist derived from the amanita muscaria mushroom), and salvinorin A (a κ-opioid receptor agonist derived from the plant salvia divinorum), are also said to be dissociative drugs, and have been used in mystic and religious rituals (► Ritual uses of psychoactive drugs).

Mechanisms of Action

The primary direct molecular mechanism of action of ketamine (in common with other dissociative agents such as nitrous oxide, phencyclidine, and dextromethorphan) occur via an antagonist effect at the ► N-methyl-D-aspartate (NDMA) receptor. It may also act via an agonist effect on ► κ-opioid receptors (► Opioids). (Sharp 1997) ► Positron emission tomography (PET) imaging studies suggest that the mechanism of action does not involve binding at the ► γ-amino butyric acid ► GABAA receptor. (Salmi et al. 2005)

Indirect, downstream effects are variable, and somewhat controversial. The subjective effects of ketamine appear to be mediated by increased release of ► glutamate, (Deakin et al. 2008) and also by increased dopamine release mediated by a glutamate-dopamine interaction in the posterior cingulate cortex. (Aalto et al. 2005) Despite its specificity in receptor-ligand interactions noted earlier, ketamine may cause indirect inhibitory effects on GABA-ergic interneurons, resulting in a disinhibiting effect, with a resulting increased release of serotonin, norepinephrine, and dopamine at downstream sites.

The sites at which dissociative agents (such as subanesthetic doses of ketamine) produce their neurocognitive and psychotomimetic effects are partly understood. ► Functional MRI (► fMRI) (► Magnetic resonance imaging functional studies) in healthy subjects who were given low doses of ketamine have shown that ketamine activates a network of brain regions, including the prefrontal cortex, striatum, and anterior cingulate cortex. Other studies suggest deactivation of the posterior cingulate region. Interestingly, these effects scale with the psychogenic effects of the agent, and are concordant with functional imaging abnormalities observed in patients with ► schizophrenia (Fletcher et al. 2006; Pomaral-Clotet et al. 2006). Despite these data, it remains unclear whether these fMRI findings directly identify the sites of ketamine action, or whether they characterize the downstream effects of the drug. In particular, direct displacement studies with PET, using ^{11}C-labeled *N*-methyl-ketamine as a ligand, do not show clearly concordant patterns with fMRI data. Further, the role of direct vascular effects of the drug remain uncertain, since there are clear discordances in the regional specificity and magnitude of changes in cerebral blood flow, oxygen metabolism, and glucose uptake, as studied by PET in healthy humans. (Langsjo et al. 2004)

The neurophysiological effects of anesthetic doses of ketamine are different from those of most other anesthetic agents. When used as the sole anesthetic agent, ketamine results in maintained or increased global cerebral metabolism and cerebral blood flow, whereas most anesthetic agents reduce cerebral blood flow and metabolism. The regional cerebrovascular and metabolic effects of anesthetic doses of ketamine have been studied in animal models, and are broadly concordant, but no data are available in humans. However, the global increases in cerebral blood flow and volume produced by ketamine mean that, in patients with poor intracranial compliance, ketamine can cause increases in intracranial pressure. ► Electroencephalography shows that electrical activity during ketamine-induced anesthesia is maintained, with alternating periods of high amplitude delta activity and periods of fast activity. Again, when there are regional variations in such effects, their relationship to regional physiology and metabolism, and their neurochemical specificity, are poorly studied in man.

Pharmacokinetics

For medical use, a 10 mg/ml or 50 mg/ml solution is administered by intramuscular injection or, more commonly, by intravenous injection. Being a lipophilic drug, the onset of clinical effects is rapid and the time to peak effect after a bolus intravenous dose is short, suggesting that the drug crosses the ► blood-brain barrier rapidly. No estimates of the blood-effect-site equilibration rate constant have been published.

The initial volume of distribution is 60–80 L. Ketamine undergoes extensive re-distribution – two and three compartment ▶ pharmacokinetic models have been described. Fast re-distribution results in a short duration of action after a bolus dose (half-life 11–17 min). Lipophilicity results in accumulation in the fatty tissues. Published volumes of distribution at steady state are in the range 200–350 L (Reilly 1994; Sinner and Graf 2008).

Ketamine undergoes hepatic metabolism. Demethylation results in the major metabolite, norketamine, which possesses sedative and analgesic properties (potency is ~20% of ketamine). After hydroxylation and conjugation, norketamine is excreted by the kidneys. ▶ Elimination half-life is 2.5–4 h. Total clearance is ~1,200 mL/min. Despite accumulation, the relatively fast rate of metabolism makes ketamine an ideal agent for use by infusion.

Ketamine in powder form is rapidly absorbed via the mucosal surfaces of the upper airway, and so when used for recreational purposes (▶ Self-administration of drugs) it is usually administered by insufflation. Oral administration is seldom used since mean bioavailability is ~16%, and drug absorbed through the gut mucosa is rapidly metabolized to norketamine, resulting in sedation, which limits the dissociative effects.

Efficacy/Doses

Ketamine is used in clinical practice in two main indications. At moderate doses, it is a powerful analgesic, whereas at higher doses it is used as an anesthetic agent in specific situations (see below). Its ability to block NMDA-receptors has prompted studies investigating its role as a ▶ neuroprotective agent, and as a treatment for refractory status epilepticus. Intriguingly, in other settings (particularly in the developing brain and in aged animals) ketamine has been shown to be neurotoxic. Very low doses of ketamine have found a substantial research role in producing human models of ▶ schizophrenia. For analgesia without unconsciousness, intravenous dose requirements are 0.25–0.75 mg/kg, whereas intramuscular dose requirements are ~0.5–2 mg/kg. Bolus doses toward the upper end of the above ranges will result in a dissociated state with sometimes profound psychiatric symptoms (such as the "▶ k-hole"). The plasma levels at which psychotomimetic symptoms develop range between 50 and 300 ng/mL, analgesic effects are observed at about 200 ng/mL, whereas anesthesia is achieved at plasma levels above 1,000 ng/mL.

For anesthesia, an intramuscular dose of 8–10 mg/kg will produce loss of consciousness within 5 min, and anesthesia lasting for approximately 30 min. An intravenous dose of 1–2 mg/kg will produce loss of consciousness within 2 min, and anesthesia lasting 10–15 min. After an initial intravenous bolus dose, anesthesia can be maintained with additional bolus doses of 0.5 mg/kg or by an infusion at 1–2 mg/kg/h.

Safety/Tolerability

Ketamine increases in upper airway secretions, which can be attenuated by prior treatment with an anticholinergic agent. It can cause post-operative nausea and vomiting, and is associated with unpleasant dreams and hallucinations on emergence, with nightmares on subsequent days. These psychiatric phenomena can be attenuated by concomitant administration of a ▶ benzodiazepine or propofol, an intravenous anesthetic agent that acts at GABA receptors.

When used for recreational purposes, ketamine causes hallucinations, and a dissociative state characterized by depersonalization and derealization. At higher doses, users may experience a constellation of symptoms colloquially known as a "k hole." In clinical studies, infusions of subsedative doses produce several of the negative symptoms of schizophrenia, producing a reversible model for studying its pathogenesis. Such studies have shown that low doses of ketamine can produce impairments in ▶ working memory and ▶ episodic memory functions found in patients with schizophrenia. (Corlett et al. 2006)

Compared with other anesthetic agents, respiratory drive, airway reflexes, and ventilation are well maintained with ketamine, although at higher doses respiratory depression and apnoea will eventually occur. Ketamine possesses sympathomimetic properties, resulting in bronchodilation, increases in heart rate, and maintained or increased blood pressure in normovolaemic patients. Very low doses may cause favorable effects on immune functions. Ketamine is a potent analgesic. Subanesthetic doses have been shown to produce postoperative analgesia and to have antihyperalgesic activity. These powerful analgesic properties make it useful in occasional patients with severe chronic pain, unresponsive to first line analgesics. Ketamine may have a role in the prevention of chronic pain when used as an analgesic for acute (typically post-operative) pain, possibly by preventing ▶ central sensitization in neural systems. Ketamine has also been used for the treatment of chronic pain, by the oral, parenteral, and spinal routes.

The paucity of cardio-respiratory depressant effects makes ketamine an ideal anesthetic agent for use in poorer countries, where facilities for ventilation and airway management may be limited, and also in trauma situations, where patients may have suffered significant blood loss resulting in hypovolaemia (and in whom other anesthetic agents may result in significant falls in blood pressure).

In children, it is sometimes used by intramuscular injection for sedation where intravenous access is difficult to achieve. The analgesic properties can make ketamine a useful agent for short-term sedation or dissociative anesthesia for painful procedures, such as burns dressing changes.

Conclusion

Recreational use of ketamine is common in many countries. In contrast, the use of dissociative anesthesia is becoming increasingly rare in the first world, since adequate sedation, analgesia, and anesthesia can be achieved with one or more newer agents with fewer adverse effects. However, ketamine is being used increasingly as an adjuvant analgesic during general anesthesia. The adverse psychiatric effects that limit its use in clinical practice do, however, provide a useful model for investigating the cognitive deficits and pathogenesis of schizophrenia. Functional imaging studies can identify the neuroanatomical sites at which altered cognitive function occurs in subjects receiving ketamine, and may thus identify the areas where altered function results in the behavioral and cognitive changes common to schizophrenia and low-dose ketamine administration. Finally, in chronic pain studies, ketamine may provide insights into the pathogenesis of chronic pain, and may have a role in the prevention and treatment of chronic pain.

Dissociative Reaction

Definition

A psychological reaction characterized by such behavior as amnesia, fugues, sleepwalking, and dream states.

Distance Traveled

Synonyms

Cumulative distance moved

Definition

Distance traveled is the sum of the distances between successive *x*–*y* coordinate pairs that define an animal's momentary position on the horizontal plane that forms the floor of the instrument that is used to quantify locomotor activity. Video tracking systems, photobeam actometers, and force-plate actometers all provide *x*–*y* coordinate pairs with varying degrees of spatial and temporal resolution. Because of a lack of calibration standards as well as a multiplicity of recording methods, it is difficult to compare distance traveled measures across laboratories, unless they happen to use the same instruments, software, and summing intervals.

Distress Vocalization

Definition

Mammalian vocalizations are the product of respiratory and laryngeal activities under the direct control of brain stem cranial and spinal motor neurons and modulated by higher brain processes (Miczek et al. 1995; Newman 2007). Distress vocalizations are sounds produced in the presence of painful, stressful, or threatening stimuli. Vocalizations are a particularly attractive candidate for psychopharmacological research because they represent species specific and ethologically relevant behaviors spontaneously expressed in response to unique provocation. Vocalizations offer the further promise of unique informational content about the emotional state of the subject. Finally, there is evidence that the form, contexts, and neural processes which modulate distress vocalizations are highly conserved between species (Newman 2007). This makes them a particularly attractive candidate for translating findings from animal models to human clinical conditions.

Pharmacological studies of distress vocalizations can be predominantly clustered according to the maturity of the subjects examined – infant or adult.

Types of Distress Calls

Infant distress vocalization: The production of vocalizations by infant mammals during parental separations has been detected in virtually every known mammalian species including humans (Newman 2007). Rat and mouse infant vocalizations have been the most vigorously studied by psychopharmacologists and are expressed in the ► ultrasonic frequency range. Drug effects on the vocalization by several nonhuman primate species have also been examined including rhesus, squirrel, and marmoset monkeys. Across species, infant vocalizations share remarkable structural as well as contextual similarities (Newman 2007) (Fig. 1).

Adult distress vocalization: Adult animals also produce intense vocalizations when provoked by painful, threatening, or stressful stimuli or during drug withdrawal. Like infant vocalizations, these too share remarkable structural similarities between species, and in rodents they are also predominantly ultrasonic (Miczek et al. 1995; Sanchez 2003).

Vocalizations in both age groups have been proposed to reflect emotional states of fear or anxiety. Consequently, they have been primarily the target of research related to ► anxiolytic drugs and/or neural substrates of emotional behavior. The separation vocalizations of infant animals have also been proposed to reflect frustration of attachment bonds and consequently a further focus of pharmacological research has examined neural processes associated with the formation and maintenance of social bonds.

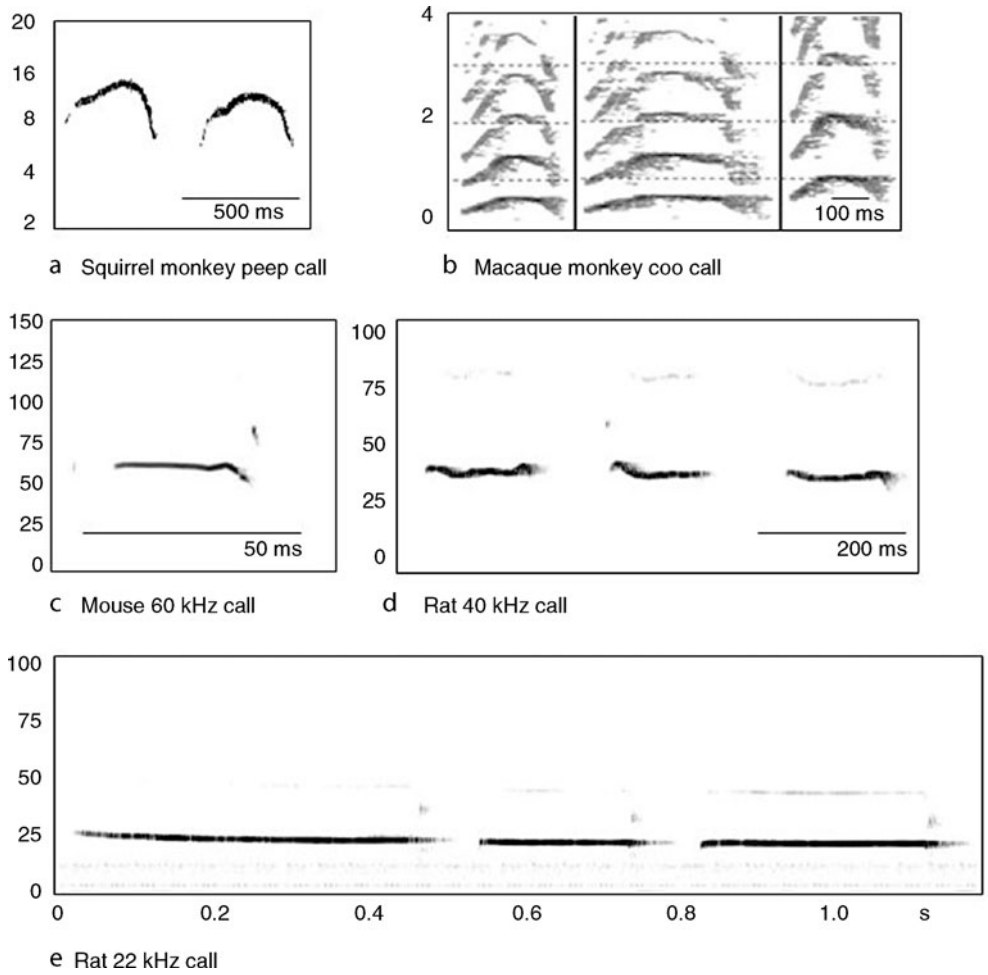
In the ensuing essay, we will focus our discussion on the ultrasonic vocalizations of rodents since the preponderance of pharmacological study has likewise been examined primarily in rodents. Nevertheless, the basic principles of measurement and many of the pharmacological findings have been replicated in nonhuman primates (Levine and Mody 2003; Winslow et al. 2007).

Measurement of Calls

Vocalizations are typically audio recorded and then defined and quantified using sound ► spectrographic techniques which also allow automated detection for some call types. For rodent species, specialized recording equipment capable of detecting ultrasonic frequency ranges is required and commercial systems are available (see Hofer et al. (2002) for an excellent guide).

Rodent infants emit ultrasonic (30–50 kHz in rat and 50–80 kHz) vocalizations ranging from 100 to 500 ms in duration virtually from the day after birth to the time of weaning. It is notable that the rate and intensity of calling varies systematically by age. Separation of a pup from its home cage, littermates, and dam into a novel test chamber elicits high rates of ultrasonic calls, and is the most frequently used eliciting stimulus in pharmacological studies.

Adult rats produce "distress" ultrasonic vocalizations in the 20–30 and 50–70 kHz range during encounters wherein they are attacked or threatened by a conspecific. 22 kHz calls are also emitted by rats in the presence of painful or stressful (e.g., startle or air-puff stimuli) stimuli as well as during opioid and cocaine withdrawal. Taken together these results suggest that distress vocalizations, particularly the 22 kHz of rats may convey an anxious or fearful emotional state common to multiple contexts. Adult mice also emit ultrasonic vocalizations; however, so far these have been detected only in reproductive encounters and not, notably, in the stressful or aversive conditions typical of rats.



Distress Vocalization. Fig. 1. Depicts distress calls expressed by infant, juvenile, and adult animals including (**a**) the isolation peep call of the juvenile squirrel monkey; (**b**) the coo call of the macaque monkey (Japanese); (**c**) the mouse pup ultrasonic separation call; (**d**) the rat pup ultrasonic separation call; and (**e**) the 22 kHz ultrasonic distress call of the adult rat. The call shows remarkable similarities in form. (Adapted from Ceugniet and Izumi 2004; Miczek et al. 1995; and www.avisoft.com/rat.)

Measurements of duration of ultrasonic vocalization, inter-ultrasonic vocalization interval, bout structure, and detailed acoustic analysis of calls have been performed, but have not been systematically studied in relation to eliciting conditions, regulation by sensory cues, or neural control though initial efforts suggest important information may be available in these parameters (Scattoni et al. 2008).

Caveats and Controversies

Developmental changes in vocalization: Infant vocalizations show a pronounced change in the pattern of calling as animals mature. Ultrasonic vocalization responses of infant rodents follow a fairly predictable developmental pattern. The first ultrasonic vocalization response to isolation occurs in a day or two after birth at a moderate rate at typical ambient temperatures (32–35°C), then rises to a peak in the first week at about 100/min, finally beginning a gradual decline until approximately the same age they obtain ▶ homeothermy, at which point few or ultrasonic vocalizations may be detected within a 10 min separation test. Conversely, adult-type vocalizations in appropriate contexts once established in puberty remain remarkably stable though not without variability between individuals.

Role of thermoregulation: The ambient temperature of the test chamber is the most easily manipulated regulator of ultrasonic vocalization rate in rat and mouse pups during their first two weeks of postnatal life (Hofer 2002). Ultrasonic vocalization rates expressed by isolated pups can be systematically varied from 10 or less calls per

minute at typical ambient temperatures up to 200 calls/min in cooler environments. The relationship between ultrasonic vocalization and temperature has led some to hypothesize that ultrasonic vocalization emissions might also play a role in pups' physiological thermoregulatory capacity (Blumberg and Alberts 1991). According to this view ultrasonic vocalization could be considered, at least in part, a byproduct of thermoregulatory physiology rather than an affective expression in a communicative system (Blumberg and Alberts 1991). Indeed, correlations have been found between ultrasonic vocalization production and thermoregulatory and cardiovascular changes. Similar proposals have been offered to account for adult rodent ultrasonic vocalizations. Nevertheless, a clear physiological role for ultrasonic vocalization in thermoregulation has yet to be demonstrated except perhaps during recovery from severe hypothermia (Hofer and Shair 1992). In contrast, there are several lines of evidence that the physiological changes involved in the act of ultrasonic vocalization emission do not play a functionally significant role in the thermoregulation of young rats, at least under typical test conditions (Hofer 2002).

Species and strain differences: As noted earlier, while there appear to be many similarities between species in context, form, and neural processes, there are nevertheless important differences between species that are evident – not the least being the frequency range within which the calls are expressed. In addition, there are differences in the sensitivity of the rodent species to the modulation of calling by social stimuli (e.g., comforting upon return of the mother to her infant) or the type and intensity of provocation by some stimuli in adult animals (Hofer 2002). These are even more evident in the wide range of differences in the rate of calling that can be obtained when comparing between various strains of mice used in genetic modeling research (Wohr et al. 2008).

Impact of Psychoactive Drugs

Pharmacological studies of distress vocalizations have been undertaken for various reasons, from aiding the development of animal models of clinical anxiety to demonstrating the functional efficacy of a system in development, or to examining the neural processes related to the formation and maintenance of social attachment – particularly infant–mother bonds.

Infant distress vocalizations have proven to be remarkably sensitive to both the anxiolytic-like effects of GABAergic, serotonergic, and glutamatergic receptor subtype selective ▶ ligands as well as the ▶ anxiogenic-like effects often reported for ligands with complementary actions at the same or related receptor subtypes (Winslow and Insel 1991). Thus, for example, GABA-A agonists such as ▶ diazepam reduce vocalizations while antagonists such as pentylenetetrazol increase vocalizations (Miczek et al. 1995). Conversely glutamate receptor antagonists such as MK801 decrease while agonists such as NMDA increase calling (Winslow et al. 1990). Similarly, serotoninergic drugs with putative anxiolytic properties such as the 5HT-1A receptor agonist ▶ buspirone reduce calling in infant rats while 5HT-1B receptor agonists appear to increase call rates, although the dose relationship may be complex (Winslow and Insel 1991). Similarly, studies of adult distress vocalizations indicate comparable predictive validity for GABAergic, glutamatergic, and serotonergic ligands as anxiolytic or anxiogenic compounds depending on the subtype of the receptor affected (Sanchez 2003; Takahashi et al. 2008).

A number of systems have been proposed to have important roles in the formation and maintenance of attachment bonds between social animals. Prominent among these are the opioid system because social attachment has some similarities to drug dependence. Oxytocin and vasopressin have also been implicated in the formation and maintenance of mother–infant bonds as well as between adults with monogamous mating strategies. Studies of the effects of ligands active in these systems have generally demonstrated that distress vocalizations provoked by maternal loss are predictably modulated. For example, oxytocin or ▶ morphine administration effectively quiets infant mice, rats, and young monkeys separated from their social companions.

Distress vocalizations are a prominent feature of withdrawal from chronic administration of a variety of pharmacological drugs of dependence including opiates, benzodiazepines, ▶ alcohol, and ▶ psychomotor stimulants (Covington and Miczek 2003). While distress vocalizations during withdrawal are evident in a variety of species, systematic study has been thus far limited to rats. These few studies have demonstrated that the rate of calling is independent of an audience and directly related to key parameters of chronic administration such as how much drug is administered, for how long and whether the drug is self-administered or administered by a researcher (Covington and Miczek 2003).

Disulfiram

Bankole A. Johnson
Department of Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA, USA

Synonyms

Tetraethylthiuram disulphide

Definition

Disulfiram is one of several aldehyde dehydrogenase (ALDH) inhibitors that increase the plasma level of ▶ acetaldehyde in the body following the ingestion of ethanol. Disulfiram is currently used in the treatment of alcoholism.

Pharmacological Properties

History

As early as 1937, it was realized that exposure to disulfiram (tetraethylthiuram disulphide) resulted in abstinence from alcohol. Tetraethylthiuram disulphide has been used since the 1880s in the manufacturing process of rubber (Suh et al. 2006). E. E. Williams, an American physician working at a chemical plant, was the first to observe that workers who were exposed to disulfiram experienced unpleasant effects after drinking alcohol and, as a result, involuntarily abstained from alcohol. Williams (1937) sent a letter to the editor of the *Journal of the American Medical Association* (*JAMA*) suggesting that the compound could be beneficial as a cure for alcoholism. The discovery remained overlooked until 1945 when Hald, Jacobsen, and Larsen, experimenting with disulfiram as

an antihelminthic drug, ingested the drug and alcohol and experienced the unpleasant side effects firsthand. Realizing the potential of the drug, they went into collaboration with a clinician, Martensen-Larsen, to expand the research of disulfiram to alcoholics (Petersen 1992). The results were promising, pointing to disulfiram as a potential pharmacological treatment for alcoholism.

► Pharmacokinetics

Absorption and Biotransformation

Following oral administration, disulfiram is rapidly absorbed from the gastrointestinal tract and is distributed across the mucosa into the blood. Endogenous thiols and the glutathione reductase system of erythrocytes then reduce disulfiram to its monomer, diethyldithiocarbamic acid (DDC). DDC, while unstable in the extremely acidic environment of the stomach, is a strong metal-chelating agent that has an affinity for cupric ions, forming a bis (diethyldithiocarbamato) copper complex ($Cu(DDC)_2$). $Cu(DDC)_2$ is rapidly degraded after its formation during the simultaneous reformation of DDC. DDC is itself unstable in biological tissues and is degraded into diethylamine (DEA) and CS_2, both of which are eliminated without further degradation.

Another metabolite of disulfiram, diethylthiomethylcarbamate (Me-DTC), is formed by oxidative desulfuration, which is mediated by microsomal ► cytochrome P450 mono-oxygenases. The last oxidative biotransformation of disulfiram produces formaldehyde, inorganic sulfate, and methanethiol (Johansson 1992).

Distribution, Protein Binding, and Excretion

Following absorption, disulfiram and its metabolites are evenly distributed throughout the body in a variety of tissues including the kidney, heart, liver, thyroid gland, adrenal gland, pancreas, and muscle, with lesser amounts observed in blood and the brain. Disulfiram and its metabolite DDC are bound to proteins by an interaction with protein-free thiol groups, while, in the blood, disulfiram and its metabolite Me-DTC are extensively bound to plasma albumin.

The metabolites of disulfiram are excreted by means of the lungs, kidney, and feces. Less than a quarter of the intact drug is excreted in the feces. The majority of metabolites, especially DDC, are eliminated by the kidneys. Although no excretion data are available for Me-DTC, the CS_2 produced from the degradation of DDC in tissues is eliminated from the lungs. Only minor amounts of DDC, Me-DTC, CS_2, and DEA are detectable in urine (Johansson 1992).

Aldehyde Dehydrogenase (ALDH) Inhibition – Mechanism of Action

Following consumption of ethanol, the first oxidation metabolite produced is ► acetaldehyde. Because acetaldehyde is toxic to cells, it is essential that it is metabolized further. The next step in the elimination of ethanol is made possible by the enzyme ALDH, which almost instantaneously metabolizes the toxic acetaldehyde to the nontoxic acetate. There are four different ► isozyme forms of ALDH although the two main forms involved in the oxidation of acetaldehyde are ALDH1 and ALDH2, both of which are found mainly in the liver.

Disulfiram has a preference for ALDH1, and this preferential inhibition causes a marked increase in acetaldehyde following the ingestion of ethanol. The rapid accumulation of acetaldehyde occurs not only because the enzyme that degrades it is inhibited, but also because the enzyme that degrades ethanol into acetaldehyde, ► alcohol dehydrogenase (ADH), has a faster turnover rate than ALDH. Not only does disulfiram block ALDH1, but its metabolites play a role in inhibiting ALDH as well. Specifically, Me-DTC has been characterized as an irreversible inactivator of ALDH1. The overall inhibition of ALDH by disulfiram and its metabolites is via a quick competitive inactivation, which is then followed by the irreversible inhibition of the enzyme, halting its activity (Johansson 1992).

The consequential buildup of acetaldehyde from blocking its metabolism by ALDH is responsible for the negative effects associated with combining disulfiram and ethanol. These negative effects are proportional to the amount of ethanol ingested. Immediately after drinking, the person experiences facial flushing, a mild headache, and sweating. The effects may then worsen to include nausea, vomiting, palpitation, hyperventilation, and hypotension. The most severe effects may include respiratory depression, arrhythmias, unconsciousness, convulsions, congestive heart failure, cardiovascular collapse, and even death (Suh et al. 2006).

Drug Interactions

There are a large number of reported compounds that adversely interact with disulfiram. Those drugs that interfere with the dopamine/norepinephrine system should not be administered with disulfiram because this may cause sleeplessness, paranoia, and even ► psychosis. Examples of drugs that interfere with the dopamine/norepinephrine system include ► bupropion, ► amphetamines, ► methylphenidate, and ► cocaine. Interestingly, the pesticide thiram acts as a disulfiram analog, and its use should be avoided by anyone taking disulfiram. The *Coprinus atramentarius* species of mushroom should also

be avoided since it is an ALDH inhibitor (Johansson 1992).

Drugs that use cytochrome P450 for oxidative metabolism have been found to change their biotransformation rate when coadministered with disulfiram. In particular, warfarin and some of the ► tricyclic antidepressants such as ► amitriptyline and ► imipramine have prolonged plasma clearance rates when given with disulfiram.

Other drugs that do not utilize cytochrome P450 for metabolic oxidation still show a prolonged clearance rate when coadministered with disulfiram. These drugs include ► barbiturates, many of the ► benzodiazepines including diazepam. ► Caffeine metabolism is also prolonged in persons taking disulfiram. Patients on the bronchodilator theophylline should also be aware that concurrent use with disulfiram will cause them to experience a prolonged effect of the bronchodilating methylxanthine (Johansson 1992).

Efficacy

While disulfiram is a useful aversion therapy drug, there are other variables at work. The efficacy of disulfiram is more dependent on compliance than only on the drug itself. When patients are closely monitored during the course of treatment, the efficacy of disulfiram is quite good. In fact, a review by Brewer et al. (2000) reported that 17 out of 18 disulfiram studies demonstrated the effectiveness of disulfiram when subjects were directly supervised. Without supervision, the adherence rate can be as low as 20% (Suh et al. 2006).

Another factor that influences the efficacy of disulfiram is the patient. When patients have stability in the home and family, are not uncontrolled heavy drinkers, and are motivated to abstain from alcohol, they display better adherence to disulfiram treatment. Although disulfiram no longer holds the key to a cure for alcoholism, it can be a very helpful tool when combined with appropriate supervision and support (Johnson 2008).

Safety/Tolerability

When disulfiram was first being evaluated as a treatment for alcoholism, the dose range was between 1,000 and 3,000 mg/day. At such high doses, severe ► adverse effects were not uncommon. Such adverse effects included psychosis, sudden circulatory collapse, and sudden respiratory collapse. It is important to note, however, that most of the patients who suffered a fatal disulfiram-ethanol reaction were reported to have consumed large amounts of alcohol following disulfiram administration, a combination that undoubtedly contributed to their deaths (Suh et al. 2006).

Besides the high doses of disulfiram, early treatments also involved an initial aversion trial in which the patient would purposefully be given disulfiram and ethanol. The point was to demonstrate to the patient, under controlled medical conditions, how the disulfiram-ethanol interaction would feel and thus prevent patients from drinking while being treated with disulfiram. The practice of the initial aversion trial was later discontinued, and patients were only given verbal descriptions of the side effects of the disulfiram-ethanol reaction. This change in practice ushered in the use of disulfiram as strictly a psychological deterrent to drinking while reinforcing the importance of close supervision during treatment.

Current treatment guidelines state that the lowest possible dose of disulfiram should be given in order to obtain the required result. The FDA recommends a daily dose of 250 mg, but some patients can take as little as 125 mg or up to as much as 500 mg. At these doses, disulfiram is safe and well tolerated for both short- and long-term treatment of alcoholism (Suh et al. 2006).

The most frequently reported side effects of disulfiram in the absence of alcohol include headache, drowsiness, dermatitis, and a garlic-like aftertaste. Another less common side effect is ► hepatotoxicity, especially in persons with liver disease. This adverse effect can, however, be avoided by providing the patient with educational materials and by conducting frequent liver function testing.

Disulfiram is contraindicated in persons with cardiovascular as well as cerebrovascular disease. Patients with severe liver function abnormalities should also refrain from taking disulfiram. Disulfiram is a pregnancy category C compound and should not be given to women who are or may become pregnant during the course of treatment.

Conclusion

In conclusion, disulfiram continues to play an important role in helping people who abuse alcohol to achieve abstinence. Although disulfiram is in no way a panacea, its use as an aversion therapeutic in conjunction with appropriate supervision can help people to effectively abstain from alcohol consumption. It is up to the clinician to determine whether the patient would be successful in adhering to the disulfiram course of treatment and to make sure that the patient has all the necessary resources to be successful.

DNA Methylation

Definition

DNA methylation is one of the most characterized epigenetic modifications and is associated with gene silencing. It refers to the addition of methyl groups to the number 5 carbon of the pyrimidine ring of the DNA base cytosine, due to activation of enzymes known as DNA methyltransferases. This usually results in a reduction in expression of the associated gene.

Dopamine

Synonyms

DA

Definition

A major modulatory brain monoamine neurotransmitter released by axons of cell groups located in the midbrain and other deep brain areas, and synthesized in the brain from the amino acid tyrosine. It is an intermediate step in the synthesis of ► norepinephrine and epinephrine. Four dopaminergic pathways have been localized in the central nervous system: mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular. Furthermore, five receptors have identified (D_1–D_5) within two families: D_1 (D_1, D_5), D_2 (D_2, D_3, D_4). Extracellular dopamine levels are regulated by at least two mechanisms: the ► dopamine transporter, which recycles dopamine into the presynaptic terminal, and the enzyme catechol-*O*-methyltransferase, which degrades extracellular dopamine and norepinephrine.

Dopaminergic projections reach many regions of the brain, especially the dorsal striatum, where dopamine participates in the selection of motor actions; the ventral striatum or nucleus accumbens, involved in motivation and prediction of future rewards; the amygdala, processing emotional reactions, and the cerebral cortex (especially prefrontal), where dopamine regulates executive functions like attention and working memory. Thus, via its interactions with ► glutamate and ► GABA-based synaptic transmission in these regions, dopamine plays a key role in attention, cognition, motivation, and both pharmacological and biological rewards, as well as in sensory and motor functions. Dopamine is implicated in ► Parkinson's disease, ► schizophrenia, and drug ► dependence. It has long been hypothesized that at least the positive symptoms of schizophrenia (e.g., delusions, hallucinations) reflect hyperdopaminergic activity. The dopamine D_2 receptor has been tied to this effect and all available ► antipsychotics demonstrate some degree of dopamine D_2 blockade. The D_3 receptor has also been implicated in ► psychosis, while the D_1 receptor is involved in cognitive processes. The majority of abused drugs target dopaminergic synapses in the ventral striatum, inducing an increase of dopaminergic signaling.

Double-Blinded Study

Synonyms

Double-blind study; Double-masked studies

Definition

Blinded studies are part of a scientific method to prevent research outcomes from being influenced by various biases such as patient expectations (placebo effect) and experimenter expectancy (observer bias). The term blind is a figurative extension of the literal idea of blindfolding someone. The opposite of a blinded trial is an open trial. An open trial or open-label trial is a clinical trial in which both the researchers and participants know which treatment is being administered. There can be varying degrees of blinding such as single-blind, double-blind, triple-blind, etc. Double-blinded study is a term used to described a study in which both the investigator or the participant are blind to (unaware of) the nature of the treatment the participant is receiving. In a double-blind experiment, neither the individuals nor the researchers know who belongs to the control group and the experimental group. Double-blind trials are thought to produce objective results, since the expectations of the researcher and the participant about the experimental treatment such as a drug do not affect the outcome. Double-blinded studies are often chosen when a treatment shows particular promise and the illness involved is serious. It can be hard to recruit human subjects for a blinded study of a promising treatment when one group will receive only a placebo or an existing medicine.

Driving and Flying Under Influence of Drugs

Definition

Driving and flying under the influence of drugs are common, since most people who use psychoactive medication are outpatients who participate fully in society. Psychoactive medication may produce adverse effects that impair driving and flying such as reduced alertness, psychomotor impairment, and impaired vision. Most commonly prescribed psychoactive drugs include hypnotics, antidepressants, antihistamines, analgesics, and stimulant drugs. Within these categories of medicines, significant differences concerning their impact on driving and flying ability are evident. For example, benzodiazepines and tricyclic antidepressants (TCAs) significantly impair driving and flying, whereas selective serotonin reuptake inhibitors (SSRIs) do not. These differences should be taken into account when prescribing psychoactive medication to patients who are willing to drive a car or fly a plane.

Current Concepts and State of Knowledge

Introduction

In modern society, driving and flying are common modes of transportation. The majority of adults in Western society drive a car on a daily basis and worldwide over 50,000 commercial flights are performed daily. Unfortunately, driving and flying are not without risk: accidents can happen that may result in injury or even death. The World Health Organization is concerned about the worldwide increase in traffic accidents and launched various campaigns to enhance traffic safety (Peden et al. 2004). Traffic accidents are often caused by human error, distraction, and reduced alertness.

Psychoactive medication may cause sedation and reduce alertness. Therefore, these drugs can impair performance and increase the risk of traffic accidents. It is estimated that alcohol and psychoactive drugs are involved in 5–35% of road accidents (Verster et al. 2009). These percentages seem high, but one should consider that most people who use psychoactive medication are outpatients who are therefore likely to participate in traffic.

Driving

Alcohol

Experimental studies have shown that ► alcohol impairs driving performance in a dose-dependent manner. Since alcohol is the most frequently used psychoactive substance, this is of great concern. About 50 years ago, Borkenstein and colleagues performed a landmark study that showed the relationship between ► blood alcohol concentration (BAC) and the risk of becoming involved in traffic accidents. After the results of this study became public, many countries enforced laws to limit driving after alcohol consumption. Most commonly applied legal limits to drive a car are 0.05% (e.g., the Netherlands), 0.08% (UK and USA). During the last decade, many countries are lowering their legal limit to further reduce traffic accidents.

For example, for novice drivers in The Netherlands, the legal limit is lowered to BAC 0.02%. The main reason for this is the fact that young novice drivers are inexperienced drivers and often overestimate their driving skills. Despite returning public campaigns and intensified police controls, a minority of people still drive a car while intoxicated, putting themselves and others at risk. Currently, alcohol is still the number one cause of traffic accident death among young drivers.

Sleep medication

Insomnia and sleep apnea are examples of common sleep disturbances. People who suffer from these sleep complaints do not wake up refreshed and this is reflected by daytime sleepiness. The reduced alertness and distraction produced by sleepiness is the cause of many traffic accidents. This is one of the reasons that throughout the European Union, current traffic safety campaigns specifically warn against sleepy driving. The use of sleep medication is meant to help patients fall asleep or maintain sleep during the night. Unfortunately, many hypnotic drugs produce residual effects after the patient has woken up. That is, patients feel sedated and drowsy after waking up. Particularly, the traditional hypnotic drugs, i.e., the ▶ benzodiazepines, have shown this unfavorable adverse effect profile. A number of these hypnotics, including ▶ flurazepam, ▶ oxazepam, and ▶ temazepam, were studied applying the on-the-road driving test in real traffic (Verster et al. 2004). In this test, subjects drive a car over a 100-km public highway. They are instructed to maintain a constant speed (95 km/h) and steady lateral position within the right slower traffic lane. Primary parameter of the test is the Standard Deviation of Lateral Position (SDLP), i.e., the weaving of the car. A camera mounted on the roof of the car records the SDLP (see Fig. 1).

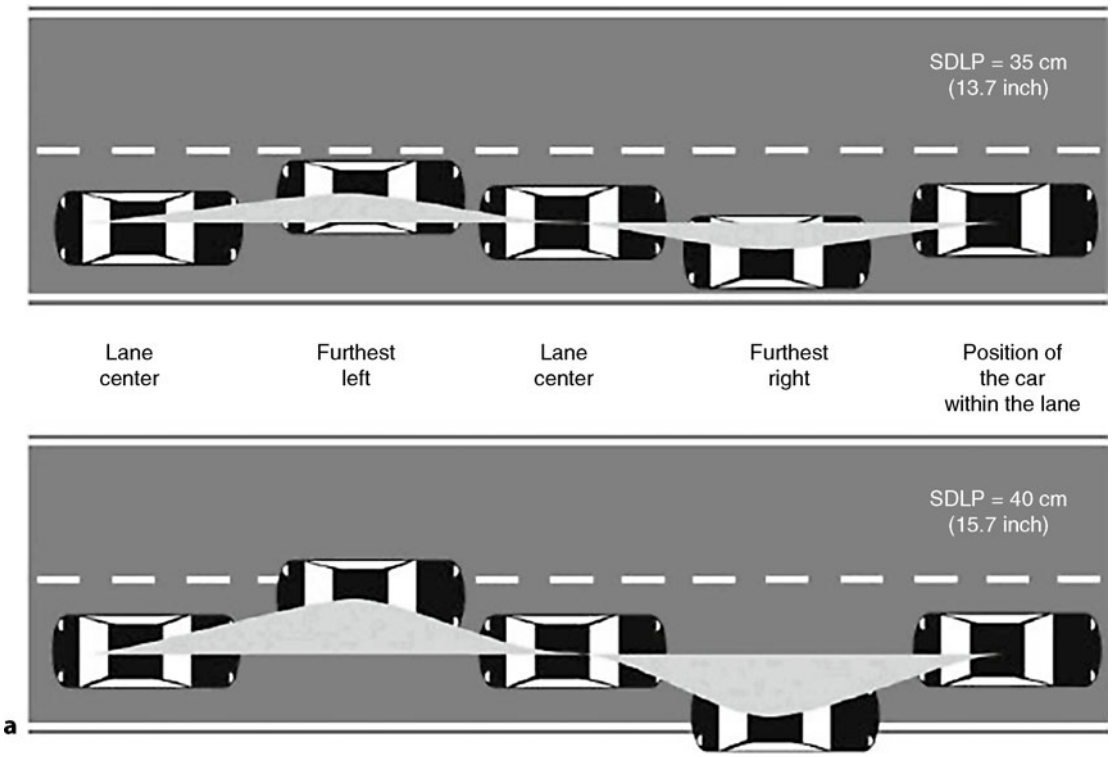
Benzodiazepine hypnotics were administered at bedtime and driving performance was tested the following morning (10–11 h after intake) and afternoon (16–17 h after intake). In the morning test, benzodiazepine hypnotics significantly impaired driving performance in a dose-dependent manner. Using twice the recommended dose (which is common in practice), driving was also significantly impaired in the afternoon. Epidemiological evidence confirmed these findings by revealing increased traffic accident risks for those using benzodiazepine hypnotics. ▶ Tolerance to the impairing effects develops slowly: increased traffic accident risks have been reported in chronic users (>1 year) as well. ▶ Zopiclone, a nonbenzodiazepine hypnotic, showed no improvement relative to the benzodiazepines. Significant increased weaving in the driving tests showed that driving was impaired and epidemiological evidence revealed a fourfold increased traffic accident risk for drivers who use zopiclone. ▶ Zolpidem and ▶ zaleplon, two other nonbenzodiazepines, did not impair driving performance when used as recommended. Future research should develop new hypnotics, preferably with a different mechanism of action, that do not produce residual effects on driving ability.

Anxiolytics

Benzodiazepines are also used for the treatment of anxiety. It is not surprising that these anxiolytics impair driving performance similar to benzodiazepines that are used as hypnotics (Verster et al. 2005). In fact, driving impairment is often much more profound because the time between drug intake and driving is much shorter when compared with hypnotics. On-the-road studies have shown significant impairment with benzodiazepine anxiolytics such as ▶ alprazolam, ▶ diazepam, and ▶ lorazepam. Epidemiological evidence shows that tolerance develops slowly when using these drugs. Driving studies confirmed that after 1 week of treatment, benzodiazepine anxiolytics also significantly impair driving performance and even after 4 weeks of treatment SDLP was significantly increased in patients treated with diazepam. TCAs such as ▶ imipramine and ▶ amitriptyline also significantly impair driving performance. Although tolerance develops more quickly when compared with benzodiazepines, in terms of traffic safety TCAs were no improvement. In contrast, a newer class of antidepressants, the SSRIs such as ▶ paroxetine and ▶ fluoxetine, and related compounds such as venlafaxine showed no impairing effects on driving performance. Also, ritanserin and ondansetron (both 5-HT antagonists), and ▶ buspirone do not affect driving ability. Thus, in terms of traffic safety, SSRIs and related compounds seem first-choice treatments.

Antidepressants

About 15% of the population suffers from ▶ depression at least once during their life and the disease is 2–3 times more common among females. Research has shown that both treated and untreated depression may impair driving performance (Ramaekers 2003). Traditionally, depression was treated with TCAs, ▶ mianserin, and ▶ mirtazapine. The first week after treatment initiation, these drugs significantly impair driving performance. Thereafter tolerance develops. Nocturnal treatment increases the time between drug use and driving and may be a solution for patients who want to drive a car. Research showed no driving impairment the morning following bedtime



Driving and Flying Under Influence of Drugs. Fig. 1. SDLP and the instrumented vehicle. (**a**) The Standard Deviation of Lateral Position (SDLP). SDLP represents the weaving of the car and is a measure of overall vehicle control. With increased SDLP, driving becomes unsafe. (**b**) The instrumented test vehicle. administration of these antidepressants. SSRIs (e.g., ► escitalopram) and ► moclobemide are also used to treat depression and do not affect driving performance. The World Health Organization expects depression to be the second highest cause of mental disability by 2030. By that time, many outpatients will be treated with antidepressants. Therefore, it is of great importance that pharmaceutical companies continue the search for new antidepressants without negative effects on driving ability.

Antihistamines

The first-generation antihistamines such as diphenhydramine and triprolidine are effective against hay fever but had the disadvantage to produce significant sedation. Patients using these antihistamines often report sleepiness and reduced alertness. Driving studies showed significant impairment, both after acute and subchronic use (Verster and Volkerts 2004). Second-generation antihistamines such as cetirizine and loratadine produce much less sedation and driving tests have not consistently shown impairment. The magnitude of impairment, if any, differed between individuals and depended on the administered dose, time between drug intake and driving, gender, and age. Tolerance usually develops after 4–5 days of treatment, but a subgroup of patients shows increased vulnerability to the potential sedative effects of antihistamines and continues to experience adverse effects that may impair driving.

The third-generation antihistamines (fexofenadine, desloratadine, and levocetirizine) were developed to establish treatment options devoid of sedative effects. Driving studies showed that these antihistamines are a considerable improvement: with similar or improved clinical efficacy, these compounds do not affect driving ability.

Analgesics

Pain significantly impairs driving performance (Veldhuijzen et al. 2006a). Common pharmacological treatment of pain includes ► non steroid anti-inflammatory drugs (NSAIDs) and opioids. Laboratory tests of cognitive functioning and psychomotor skills generally do not show significant performance impairment in patients using NSAIDs or acetaminophen. Laboratory studies failed to find consistent results when testing ► opioids such as ► morphine and ► oxycodone (Zacny 1996). Up to now, one driving study examined the effects of bromfenac (an NSAID no longer marketed) and oxycodone. Neither analgesic affected driving performance. Chronic pain patients are often treated with antidepressants such as amitriptyline instead of opioids and NSAIDs. A driving study showed that 13 h after treatment administration, amitriptyline (25 mg) significantly impaired performance in neuropathic pain patients (Veldhuijzen et al. 2006b). After 2 weeks of daily use, tolerance developed to the impairing effects of amitriptyline. More driving research is needed to examine the effects of analgesics on driving ability.

Stimulant drugs

Stimulant drugs are used to improve attention and daytime alertness in the treatment of ADHD and narcolepsy. The effects of 3,4-methylenedioxymethamphetamine (► MDMA) and ► methylphenidate on driving performance have been studied in recreational MDMA users. Methylphenidate has been studied in patients with ADHD as well. Driving performance after using methylphenidate and MDMA was significantly improved when compared with placebo.

Summary

Table 1 gives an overview of most commonly used psychoactive drugs and their effects on driving ability. Classification is conducted according to the categorization of the International Council on Alcohol, Drugs and Traffic Safety (ICADTS). Drugs are allocated to one of the following categories:

1. Presumed to be safe or unlikely to produce an effect
2. Likely to produce minor or moderate adverse effects
3. Likely to produce severe effects or presumed to be potentially dangerous

To make the categories understandable, a comparison with BAC is made. Driving impairment for the categories I, II, and III are equivalent to BAC $<$ 0.5 g/l ($<$0.05%), BAC 0.5–0.8 g/l (0.05–0.08%), and BAC $>$ 0.8 g/l ($>$0.08%).

It is evident from Table 1 that for many diseases, a number of treatment options are available. These treatments differ greatly on how and if they affect driving ability. Physicians should take this into account when prescribing psychoactive medication for patients who want to drive a car.

Flying

Flying is an example of complex behavior. Alcohol and psychoactive medication may affect skills and abilities to fly a plane, especially during take-off and landing maneuvers. In addition, radio communication and following instructions during the flight require efficient use of working memory and decision-making processes.

Alcohol

Aircraft personnel have specific guidelines for alcohol use. The US Federation Aviation Administration (FAA)

Driving and Flying Under Influence of Drugs. Table 1. International Council on Alcohol, Drugs and Traffic Safety (ICADTS) categorization of commonly used psychoactive medication. For a complete listing, see Verster et al. (2009).

applies a BAC limit of 0.04% and European regulations apply a BAC limit of 0.02%. Pilots may not drink within 8 h of flying a plane or when they feel impaired. Research shows that flight personnel often underestimate the risk of alcohol use and admit that they sometimes disobey these rules (Verster 2007). This is of concern because over the past decade, approximately 8% of flight crashes have been associated with alcohol use. Studies performed in flight simulators have shown dose-dependent impairment in flying performance. In addition, other studies have pointed at significant impairment when BAC was below 0.04% or even zero. Alcohol hangover studies revealed that flying was significantly impaired in pilots who consumed alcohol the evening before flying, also when a sobering period of more than 8 h preceded flying. Flight personnel have the responsibility for the lives of hundreds of passengers. Therefore, a zero alcohol policy is preferable. Flight personnel should be educated about the risks of flying after drinking and their alcohol use should be monitored on a regular basis.

Psychoactive medication

When compared with driving, much less research has been devoted to examine the effects of psychoactive medication on flying. Most information about the capability to fly an airplane comes from general studies testing the effects of psychoactive medication on cognitive and psychomotor functioning. Based on these studies, FAA has composed guidelines about medical conditions and psychopharmacological treatments that prohibit pilots to fly a plane. These include ► insomnia, ► bipolar disorder, epilepsy, ► substance abuse, ► psychosis, and personality disorder. More recent studies tested pilots in advanced flight simulators whereas older studies tested flying-related skills and abilities in isolation.

Pilots diagnosed with depression are often not allowed to fly a plane, with or without antidepressant treatment. This is understandable when treated with TCAs. Nevertheless, several studies showed that SSRIs (e.g., ► sertraline, citalopam, escitralopam) and buproprion do not affect flying performance.

Antihistamines are commonly used to treat hay fever or motion sickness. Various first- and second-generation antihistamines including ► promethazine, meclizine, diphenhydramine, and triprolidine impair flying performance up to several hours after intake. In contrast, no significant effects were found for loratadine and desloratadine. After a couple of days, tolerance develops to the impairing effects of antihistamines.

Conclusions

Psychoactive medication may impair the ability to drive a car or fly a plane. However, for various medical conditions, different treatment options are available, and for some treatments it has been shown that it is safe to drive a car. Patient willing to drive a car should always ask their physician if these alternative treatments are available.

Much more research is necessary to examine flight simulator performance after intake of psychoactive medication. For alcohol, public health campaigns have proven to be effective. The general public is much less aware of the possible impairing effects of psychoactive medication. Therefore, educating patients about the possible side effects of medication is important to prevent impaired driving and flying.

Dronabinol

Definition

Dronabinol is a synthetic form of Δ^9-tetrahydrocannabinol, the main psychoactive substance in marijuana/cannabis. It is a cannabinoid agonist acting on cannabinoid CB1 and CB2 receptors. The cannabinoid CB1 are mostly located in the brain and involved in addictive properties of marijuana; the CB2 receptors are located in the periphery notably in the immune system, but may be also located in the brain. Dronabinol has been used in AIDS-related anorexia associated with weight loss and in nausea and vomiting associated with cancer chemotherapy. It has the potential to be abused and is a controlled substance.

Definition

This is a generic term referring to drug-related stimuli. These are stimuli previously experienced during self-administration of that drug and it is generally assumed that these stimuli have been paired in some way with the drug effect. The stimuli can comprise external, internal, and cognitive stimuli; they can occur just before or long before drug intake. In the human, they can be described subjectively and usually increase the desire for the drug. The term is often used in clinical work to refer to stimuli that increase the risk for drug relapse in abstinent persons or the risk of continued drug intake in an active drug consumer. The actual word "cue" can be traced to its use in theatrical or musical pieces to indicate when an artist is to start playing part. In the learning literature, a cue is usually a signal that leads to reinforcement in one of two different ways: The cue can simply set the occasion for a reaction or act as a ► discriminative stimulus. The cue can also elicit a reaction, which is said to be an appetitive response or ► conditoned reinforcement. These are analogous to the use of cue in the literature on cognitive processes of drug intake where a cue is seen to produce variations in different forms of activation (memories, feeling, arousal, etc.) or to elicit selectively particular responses (cue reactivity). The term is often replaced by words such as secondary reinforcer, conditioned stimulus, context stimuli, and so on.

Definition

Drug discrimination refers to behavioral paradigms in which the subjects learn to recognize the effects of a drug and report its presence by behavioral responses emitted to obtain reward or to avoid aversive stimuli. More formally, the presence of a drug generates an interoceptive ► discriminative stimulus (cue) signaling that an appropriate behavioral response will be reinforced. Drugs belonging to a wide range of pharmacological classes can serve as discriminative stimuli, and the subjects participating in a study may be either animal or human.

Principles and Role in Psychopharmacology

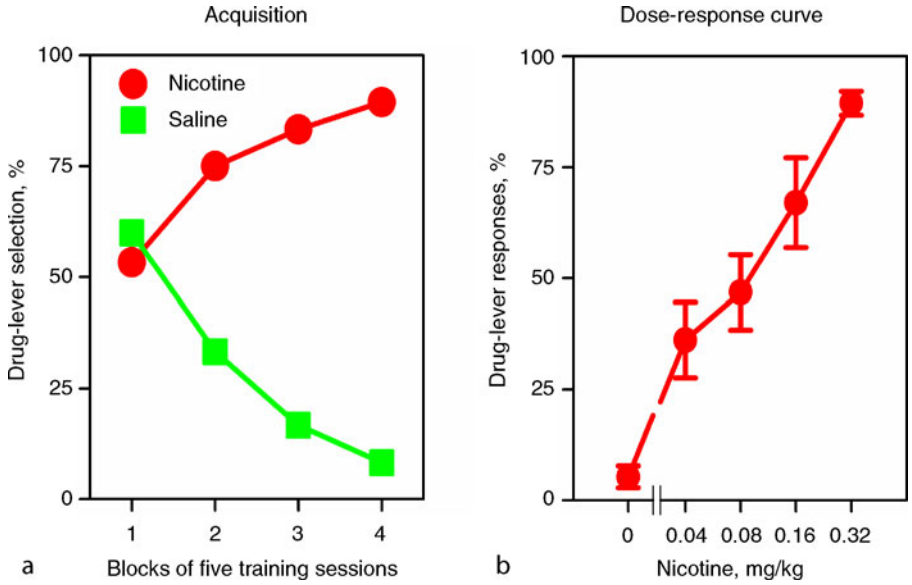
Most psychoactive drugs have effects that can be recognized and reported by people who have consumed them. Such self-reports may be seen conceptually as a consequence of an individual's natural history of learning to describe moods during his or her lifetime. Responses acquired during drug discrimination experiments with human subjects also reflect the reporting of subjective states, but under more carefully controlled conditions and with known drugs given in defined doses (Schuster and Johanson 1988). By imposing a analogous history of conditioning upon animal subjects, it is possible to implement drug discrimination experiments that establish responses that are similarly controlled by the recognition of drug effects. The development of the field owed much to the pioneering work of Donald Overton and was initially documented in a series of books (e.g., Colpaert and Rosecrans 1978; Glennon et al. 1991; Lal 1977), after which the area has become more fully integrated in the broader field of behavioral pharmacology. The experimental paradigms that emerged assist the development of novel drugs for treating psychiatric conditions, for characterizing the receptors and neurotransmitter systems through which psychoactive drugs act, and for evaluating the ► abuse liability of substances that might produce dependence or addiction (Ator and Griffiths 2003; Solinas et al. 2006; Stolerman 1992). Drug discrimination should be considered not as one technique but as a family of closely related methods. One of its distinctive features is a unique bibliographic database (www.drugrefs.org).

Simple Drug Versus Vehicle Discrimination

Simple, drug versus vehicle discrimination studies using two-lever ► operant conditioning methodology and food reinforcers account for about three-quarters of all reports of original investigations in the field (www.drugrefs.org). In a typical animal discrimination study with exteroceptive stimuli, the subject is placed in a test chamber and lever pressing responses result in the delivery of food. If a

stimulus light is turned on only during periods when lever presses produce food pellets, then lever pressing occurs at a high rate when the light is on and at a relatively low rate when it is off. The light is thereby established as a discriminative stimulus that controls the lever-pressing behavior. In drug discrimination, the effects of a drug serve a discriminative function in relation to behavior that is similar to that of the light in the preceding example. Thus, animals are trained to press one of two levers to obtain food after receiving drug injections, and to press the other lever after control injections in which no drug is given. Intermittent schedules of reinforcement facilitate the development of optimal performance. After learning the discrimination, the animal identifies the presence or absence of the drug effect and reliably selects the appropriate lever. Discriminative stimulus effects of the drug are distinguished from those of the food by using data from test sessions where differential reinforcement of responses on the two levers is temporarily withheld. Figure 1a illustrates the acquisition of drug discrimination behavior in a typical study using animal subjects. Human studies are carried out in a functionally equivalent way but with responses appropriate for the species and with monetary reinforcers instead of food or water.

Once a subject has been trained with a given drug, further investigations are possible, where the dose of the substance is varied, or other drugs are administered. Figure 1b shows a typical dose–response curve, from which the potency of the drug can be estimated by the ► ED_{50} value. These dose-response curves are also psychophysical generalization gradients along the dimension of stimulus intensity, through which the subjects indicate how they perceive similarities between the test stimuli (drug doses) and those used for training. When a different drug is given during test sessions, a dose–response curve similar to that for the training drug may be obtained (► stimulus generalization); this typically occurs when the two substances belong to the same pharmacological class and therefore have similar psychoactive effects. For example, ► amphetamine is generalized with ► cocaine because both drugs act as psychomotor stimulants. In contrast, if an ► anxiolytic or sedative-hypnotic drug is administered to rats trained to discriminate cocaine, then they do not identify any psychomotor stimulant effects,



Drug Discrimination. Fig. 1. (**a**) Typical pattern of acquisition of simple drug discrimination by a group of eight rats. Initially responding was at the chance level of 50% regardless of drug or saline injection. Over 20 saline training days responding on the drug-appropriate, lever decreased progressively. In the 20 randomly interspersed training days with nicotine (0.4 mg/kg) responding on the drug-appropriate, lever increased progressively. Data shown as percentage of sessions in which rats initially chose to press the drug-appropriate lever averaged across successive blocks of five sessions. (**b**) Typical dose-response curve for nicotine obtained in a group of eight trained rats. Different doses of nicotine and saline were given in random order before test sessions that took place twice weekly, with normal training on intervening days. and they press predominantly upon the nondrug lever. Such observations show that in typical two-lever drug discrimination experiments, the discrimination that is acquired is not between abnormal and normal states, but between the presence and absence of the specific pharmacological effects of the training drug. Thus, the trained rats can serve as a "litmus-paper" for a test drug that has pharmacological effects shared with those of the training drug. In such cases, the generalization gradient (dose–response curve) reflects the extent of qualitative similarity between training and test drugs as well as the intensity of the drug stimuli.

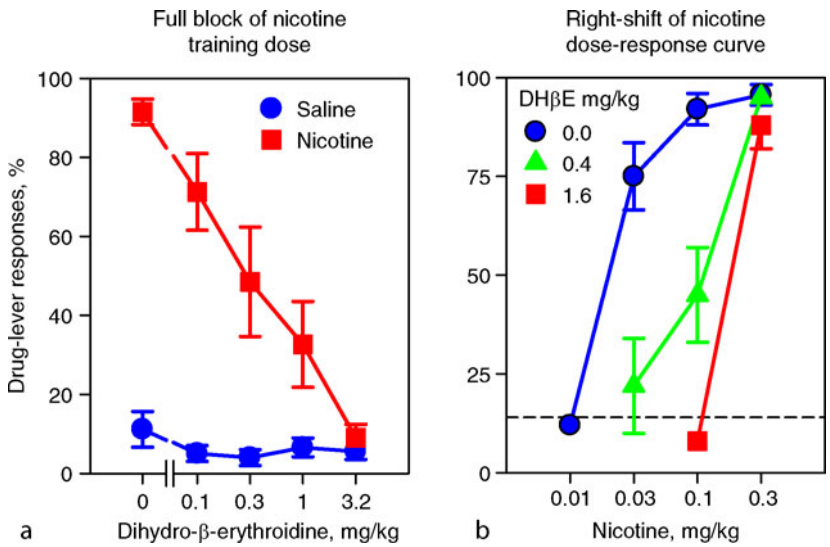
Discriminative stimuli produced by drugs with well-defined actions at known receptors are blocked by the appropriate specific antagonists (e.g., Fig. 2) and agents that influence the release, reuptake, and degradation of neurotransmitters can show orderly and comprehensible profiles of generalization according to the drug used for training. The influence of variables such as drug dose used for training, timing, and route of drug administration and ▶ schedule of reinforcement have been studied and are well understood. Such information has established the validity of the approach for investigating the neuropharmacological mode of action of drugs. The simple, drug versus vehicle discrimination using two-lever operant conditioning methodology and food reinforcers accounts for about three-quarters of all reports of original investigations in the field. Drug discrimination may be related to ▶ state-dependent learning, but some experts argue on theoretical and empirical grounds that the two phenomena are fundamentally dissimilar.

Discriminative drug effects nearly always originate within the central nervous system, as has been shown by the typical lack of generalization to agents that share the peripheral actions of psychoactive substances but do not penetrate into the central nervous system. Similarly, receptor antagonists that penetrate poorly into the brain are rarely effective. However, generalization and blockade can be seen with agonist and antagonist drugs that are poorly brain-penetrant if they are administered intracerebrally.

Applications

Drug discrimination methodology has been much used in the later stages of searches for new and improved pharmaceuticals. It may be used to identify compounds with specific actions at novel receptor sites when there is a prototypical agonist available for use as the training drug. Alternatively, putative antagonist drugs can be evaluated against a range of agonists to determine whether they produce full or partial block and whether the effect is specific for the targeted agonist. By such means it is possible to verify that substances initially identified



Drug Discrimination. Fig. 2. (**a**) Dihydro-β-erythroidine (DHβE) blocked the discriminative stimulus effect of a 0.1 mg/kg training dose of nicotine in a group of eight rats. The nicotine stimulus did not generalize to DHβE when the antagonist was administered alone. (**b**) DHβE shifted the dose–response curve for the nicotine (0.1 mg/kg) discriminative stimulus to the right in a dose-related manner (nine-fold increase in the nicotine ED_{50} after 1.6 mg/kg of DHβE). mainly by in vitro methods or with quicker but less specific in vivo approaches have the intended effects. The 5-HT_2 antagonist drugs are an example of such substances, some of which have proven valuable as ► antipsychotics. It was shown that whereas older compounds such as ► methergoline acted as ► partial agonists in relation to ► LSD, novel agents such as ► risperidone and ritanserin, acted as pure antagonists (Colpaert 2003).

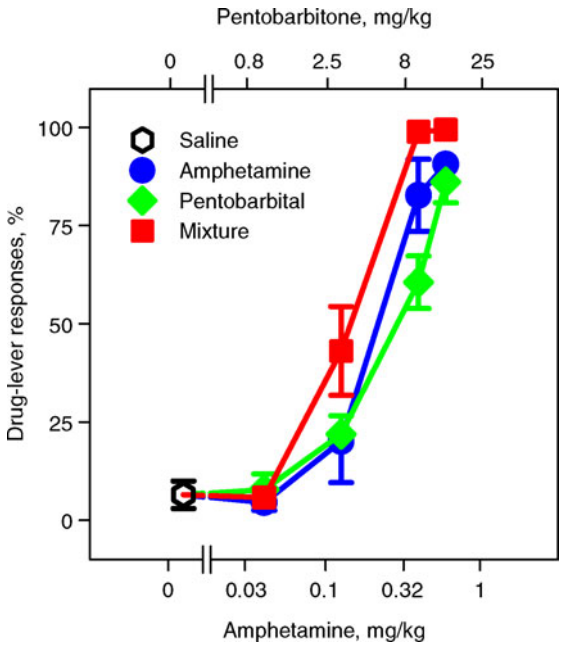
Academic researchers have also made very extensive use of discrimination methodology in studies of the mode of action of an extraordinarily wide range of drugs. Prior to the development of robust ► self-administration techniques for ► nicotine in the 1980s and for ► cannabinoids from 2000 onwards, drug discrimination was the main approach for studying their dependence-related effects in animals. Thus, discrimination studies using a variety of agonist and antagonist drugs suggest that the nicotine discriminative stimulus is mediated mainly through high-affinity heteromeric nicotinic receptor subtypes and this is verified by studies with knockout mice lacking different nicotinic-receptor subunits; the findings are concordant with results of studies on nicotine self-administration. However, improvements in self-administration techniques and the increased range and sophistication of such approaches are contributing to a decline in use of discrimination methods in the current millennium.

Both American and European authorities regard drug discrimination as a key technique in the evaluation of ► abuse liability. The fact that a substance supports discrimination learning is not by itself evidence for abuse potential because some non-abused substances have that ability. The key principle underlying its use in assessing abuse liability is stimulus generalization; only if a test compound generalizes with a known abused compound is there evidence for abuse (Ator and Griffiths 2003). Tests may be made by training with the test compound itself and then testing for generalization to prototypical agents of each class of abused substance. This is the more cost-efficient approach as less work and fewer subjects are required, but it may fail if the test substance does not produce a robust discriminative stimulus. Alternatively, separate groups of subjects are trained with abused drugs from different classes and then generalization to the novel compound is examined.

Complex Drug Discrimination Paradigms

Diverse models for drug discrimination broaden its applicability. Three variants are discussed here and others are known (Stolerman 1993). In drug versus drug discrimination procedures one response is associated with administration of one psychoactive drug and a second response is associated with a different substance. This procedure facilitates finer distinctions between closely related substance, such as full and partial agonists acting at the same receptor site. In practice the most useful model is a three-response variant in which the third response is associated with the undrugged state; although training takes longer, it avoids a problem with the simpler procedure in which test results for substances different from each of the training drugs are not readily interpretable.

Discrimination experiments where mixtures of dissimilar drugs were used as stimuli have shed light on how subjects process the different elements in a complex drug-induced stimulus. These studies have shown that in most cases the stimuli produced by the component drugs in binary mixtures are perceived and processed independently. Figure 3 illustrates such findings for a mixture of stimulant and depressant drugs that



Drug Discrimination. Fig. 3. Identification of the components of a drug mixture. Dose-response curves for a group of ten rats trained to discriminate a mixture of (+)-amphetamine (0.5 mg/kg) plus pentobarbitone (12 mg/kg) from saline. Each drug administered alone increased drug-appropriate responding in a dose-related manner, and at the largest doses tested their effects were not significantly below those of the drug mixture. Results shown as mean percentage of responses on the drug-appropriate lever (±s.e.m.) during 5-min sessions when no food was available. (Redrawn from Mariathasan et al (1991) Behav Pharmacol 2:405–415.)

produce unique effects in less refined procedures; the drug mixture did not produce a distinctive, novel discriminative stimulus.

Finally, novel-response procedures for drug discrimination in human subjects facilitate the interpretation of placebo-appropriate response choices (Bickel et al. 1993). In standard procedures placebo-appropriate responding indicates either the absence of any drug effect or a drug effect unlike the training drug. Instructions to subjects exposed to novel-response procedures inform them that responses on a novel-appropriate device should be made if an active test substance unlike the training drug is detected. This methodology increases the selectivity of placebo-appropriate responding and has been used in studies with psychomotor stimulants, opioids, nicotine, sedative-hypnotics, and other agents.

Advantages and Limitations of Drug Discrimination Procedures

The major advantages of discrimination procedures have resided in (1) applicability to an extremely wide range of psychoactive substances; (2) typically excellent pharmacological specificity as shown in generalization tests between agents from different classes; (3) the robust, highly reproducible nature of effects seen in many studies; (4) relative ease of collecting high-quality quantitative data. On the other hand, the time taken to train animals militates against use in primary screens or in combination with procedures that cannot be carried out repeatedly in the same subjects, such as those involving intracerebral drug administrations. Intermediate results from generalization tests can be difficult to interpret. Although a strong case has been made on both theoretical and empirical grounds that drug discrimination is functionally equivalent to the self-reporting of drug-induced subjective states, attempts to link discriminative drug effects to specific changes such as relief of anxiety, as distinct from sedation, have not been successful. Perhaps paradoxically, the greatest success with the procedures has been attained in analyses of the neuropharmacological mode of action of drugs where in many cases drug action at the molecular level has been firmly related to behavior.

Definition

A phenomenon in which one drug affects the pharmacokinetic or pharmacodynamic properties of another drug. This is commonly mediated by effects on protein binding in the circulation, or on liver-mediated metabolism of the second drug, and can give rise to changes in the levels of circulating drug, changing the effects of a given dose on therapeutic efficacy or side effects.

Definition

When multiple drug therapy is prescribed, there is a possibility of drug interactions. They occur when the effectiveness or toxicity of a drug is altered by the concomitant administration of another drug. This may have beneficial effects such as increasing therapeutic efficiency or reducing risk of side effects. Often, however, they are critical because the outcome is diminished therapeutic efficacy or enhanced toxicity. Mechanisms of drug interactions are usually divided into two categories: ► pharmacodynamic and ► pharmacokinetic. Pharmacodynamic interactions occur when two drugs act at the same or interrelated receptors. This may lead to additive, synergistic, or antagonistic effects. Additive effects may be useful in case of ► lithium ► augmentation under insufficient response to a ► selective serotonin reuptake inhibitor or a ► tricyclic antidepressant. Another useful indication of a combination therapy may be the treatment of unwanted drug effects such as the use of biperiden to alleviate extrapyramidal symptoms induced by ► antipsychotic drugs. Additive effects, however, can also lead to intoxication, e.g., when combining two drugs with QT interval prolongation. Pharmacokinetic interactions consist of changes in the absorption, distribution, metabolism, or excretion of a drug and/or metabolites. This has consequences for the amount of the drug that reaches the site of action. In clinical practice metabolic drug interactions in the liver are most relevant. Since ► polypharmacy is commonly used and frequently required in psychopharmacotherapy, it is important to understand the mechanisms of drug–drug interactions and how to use polypharmacy as rationally and safely as possible.

Current Concepts and State of Knowledge

Since the accidental discovery of lithium, ► chlorpromazine, iproniazid, and ► imipramine as effective drugs for the treatment of major psychiatric diseases, more than 100 psychoactive drugs have become available – ► antipsychotics, ► antidepressants, ► anxiolytics, ► cognitive enhancers, ► hypnotics, ► mood stabilizers, and ► psychostimulants. The drugs have been approved for many psychiatric diseases, and controlled ► randomized clinical trials have proved their therapeutic efficacy. Intensive basic and clinical research during the last 50 years has built up a detailed knowledge base of the mechanisms of the actions of psychoactive drugs, which is summarized in Table 1. Enzymes involved in metabolic degradation were characterized in vitro and in vivo, and enzymes of the ► cytochrome P450 (CYP) family were found to be highly active in detoxifying the mostly lipophilic psychotropic drugs (Table 1). Target structures and clinical consequences following inhibition or stimulation in the central nervous system have been identified (Table 2). Taken together, this wide knowledge has become the basis of rational psychopharmacotherapy.

Regarding actual guidelines for pharmacological treatment of psychiatric disorders, monotherapy is the mainstay. In clinical practice, however, polypharmacy is more common than monotherapy, despite limited information on the efficacy of combination treatments (Glezer et al. 2009; Goodwin et al. 2009). Psychiatric patients need concomitant medication when monotherapy fails to achieve sufficient improvement. Moreover, incomplete remission, chronic symptoms, or drug-induced side effects may give rise to the need for additional drugs. Another significant reason for polypharmacy is comorbidity. When

Monoamine oxidase	Inhibition has antidepressant effects	Inhibition effects sleep disturbances, agitation, anxiety, restlessness, dizziness, headache, paraesthesia, visual disturbances, flushing, dry mouth, nausea, vomiting, diarrhea, constipation
Muscarinic acetylcholine receptor, M_1		Inhibition effects disturbed accommodation, dry mouth, sinus tachycardia, obstipation, urinary retention, glaucoma, cognitive disturbances, delirium, seizures
Nicotinic acetylcholine receptors	Stimulation relieves nicotine withdrawal symptoms, improves cognition	Stimulation effects headache, dizziness, nausea, vomiting, indigestion, heartburn, increased salivation, muscle ache
Noradrenaline uptake	Inhibition has antidepressant potential	Inhibition effects insomnia, vertigo, tachycardia, palpitation, vasodilatation, postural hypotension, abnormality of accommodation, dry mouth, constipation, urinary hesitancy, sensation of incomplete bladder emptying
Opiate receptors, μ	Stimulation effects euphoria. Inhibition maintains opioide dependence after detoxification, reduces alcohol consumption and craving behavior	Stimulation effects drowsiness, headache, miosis, dry eyes, nausea, vomiting, constipation, dry mouth, confusion sleep disturbances, euphoria, restlessness, decreased libido, dependence. Inhibition effects difficulty in sleeping, anxiety, nervousness, abdominal pain, nausea, vomiting, low energy, joint and muscle pain, headache
Serotonin receptors, 5-HT_2	Inhibition affects anxiety, negative symptoms, sleep, appetite	Inhibition affects weight gain, gastrointestinal functions, regulation of body temperature
Serotonin uptake	Inhibition has antidepressant effects and delays ejaculation	Gastrointestinal disturbances, nausea, vomiting, serotonin syndrome (increased heart rate and blood pressure, confusion, agitated delirium, muscular rigidity and tension)

[a]The occurrence of adverse events depends on the dose and the disposition of the individual patient

the patient is still not doing well and the clinician is afraid to withdraw any of the drugs, the list of drugs becomes longer and longer and the pharmacology becomes more and more complex. Drug–drug interactions, especially, complicate the treatment (Rothschild et al. 2007). Polypharmacy is reportedly associated with an increased risk of adverse events and medication errors (Paterno et al. 2009).

Pharmacodynamic Interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the addition of another drug. The drugs may compete for the same receptor or interact indirectly by interfering within a common physiological pathway (Table 1). Pharmacodynamic interactions are often based on the intention to enhance a therapeutic effect; such strategies are termed "► add on,"

"potentiation," or "synergistic" therapy, and for most of these combination strategies more or less well-designed clinical trials give evidence if they are effective and safe. When clinical trials on a distinct drug combination are lacking, an experimental combination therapy must consider the pharmacodynamic profile of the combined drugs to predict the add on effect. Based on the target profiles summarized in Table 1, it seems likely that the combination of ▶ clozapine and ▶ olanzapine makes little sense, as the receptor profiles of the two atypical antipsychotic drugs are very similar. The expected add on effect should also be attained by increasing the dose of a single compound. It would be more appropriate to use ▶ haloperidol or ▶ risperidone in addition to clozapine. There are, however, also combination strategies that are helpful in one group of patients and harmful in other patients. Wellknown examples are augmentation therapies in antidepressant drug treatment. A ▶ serotonin syndrome that includes mental, autonomic, and neuromuscular dysfunctions is the result of over-stimulation of serotonin receptors. It may occur by combining a selective serotonin reuptake inhibitor and lithium. Enhancement of the serotonergic activity, however, can also be a strategy to overcome treatment refractory depression in an individual patient. Therefore, each combination treatment that uses pharmacodynamic interactions must be well supervised to maximize benefits and minimize risks.

Pharmacokinetic Interactions

Pharmacokinetic interactions are those that affect the absorption, distribution, metabolism, or excretion of a drug. Most psychoactive drugs are given orally. Interactions during absorption through the gastrointestinal tract are rare. One example is ▶ ziprasidone; its ▶ bioavailability is increased when taken with food. Most psychotropic drugs, however, are rapidly absorbed. Independent of the absence or presence of food, maximal concentrations in blood are attained at 1–3 h after drug intake. For some drugs bioavailability is limited by the action of drug transporter proteins such as P-glycoprotein (Pgp), which eject drugs that have diffused across the gut. Risperidone is a substrate of Pgp, and Pgp limits its availability. So far, however, evidence is lacking that Pgp in the gut plays a significant role as a target for drug interactions. Following absorption, drugs are rapidly distributed in the body by circulation. Due to high lipid solubility, most psychotropic drugs are bound to transport proteins, primarily albumin. The binding is reversible, and only the unbound drug is pharmacologically active. Drug interactions may occur by displacement from transport proteins. With the exception of anticonvulsant drugs, however, displacement interactions are not relevant for combinations with psychiatric drugs.

The vast majority of clinically important pharmacokinetic interactions of psychoactive drugs result from the induction or inhibition of drug metabolizing enzymes (Spina et al. 2003), primarily isoenzymes of the cytochrome P450 family (CYP).

Enzyme Induction

▶ Carbamazepine, ▶ phenobarbital, and a number of drugs shown in Table 3 are "inducers." In addition, constituents of food or herbal drugs may contain inducers. They stimulate the activity of a variety of CYP enzymes by enhancing the synthesis of proteins such as CYP1A2, CYP2C9, CYP2C19, and CYP3A4. Moreover, smoked or

charcoal-broiled food that contain polyaromatic carbohydrogens most effectively induce CYP1A2. As these enzymes are involved in biotransformation of many therapeutic agents, patients take enzyme inducers that quickly metabolize a wide range of concomitantly administered drugs. Depending on the therapeutic range, dosages must be increased to avoid the risk of loss of therapeutic effects (Fig. 1). One example is the combination of ▶ quetiapine and carbamazepine. Quetiapine blood levels will markedly decrease when combined with carbamazepine. Therefore, this combination is not recommended. It must also be considered that doses have to be reduced after discontinuation of inducers. Decreased enzyme activity may lead to high drug concentrations and thus bear the risk of intoxications (Fig. 1). The latter has been reported in patients who underwent treatment with the antipsychotic drugs olanzapine or clozapine after discontinuation of smoking. For drugs that are converted to active or toxic metabolites, ▶ enzyme induction may result in enhancement of the activity of the affected drug. An example is the induction of primidone metabolism by ▶ phenytoin, which results in increased concentrations of the active metabolite phenobarbital.

Enzyme Inhibition

▶ Enzyme inhibition is rather common in psychotropic drugs (Lynch and Price 2007). Among the five selective serotonin reuptake inhibitors, ▶ paroxetine, ▶ fluoxetine, and ▶ fluvoxamine are potent inhibitors of CYP enzymes (Table 4). Combining two drugs of which one is an inhibitor and the other a substrate of the same enzyme, the concentration of the substrate will increase as shown in Fig. 2. Whether this increase has clinical consequences by inducing a toxic reaction, will depend on the therapeutic range of the drug. This may be controlled by determining drug concentrations in blood through therapeutic drug monitoring (TDM). Pharmacokinetic drug interactions are therefore an important indication to use TDM (Baumann et al. 2004; Bengtsson 2004). Considering the enzymes involved in the metabolism, it may be predicted whether plasma concentrations increase after the addition of another drug (Fig. 2). Using TDM and dose reduction it is possible to avoid toxic reactions. TDM may also be useful after discontinuation of the inhibiting drug, as plasma concentrations may decrease to low levels, leading to the risk of loss of action. Considering the pharmacokinetic profile of the combined drugs, it is possible to use interacting drugs safely. However, prediction is not always easy. Psychoactive drugs can be metabolized by a single enzyme such as ▶ atomoxetine by CYP2D6 or by several enzymes such as amitriptyline by CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. A drug can also be a substrate and inhibitor of the same enzyme such as paroxetine for CYP2D6 or fluvoxamine for CYP1A2. Therefore, it is advisable to control drug concentrations in blood to measure the effect of the comedication. This is especially useful when combining a drug with a CYP inhibitor (Hiemke 2008). The therapeutic index of the affected drugs is also of great concern. In combination with an inhibiting or inducing drug, plasma levels of a given substrate are more likely to reach toxic or subtherapeutic values when the substrate has a narrow therapeutic index. This is of importance for ▶ tricyclic antidepressants, clozapine, and also some new antipsychotic drugs (e.g., loss of action of quetiapine after addition of St John's wort).

Clinical Evaluation of Drug Interactions

Information on the pharmacodynamic and pharmacokinetic profile of the combined drugs suggests possible interactions. Because of the understanding of the relevance of pharmacokinetic drug interactions during the last 15 years, it is today necessary that preclinical drug development include not only characterization of the pharmacodynamic profile of the drugs and its metabolites but also identification of the enzymes involved in the metabolism. Substrate and inhibitor properties of the drugs and the major metabolites must be clarified in the preclinical phase of drug development. Based on this knowledge, risks of concomitant use of co-medication can be defined. Because of possible risks due to pharmacodynamic or pharmacokinetic interactions, relevant co-medications are normally not allowed during the phases of clinical evaluation. Therefore, systematic clinical testing of drug combinations is rare or even lacking, and it is difficult or even impossible to evaluate the clinical relevance of combination treatments, especially the consideration of safety aspects. This information is normally raised when the drugs are used under naturalistic conditions. For this purpose, pharmacovigilance programs are most important (Grohmann et al. 2004). In the past, many interactions of psychoactive drugs were observed

accidentally, especially pharmacokinetic interactions of TDM controls. An increasingly important help is the use of computer-based drug interaction programs (e.g., https://www.medicinescomplete.com/mc/stockley/current/login.htm, http://www.medscape.com/druginfo/druginterchecker, http://www.psiac.de, http://www.mediq.ch/). Their quality has improved during the last years. However, only a few systems provide adequate information about the clinical effects of drug interactions or use medical advice.

Practical Issues

Combination treatment should be used as a last resort. One must be aware of drug–drug interactions. Computerized systems have shown that drug–drug interactions are among the most frequent alerts presented to clinicians writing medication orders (Paterno et al. 2009). The choice of particular drugs for individual patients requires a balancing of efficacy and side effects. This holds true for monotherapies and even more for polypharmacy. Risks of adverse effects increase under polypharmacy, and valid data on safety and efficiency of combinations are mostly lacking. Polypharmacy can be a validated or an empirical strategy. Whenever available, validated combinations should be used. When an empirical treatment lacking research-based evidence is used, objective symptom ratings should be applied to evaluate the result of the treatment.

Whenever a combination treatment is required, the following should be considered to make polypharmacy as effective and safe as possible:

- Combination therapies should be used only when preceding therapeutic trials with a single agent were of sufficient length, sufficient dose, and sufficient drug concentrations in blood.
- For most combination therapies, effectiveness or efficacy data are rare or even lacking.
- Combination therapies increase the risk of morbidity and mortality.
- Combination treatments must consider possible pharmacodynamic and pharmacokinetic interactions.
- Ineffective or minimally effective medications should be discontinued.
- Pharmacodynamic drug interactions require careful clinical supervision.
- Pharmacokinetic drug interactions should be controlled by determining drug concentrations in blood plasma or serum (TDM), especially for drugs with a narrow therapeutic range.
- To evaluate the results of a combination treatment, objective symptom ratings should be used.
- Computer programs should be used to check the medication orders to control for possible drug–drug interactions.

Drug Self-Administration

Definition

In the drug self-administration procedure, animal or human subjects perform an operant response (e.g., lever press, nose-poke) to receive abused drugs that serve as appetitive unconditioned stimuli, paralleling effects of palatable food, or other non-pharmacological rewards. The drug is often administered via a chronically indwelling venous catheter although other routes are also used (e.g., oral). The premise of these studies is that the drug rewards control behavior by functioning as a positive reinforcer. A stimulus is defined as a positive reinforcer if its presentation following a response increases or maintains the likelihood that the response will reoccur.

Drug Taste Preference Conditioning

Synonyms

Drug preferences; Oral self-administration

Definition

This is a term used to describe situations where taste conditioning takes place while an organism learns to drink a sapid drug solution. Except in the cases of drinking solutions prepared with highly potent drugs (e.g., etorphine) the solution is usually given its flavor by the drug itself. Different ways can be used to extract information on taste preferences, such as consumption of a single drug solution, intake of the drug solution as choice with water or other taste, and measurement of consumption of a solution that has the same taste as the drug solution but does not contain the drug. This would be accomplished by flavoring the drug solution, but in ► morphine taste preference conditioning, a conditioned morphine taste preference can be shown by substituting a solution of quinine for the morphine.

Drug Tolerance

Definition

Drug tolerance is when an individual's reaction to a drug decreases so that larger doses are required to achieve the same effect. Drug tolerance can involve both psychological drug tolerance and physiological factors. Characteristics of drug tolerance: it is reversible; the rate depends on the particular drug, dosage, and frequency of use; differential development occurs for different effects of the same drug. There are three major mechanisms for tolerance:

- Dispositional tolerance: occurs because of a decreased quantity of the substance reaching the site it affects.
- Reduced responsiveness: the response to the substance is decreased by cellular mechanisms.
- Conditioned tolerance

Drug Toxicity

Synonyms

Side effects

Definition

Drug toxicity refers to the level of damage that a compound can cause to an organism. The toxic effects of a drug are dose-dependent and can affect an entire system as in the CNS or a specific organ such as the liver. Drug toxicity usually occurs at doses that exceed the therapeutic efficacy of a drug; however, toxic and therapeutic effects can occur simultaneously. It can be assessed at the behavioral or physiological level. Behaviorally, drug toxicity can be exhibited in a variety of ways, for example, decreases in locomotor activity, loss of motor coordination, cognitive impairment. Examples of physiological effects include lesions to tissue, neuronal death, and disrupted hormonal cycles.

Definition

Dysthymic disorder is a ► mood disorder that is characterized by chronic mild depression. To meet DSM-IV criteria of dysthymic disorder, an individual must have "depressed mood for most of the day, for more days than not" for at least 2 years. In addition, there must be two or more of the following symptoms: poor appetite or overeating; insomnia or hypersomnia; low energy or fatigue; low self-esteem; poor concentration or difficulty making decisions; and feelings of hopelessness. There cannot have been any periods of normal mood lasting more than 2 months during the most recent 2-year period. In addition, there cannot have been an episode of major depression during the first 2 years of the disorder, and there cannot be a history of manic or hypomanic episodes. The disorder must cause distress or impaired social functioning. Onset before or after 21 years is specified as "early onset" or "late onset," and the disorder can also be described as having (or not having) atypical features such as lethargy, increased sleep, and increased appetite.

Role of Pharmacotherapy

Individuals may present with a variety of forms of chronic depression. In 1980, the DSM-III (American Psychiatric Association 1980) recategorized what had previously been called "neurotic depression" into the diagnosis of dysthymia, a condition that was placed among the mood disorders. Renamed dysthymic disorder (DD) in the 1994 DSM-IV, this condition is characterized by the presence of chronic low-grade depressive symptoms that last for a minimum of 2 years (American Psychiatric Association 2000). In clinical settings, patients often present for care after having depressive symptoms for decades rather than just for a few years. Some have been depressed since childhood; others describe onset in adolescence, adulthood, or even in geriatric years. Some patients may have milder forms of symptoms commonly seen in major depression, such as decreased sleep, weight loss, or insomnia, whereas others may have more "atypical" depressive symptoms such as weight gain, lethargy, and increased sleep. In addition, many patients present for treatment in the context of having both dysthymic disorder and major depression, or what is called "double depression."

DD has been called a paradoxical disorder because on a cross-sectional basis it appears to be mild, whereas on a longitudinal basis it has major consequences on quality of life and can justly be described as a "severe" disorder (Klein et al. 2000). Individuals with DD have been shown to have impairment in psychosocial functioning, marital and intimate relationships, and work functioning (including increased absenteeism and greater disability). They have an increased level of health care utilization, though their depression may be ignored by care providers. They also may have a greater risk for suicidal behavior than patients with acute major depression. Of note, in some cases chronic depression may result from other causes than a primary "unipolar" mood disorder. Causes may include psychiatric (such as ► bipolar disorder or psychotic illness), medical (such as thyroid disease), and chronic ► substance use (such as alcohol or marijuana use). In those situations, the patient would not meet DSM-IV criteria for DD, and treatment of the primary disorder is essential in addition to addressing depressive symptoms. Importantly, some patients presenting with mild depression may have conditions that do not meet criteria for DD. For instance, if the depression is of relatively brief duration, the appropriate diagnosis might be an adjustment disorder with depressed mood.

Stressful experiences in early life, including experiences of neglect and abuse, increase the risk of developing DD. The biological underpinnings of DD have not been well ascertained; data suggest that individuals with DD resemble those with major depression in measures such as sleep architecture and changes in stress-induced skin conductivity, as well as by family history, but in other ways are distinct (for instance, having lower rates of dexamethasone nonsuppression). On a broader level, many authorities believe that DD is likely to be a heterogeneous condition, resulting from a variety of causes ranging from genetic to environmental, and that there is unlikely to be a single underlying pathophysiology or a single mechanism for effective treatment (Griffiths et al. 2000).

Efficacy of Medications

Numerous classes of medication have been demonstrated to be effective in the treatment of dysthymic disorder (Hellerstein 2001; Lima et al. 2005; Thase et al. 1996; Vanelle et al. 1997). These include major classes of

antidepressant medications, such as ▶ tricyclic antidepressants, ▶ monoamine oxidase inhibitors (MAO), ▶ serotonin reuptake inhibitors, and other medications (such as the atypical antipsychotic ▶ amisulpride and the 5HT2 antagonist ritanserin). At the time of the most recent Cochrane review, there were approximately 17 ▶ double-blind placebo-controlled studies of DD in the literature, with a duration of 6–12 weeks. Generally, studies suggest that about half of the people with DD respond to any single medication trial. Forms of psychotherapy such as interpersonal psychotherapy and cognitive behavioral therapy have also been shown to be effective in small studies. Nonetheless, as various authors have pointed out, the number of high-quality studies of treatments of dysthymic disorder is small, and most existing studies suffer from a variety of defects, including small sample size and methodological deficiencies. In particular, because there are few studies of long-term treatment of dysthymic disorder, there is only a limited understanding of whether treatment can achieve long-term remission of this disorder. Furthermore, there are few studies of medication treatment for patients who have not responded to an initial trial. Finally, the literature on combined psychopharmacology and psychotherapy treatments of DD is extremely limited, and it is not clear whether one can justifiably extrapolate from such studies in major depression to the treatment of DD.

Typically, antidepressant treatment of DD uses doses of medication similar to those used in the treatment of major depression, e.g., the equivalent of 20–80 mg/day of fluoxetine. Studies of antidepressant medications in DD use criteria for treatment response similar to those used in the treatment of major depression: responders are generally defined as having a 50% or greater improvement in depressive symptoms (typically measured by the ▶ Hamilton Depression Rating Scale [Ham-D] or specific dysthymia rating scales such as the Cornell Dysthymia Rating Scale), and remitters are defined in various ways, such as having a score less than 7 on the Ham-D, or a score of 0 on Ham-D item 1 (depressed mood) and no longer meeting DSM criteria for DD. In studies using such criteria, response rates are generally higher in open-label than in double-blind studies. In the absence of long-term data, duration of antidepressant treatment needed in DD is unclear; the few follow-up studies indicate that medication improvement generally persists over a year or more when medication is continued, and that depressive symptoms tend to return after medication is discontinued. However, it is not clear whether lifetime medication treatment is needed, or whether some patients may remain in remission after a period of medication treatment. Some clinicians attempt to gradually taper medications after DD has been in remission for a year or more.

Studies indicate that social function improves following effective treatment of depressive symptoms of DD (Kocsis et al. 1997). This suggests that a broader process of recovery may be initiated in many patients. However, despite such improvement, studies have shown that only 24% of dysthymics who have responded to treatment have returned to psychosocial functioning in the normal range (as measured by the Social Adjustment Scale [SAS]) after 6 months (Friedman et al. 1999). Therefore, augmenting medication or psychotherapy treatments may be indicated.

Side Effects and Advantages and Disadvantages of Various Agents

Because DD is a chronic disorder and may often require many years of medication treatment, it is important to consider the long-term tolerability of any medication chosen. Side effects such as weight gain or sexual dysfunction may have a major effect on quality of life and medication compliance. In current practice, ▶ selective serotonin reuptake inhibitors (SSRIs) are most commonly used as first choice medications in the treatment of DD; they have the advantage of broad efficacy on a variety of depressive and anxiety symptoms, high tolerability, and low levels of toxicity. In addition, a number of studies provide evidence for their efficacy. Other medications are widely used in treatment of DD despite limited evidence of benefit. These include ▶ bupropion, a medication hypothesized to work through dopamine and norepinephrine reuptake inhibition, and which is associated with low levels of sexual dysfunction and weight gain. The serotonin–norepinephrine reuptake inhibitors (▶ venlafaxine, desvenlafaxine, ▶ duloxetine, etc.) are also used despite a lack of efficacy data in DD, but with the thought that they may alleviate a broader range of dysthymic symptoms than SSRIs. Older classes of medications, such as the ▶ tricyclic antidepressants (TCAs) and ▶ monoamine oxidase inhibitors (MAOIs) have been shown to be effective in the treatment of DD, but are less frequently used as first-line agents because of their greater side effects and potential toxicity. The reversible MAOI ▶ moclobemide may have lower risks for adverse events such as tyramine-induced hypertension than other medications in its class, and has been shown to be effective in DD. Moclobemide is not available in the USA. Still other classes of medications have demonstrated some benefit in the treatment of DD, including the atypical antipsychotic ▶ amisulpride, possibly via dopamine modulation. In some instances, where there is inadequate response to a single medication, medication

combinations are used. Examples include bupropion combined with an SSRI, or augmentation of antidepressants with stimulants. However, data are lacking on the efficacy of such approaches in DD.

Energy Intake

Definition

Feeding reflects the behavioral response necessary for replenishing energy substrates critical for the survival, whereas appetite refers to the motivational component of this behavior.

Impact of Psychoactive Drugs

Feeding can be defined as the behavioral response necessary for replenishing energy substrates to maintain energy balance and, ultimately, the survival of all humans. Predictably, a shortage of food sources is associated with increased motivational states that promote food seeking, as well as metabolic changes that allow for energy stores to be amassed in the form of adipose tissue. In general, increases in these motivational states are commonly referred to as appetite (Berthoud and Morrison 2008). Feeding can also be elicited by the mere presence of food and, in the absence of negative energy state, possibly as an adaptive behavioral response directed at storing excess energy in anticipation of future shortages. Clearly, the mechanisms regulating feeding behavior are complex and involve both regulatory and nonregulatory processes.

Peripheral signals regulating energy balance. Both food intake and appetite are influenced by multiple neural

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

and peripheral signals. These include energy substrates such as glucose, free fatty acids, and amino acids; hormones such as ▶ leptin, ▶ cholecystokinin (▶ CCK), insulin, and ghrelin; and neurotransmitters, including ▶ dopamine (DA), ▶ serotonin (5HT), ▶ norepinephrine (NE), and ▶ endocannabinoids. Moreover, drugs that affect these systems are currently used as a mean to curb obesity and treat Type II diabetes or to increase feeding in pathological conditions that lead to anorexia and cachexia (e.g., cancer and chronic renal disease). Finally, drugs used to treat other conditions have side effects that include abnormal feeding behaviors (▶ anorexia or overeating) (Berthoud and Morrison 2008).

Pharmacological agents affecting feeding and appetite. The complexity of neural mechanisms underlying feeding behavior is reflected by the number of pharmacological agents that are known to affect this behavior. Commonly, these actions are identified as side effects of treatments to other pathological conditions and, subsequently, are used to control feeding behaviors. In some cases, these medications are used to stimulate feeding in circumstances where patients are anorexic, but the great majority of drugs aimed at modulating feeding behavior are aimed at reducing caloric intake. It is difficult, however, to identify a single neurotransmitter system as critical for food intake, as many have been implicated in the regulation of feeding (Bray and Greenway 2007).

Most ▶ appetite suppressants are drugs that modify the release of monoamine and catecholamine neurotransmitters in the brain. The most successful of these is ▶ sibutramine, a drug approved by the United States Drug and Food Administration (FDA) for the treatment of obesity and one that primarily inhibits the reuptake of 5-HT and NE and, to a lesser extent, dopamine. Sympathomimetics had also been approved by the FDA and include ▶ amphetamine, ▶ phentermine, benzphetamine and phendimetrazine, although these are only prescribed for short-term use given their potential addictive properties. Finally, some ▶ antidepressant medications have anorectic effects, including drugs such as ▶ fluoxetine, which is a selective serotonin reuptake inhibitor (SSRI), and ▶ bupropion, a dopamine and norepinephrine reuptake inhibitor (Bray and Greenway 2007).

There are a number of appetite suppressants that act through physiological mechanisms other than direct action onto aminergic neurotransmitters. ▶ Rimonabant, a compound that blocks the CB1 ▶ cannabinoid receptor has been recently rejected as an anti-obesity medication and has some appetite suppressant properties. Leptin, a hormone produced by white fat cells, also lowers food intake and body weight and continues to be considered as a potential drug to treat obesity and metabolic syndrome (Bray and Greenway 2007). All of these drugs have been reported to be effective in reducing appetite, but their effects are short-lived possibly because of the development of ▶ tolerance (Fernstrom and Choi 2008).

It is well known that typical (▶ haloperidol) and some ▶ atypical antipsychotic drugs (▶ clozapine, ▶ olanzapine, and ▶ risperidone) increase appetite and body weight significantly. Conversely, some atypical antipsychotic drugs like ▶ ziprasidone decrease appetite. Similarly, ▶ tricyclic antidepressants, ▶ monoamine oxidase inhibitors, and some atypical antidepressants also cause weight increases that range from moderate to high (more than 10%) over the treatment period. These medications include ▶ Imipramine, phenazine, ▶ mirtazapine, and ▶ trazodone. Selective serotonin reuptake inhibitors are commonly associated with weight decreases early in treatment, but with body weight increases after prolonged use. Treatment with the atypical antidepressant ▶ bupropion results in decreased body weight (Jensen 2008).

Central Regulation of Feeding and Appetite. Feeding and appetite are both regulated by multiple brain regions (Berthoud and Morrison 2008; Bray and Greenway 2007). The ▶ hypothalamus plays a predominant role in eliciting feeding responses as a means of achieving a homeostatic state. Early studies using hypothalamic lesions emphasized the role of the mediobasal hypothalamus in mediating satiety responses, and that of the lateral hypothalamus in mediating appetitive responses. More recently, however, it has become clear that the hypothalamus contains a massive peptidergic network that regulates food intake and energy expenditure in response to hormonal and nutritional signals. One current idea is that the hypothalamic arcuate nucleus (ARC), a bilateral hypothalamic structure that surrounds the ventral portion of the third ventricle, plays a fundamental role in regulating feeding and energy homeostasis (Cone 2005). Indeed, the ARC contain cells that are sensitive to all peripheral signals that convey information about energetic state, and produce a number of peptides that influence food intake and appetite. A subset of neurons in the ARC produce the ▶ α-melanocyte stimulating hormone (α-MSH), a cleaved product of the proopiomelanocortin (POMC) precursor that decreases food intake and increases energy expenditure. A second subset of ARC neurons release two peptides that have a strong orexigenic effect: ▶ Neuropeptide Y (▶ NPY) and the ▶ agouti related peptide (▶ AGRP). Both α-MSH and AGRP compete for the same receptors (the melanocortin receptors 3 and 4, or MCR3, and MCR4) at target regions, with AGRP being

a natural antagonist and ► α-MSH being an agonist to these receptors (Cone 2005). Given these properties, the cells in the ARC and the MCR3 and MCR4 receptors at their target brain sites are referred to as the melanocortin system of energy regulation. In addition to NPY and melanocortin, peptides secreted by other hypothalamic nuclei also play an important role in modulating feeding and appetite. For example, cells in the lateral hypothalamus produce ► orexins/hypocretin or melanin concentrating hormone (MCH), both of which stimulate food intake and appetitive responses. In contrast, cells in the paraventricular nucleus (PVN) of the hypothalamus release corticotrophic and thyrotropin releasing hormone (► CRH and TRH respectively), which have an anorectic effect and stimulate metabolic rate (Berthoud and Morrison 2008).

Although the hypothalamus is important for the regulation of energy balance, integration of circulating metabolic signals occurs in several brain stem nuclei (Grill 2006). These nuclei are intimately associated with autonomic responses that follow the activation of the stress axis by psychogenic, metabolic or immunological challenges. Within the brain stem, the three divisions of the dorsal vagal complex (DVC) play a key role in integrating metabolic signals, interoceptive afferent signals relaying information from the digestive system via the vagus nerve, and information transmitted from cranial nerves that carry taste, texture, and sensory-motor signals from the mouth. Within the DVC, the nucleus of the solitary tract (NTS) is the main target for information ascending from the gut via the vagus nerve and the enteric nervous system. The NTS contains noradrenergic neurons that target and modulate the activity of hypothalamic and limbic structures implicated in feeding, including the PVN and central nucleus of the ► amygdala (CeA). The area postrema (AP), a second division of the DVC, lies outside of the blood brain barrier and is thus especially sensitive to blood borne nutritional signals, including those that are relayed by hormones like leptin, insulin, ► cholecystokinin (CCK), and ghrelin, as well as being sensitive to changes in circulating plasma levels of glucose. The AP transduces these signals and conveys them primarily to the NTS where they are integrated with ascending visceral signals, but also directly onto the PVN, where they may elicit feeding and autonomic responses. In addition to the regulation of feeding responses, the brain stem plays a key role in the generation of the autonomic responses, being involved in blood pressure regulation, respiration, glucose release from the liver, vasoconstriction, lipolysis, and thermogenesis (Grill 2006).

Recent evidence has highlighted the role of the midbrain in the regulation of feeding and appetite (Volkow and Wise 2005). The midbrain contains a number of cell groups implicated in brain functions underlying reward seeking, learning and memory processes, affective states and the generation of locomotor responses (Wise 2004). Their role in the modulation of feeding responses is considered within the context of these processes. Moreover cells in these midbrain nuclei release neurotransmitters commonly implicated in the regulation of feeding and appetite. For example, Dopamine (DA) cells of the ventral tegmentum (VTA) and substantia nigra have been implicated in the modulation of food intake through their projection to the striatum, prefrontal cortex, hippocampus, and amygdala. Destruction of these pathways results in hypophagia similar to that reported in animals with lateral hypothalamic (LH) lesions, and DA deficient mice die of starvation unless they are given exogenous L-DOPA (Palmiter 2007). In addition to DA-related processes, serotonergic components of the raphe nuclei have been implicated in the regulation of food intake. Indeed, there are 5-HT projections to hypothalamic and limbic centers involved in the regulation of food intake and several lines of evidence demonstrate that 5-HT has an inhibitory effect on food intake, including clinical and experimental data on the anorectic effects of SSRIs. The effects of 5-HT on food intake and metabolic function are mediated, at least in part, through the stimulation of POMC cells in the hypothalamic ARC, as well as through direct effects of 5-HT onto cells of the PVN (Zhou et al. 2005).

Circuits in the midbrain and brain stem are often viewed as either secondary or connected in series with the hypothalamus. In effect, their role in food intake regulation is that of an accessory to the function of the hypothalamus. The fact that these centers are sensitive to the same peripheral signals affecting the hypothalamus, however, suggests that feeding regulation occurs via the parallel activation of these circuits. In addition, activation of brain stem or midbrain pathways may override regulatory signals from hypothalamic homeostatic centers to modulate appetite.

The relative contribution of these brain pathways in mediating the effects of most drugs regulating feeding and appetite has not been fully elucidated, and continues to be a primary focus of investigation. Moreover, alterations in the activity of these circuits are thought to underlie ► eating disorders such as ► anorexia nervosa, bulimia, binge eating disorder, and obesity. Undoubtedly, better knowledge of these brain circuits and the way in which drugs affect them will improve their effectiveness, and minimize side effects ultimately producing better appetite suppressants and orexigenic drugs.

Eating Disorder: Anorexia Nervosa

Definition

Anorexia nervosa is a mental disorder characterized by extremely low body weight (▶ BMI 17.5 kg/m^2 or less in ▶ ICD-10 and 85% of expected weight for height and age in ▶ DSM IV), body image distortion, and an obsessive fear of gaining weight and becoming fat. Individuals with anorexia control their body weight by voluntary starvation, excessive exercise or other weight control behaviors such as self-induced vomiting, or the misuse of ▶ laxatives, ▶ diuretics, or ▶ enemas. Women with this disorder develop ▶ amenorrhea.

Role of Pharmacotherapy

Diagnostic Categories

Anorexia nervosa primarily affects adolescent females and young women, and only about 5–10% of people with the diagnosis are male. Two subtypes have been specified:

- *Restricting Type*: the person does not regularly engage in binge-eating or purging behavior (i.e., self-induced vomiting, excessive exercise, or the misuse of laxatives, diuretics, or enemas)
- *Binge-Eating Type or Purging Type*: the person regularly engages in binge-eating or purging behavior (i.e., self-induced vomiting, excessive exercise or the misuse of laxatives, diuretics, or enemas).

Anorexia nervosa is a serious and potentially life-threatening disorder with the highest standardized mortality rate among all psychiatric disorders, due to the chronic course, the associated medical complications, and the mental comorbidity. The cumulative lifetime prevalence is estimated to be 0.6% in the general population (Hudson et al. 2007) with an onset peak around 15–19 years. Anorexia nervosa is frequently associated with other psychological symptoms including ▶ depression, ▶ anxiety, and ▶ obsessive–compulsive features. Therapy typically includes nutritional rehabilitation and psychotherapeutic interventions, inpatient treatment is frequently required.

Drug Treatment

There is no officially approved medication for the treatment of anorexia nervosa. A variety of agents have been examined with mostly discouraging results with regard to facilitating weight gain or reducing associated cognitive and emotional symptoms such as body image distortion or fear of weight gain. In addition, only very few randomized controlled studies exist, usually with inadequate sample sizes and high drop out rates. Poor medication compliance seems to be a particular prominent problem in the treatment of anorexia nervosa most likely due to the patients' ambivalence about treatment in general

(Crow et al. 2009). Medication should not be used as the sole or primary treatment for anorexia nervosa (APA 2006; NICE 2004). ► Antidepressants and other psychiatric medications may be used to treat associated symptoms of depressive, anxiety, obsessive-compulsive, and other co-morbid disorders; however, these symptoms may resolve with weight gain alone. When medication is used to treat people with anorexia nervosa, the side effects of drug treatment (in particular, cardiac side effects) should be carefully considered. Bupropion is contraindicated in patients with eating disorders because of the increased seizure risk in these patients. Adverse reactions to ► tricyclic antidepressants and ► monoamine oxidase inhibitors (MAOIs) might be more pronounced in underweight individuals (Roerig et al. 2009).

Recently, ► second-generation antipsychotics, particularly ► olanzapine, have been used in small controlled trials. There is some evidence that olanzapine in a dose of 2.5–15 mg daily might increase the rate of weight gain and might reduce obsessive symptoms in patients with anorexia nervosa. If olanzapine is used, it is recommended that the patients be carefully monitored for ► extrapyramidal symptoms as well as for insulin resistance, abnormal lipid metabolism, and prolongation of the QTc interval.

Conclusion

There is a very limited evidence base for the pharmacological treatment of anorexia nervosa and there is no convincing evidence to date of efficacy for any drug treatment for anorexia nervosa in either the acute or chronic phase of the disorder.

Definition

► Animal models have been developed for the study of each of the three most common eating disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (► DSM-IV): anorexia nervosa, bulimia nervosa, and binge-eating disorder. These models attempt to mimic the altered patterns of food intake that comprise the core behavioral features of the human disorders. Some models also seek to mimic motivational, endocrine or morphometric aspects of eating disorders.

Current Concepts and State of Knowledge

Applicability of Current Models to Human Eating Disorders

In addition to replicating the core symptoms defined in the DSM-IV (see Table 1), animal models of eating disorders should address three key elements: gender bias, ► comorbidity with other psychiatric disorders, and adolescent onset. ► Anorexia and bulimia affect three times as many women as men (Hudson et al. 2007). The gender bias of binge-eating disorder is only slightly less pronounced, with 1.75 times as many women as men affected during their lives. Given this differential risk, animal models should incorporate the study of females whenever possible. Animal models should also address the high ► comorbidity with anxiety disorders, mood disorders, impulse control disorders, and ► substance abuse. For example, anxiety- or depression-related variables might be conceived as experimental end points or as means to initiate disordered eating behavior. Finally, because the median age of onset for all three disorders ranges from the late teens to early twenties in humans, models should prioritize the use of juvenile and young adult animals.

An ideal animal model would possess face, construct, and predictive validity, but eating disorders present significant challenges to the development of such a model. Because the causes of anorexia, bulimia, and binge-eating disorder in humans remain unclear, assessing the

Eating Disorders: Animal Models. Table 1. Summary of eating disorder diagnostic criteria.

Anorexia nervosa	Refusal to maintain body weight above 85% of the expected value for age and height
	Intense fear of weight gain
	Disturbed perception of body shape or denial of seriously low body weight
	Amenorrhea (in females) for three consecutive months
Bulimia nervosa	Recurrent episodes of binge eating
	Recurrent compensatory behaviors to prevent weight gain (e.g., vomiting, laxative use)
	Binging and compensatory behaviors occur at least twice weekly for 3 months
	Self-evaluation excessively influenced by body shape
	Does not meet criteria for anorexia nervosa
Binge-eating disorder[a]	Recurrent episodes of binge eating
	Feelings of distress about binge eating
	Binges occur at least twice weekly for 6 months
	Does not meet criteria for anorexia or bulimia nervosa

[a]Binge-eating disorder is currently listed in the Appendix of the DSM-IV as a potential eating disorder for full inclusion in the next edition

► construct validity is difficult. The dearth of pharmacological agents effective for the treatment of eating disorders also hinders assessment of ► predictive validity. No FDA-approved treatment currently exists for the treatment of anorexia or binge-eating disorder, and ► fluoxetine is the only medication currently approved by the FDA for the treatment of bulimia. Due to these issues, animal models have sought to achieve ► face validity. Animal models are further limited, however, by their inability to mimic certain psychological or social components of eating disorders. Despite these limitations, animal models can serve as powerful hypothesis generators for further study in humans of the biological underpinnings or consequences of eating disorders. Current models have focused overwhelmingly on rodents and can be broadly divided into anorexia-like and binge-like paradigms.

Models of Anorexia Nervosa

An effective model of anorexia nervosa should mimic the core symptoms of a voluntarily low body weight (less than 85% of normal), reduced food intake, and ► amenorrhea in females. Hyperactivity with high levels of energy expenditure (e.g., compulsive exercise), though not part of the core diagnostic criteria, is also extremely common. Efforts to recreate these symptoms have included both genetic and environmental models. As mentioned previously, animal models are not suited to address the intense fear of weight gain and distorted body image seen in anorexics.

The *anx/anx* Mouse

The most commonly studied genetic model is the *anx/anx* mouse. Additional, less widely studied genetic models of anorexia include the contactin-deficient mouse and the dopamine-deficient mouse; others too have studied the hypophagic phenotypes of knockout mice, including the MCH, Crh2, and M3 receptor null mutants, as modeling aspects of the anorexia nervosa syndrome. The *anx* mutation, which arose spontaneously at Jackson Laboratories, is an autosomal recessive trait that results in a dangerously low food intake. *Anx/anx* mice are emaciated and exhibit motor symptoms including body tremors, hyperactivity, headweaving, and uncoordinated gait. The *anx* mutation is lethal within 3–4 weeks of birth depending on the genetic background. The gene product of *anx* is unknown, but the mutation has been localized to a 0.2-cM interval corresponding to 1.28 Mbp on mouse chromosome 2 (Johansen et al. 2003). The model is valuable due to its ability to reduce food intake without forced starvation or use of a pharmacological agent as an appetite suppressant. It has been simultaneously criticized, however, because appetite itself, if not hunger, appears intact in human anorexics. Moreover, based on gene expression profiling, the *anx/anx* mouse has been recently suggested to model ► cachexia, rather than anorexia nervosa or starvation.

The *anx/anx* mouse shows several neurobiological abnormalities that may underlie its phenotype. Two cell populations in the arcuate nucleus of the hypothalamus exert opposing influences on food intake in normal individuals. One population produces the ► orexigenic signals ► neuropeptide Y (NPY) and agouti gene-related protein (AgRP). A second population that produces proopiomelanocortin (POMC) and cocaine- and amphetamine-related transcript (CART) yields ► anorexigenic signals. In *anx/anx* mice, NPY and AgRP accumulate in the cell body but are reduced in axon terminals. Decreased NPY receptor mRNA levels have also been seen, as well as possible compensatory responses to starvation, including reduced POMC and CART levels and low serum ► leptin levels. Serotonergic hyperinnervation of several forebrain structures, including the arcuate nucleus, has also been observed. This hyperinnervation may be behaviorally relevant given the anorectic influence of ► serotonin. Outside the ► hypothalamus, the *anx/anx* mouse also exhibits

reduced striatal dopamine levels and reduced sensitivity to dopamine's action to reduce Na^+,K^+−ATPase activity.

Activity-Based Anorexia

The most widespread nongenetic model of anorexia nervosa is activity-based anorexia, also known as starvation-induced hyperactivity. Rodents receiving time-limited daily access to food will increase intake during that time to maintain a stable body weight. In the activity-based anorexia model, this compensatory feeding behavior is disrupted by providing access to a running wheel. Details of food and wheel availability vary between investigative groups, but wheel access typically exceeds food access in duration. Under these conditions, animals dramatically reduce food intake while increasing wheel running, such that energy expenditure surpasses energy intake. Body weights decline, and animals will eventually die without experimenter intervention. This paradigm thus jointly models the hyperactivity and voluntary decrease in food intake seen in human anorexics. Female rats also escalate their running more rapidly than males and stop estrous cycling. Unlike human anorexia, however, body weights recover under activity-based anorexia conditions if food access is increased or if palatable, high-fat food is provided.

As in the *anx/anx* mouse, several neurochemical abnormalities have been observed in the hypothalamus following activity-based anorexia. Rodents subjected to activity-based anorexia show increased NPY and AgRP mRNA in the arcuate nucleus after 3 days of hyperactivity combined with lower levels of POMC and CART mRNA. Leptin levels drop rapidly during activity-based anorexia, and leptin administration can rescue low body weights. Hypothalamic levels of β-endorphin are elevated when animals on this paradigm lose 25% of their normal body weight, and serotonin levels are elevated in the medial basal hypothalamus (Hillebrand et al. 2008). In this respect, activity-based anorexia may parallel the human condition, as reduced CSF levels of the serotonin metabolite 5HTIAA are observed in anorexic patients. Perhaps lending some predictive validity, the atypical antipsychotic olanzapine appears to attenuate hyperactivity in both activity-based anorexia and human subjects. Further work is necessary to characterize fully any causal relationship between the neurochemical changes and the hyperactivity and starvation seen in the model.

Models of Bulimia Nervosa and Binge-Eating Disorder

Both bulimia nervosa and binge-eating disorder are characterized by recurrent episodes of ► binge eating – consuming more within a given time than a normal individual would eat under the same circumstances – and animal models have sought to replicate this core symptom. Several factors believed to contribute to or precipitate binges in humans have been used to elicit binge eating in rodents, including food restriction followed by free feeding, intermittent access to highly palatable food, and stress. As in anorexia nervosa, animal models cannot mimic several psychological features of the disorder, including preoccupation with body image.

Sham Feeding

Bulimia can be differentiated from binge-eating disorder by the presence of compensatory behaviors including purging, laxative abuse, fasting, or compulsive exercise. Rodents lack a vomiting reflex, but sham-feeding models have been used to mimic purging in rodents. In sham feeding, a gastric fistula is used to drain the recently ingested meal from the stomach before it reaches the intestine. The animal thus experiences gustatory feedback while consuming the meal, but receives minimal postingestive ► satiety signals from the digestive tract. Sham-fed animals increase their meal size and consume meals more rapidly, analogous to human bulimics. A limitation of the sham-feeding model is that compensatory behaviors in humans are voluntary and thought to occur despite homeostatic regulation, whereas sham feeding is experimentally induced and results from homeostatic processes.

Restriction and Refeeding Cycles

Binge-like behavior can be elicited in rodents by restricting food access for an extended period and then returning the animals to *ad libitum* food access for a refeeding period. This cycle of restriction and refeeding may be repeated numerous times. Animals typically increase their intake during the refeeding period relative to animals without a history of restriction, a phenomenon known as rebound ► hyperphagia. A normal individual would be expected to increase consumption after forced restriction; thus, this hyperphagia is not a perfect analog of human binges, which frequently occur even in the absence of ► hunger. Additional factors such as palatable foods and stress can be added, however, to increase the validity of the model. Rats allowed to refeed on palatable food, such as a high-fat cookie diet or sucrose, have greater hyperphagia than those allowed to refeed on chow. Such palatable foods share greater similarity to the high-fat, high-sugar foods typically consumed during human binges. Rats with a history of restriction and refeeding on palatable food also show depressive-like and anxiety-like symptoms, suggesting that such models might be useful for studying the high comorbidity of binge eating with mood and anxiety disorders. Alterations in monoamine function in these animals have also been observed. Changes include

reduced extracellular dopamine accompanied by increased acetylcholine in the ▶ nucleus accumbens shell when fasting (Avena et al. 2008), reduced hypothalamic dopamine, and reduced serotonin and dopamine in the medial prefrontal cortex (Chandler-Laney et al. 2007).

Palatable Food

Palatable foods high in sugar or fat can promote binge-like intake with little or no food restriction. It has been proposed that limiting access to these "forbidden foods" contributes to their overconsumption during episodes of human binge eating or when dieters "cheat" on a diet. Several animal models alternate between access to a standard chow diet and access to a preferred diet to mimic this cyclical pattern of restraint and relapse. As access to a palatable food is decreased in rodents, the rate at which it is consumed when it becomes available again increases. Corwin and Wojnicki (2006) have developed a model using a pure fat (vegetable shortening), provided for only 1–2 h three times per week while chow remains available ad lib at all times. After approximately four weeks on this schedule, intake of the pure fat increases dramatically, eventually comprising approximately 70% of normal total daily intake in ad lib chow-fed rats. Fat intake under these limited access conditions is unaffected by administration of galanin or enterostatin, two peptides involved in regulating fat consumption, but can be reduced with the GABA-B agonist baclofen. Baclofen does not alter the intake of chow, suggesting that the binge-like intake of the fat is driven by some property of the high-fat diet, perhaps its palatability.
