Further restricting palatable food access can produce binge-like behavior more rapidly. Cottone et al. (2008) have developed a model of binge eating where a daily 2-h period of food deprivation is followed by access to a high-sucrose diet for only 10 min. Chow is available ad lib at all other times. On this schedule, rats rapidly increase their intake of the high-sucrose diet beginning on the second day of exposure, eventually consuming 40–50% of total daily intake during the 10-min limited-access session. Binge magnitude is reduced by administration of the mu- and kappa-opioid antagonist nalmefene (▶ endogenous opioids).

Anxiety appears to be increased on both the 2-h and 10-min binge schedules. Heightened anxiety may reflect a dysphoric state (▶ affective state) induced by withdrawal from the preferred diet. Rats alternating between 5 days of access to standard chow and 2 days of access to a palatable high-sucrose diet show an increase in anxiety-like behavior only when tested on days when the palatable food is unavailable.

▶ Benzodiazepines, known for their potent anxiolytic effects, increase palatable food consumption in nondeprived animals and humans. These orexigenic effects are dissociable from effects on anxiety, as not all benzodiazepine ▶ partial agonists that are anxiolytic also stimulate food intake. Benzodiazepines may instead act to enhance hedonic responses to palatable foods. They enhance preferences for sweet or salty tastes and increase motivation to obtain a food reinforcer in rats trained on a ▶ progressive ratio schedule. In contrast, benzodiazepine ▶ inverse agonists attenuate taste preferences and reduce palatable food intake by reducing the length of feeding bouts (Cooper 2005).

Stress

Acute ▶ stress typically reduces food intake in rodents, but Boggiano et al. (2005) have developed a model that combines restriction–refeeding cycles with palatable food and stress to cause binge-like behavior. In this model, rats are placed on food restriction (67% of normal intake) and are allowed to refeed on chow or palatable food ad lib, then are exposed to a foot shock stressor. Rats placed on this restriction/stress schedule increase their intake of palatable food after the foot shock relative to rats exposed to either restriction or stress alone, indicating that a synergistic effect of restriction and stress drives the binge. Binges can be attenuated with ▶ naloxone (▶ opioid antagonist) treatment, suggesting that the drive to consume the palatable food is related to reward seeking. If chow alone is available during the refeeding phase, binge-like behavior is absent. Other stressors can also precipitate a binge. Rebound chow hyperphagia is enhanced if rats with a history of 2-h time-limited daily food access are allowed to refeed in cages that severely restrict movement (Inoue et al. 1998). This cycle of restriction, stress, and binging on a rewarding stimulus bears a remarkable similarity to drug addiction, and it has been suggested that binge eating should be examined from the same perspective as substance abuse disorders. As with addiction, humans with bulimia or binge-eating disorder report a loss of control during a binge despite feelings of shame or guilt. Uncovering further similarities in the mechanisms of substance use and binge eating may help refine existing models of both categories.

Echolalia

Definition

The involuntary repetition, usually immediate, of words, phrases, or other vocalizations made by another person; usually seen in psychotic and pervasive developmental disorders (e.g., autism).

Echo-Planar Imaging

Synonyms

Gradient-echo EPI; Spin-echo EPI

Definition

Echo-planar imaging (EPI) is a magnetic resonance imaging (MRI) technique that permits the rapid collection of entire two-dimensional MR images (slices) in only a fraction of a second (40–100 ms). It has been fundamental to the development of BOLD fMRI.

Cross-References

Echopraxia

Definition

The involuntary imitation or mirroring, usually immediate, of the movements made by another person; usually seen in Tourette syndrome and in psychotic and pervasive developmental disorders (e.g., autism).

Ecogenetics

Synonyms

Ecological genetics

Definition

Ecogenetics is a branch of genetics that studies how the genetic makeup affects the way organisms respond to all kind of environmental substances. This field deals with the genetic basis of environmental toxicity to develop methods for the detection, prevention, and control of environmentally related disease. According to the environmental agents involved, one may distinguish infection ecogenetics, nutritional ecogenetics, physical ecogenetics, and chemical ecogenetics.

ED_{50}

Definition

The ED_{50} is a commonly used abbreviation that denotes the Effective Dose of a drug needed to produce a particular response in 50% of a population of test samples. It is a quantitative measure of the potency of a drug; the smaller the ED_{50} value, the more potent is the substance in the test system used. The original use of the term related to drug effects of an all-or-none (quantal) nature and it was assumed that the full range of effect frequencies from 0% to 100% actually occurred. Subsequently the term was adapted to a wider range of test situations including those where quantitative (graded) data were obtained for drug effects did not necessarily reach the extremes of a percentage scale. For example, in drug discrimination experiments using graded scales, the ED_{50} value is often defined as the dose of the drug that produces a mean of 50% drug-appropriate responding, as estimated from dose-response data by an appropriate statistical method. The ED_{50} is a valuable index for comparing potency in a series of related substances.

Effect Inversion

Synonyms

Opposite effect

Definition

Inversion in the nature of the effect(s) exerted by a biologically active substance. This phenomenon may be triggered, on the one hand, by the intake (or administration) of a dose much higher than the one capable of exerting the required effect. On the other hand, effect inversion may emerge as a consequence of the prolonged consumption (or administration) of low to moderate doses of an active substance. In the latter case, effect inversion is distinct from tolerance and leads to the manifestation of effects that are opposite to those exerted by the substance upon its single intake (or acute administration).

Cross-References

► Caffeine

Effect Size

Synonyms

Standardized mean difference

Definition

Effect size (ES) is a term given to a family of indices that measure the magnitude of a treatment effect. Unlike significance tests, effect size is independent of sample size. Effect sizes are used when treatment effects are defined over a continuous measure. For a given treatment, effect size is usually defined as the mean improvement over the course of a trial divided by the standard deviation for the treatment group. Based on convention, a small effect size is considered less than 0.3, medium effect size 0.3–0.7, and a large effect size greater than 0.7.

Effectiveness

Synonyms

Pragmatic outcome; Usefulness

Definition

The beneficial effect of a medicinal product seen in everyday clinical practice, in relatively unselected patients who may have psychiatric or medical comorbidities, who may be taking concomitant medication, whose compliance

with medication is unsupervised and where the outcome is useful to the patient in terms of quality of life.

Effectiveness of Antipsychotic Drugs in First-Episode Schizophrenia and Schizophreniform Disorder

► EUFEST

Effectiveness Studies

Definition

Efficacy trials in psychopharmacology examine the performance of an agent under "ideal" conditions. They are routinely short-term (e.g., 4–8 weeks), with strict inclusion/exclusion criteria and placebo and/or comparator drug control groups. Such trials are integral to regulatory approval in drug development. In contrast, effectiveness trials evaluate the performance of an agent in the "real world" of actual clinical practice, unencumbered by the same restrictive criteria and required control groups.

Efficacy does not ensure effectiveness, as has been demonstrated recently with development of the atypical antipsychotics. Numerous efficacy trials with individual agents demonstrated their superiority when compared to placebo, as well as a typical or conventional antipsychotic. However, subsequent effectiveness studies tempered these findings; in the more naturalistic surroundings of actual clinical practice, the atypical antipsychotics failed to distinguish themselves from conventional agents in the manner reported in efficacy trials.

These findings highlight the need for both efficacy and effectiveness studies in drug evaluation. Proven efficacy is necessary, but not sufficient, to guarantee effectiveness in actual clinical practice.

Cross-References

► Second- and Third-Generation Antipsychotics

Efficacy

Synonyms

Clinical outcome; Therapeutic benefit

Definition

In pharmacological investigations, efficacy is the property of an agonist drug at its receptor that reflects its ability to produce a response. Drugs that act at the same receptor can vary in their efficacies. Efficacy also depends on whether a drug acts as a full, partial, or inverse agonist. Pure antagonist drugs occupy receptors but have no efficacy.

In clinical situations, efficacy refers to the beneficial effect of a medicinal product under ideal conditions – usually phase 2 or 3 clinical trials conducted at least partially in a hospital setting and involving a selected subsample of the population for which the medicine will eventually be indicated, and where outcome is typically measured by symptom ratings.

Effort Cost

Definition

The subjective appraisal of the physical exertion required to procure a reward.

Egocentric

Definition

In terms of spatial cognition, an egocentric frame of reference is centered on the ego or navigator. Thus, object location can be described in terms of angle subtended from the head direction and distance from the navigator.

Ejecting Current

Definition

A current (either positive or negative) that causes the exit of charged transmitters, drugs, or other compounds of interest from the iontophoretic pipette into the extracellular environment.

Ekbom's Syndrome

► Delusional Disorder

Elasticity

Synonyms

Adjustability; Flexibility; Malleability; Plasticity; Pliancy

Definition

The *elasticity* is the degree to which a change in price or income changes the demand for a commodity.

Synonyms

Amperometry; Fast-scan cyclic voltammetry; High-speed chronoamperometry

Definition

Electrochemical Techniques: A group of analytical methods based on measuring the current produced by oxidation or reduction of electroactive molecules at an electrode or microelectrode surface. Loss or gain of electrons, respectively, occurs in response to varying the applied potential at the working electrode with respect to a reference electrode: commonly called voltammetry, amperometry, chronoamperometry, or fast-scan cyclic voltammetry due to the way the voltage is applied. The resulting current produced by the oxidation/reduction of analytes is proportional to analyte concentration at the electrode surface. Historically, electrochemical techniques have been utilized to study chemical reactions, but more recently, they have been used to measure the concentrations of neurotransmitters and other endogenous substances in biological systems. Considerable work has been carried out over the last three decades to develop and to modify electrodes and recording techniques to make these methods selective and sensitive for biogenic amine neurotransmitters. Newer versions of microelectrodes are modified with enzyme layers, such as oxidases, that allow for the formation of reporter molecules for neurotransmitters and neurochemicals that cannot be directly oxidized or reduced at microelectrode surfaces. This has increased the capabilities of electrochemical techniques so that neurotransmitters such as glutamate and acetylcholine can be measured. At this time, measurement of ► neuropeptides is not within the scope of this methodology.

Principles and Role in Psychopharmacology

Introduction: Electrochemical techniques are widely used in many varied research arenas, including the disciplines of chemistry, physics, and biology. Here, we focus on the application of electrochemical methods to the field of neuropsychopharmacology and recent advances in this field. In particular, we illustrate some of the breakthroughs made in our understanding of brain ► neurotransmitter transporters. These highly regulated transmembrane proteins are critical for clearance of released neurotransmitters from the extracellular milieu. Transporters are also primary targets for numerous psychotherapeutic and addictive drugs. Moreover, neurotransmitter transporters are implicated in the pathophysiology of psychiatric disease states including depression, anxiety disorders, schizophrenia, autism, and addiction, as well as Parkinson's and Alzheimer's diseases. The following sections focus on the basic principles of chronoamperometry and amperometry coupled with microelectrodes as they have been applied to advances in the field of psychopharmacology.

High-Speed Chronoamperometry to Measure Biogenic Amines Using Carbon Fiber Microelectrodes: Chronoamperometry is based on methods originally described by Cottrell in 1902. Modern electronics and digital data acquisition have led to the ability to measure current at rapid sampling intervals (1 Hz or faster) permitting high-resolution measurements of neurotransmitter transport. To investigate the uptake of ► biogenic amines, such as serotonin (5-HT), norepinephrine (NE), or dopamine (DA), a carbon fiber microelectrode (CFE), which is often coated with ► Nafion to repel interfering anions, and a reference electrode are positioned in a suitable buffer solution, cell suspension, synaptosomal preparation, tissue section, or directly into the brain (Daws and Toney 2007; Perez et al. 2007). The CFE is held at a constant resting potential (typically 0 V) versus a Ag/AgCl reference electrode. A 1–10 Hz square wave step potential (typically +0.55 V) is applied. This voltage step is selected to encompass the

range at which most biogenic amines are oxidized, i.e., lose electrons, histamine being a notable exception, as it requires a voltage of +1.0 V for oxidation. The applied voltage is held for 100 ms and this produces a change in oxidative current (typically in the range of pA to low nA) recorded at the CFE. Initially, the current decays quickly as a function of time, which reflects the capacitive or charging current at the surface of the electrode. The remaining Faradaic current produced by each step potential can be integrated and used to calibrate the CFE against known concentrations of neurotransmitter prior to use in an experimental setting. The voltage is then returned to the resting potential and held for 100–900 ms (depending on the neurotransmitter being measured). This gives rise to a reductive current. The ratio of the oxidative and reductive currents can be used to aid in identification of biogenic amines. Currents that result from repeated step potentials are measured as a function of time to determine the rate of change in neurotransmitter concentrations resulting from the action of neurotransmitter transporters. The limit of detection for most biogenic amines by chronoamperometry is in the nanomolar range and this technique has found its greatest successes in measuring the uptake of exogenously applied neurotransmitters. A limitation of this approach is that basal concentrations of neurotransmitter are not readily determined because microelectrodes have limited selectivity, and other oxidizable species in brain tissue that contribute to the measured current are not easily distinguished from basal neurotransmitter levels. One of the advantages of chronoamperometry is that the high frequency at which recordings are made (1–10 Hz) enhances signal-to-noise because small changes in current due to the detection of biogenic amines are not masked by large and potentially varying background current (see Daws and Toney 2007). Additional advantages include the spatial (micrometer) resolution at which recordings are made. There are many variations of this approach and these are described in detail in "Electrochemical Methods for Neuroscience (2007)."

Applications in Psychopharmacology: Chronoamperometry approaches used by us, and others, stem from the pioneering work of Ralph Adams in the late 1970s and 1980s. In brief, Nafion-coated CFEs, precalibrated to the neurotransmitter of interest, are exposed to brain tissue or implanted stereotaxically into the brains of anesthetized mice or rats. By coupling CFEs to glass, multibarrel micropipettes, drugs, or neurotransmitters can be exogenously applied directly to the brain with excellent spatial resolution (e.g., the typical active recording areas of CFEs range from 50 to 300 μm in length and from 5 to 30 μm in diameter, and micropipettes can be closely positioned within 300 μm). Bath application or direct pressure-ejection of exogenous neurotransmitter provides a straightforward but powerful means to determine the kinetic parameters associated with transporter function and to tease apart contributions from different transporters, enzymes, and diffusion to the clearance rates of individual neurotransmitters. Likewise, factors regulating transporter function, such as kinases and growth factors, can be studied *in vivo*. The following section provides some examples of how this approach has been used to advance psychopharmacology.

Transporter Kinetics: High-speed chronoamperometry and other electrochemical techniques have given us the unprecedented ability to investigate the kinetics of biogenic amine transport mechanisms on a second-by-second basis in vitro, ex vivo, and in vivo, the latter in both anesthetized and freely moving animals. One of the findings that have emerged is that uptake rates may be significantly higher and affinities substantially lower than previously thought based on radiochemical studies of neurotransmitter transporters (Perez et al. 2007). For example, 5-HT uptake rates measured by chronoamperometry in synaptosomes (Perez and Andrews 2005) or in vivo (Daws 2009) are up to 100 times higher than those determined radiochemically. Likewise, the affinity of the 5-HT transporter (SERT) for 5-HT is 1 μM by chronoamperometry compared with values in the low nanomolar range determined by uptake of [^{3}H]5-HT. The reasons for these discrepancies are complex; however, some of the contributing factors have been elucidated and involve loss of transported neurotransmitter during the filtration process used for synaptosomes, which is necessary for radiometric assay, but not for direct chronoamperometric measurements of uptake ex vivo or in vivo (Perez et al. 2006). Additionally, chronoamperometry is typically carried out in synaptosomes or cells incubated in oxygenated buffer or in intact respiring brain tissue. Finally, because changes in neurotransmitter concentration due to transporter activity are resolved on a second-by-second timeframe by chronoamperometry, compared with a single measurement obtained over minutes by radiochemical methods, the entire nonlinear kinetics associated with transport can be resolved using chronoamperometry, including initial uptake rates.

Biogenic Amine Promiscuity: Studies carried out in the 1960s and 1970s using in vitro uptake assays of tritiated neurotransmitters gave rise to the notion that transporters for the biogenic amines, for example the 5-HT, NE, and DA transporters (SERT, NET, and DAT, respectively), take up not only their native neurotransmitter, but are capable, albeit with lower affinity, of taking up other neurotransmitters (see Daws 2009 for review). However, this concept

of neurotransmitter transporter promiscuity has only recently become more widely accepted in our thinking about central neurotransmission. Studies using chronoamperometry have played a significant role in advancing this idea (see Daws 2009). A recent example comes from studies in mice lacking one intact copy of the SERT gene. These SERT-deficient mice are a useful model for humans carrying variants of the SERT gene that confer constitutively lower SERT expression and function. Interestingly, humans with lower expressing SERT alleles show somewhat greater susceptibility to ▶ depression and other stress-related disorders on average and may be less responsive to treatment with 5-HT selective reuptake inhibiting antidepressants (SSRIs), such as ▶ fluoxetine (Prozac), which act to inhibit SERT. One possible explanation for SSRI resistance is upregulation of other transporters capable of taking up 5-HT. These transporters thereby buffer the ability of SSRIs to increase extracellular 5-HT, presumably the first step necessary for triggering the cascade of events leading to therapeutic benefit. One such promiscuous transporter is the organic cation transporter type-3 (OCT3), for which SERT-deficient mice have higher expression levels (Baganz et al. 2008). Like 5-HT, histamine is also a substrate for OCT3; however, it is not a substrate for SERT. Using high-speed chronoamperometry, histamine clearance from the extracellular fluid in the hippocampus was found to be significantly faster in SERT-deficient mice than in wild-type mice, a relationship opposite to that for 5-HT clearance in these animals (Baganz et al. 2008). Blockers of OCT3 were found to inhibit 5-HT clearance more efficaciously in SERT-deficient mice than in wild-type mice, suggesting the possibility of using OCT3 antagonists as novel antidepressants or adjuvant therapy (Baganz et al. 2008). Preliminary studies assessing the antidepressant-like activity of the OCT3 blocker, decynium-22, suggest that this is an avenue for further research and potential drug development. This example of transporter promiscuity is one of many that have been revealed using electrochemical approaches (see Daws 2009) and it has wide-ranging implications for understanding treatment responses in numerous psychiatric disorders, as well as sensitivity to abused drugs.

Regulation of Biogenic Amine Transporters: Biogenic amine transporters were once thought to be relatively invariant regarding their expression and function; however, research over the past 15 years has shown that these transporters are highly regulated at a number of different levels (Blakely et al. 2005). Our understanding of the underlying signaling pathways and neuroadaptive scenarios that regulate transporters has grown substantially and much research in this area has been carried out using in vitro systems. Amperometry has been employed in transfected cell lines to reveal that biogenic amine transporters can operate in different modes e.g., similar to a gate in an alternating access turnstile, or under other circumstances, like an open channel (Blakely et al. 2005). Furthermore, chronoamperometry has demonstrated that signaling pathways regulating biogenic amine transporters, as identified in vitro, are also at work in vivo. These regulatory pathways include those coupled to 5-HT_{1B} autoreceptors, alpha_2-adrenoceptors, adenosine receptors, and dopamine D_2 autoreceptors (Daws and Toney 2007). In the future, in vivo electrochemical techniques can also be used to investigate the therapeutic potential of drugs targeted to sites downstream of receptors, such as second messengers and kinases.

Regulation of transporters by other signaling molecules, including brain-derived neurotrophic factor (BDNF), neurotrophic growth factor (NGF), corticosterone, and insulin, have also been studied in vivo using amperometric approaches. Results from these studies are providing vital clues into how stress, nutrition, and aging influence biogenic amine transporter function, as well as individual variations in response to therapeutics that target these transporters. In addition, future studies using in vivo electrochemical techniques aimed at answering questions such as determining how psychotherapeutics exert their effects on brain neurochemistry, why their therapeutic actions might be delayed (as is the case with current antidepressant medications), and what compensatory changes might occur in other transporter systems, have the potential to provide new information leading to the development of novel pharmacologic approaches for the treatment of psychiatric and neurodegenerative disorders.

Summary: This section has focused primarily on chronoamperometry to measure biogenic amine clearance. A brief description of the principles underlying this technique and examples of its applications to psychopharmacology are described. For more comprehensive information on fundamental principles and applications, the reader is referred to *Electrochemical Methods for Neuroscience* (2007). Notably, electrochemical techniques, such as amperometry, provide the only means currently available for the study of the time-resolved kinetics of neurotransmitter release and clearance in vivo, in both anesthetized and freely moving animals. The following section focuses on technological advances that enable the study of fast synaptic neurotransmission of nonelectroactive transmitters, such as glutamatergic signaling, using electrochemical techniques.

Real-Time (2 Hz) Measurements of Neurotransmission In Vivo Using Enzyme-Based Microelectrode Arrays: Numerous advances in electrochemical techniques have

now allowed the measurement of fast excitatory neurotransmission using enzyme-modified microelectrodes (Hascup et al. 2007). This was not previously possible using standard electrochemical techniques because neurotransmitters, such as glutamate, cannot be oxidized or reduced at electrode/microelectrode surfaces at usable working potentials (typically <1 V). ▶ Microelectrode array (▶ MEA) technology can now be used for direct in vivo determination of basal or resting levels of ▶ glutamate and other neurotransmitters, as well as evoked overflow due to stimulation or behaviorally induced events (Hascup et al. 2007). These MEAs are microfabricated using photolithographic techniques. The design employs Al_2O_3 substrates patterned with Pt or Ir electrode surfaces, which are coated with polyimide layers for insulation (Burmeister et al. 2000). The resulting 4–16 recording site arrays are modified with enzymes and organic molecules to make them sensitive and selective for the reproducible and rapid measurement of L-glutamate (▶ Glutamate MEAs), which is the major excitatory neurotransmitter in the CNS. Recently, MEAs have been manufactured by the thousands and routinely exhibit limits of detection for L-glutamate <0.2 μM, with response times of 2 Hz. Early designs employing Nafion coatings have now been replaced with ▶ meta-phenylenediamine (▶ m-PD) to greatly increase the selectivity of the measurements, which can detect changes in glutamate from 0.2 to 500 μM with Pearson's coefficients >0.99. Despite these advances, weaknesses in the designs still include: in vivo lifetimes limited to 30 days, enzyme coatings that require 2 days for curing, response times limited to 2 Hz, and the fact that MEAs have higher fabrication costs than CFEs.

Applications in Psychopharmacology: MEA technology has recently been applied to study changes in the CNS in normal aging (see Hascup et al. 2007) and in mice that lack the D_4 dopamine receptor (Thomas et al. 2008), which is a receptor possibly implicated in ▶ attention deficit hyperactivity disorder (ADHD). Reliable measures of basal glutamate have been determined in awake rats, mice, and monkeys in striatum and ▶ prefrontal cortex. Using self-referencing recording methods, extracellular glutamate can be reliably measured and generally ranges from 5 to 10 μM. In rats, extracellular levels of glutamate are diminished by >50% with transient application of tetrodotoxin, a sodium channel blocker, and >50% with local application of α-conotoxin, a calcium channel blocker, supporting the idea of neuronal origin of these extracellular glutamate signals. Local application of the glutamate transporter inhibitors, DL-*threo*-beta-benzyloxyaspartate (TBOA) or DL-*threo*-beta-hydroxyaspartate (THA), increases extracellular glutamate concentrations. Reproducible potassium-evoked release (1–2 s pressure ejection of 50–150 nL of 70 mM KCl) of glutamate ranging typically from 5 to 40 μM has been recorded in regions of the ▶ hippocampus, frontal cortex, striatum, and cerebellum of anesthetized rats, mice, and monkeys. These signals have average rise times of 1–3 s with total time courses of typically 5–12 s. Signals appear to be governed by Michaelis–Menten-like kinetics, with the rate of decay of the signals increasing as the maximum amplitude of the signals increases. Typical rates of clearance of glutamate range from 1 to 10 μM/s when measured by MEAs. Potassium-evoked release of glutamate can be repeated at 30 s intervals in most brain areas. In addition, MEAs have been modified with different enzymes and polymer coatings to measure a number of nonelectroactive neurotransmitters, metabolites, and drugs, including but not limited to choline, acetylcholine, glucose, aspartate, lactate, peroxide, GABA, dopamine, and ethanol in CNS tissues. Interestingly, the MEA technology is the first to allow in vivo measures of resting or basal levels of neurotransmitters by virtue of the ability to carry out self-referencing recordings with this microelectrode, in addition to stimulus-evoked release of neurotransmitters.

In summary, the electroanalytical techniques described here can be used to address a large number of pharmacological questions in anesthetized and freely moving experimental animals. In addition, the rapid recording capabilities of MEAs allow for the assessment of the kinetics of electroactive and nonelectroactive neurotransmitter release and clearance in vivo, analogous to the aforementioned studies of biogenic amines investigated using chronoamperometry in combination with CFEs.

Definition
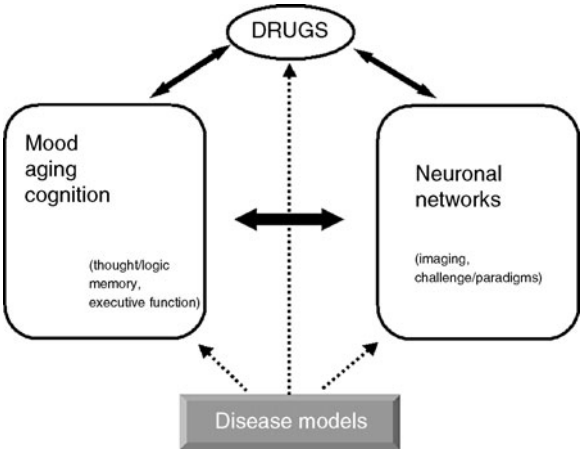
The Electroencephalogram (EEG) is a classical method to study dynamic properties of brain circuits; the EEG reflects a summation of extracellular potentials of synchronized populations of neurons with high temporal resolution (Niedermeyer and Lopes Da Silva 2005). Electroencephalography is used to passively record continuous electrical brain activity. Electrodes are either positioned on the surface of the scalp to record the activity emanating from the underlying cortex or inserted through the skull and positioned to record the activity from deeper brain structures both in animals and humans. After appropriately amplifying and filtering the signals, they are displayed as an EEG. The EEG shows the spontaneously generated aperiodic as well as slow and fast oscillatory brain activity recorded by the electrode(s). The fields of application of electroencephalography range from performance in activated states, quiet waking or ► wakefulness, normal and pathological ► sleep, as well as ► general anesthesia. EEG is widely used for the detection and diagnosis of epilepsy and other seizure disorders.

Early hopes that brain wave recording would allow one to understand how the human brain operates and help solve the mind–brain problem are yet too ambitious. Nevertheless, behavioral state changes in a certain context (or pathology) are believed to correlate with the neuronal events, which are quantifiable in the EEG (Fig. 1). This chapter emphasizes that many drugs acting on neurotransmitter systems (reversibly) perturb the EEG, which can then be used during clinical trials to indicate if and when a given drug has successfully reached its target in the brain and to quantify its duration of action.

Principles and Role in Psychopharmacology
To record a typical EEG from humans, multiple surface recording electrodes are glued to the scalp and one ► reference electrode is positioned preferably over an isoelectric part (linked earlobes, nose, and mastoid bone). The signals of interest are in the microvolt (millionths of a volt) range and sensitive to extracerebral



Electroencephalography. Fig. 1. Diagram summarizing common straightforward relationships in brain physiology, behavior, and psychopharmacology research and applications.

noise-sources. Although there exists no ideal zero-reference, scalp electrode recordings are improved by subtracting the common reference signal. Artifacts due to muscle activity or movement occur in EEG recordings, and they must be removed. Such artifacts are frequently caused by eye movements, blinks, heart beating/blood circulation, facial/scalp muscle activity, breathing, and swallowing. To help with artifact removal, polygraphic recordings are often performed alongside the EEG recording in both humans as well as animals, by the placement of additional sensors for monitoring, e.g., eye movements (EOG), postural/neck muscles (EMG), heart activity (EKG), thoracic expansion, and blood pressure. In practice though, the eye of the expert, who examines the entire multichannel EEG recording in addition to the accessory records, is the best means for artifact removal and epoch selection for the analyses in both wakefulness and ▶ polysomnography.

Sleep pattern characterization is usually carried out by visual inspection (see scoring rules in Iber et al. 2007) on cleaned traces in the temporal domain. Digital EEGs in animals and humans are nowadays nearly always obtained (as recommended, e.g., Penzel and Conradt 2000) with commercially available equipment. This has promoted the field of quantified wake EEG or ▶ qEEG which uses the fast fourier transform to calculate power spectra of the EEG segments and thus to quantify changes in the various frequency bands. Multivariate EEG-analysis by way of ▶ spectrograms provides valuable biomarkers for the endogenous modulation (by speeding or slowing) of the level of arousal, for the continuum in the change of patterns from adolescence, adulthood to normal brain aging, or for occasional EEG-changes related to life style, but also pathological states. Importantly, multivariate EEG-analysis also allows the study of perturbations induced by drugs.

Pharmaco-EEG is a technique to evaluate the effect of drugs on electrical brain activity in a defined context and implicitly makes use of qEEG. A large number of currently available therapeutics act on receptors/channels/▶ neurotransmitter transporters/enzymes in the brain, which take part in or influence synaptic transmission. Many of these drugs also influence the EEG power spectra, thus pharmaco-EEG has become a useful research tool in psychopharmacology; it is most commonly (but not exclusively) used in preclinical and early phase I ▶ randomized controlled trials for novel drugs. This technique allows to evaluate the cerebral ▶ bioavailability of compounds in man in comparison to animals (▶ translational research). qEEG provides a high-dimensional biomarker with the potential to perform systematic ▶ classification of psychoactive drugs, drug "finger-printing" (Saletu 1987), and risk evaluation. The versatility of EEG parameters lies in the fact that it provides a metric which is objective and can be expressed as (single subject or group) "raw" data, either as predose-adjusted value or as placebo-adjusted value. EEG data with good test–retest reliability are obtained when the volunteer is awake but with the eyes closed, whereas in freely-moving animals, the exact behavioral state and other confounding factors are more difficult to control.

Cortical Basis of EEG

Neurons firing action potentials generate extracellular electromagnetic gradients (▶ extracellular recording) in the cortex. When the timing is sufficiently coherent, synchronous activity gives rise to the microvolt signals named ▶ field potentials that make up the EEG by volumic summation of these elementary (neuronal) events; optimal geometry is an arrangement in the form of a "palisade-like" array. The macroscopic EEG signals switch polarity in a cyclic manner, and zero-crossings for the alternating waveforms can be as fast as 20 ms for a particular structure, or up to >1,000 ms for a different structure. The technique does not allow to reconstruct the individual ▶ firing patterns of neurons. Exactly which type of neurons and interactions contribute to the EEG and from where in the brain the different characteristic rhythms originate are the subjects of intensive research. The present view of the cellular aspects of generators of EEG is that particular neuron types, which are located in different parts of the CNS, have membrane properties that

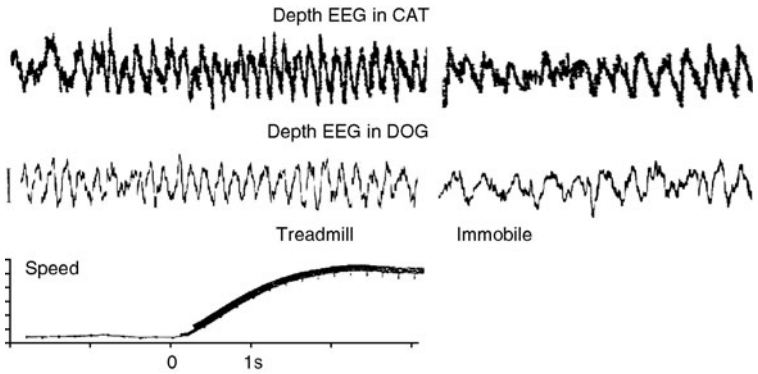
enable them to rhythmically fire action potentials and to participate in generating network oscillations in some frequency range. These membrane properties can be measured by performing ► intracellular recordings or patch clamp recordings. These neurons are, by virtue of their synapses from and onto other neurons, embedded in local network loops and the balance of net interactions determines the composite frequencies. Indeed, remotely located pacing structures, as is the case for thalamocortical loops, are necessary to entrain alpha and beta frequencies as described (e.g., Steriade 2001) by correlating signals from depth electrodes with cortex recordings; in practice, the net result of cortical generator events in the crown of sulci (cells with dendrites oriented radially to the skull) are most likely to be detected on the scalp of e.g., human or rat skull.

Similarly, impinging volleys via afferent septohippocampal pathways drive/impose the theta rhythm that arises primarily from the ► hippocampus (Buszaki et al. 1983). In animals, the pharmacology of the hippocampal theta rhythm is well studied. Theta rhythm is largely abolished by the muscarinic acetylcholine receptor antagonist atropine, whereas muscarinic agonists, like carbachol, induce "theta-like" rhythmic network activity in isolated hippocampal slice preparations. Hence there is a neurochemical basis for oscillatory brain potentials. The study of scopolamine-induced deteriorations in EEG (see ► Dementias: Animal Models and also ► scopolamine) helps in the development of ► Acetylcholinesterase inhibitors and ► Cognitive Enhancers or drugs for ► Dementias and Other Amnestic Disorders.

Neuropharmacology is applied to study the organization of brain rhythms. Systemically administered ► benzodiazepines modify beta-activity in the cortex of rats. EEG effects, when plotted as a function of blood concentration of ► midazolam (PK–PD), follow a sigmoidal curve evidencing a relationship of beta waves and the enhancement of the functions of ► $GABA_A$ receptors; moreover, the position of curves for e.g., drug-analogs with comparable EEG-effects reflect potency differences (Mandema and Danhof 1992). Experimental conditions can be refined (topic application of drugs) and pharmacology is useful for the understanding of how brain structures presumed to play a role in the generator process do cooperate with other regions to make up the EEG, but also to understand the normal equilibrium state in neural circuitry in general.

Components of the EEG

There is consensus to divide EEG (quasi-sinusoidal) waves into the following frequency bands: delta (1–4 Hz), theta (5–8 Hz), alpha-1 (9–10 Hz), alpha-2 (10–12 Hz), beta-1 (13–17 Hz), beta-2 (18–20 Hz), beta-3 (21–30 Hz), and gamma (31–100 Hz) in accordance with the International Pharmaco EEG Group (IPEG). To study the role of these waves, EEG experiments have been performed in numerous animal species, making use of conditioning paradigms. Repeated walking on a treadmill (see ► operant behavior in both animals and humans and ► instrumental conditioning) was used by Lopes Da Silva to establish empirically behavioral correlates of EEG components. Figure 2 shows examples of performance-related

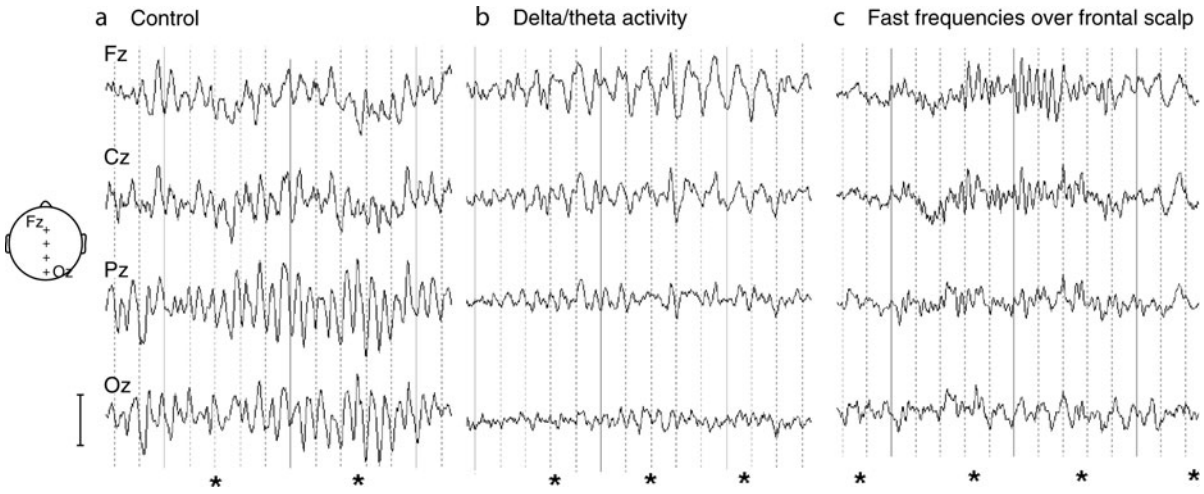


Electroencephalography. Fig. 2. Functional correlates of EEG rhythms. Examples of EEG traces from the hippocampal formation for two mammalian species. The animals were conditioned to perform treadmill-walking and to remain alert, resting wakefulness. Note the presence of regular quasi-sinusoidal waves when the animals are moving, which disappear under immobility. Calibration bar 250 μV; speed in arbitrary units (remastered own unpublished ink-on-paper recordings from a Siemens ELEMA Mingograf® 16-channel EEG-machine (mfi-TNO); the author acknowledges P Dalenconte, a professional photographer, for image processing).

hippocampal theta in two animal species; 4–5 Hz dominant activity is more synchronized during walking than during rest or eating. The result fits in with the concept that theta rhythm, also named ► RSA (Vanderwolf 1969), is related to voluntary movement. The hippocampal formation is believed to play an important role in memory updating. J O'Keefe, L Nadel and collaborators, have produced evidence that the theta rhythm serves as a reference framework for a higher mental function, namely spatial navigation (http://www.congnitivemap.net/). Interestingly, subpopulations of individual neurons have properties like place-specific firing at a given location in e.g., a foraging task on an ► elevated plus-maze, and the moment of firing displays a phase relationship with hippocampal electrical field potentials in the theta frequency band suggesting that theta rhythm plays a role in navigation (Lisman 2005) and ► Spatial Learning in Animals. This finding can be extrapolated to ► Spatial Learning in Humans.

Examples of human EEG-components from four midline scalp locations in normal quiet resting state with eyes closed, show clearcut alpha spindles (Fig. 3 *left panel*) and correlates of hypovigilance or psychotropic drug states give changes in slow wave (Fig. 3 *middle panel*) and beta frequency bands (Fig. 3 *right panel*). What is known about the functional correlates of the frequency bands in man during waking and/or sleep? In brief, high power in the alpha band can be seen during certain attention tasks and/or when the subject is awake with the eyes closed and mixed beta frequencies are associated with active thinking and concentration. Gamma frequency activity is associated with higher mental function and can be generated in many different brain regions. EEG segments characterized by ongoing activity in the theta frequencies may indicate that the subject is involved in active exploration of the environment. Paradoxically, sleep stage N1 is associated with low amplitude 4–7 Hz activity (mostly theta frequency band, Iber et al. 2007). EEG segments with a preponderance of large amplitude waves in the delta frequency band (see ► function of delta waves), in particular, during polysomnography recordings (one or few EEG-channels) are scored according to the latest guidelines from the American Academy of Sleep Medicine as sleep stage N3, slow wave sleep (SWS) which makes part of ► NREM sleep and distinguishes from the ► REM sleep stage. The translational value from animal to human (and vice versa) is evident. The EEG montage along with an EMG from a postural (usually neck) muscle and a motion detector and/or a video monitor are used together to discriminate the different stages in animal studies. In drug development, it is well known that e.g., rat sleep-EEG has predictive value for the efficacy of new ► hypnotics and possibly for the development of ► antidepressants, in particular by studying REM-suppression.

Digital EEGs and related analyzes in the frequency domain are performed more frequently in animal and in



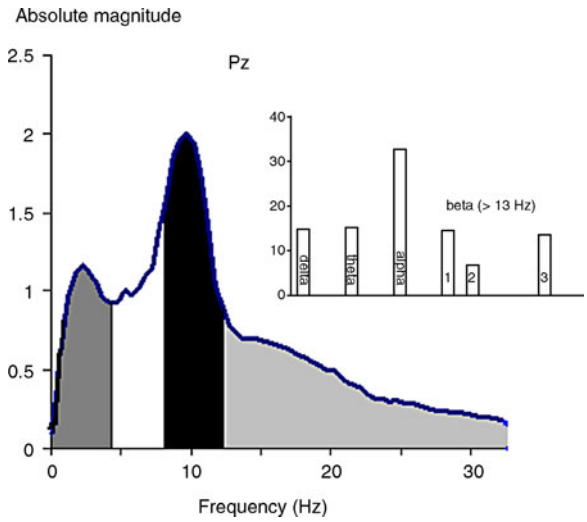
Electroencephalography. Fig. 3. EEG and (drug-induced) state changes. (**a**) epoch of scalp EEG simultaneously recorded from four midline electrodes according to the international 10–20 montage system showing a gradient of occipital alpha (spindle at Oz and Pz approximately 10 Hz) rhythm, "fading-out" in more anterior topography domains (**b**) dramatic EEG changes on clonazepam (1 mg i.v.); note the lack of alpha, and the slow wave activity in frontal leads. (**c**) drug-induced increased (fast) beta commonly occurs. Major tick 1 s, minor ticks 200 ms; calibration bar 100 μV. * *R-R interval from EKG.

man during waking states, but can be applied to sleep as well. For the hippocampal theta recordings (Fig. 2), power spectra have been used to perform statistical comparisons on extracted features under different behavioral conditions; dominant frequency associated with resting amounts values of 4 Hz which shift to about 5.5 Hz during walking. Rat EEG-recordings to relate beta-increases to midazolam plasma levels mentioned above are another good application of power spectral analysis. As pointed out, pharmacologist derive drug potency from dose (► ED50) or concentration-EEG effect relationship; for animals treated with ► flumazenil, a blocker of the benzodiazepine receptors, higher ► midazolam concentrations are necessary to induce the same EEG changes, which fits with a competitive agonist–antagonist interaction model. ► Benzodiazepines are widely studied because of known properties as anxiolytic, anticonvulsant, muscle relaxant, and sedative–hypnotic effects, but other mechanisms and therapeutic application can benefit from EEG. Straightforward examples of applied neuropharmacology in animal EEG are seen, for example, in natural or experimentally induced epileptiform, activity of great interest in the understanding and development of new ► anticonvulsants or novel compounds for the induction of ► general anesthesia. The translatability to humans is straightforward and is illustrated in the next section.

Clinical Applications

Shortly after computerized EEG analysis became available, the idea of using EEG as a diagnostic tool in patients suffering from neurological/psychiatric disorders began to be explored. EEG recording is harmless, easy to implement, and of low cost. Computational methods are available, but need group clusterization, hence are not very useful for individual subjects. EEG is commonly used in the diagnosis of epilepsy, sleep disorders, and as a research tool in a number of CNS-disorders. Cognitive decline is associated with EEG changes: a hallmark in Alzheimer's patients is the increase in slow waves and the decrease in alpha activity. Basic knowledge on the progression rate in EEG deteriorations needs follow-up tests over weeks or months. This can be assessed on different occasions in eyes-closed recordings which last for only a few minutes. An example of the magnitude (approaching EEG-amplitude, see Kiebel et al. 2005) as a function of frequency or spectrogram is shown in Fig. 4 for a healthy subject; the recording lasted 3 min.

Finally, the technique is widely applied for on-line monitoring of anesthesia. An illustration of benzodiazepine sedation can be found in Fig. 5a. It is important to stress the similarity in time course of both plasma levels

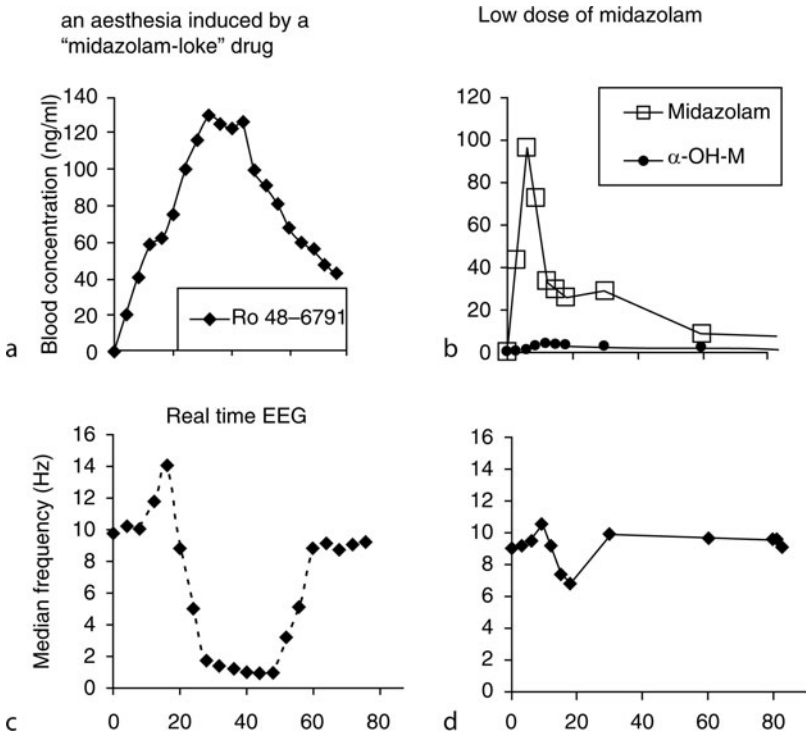


Electroencephalography. Fig. 4. Example of signal representation in the frequency domain as a spectrogram. The shaded areas give demarcations between classically defined bands; eyes-closed resting EEG can easily be repeated, has good test–retest reliability (not shown) and is recommended in drug studies. *y*-axis: square-root of power per spectral value yield a "magnitude," the center of gravity (=median frequency on *x*-axis) is normally around 9–10 Hz. Inset: Bargraph with labels of extracted features according to the names of the frequency bands. Drugs can almost independently modulate these, and this can even be different depending on the topographic location.

(plateau around 30 min) and the drop in EEG overall frequency (following a transient elevation in line with increased fast frequencies). Compartmental modelisation of PK-PD relationships fully validates the causality between input (drug i.v.) and output seen on the EEG. Sub-anesthetic doses of midazolam for the volunteer of Fig. 5b, for which EEG modifications are less pronounced than in the first case, rely on the same mechanistic principle and yield a good EEG pharmacodynamic response timing in relation to infusion onset. As for beta-EEG in animals shown previously, proper consensus on model characteristics is provided, e.g., ► triazolam (Greenblatt et al. 1994) for high frequency content in humans as is the case for midazolam (Fiset et al. 1995) but on the content of the whole spectrum.

Pharmaco-EEG in Humans

Signals as shown in left panel from Fig. 3a and "raw" spectrogram of Fig. 4 can be used to evidence a range of modulations/perturbations. Thus, the level of vigilance is reflected by the spectral composition of the brain signals.

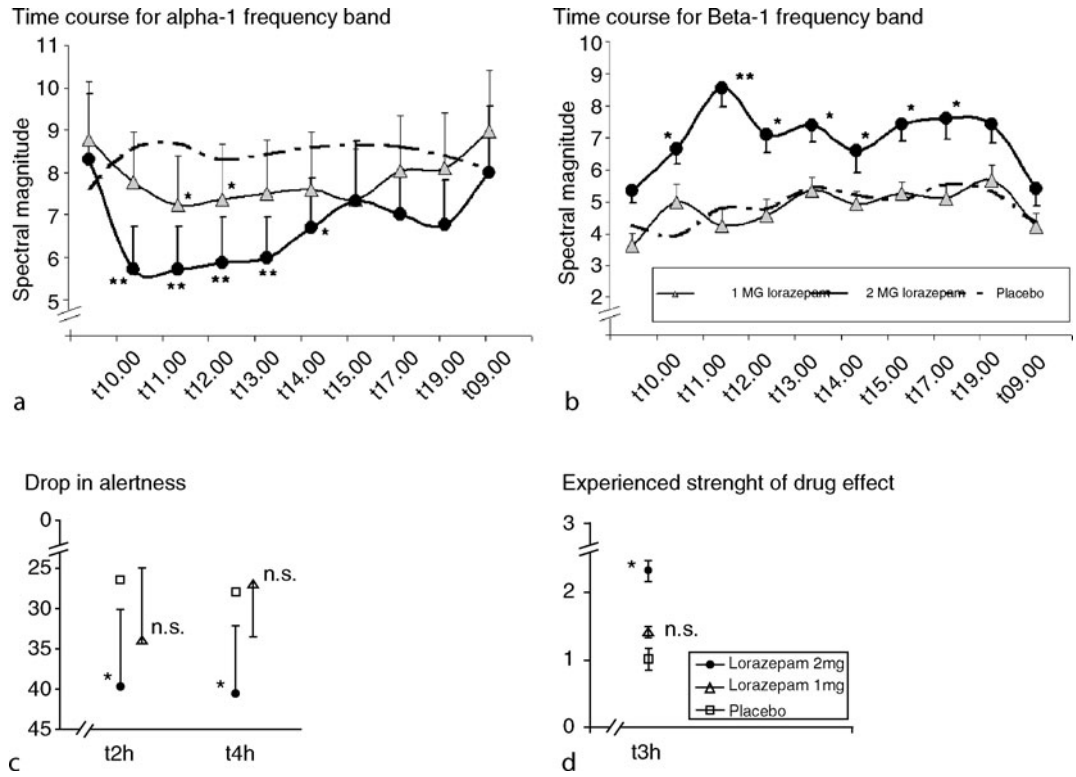


Electroencephalography. Fig. 5. (**a**) Pharmacokinetics for a single injection of the "midazolam-like" drug Ro 48-6791 at controlled infusion rate (3 ng/mL/min) in induction of anesthesia and conscious sedation. Curve peaks around 30 min when subject stopped responding. (**c**) changes in median frequency (qEEG) ; note the dramatic drop to 1–2 Hz center of gravity which remains stable around 30 min (adapted from Ihmsen H, Albrecht S, Hering W, Schüttler J, Schwilden H (2004) Modeling acute tolerance to the EEG effect of two benzodiazepines. Br J Clin Pharmacol 57(2):153–161). (**b**) Pharmacokinetic profile in a separate (own) experiment for a single i.v. injection for 15 min of a nonanaesthetic dose of midazolam (5 mg, 1/15th of dose for full sedation); note the rapid rise and fall in mother compound, and delay in (alpha-hydroxy) metabolite concentrations (concentration difference in the order of about one log-unit). (**d**) off-line analysis of the same parameter as in (**c**) but the lowering is less than one third of predrug values.

A simple experiment is to record the EEG during active waking with eyes closed: as the eyes open, dramatic changes in the EEG patterns occur (called "alpha-block"). More interactive recordings are beyond the scope of the present contribution, but can be found under ▶ event related potentials, which are the responses to specific stimuli, often sounds, recorded in the same manner as the EEG.

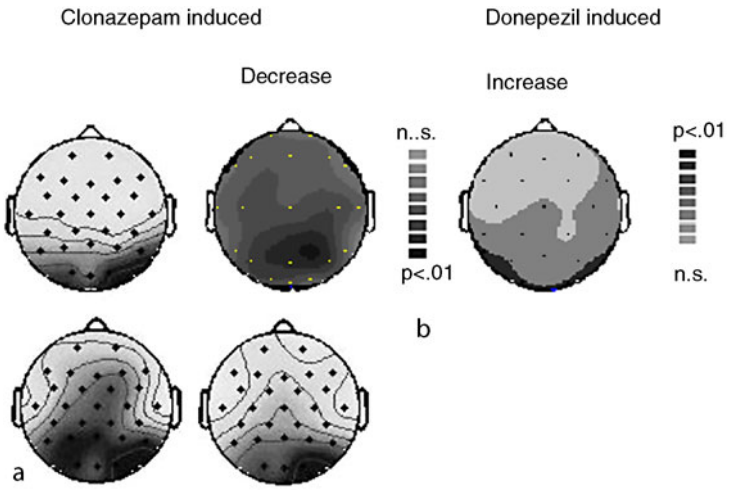
Life-style and habits also affect the EEG and must be taken into consideration. For example, long lasting changes are present in the EEG of cigarette smokers, particularly over parietal scalp regions (see Domino 2003 and ▶ Nicotine Dependence and its Treatment for relevant papers). Furthermore, consumption of ▶ caffeine and ▶ alcohol perturb the EEG (Gevins et al. 2002) and can bias study results. Gender, age, and mental health also affect the EEG and must be taken into consideration during the evaluation of drug effects in both healthy subjects and patient populations. When eliminating most of these confounding factors, the stability of spectrograms over time is satisfactory for the empirical detection of drug effects. EEG characteristics are strongly hereditary and as a consequence, intra-subject variability is low compared to inter-subject variability. Therefore, a cross-over design where the same individual receives both the drug and a placebo treatment is recommended whenever possible; this also controls better for systematic fluctuations unrelated to the actual drug (see ▶ Randomized Controlled Trials).

The top panels in Fig. 6 illustrate time course of EEG-effects induced by two doses of a benzodiazepine, ▶ lorazepam, and matching placebo. qEEG activity for beta-1 increased transiently followed by sustained elevations throughout the experimental day; alpha-1 was diminished

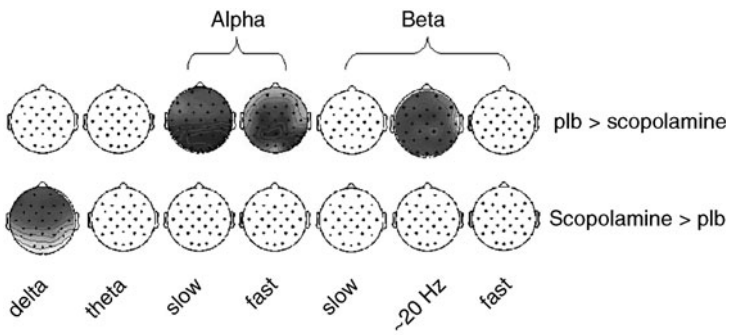


Electroencephalography. Fig. 6. Group data as part of a large project of qEEG for ten healthy volunteers, 1 or 2 mg doses. (**a**) Line-graphs (mean ± S.E.) for repeated measures of posterior alpha-1 EEG and the effects of two escalating (nontherapeutic) doses of lorazepam, a benzodiazepine drug having clearcut decreases for both treatments lasting about 4–5 h, with dose-dependency specially around 2 h postdose. Note the stability over time under placebo conditions. (**b**) same as in (**a**) but for frontal beta-1 EEG. (**c**) self rated alertness issued from VAS analog scales around the moment of significant EEG effects; only the 2 mg dose yielded a significance on the items interpreted as hypovigilance. (**d**) judgment of strength in drug effect (part of a separate project on metamemory) for the same two doses of lorazepam (adapted from Mintzer MZ, Griffiths RR (2005) Drugs, memory, and metamemory: a dose-effect study with lorazepam and scopolamine. Exp Clin Psychopharmacol 13:336–347).

for both doses from the first hour onwards, lasting >4 h, with a hint for dose dependency (see e.g., the 2 h). Comparative neuropharmacology of ► function of slow and fast alpha, issued from our unpublished multielectrode mapping of significant clonazepam modifications compared to placebo (Fig. 7 *middle column*, *top* p-values), or as single valued placebo-adjusted metric placebo (*middle column, bottom*). The decreased values cover almost the whole scalp. At the right, a similar statistical procedure shown increases for a single dose of donepezil which is more limited to the posterior scalp. Effects on other frequency bands are shown for the muscarinic acetylcholine receptor antagonist scopolamine (see ► Muscarinic Agonists and Antagonists). Scopolamine decreases slow and fast alpha (Fig. 8, *top row*) and has differential effects on e.g., the delta amplitude, which reaches enhanced levels in large precentral scalp regions (Fig. 8, *bottom row*). The decreasing alpha frequencies together with the increase in delta waves (► function of delta waves) show an increased sleep propensity, and are interpreted at the functional level as sedative "signature." Interestingly, ► benzodiazepine agonists (see also ► Benzodiazepines), anticholinergics, and first generation antihistamines (e.g., diphenhydramine, see ► Histaminic Agonists and Antagonists) yield similar EEG "signatures" and are all sedative. This suggests that their mechanisms of action converge onto similar vigilance-controlling substrates in the brain, despite the fact that their primary targets are different. A similar overlap has been found for drugs that cause increases in the beta frequency band: benzodiazepine anxiolytics, ► antidepressants, and ► barbiturates have similarities in their "signatures," most probably linked to $GABA_A$ receptor modulation. Such findings illustrate our increased understanding obtained by combining psychopharmacology and qEEG studies.



Electroencephalography. Fig. 7. *Left column*: descriptive qEEG topography for the alpha frequency band for a single subject without drug (*bottom image* with isocontours every 25 μV) and on clonazepam (*top row, left panel*). The crossover design allows subtraction (*bottom, middle image*) of EEG variables; finally inferential nonparametric testing of differences (mapping for groups) confirms drug-induced significant decreases. Topographic maps are constructed by interpolation for the values on 19 standard electrode positions+Oz and eight intermediate leads for active treatment. Example at the right mapping for a member of the class of acetylcholine esterase inhibitors, donepezil; a similar statistical procedure demonstrate that alpha frequency band increases in healthy volunteers (adapted from Boeijinga PH, Calvi-Gries F, Demazieres A, Luthringer R (2002) Planning of pharmacodynamic trials: specificities and possible solutions and interpretation of drug effects on EEG. Methods Find Exp Clin Pharmacol 24(suppl C):17–26).



Electroencephalography. Fig. 8. Pharmaco-EEG profile of scopolamine: inferential non-parametric testing ($N=12$) of differences has been carried out on an electrode-by-electrode basis with decreases in several bands at frequencies >8 Hz, and increases in delta, compared to placebo. Note that overall, a slowing in EEG can be deduced; the biomarker can be used to test reversal by (new) antidementia drugs and hence a single Phase I trial in a co-administration design, known as scopolamine model, predicts efficacy at an early stage.

EEG as Biomarker in Clinical Studies

In addition to being a diagnostic tool, EEG may be useful in assessing the effectiveness of particular therapies. EEG modifications in the diseased state are likely to reflect deficits in one or several neurotransmitter systems and conversely, pharmacotherapy should ideally normalize such deficits. For example, Acetylcholinesterase inhibitors as cognitive enhancers have been shown to reverse EEG abnormalities in patients with Alzheimer's disease, even after short-term treatment (rivastigmine; Brassen and Adler 2003). Similarly, EEG can be useful to assess directly and objectively the effectiveness of new hypnotics in sleep disorders and of anticonvulsants for epilepsy in patients. EEG

Electroencephalography. Table 1. Summary of EEG profiles for members of various classes of psychotropic drugs, separated in (**a**) increases in EEG variables, and (**b**) decreases in EEG variables compared to placebo (consensus from Mucci A, Volpe U, Merlotti E, Bucci P, Galderisi S (2006) Clin EEG Neurosci 37:81–98; Saletu B, Anderer P, Saletu-Zyhlarz, Arnold O, Pascual-Marqui RD (2002) Methods Find Exp Clin Pharmacol 24(suppl C):97–120 for the new generations of drugs like clozapine and citalopram, respectively, in the first two lines in (**a**) and (**b**), third and fourth line according to Boeijinga PH, Calvi-Gries F, Demazières A, Luthringer R (2002) Planning of pharmacodynamic trials: specificities and possible solutions and interpretation of drug effects on EEG. Methods Find Exp Clin Pharmacol 24(suppl C):17–26).

recordings can be valuable as a biomarker in the development of drugs that perturb neurotransmitter systems and act in the central nervous system. Figure 1 schematically illustrates the theoretical interrelations between brain state, neurophysiology, and drugs that form the basis for using EEG to evaluate drug effects.

Whereas plasma levels of compounds are nearly always obtainable, measuring brain exposure of the same drugs in humans is not possible. Due to the very nature of compartmentalization, a delay with respect to plasma-T_{max} may occur for CNS-effects. Since eyes-closed resting EEG has good test–retest reliability and can easily be collected continuously or repeated at regular intervals, the technique can be used to determine the pharmacodynamics at an early stage of development in healthy volunteers (Phase I), that is the time of onset and duration of the drug effects in the target organ, the brain. The continuous metric of the EEG can vary in a dose-dependent manner; hence, measurements can assist in dose-finding. Comparing the pharmaco-EEG profile with that of substances for which the pharmacological mechanisms are known may help predict efficacy and action in patients from the results in healthy volunteers. This aspect must be seen in the light of the Classification of Psychoactive Drugs as summarized in Table 1.

Advantages of Using EEG/ERP Relative to other CNS Biomarkers

Electroencephalogram recording constitutes one of the most frequently explored physiological parameters during both waking and sleeping. Since the receptor composition in neuronal circuits has a large overlap across species, pharmaco-EEG is highly translational and can be used as a biomarker throughout preclinical and clinical development in both in vitro and in vivo animal and human studies. In all species this can range from EEG at wakefulness to sleep and sleep disorders or animal models. Using EEG as a biomarker does not require labeling of a radioactive ligand as is necessary for the ▶ PET imaging method. In addition, EEG is a readout of the functional activity of neural networks. The time resolution of EEG is highly superior to that of ▶ magnetic resonance imaging (functional). The sensitivity of EEG/ERP also compares favorably to that of symptom inventories or subjective evaluations of volunteers or patient's "feelings" as indicators of brain penetration and pharmacodynamic effects. As an addendum to sustained EEG effects (see above), subjective feeling (alertness, a nine item VAS factor) was significantly affected for only the highest dose from the second hour onwards (Fig. 6b). In another experiment, healthy subjects subjectively rated the strength of a drug

effect. The dose of 2 mg yielded clearcut effects, but the 1 mg dose was not different from placebo (Fig. 6c). Without EEG "monitoring," one would falsely conclude to the absence of bioavailability in the brain of the low dose. EEG perturbations may suggest potential effects on endogenous vigilance processes, memory, and cognitive functions, hence an interpretation of side effects such as attention deficits (e.g., sedation or pro-convulsant effects). Other successful EEG applications are the evaluation of limitations due to ▶ blood–brain barrier properties with respect to a comparator, or to prove the presence and disentangle the direction of effects for unknown active metabolites. Finally, one can infer the efficacy of enantiomers; for the racemic mixture of the dissociative anesthetic ▶ ketamine, in line with Fig. 5, median frequency of the EEG drops, but does so to a larger extent for S(+)−ketamine than for a similar dose of R(−)−ketamine.

One disadvantage of EEG is the high inter-subject variability, which makes comparisons between parallel groups problematic. In any case, age and gender must be matched. As pointed out, reproducible EEG results can be obtained when the volunteer is awake, with the eyes closed. Nevertheless, one aspect in data processing concerns artifact rejection, which is laborious and not devoid of subjectivity. Improved methods to automatically remove artifacts are available (e.g., independent component analysis (ICA) on the free access EEGLAB website (A Delorme and S Makeig) http://sccn.ucsd.edu/wiki/Chapter_01:_Rejecting_Artifacts. Even today, the evaluation of sleep-parameters is still carried out manually, and the quality of research relies heavily on inter-rater reliability; hence regular consensus meetings are very important. Professional organizations like the American Society of Electroneurodiagnostic Technologists (http://www.aset.org/) propose such events.

EEG

Definition

Electroencephalography (EEG) is used to detect and record the electrical signals of the brain. The test is noninvasive and involves the placement of surface electrodes (flat metal discs) to the scalp of the test subject. This is particularly

useful in diagnosing a number of conditions that affect the brain such as certain types of epilepsy, where abnormal patterns of brain activity are observed even in the absence of a seizure. EEGs can also be used to assess brain function following a head injury or hemorrhage and serve as a useful tool to investigate sleep-related disorders.

2-D Electrophoresis

► Two-Dimensional Gel Electrophoresis

Electrospray Ionization

Synonyms

Elevated Plus Maze

Antonio Pádua Carobrez, Grasielle C. Kincheski, Leandro J. Bertoglio
Departamento de Farmacologia, CCB, Universidade Federal de Santa Catarina, Florianópolis, SC, Brazil

Synonyms

Elevated X-maze; plus maze test

Definition

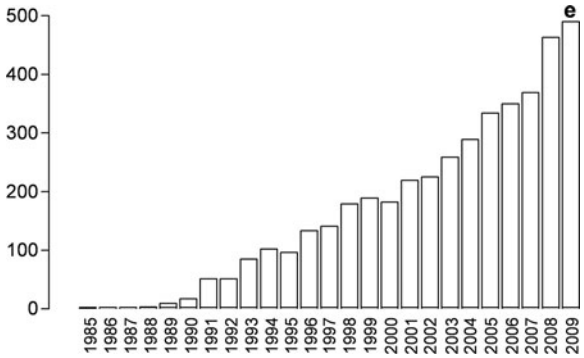
The elevated plus-maze (EPM) has been widely used (Fig. 1) as a reliable measurement tool to evaluate ► defensive behaviors related to ► anxiety in rodents, particularly mice and rats. Derived from Montgomery (1955) study concerning exploratory patterns, the EPM creates an approach–avoidance conflict where the environmental novelty is capable of simultaneously evokes fear and curiosity. This task was modified into an elevated maze with four arms arranged to form a plus shape (Fig. 2a) by Handley and Mithani (1984) as to detect either the anxiolytic- or the anxiogenic-like effect of drugs. An extensive pharmacological, physiological and behavioral validation of the EPM as an animal test of anxiety in rats was performed 1 year later by Pellow et al. (1985) and further extended to mice by Lister (1990).

Principles and Role in Psychopharmacology

The EPM stands as one of the most popular in vivo animal tests currently in use not only to drug discovery/development, but also to investigate the neurobiological mechanisms underlying ► anxiety. According to Fig. 3, over forty percent of EPM current use, estimates the emotionality of rodents submitted to previous genetical, biochemical and/or behavioral manipulations. Moreover, the EPM is an excellent example of task based on the study of unconditioned or spontaneous behavior. Its popularity, with around 4,300 published papers so far (Fig. 1), is likely due to its obvious and numerous advantages, namely: economy, rapidity, simplicity of design and bidirectional drug sensitivity, couple with the fact that it does not require lengthy training procedures or the use of food/water deprivation or electric shock (Pellow et al. 1985; Lister 1990; Rodgers et al. 1997; Carobrez and Bertoglio 2005).

The behavioral measures routinely scored during the 5-min EPM session are the frequency of open- and enclosed-arms entries and the amount of time spent on the open- and enclosed-arms. These data are used to calculate the percentage of open-arms entries {%OAE; [open entries/(open + enclosed entries)] × 100} and the percentage of time spent in open-arms {%OAT; [open time/(open + enclosed time)] × 100}. As illustrated in Fig. 2, there is a clear enclosed-arm preference. Under the influence of an anxiogenic-like drug, a further reduction in the open-arms exploration is observed. After being administered with anxiolytics, however, the animal displays significantly more open-arms exploration. In this context, it is worth mentioning that the efficacy of the EPM test in discriminating anxioselective compounds has been increased with the adoption of more ethologically-based analysis, i.e., the measurement of some acts and postures such as stretched-attend, head-dipping and grooming (Cruz et al. 1994). For instance, the frequency

of stretched-attend postures towards the open-arms (Fig. 2c,g) can be used as an index of ▶ risk assessment, a close behavioral dimension related to anxiety (Rodgers et al. 1997; Carobrez and Bertoglio 2005). The anxioselective discriminative property confers to the EPM test the predictive validity required to screen putative compounds and/or to identify alternative pharmacological interventions in anxiety field.

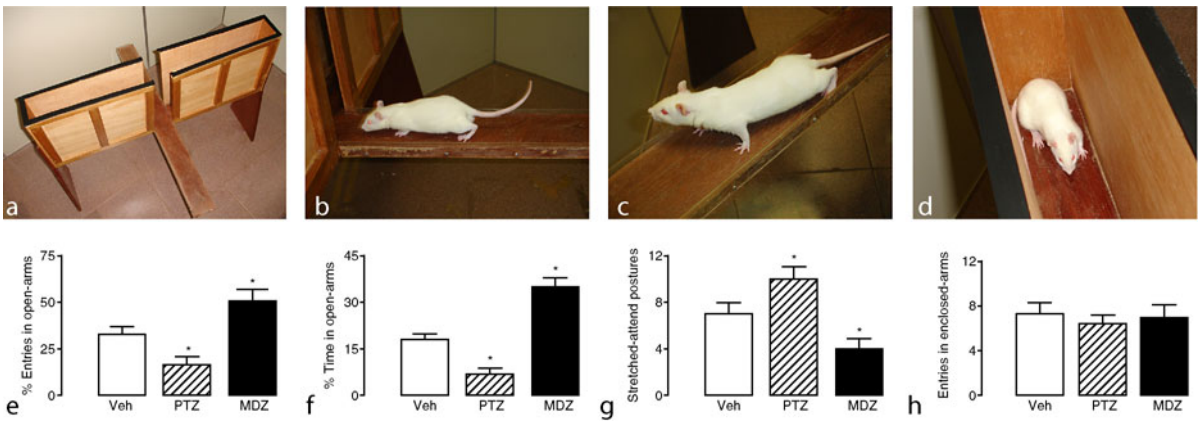


Elevated Plus Maze. Fig. 1. Published papers using the elevated-plus maze test in each year, according to the search performed on the PubMed site (http://www.ncbi.nlm.nih.gov/pubmed) in November 2009. e=estimated value based on the mean number of published paper per month in 2009.

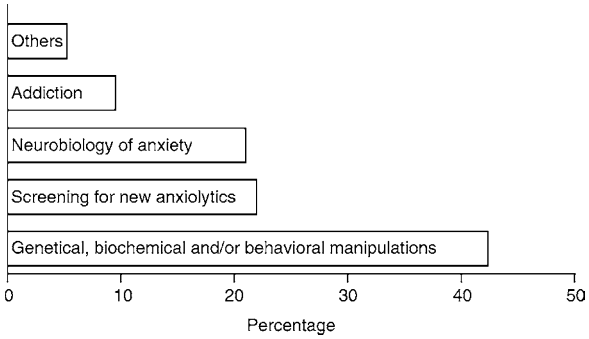
Methodological Variables

The main organismic variables of interest in the EPM test are species, strain, age, gender and estrus cycle/lactation, all of which have proven to interfere with its behavioral baseline level (Rodgers and Cole 1994). Furthermore, the different social role in the rodent group can be an important source of variation among dominant/subordinate males and females. As a consequence, either ▶ false-negative or ▶ false-positive results can occur if these important caveats are not taken into account. For instance, in spite of having similar defensive responses, mice and rats show a different level of general exploratory activity in the EPM test (mice been more active than rats). Anxiety scores also tend to change with age, apparently reflecting distinct brain development and/or the behavioral repertoire of the species.

Some procedural variables have also been shown to impact on the EPM baseline level. They include housing conditions, ▶ circadian rhythm, illumination level, time of testing, apparatus construction, definition of behavioral measures, prior handling/stress, and prior test experience. Together with organismic variables, these are the main sources of inter-laboratory variability in the use of the EPM (Carobrez and Bertoglio 2005). Based on the fact that behavioral responses and pharmacological effects observed in the EPM are under the influence of these



Elevated Plus Maze. Fig. 2. The (rat) elevated plus-maze consists of two opposite open-arms (surrounded by a small ledge), and two enclosed-arms, about 50-cm above the ground (**a**). Its use to measure anxiety is relatively simple: one may score the number of entries and the time spent on the open-arms (**b**). Besides these spatiotemporal measures, there are more subtle postures associated with anxiety such as the stretched-attend (**c**). They are collectively referred to as risk assessment behaviors. An ''anxious'' animal is one that displays risk assessment behavior very often, and rarely ventures out on the open-arms. In general, as can be seen in bottom panels, anxiolytics (e.g., midazolam, MDZ) increase open-arm exploration (**e**,**f**) and reduced stretched-attend postures (**g**) whereas anxiogenic drugs (e.g., pentylenetetrazole, PTZ) produce the opposite effect (**e**, **f** and **g**). One possible complication that an animal might not come out because it is inherently inactive, rather than anxious, can be dealt with by scoring the number of enclosed-arms entries, an index of general exploratory activity in this test (**d**, **h**).



Elevated Plus Maze. Fig. 3. The main focus of published papers using the elevated-plus maze test in 2008, according to the search performed on PubMed site (www.ncbi.nlm.nih.gov/pubmed).

variables (Hogg 1996), it would be imperative that laboratories using, or planning to use this test dedicate time and effort in order to define the optimal experimental conditions before starting their respective studies (Rodgers and Cole 1994).

Limitation of the EPM Task

Regarding possible apparatus limitations, it has been pointed out that within the rodent repertoire of defensive behaviors, the EPM is able to detect inhibitory avoidance and risk assessment. The expression of overt defensive behaviors such as ▶ freezing or flight, however, is not necessarily in the EPM range detection. Although both responses could be elicited by anxiogenic-like drugs, freezing could also be confounded with the enclosed reduced activity found in subjects treated with anxiolytics at sedative-like doses. Likewise, flight behavior induced by anxiogenics could also be confounded with the higher open-arms activity normally detected in animals treated with anxiolytic-like drugs. Overall, this limitation can also be applied as a note of caution when testing genetically modified organisms in the EPM. In fact, it might be extended to all organismic and procedural variables listed above.

A tendency towards automatic scoring of behavioral measures has been proposed to avoid subjective interpretation of the animals' behavior. Although these computer programs permit the analysis of spatiotemporal patterns of exploration in the EPM, some relevant (risk assessment) behaviors cannot be automatically recorded (Carobrez and Bertoglio 2005).

Furthermore, inconsistent results obtained in this test may indicate that the associated emotional state/reaction is critically dependent on stimulus parameters (Hogg 1996; Rodgers et al. 1997). Clearly, the behavioral expressions displayed in the EPM test represent a combination of exploratory and avoidance behaviors, as well as general activity, all of which are influenced by both genetic and environmental factors (Carobrez and Bertoglio 2005).

Elimination

▶ Excretion

Elimination Half-Life

Synonyms
Biological half-life; Terminal half-life

Definition
The plasma half-life of a drug ($t½$) is the time necessary to reduce the plasma concentration by half, for example, to decrease from 100 to 50 mg/L. The knowledge of the half-life is useful for the determination of the frequency of administration of a drug (the number of intakes per day) for obtaining the desired plasma concentration. Generally, the half-life of a particular drug is independent of the dose administered. In certain exceptional cases, it varies with the dose: it can increase or decrease according to, for example, the saturation of a mechanism (elimination, binding to plasma proteins, etc.).

Definition
An alkaloid that inhibits protein synthesis by interfering with mRNA–ribosome interaction.

Emotion and Mood

David H. Zald
Departments of Psychology and Psychiatry, Vanderbilt University, Nashville, TN, USA

Synonyms
Affect; Feeling

Definition
At the broadest level, an emotion is a highly valenced experiential state. More precisely, emotions comprise coordinated neural, neuromuscular/expressive, and experiential responses to meaningful stimuli or events. In the affective sciences, the term emotion (or *basic* or *discrete* emotion) is used to specifically refer to strong transient states, such as anger, disgust, fear, sadness, surprise, and joy, which have a quick onset, a brief duration, possess clear behavioral tendencies, definable expressive and autonomic characteristics, and occur in response to species typical antecedents. These discrete emotions are distinguished from *moods*, which are valenced experiential states that occur over longer temporal spans, often lasting minutes or hours.

Principles and Role in Psychopharmacology
The modulation of mood and discrete emotional states are common targets of psychopharmacology. Additionally, agents designed to address neuropathological processes or improve cognitive functioning often have effects on mood, sometimes to enough of an extent as to influence patients' willingness to take the agent. Thus, accurate measurement of mood and emotion is critical to psychopharmacological research. Unfortunately, there is no accepted "gold standard" for assessing mood and emotion. However, the science of measuring mood and emotion has grown in sophistication in recent years, and attention to the details of assessment can substantially increase one's ability to detect pharmacological influences on emotional processing.

Assessing Basic Emotions
Basic emotion assessments are appropriate in situations where a pharmacological agent is intended to directly regulate or reduce the occurrence of a basic emotion such as fear or anger, as might occur during treatment of a phobia or borderline personality disorder. Basic emotions may also warrant assessment when administering pharmacological agents with extremely fast pharmokinetics, since such agents may directly induce a discrete emotion, such as fear or euphoria.

Because basic emotions are most frequently seen in response to characteristic situations or stimuli, it is essential to assess these emotions in relation to the occurrence of such triggering events. This can be accomplished either through retrospective self-report ratings or through laboratory-based exposure paradigms in which the individual is exposed to triggering stimuli or situations. Retrospective ratings have the advantage of potential aggregation over multiple time periods and triggering events in the person's everyday life, but provide limited, if any, ability to standardize the frequency, qualitative nature, or intensity of triggering events across conditions or individuals. Furthermore, the verification and coding of such events can be highly subjective and difficult to reliably

code. Additionally, unless the person is fitted with an ambulatory psychophysiological and videorecording system, it is not possible to collect any additional objective measures of the emotion.

In contrast, laboratory exposure techniques can be highly standardized, and allow the collection of data time-locked to the triggering event. By time-locking self-report ratings, an individual does not have to evaluate already long-past experiences to determine ratings. More importantly, time-locking allows the use of objective measures, which can compliment, or in some cases replace, self-report ratings. These objective measures consist of coding or direct measurement of facial muscle activity and psychophysiological measurements of correlates of sympathetic and para-sympathetic autonomic activity. Because basic emotions are accompanied by specific patterns of facial muscle movement (indeed, this is a common criteria for a basic emotion), the coding of facial expression are frequently used as markers of emotion. Detailed coding systems of facial expressions are well validated, and can be applied to video recordings of participants (Ekman et al. 2002). An alternative approach is to measure facial muscle activity with electromyography (EMG). EMG can detect weak activity of muscles even in cases in which a full expression is not completed. However, it is important in using this technique to record from a number of muscle groups simultaneously, as single muscle groups are often multidetermined. For instance, the corrugator supercilii muscles above the orbits are sensitive to anger, but also show increased activity during exposure to ambiguous or difficult stimuli (Pope and Smith 1994). ▶ Psychophysiological measures, such as electrodermal response, blood pressure, blood volume, heart rate, detailed analysis of electrocardiograms, respiration, and skin temperature are all useful as objective measures of the presence of an emotional experience. By combining psychophysiological measurements, it is possible to observe some degree of autonomic patterning specific to basic emotions. However, true discriminant validity is difficult to achieve with these measures, which often show properties characteristic of dimensional models of valence (or approach-avoidance) and arousal (Levenson 1988).

Although laboratory exposure techniques have a number of strengths for the assessment of basic emotions, they suffer from two major shortcomings. First, the laboratory events may be weak and somewhat unnatural approximations of real-life triggering events. Second, it is often difficult to aggregate over multiple exposures in the laboratory setting due to habituation. In such cases, the reliability of the assessment is often compromised.

Assessing Mood

In most psychopharmacological contexts, the assessment of more enduring mood states is more relevant than assessing basic emotions. For instance, the depressive disorders are diagnosed based on sustained enduring mood states, rather than individual discrete periods of emotion. Similarly, the goal of treatment for depression is to alter these enduring mood states as opposed to targetting discrete emotions. Such mood states may be less intense than the basic emotions, but they do not require assessments that are time-locked to triggering events.

Self-report remains the only viable option in most studies of mood, because there are few objective measures of mood. A first question arises regarding which mood terms a subject should rate. Factor analytic studies indicate that mood data are marked by two higher-order factors (Watson and Tellegen 1985), which are respectively labeled positive affect (PA) and negative affect (NA). (Note: The use of the term "affect" here refers to the subjective mood factor, rather than to an individual's observable expressed emotion, as the term "affect" is frequently used in psychiatric settings.) PA reflects a person's level of pleasurable engagement with the environment. High states of PA are characterized by terms such as interested, excited, and determined, which denote positive behavioral engagement. NA comprises a general factor of subjective distress, with high states of NA marked by descriptors such as distressed, nervous, and hostile. Taken together, PA and NA account for 50–75% of the common variance of mood.

An alternative dimensional schema for understanding mood states has been proposed by Russell (1980), who identifies a bipolar valence dimension (unpleasant–pleasant), and a second dimension of arousal. This schema has some advantages, particularly when examining immediate responses to stimuli, in which one often sees a clear inverse relationship between positive and negative experiences. However, when aggregating over multiple time points, or measuring longer retrospective periods, the inverse relationship between positive and negative experience weakens. This independence allows for the study of separable influences on PA and NA (which is not feasible with a single bipolar valence dimension in which pleasant and negative states are measured in opposition to each other). An important distinction can also be made between the Russell model and the PA/NA model of Watson and Tellegen in that the experience of pleasantness or unpleasantness may be seen as a consummatory response to stimuli or events. In contrast, PA and NA are more motivational in nature, with clear links to approach and avoidance. This consummatory vs. motivational

separation parallels Berridge's (1996) distinction between wanting and liking as applied to mesolimbic dopamine and opioid functions. This distinction between wanting and liking also appears useful in monitoring drug-induced mood changes. For instance, the Drug Effects Questionnaire (Fischman and Foltin 1991) asks subjects to separately rate drug wanting and drug liking, and these two ratings often show distinct patterns of correlations, and differential time courses following drug exposure.

PA and NA show different temporal patterns. Individuals typically show at least a moderate level of PA, with variability occurring around their own traitwise mean level. In contrast, NA is typically very low, with spikes occurring in response to specific negative or potentially negative events. This has implications for experimental designs, because the ability to observe a pharmacological agent's impact on NA may be limited in the laboratory environment if the person is not exposed to potentially unpleasant experiences.

The positive and negative affect schedule (PANAS), developed by Watson et al. (1988), provides a widely used measure of mood that taps the relatively pure factor structure of PA and NA. The scale includes 20 mood labels marking high (activated) PA and NA states, and has been repeatedly found to be sensitive to individual differences in both current and long-term mood. There are, however, a few important limitations of this type of scale. First, as originally designed, the PANAS does not measure mood states associated with reduced PA or NA. Specifically, terms such as fatigue (which appear to reflect an absence of PA) or calm (which appears to reflect an absence of NA) are not assessed. Subsequent measures, such as the expanded version of the PANAS (the PANAS-X), have attempted to capture these "low activation" markers. Yet, low activation markers do not possess as pure a factor structure as high activation markers of PA and NA. This occurs because terms such as boredom or tired not only reflect an absence of PA, but are also experienced as unpleasant, while states such as serenity or calm not only reflect an absence of NA, but are also experienced as pleasant. Because of this, low activation states require direct assessment, and should not be inferred by simply reverse scoring high NA or high PA terms. This issue takes on importance when we consider that many medications and street drugs are taken to alleviate feelings such as fatigue or to induce calm. Treatment studies provide further evidence of the need to directly assess low activation states, as antidepressants can produce differential effects on low activation vs. high activation PA states (Tomarken et al. 2004). Interestingly, alterations in low activation states figure prominently in the subjective effects of certain drugs. For instance, alcohol researchers frequently utilize the Biphasic Alcohol Effects Scales (Martin et al. 1993), which is a 14-item scale containing two factors: (1) a stimulant factor that corresponds to high PA, and increases during the rising limb of blood alcohol levels; and (2) a sedative factor that corresponds to an absence of PA (i.e., low activation), which increases during the descending limb of blood alcohol levels.

A second issue with the pure factor approach implemented by the PANAS arises because some important mood states reflect combinations of different levels of PA and NA. For instance, sadness can be viewed as a combination of reduced PA and heightened NA. Given the importance of sadness to the affective disorders, it is often essential to capture subjective states such as sadness, and the continued use of measures, such as the Profile of Mood States (McNair et al. 1981), which includes a Depression–Dejection scale, attest to this. In the NA domain, there is also sometimes utility in examining lower-order factors, such as anxiety or hostility. In doing so, it is important to determine to what extent observed associations are specific to the lower order factor vs. reflecting the higher order factor of NA more generally. For instance, even a scale such as the State Trait Anxiety Inventory (Spielberger et al. 1983), which is often treated as a specific measure of anxiety, captures elements of general distress, and thus cannot be used to draw conclusion about a specific subfactor of NA.

Drug-Specific Assessments

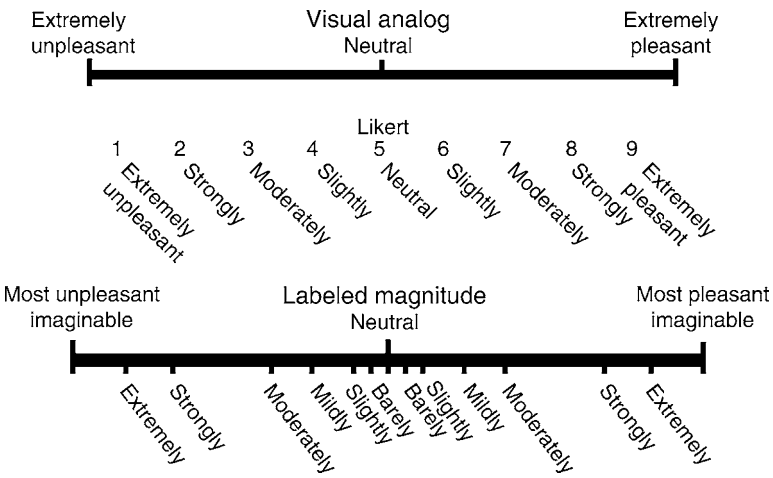
Studies examining the psychological effects of drugs of abuse require attention to the specific subjective effects of the agent. In particular, because of the intensity of basic emotion or mood states induced by drugs of abuse, typical mood scales may fail to appropriately capture such experiences, or may demonstrate ceiling effects (in which too many subjects give maximal ratings). For instance, ratings of joy may fail to capture the intensity of euphoric states. Several scales are in circulation that attempt to rectify this problem, by asking at least one question related to euphoria or related experiences. For instance, Van Kammen and Murphy (1975) developed the Amphetamine Interview Schedule to capture subjective responses to amphetamine, and include an item for euphoria, as well as related experiences of closeness to others, confidence, and overall feeling good. The Drug Effects Scale (Fischman and Foltin 1991) includes a rating of "feeling high," that may tap euphoric effects. However, the term "feeling high" is ambiguous, as it can also refer to a broad range of subjective experiences including perception of altered reality.

The most comprehensive scale for capturing the subjective effects of specific drugs is the ► Addiction Research Center Inventory (ARCI) developed by Haertzen et al. (1963), which measures subjective effects to a number of specific classes of drugs including ► morphine, ► LSD, and ► amphetamine, and among other symptoms tries to capture a euphoric–dysphoric continuum. With 550 true–false items, the inventory is problematically long for use as a real-time measure, so many investigators will restrict the questions to just those related to the specific drug of interest.

Types of Rating Scales

An important, and often overlooked, issue in studies of emotion and mood involves how to have participants rate their moods. Most studies have utilized either visual analog scales (VAS) or likert scales (LS). VAS consist of two verbal anchor descriptors that are placed on either end of a continuous line. Respondents provide ratings on VAS by indicating the point on the line that best represents the intensity of their current psychological experience. VAS may be considered to provide interval-like data in that they provide rank-order information about rating values and equal spacing exists between neighboring values along the entire scale continuum. Unfortunately, because the continuum lacks verbal descriptors, it is impossible to ascertain the qualitative intensity that corresponds to an intermediary rating. This means that intermediary ratings made by different individuals are not readily comparable. In contrast, to the VAS, LS consist of numeric points arranged along a discrete continuum, with intensity descriptor labels placed at both anchor points, and the intermediary numeric points. These labels have the advantage of leading individuals to use the intermediate ratings in a more qualitatively similar way. However, such scales are problematic, in that unless the intensity descriptors are truly equidistant, the applied numeric values do not represent the true quantitative (interval-like or ratio-like) differences in ratings. This is particularly problematic for bipolar scales (for instance, those running from unpleasant to pleasant), in that studies examining ratings of verbal descriptors have revealed that the magnitude differences of terms typically used to mark the low to moderate intensities cover a smaller distance than terms used to mark the moderate to the most intense anchors. This means a change in ratings between two descriptors in the lower intensity part of the scale cannot be considered equivalent to a change in two descriptors at the higher part of the scale (Fig. 1).

Recent research has led to the development of labeled magnitude scales (LMS), which attempt to address the weaknesses of the VAS and LS (Lishner et al. 2008). LMS utilize a visual analog scale framework, but includes descriptors that are placed along the scale at empirically determined intervals derived from rating studies of the intensity descriptors. Such scales also often use "most imaginable" instead of a term such as "extreme" as the highest intensity anchor in order to limit ceiling effects. To date, the LMS approach has not been widely used in psychopharmacological research, but this type of approach can be easily integrated into existing scales. However, it may be necessary to verify that the factor structure



Emotion and Mood. Fig. 1. Example of bipolar scales of pleasantness in a visual analog, likert, and labeled magnitude format.

of the existing measures is consistent when moving from an LS or VAS format to an LMS format.

Response Biases

A final consideration in self-report data relates to potential response artifacts that lead an individual to respond in a manner that is not representative of their true level of current mood. Response biases, including acquiescence biases, nay-saying biases, carelessness, and socially desirable response sets, all may contribute to error in the measurement of mood. However, such response artifacts do not invalidate mood ratings. They merely make it less accurate. Moreover, in some cases, it is possible to correct response artifacts or identify individuals with invalid data by specifically assessing for response biases. In summary, there continue to be challenges inherent to measures of emotion and mood, but through careful research design these measures can substantially contribute to psychopharmacological research.

► Opioids

Enemas

Definition

Enema is the procedure of introducing liquids into the rectum and colon via the anus. Enemas are usually carried out as a treatment for constipation.

Energy Balance

Definition

The body maintains energy balance (EB) if energy intake (calories ingested and absorbed) matches energy expenditure (calories utilized by the body through basal metabolism, thermogenesis, and activity). If energy intake exceeds energy expenditure, a positive energy balance is achieved and excess calories are stored. Conversely, if energy expenditure exceeds energy intake, a negative energy balance is achieved and energy stores (in adipose tissue) are utilized. Sustained energy imbalance produces changes in body weight and composition.

Energy Intake

► Eating and Appetite

Energy Metabolism

Definition

Chemical energy has to be provided for brain function in the form of glucose and oxygen; glycolysis and mitochondrial respiratory chain activity are necessary to synthesize adenosine-tri-phosphate (ATP).

Engram

Definition

The material substrate or record of a particular item of memory. Also referred to as memory trace.

Enkephalinase

Definition

Enkephalinase is a neutral aminopeptidase enzyme (EC 3.4.24.11), initially thought to be responsible only for degradation of released enkephalins. It does, however, metabolize other peptides, and enkephalins are also subject to degradation by other peptidases. Nonetheless, direct application of enkephalinase inhibitors have been shown to produce opioid-like actions probably due to enhancement of endogenous opioid signaling.

Enkephalins

Definition

Two enkephalin ("in the head") pentapeptides were the first endogenous opioids discovered in 1975. They both contain the same amino acids in the first four amino terminal positions followed by either leucine ("leu-enkephalin") or methionine ("met-enkephalin") at the carboxy-terminal. Multiple copies of both peptides are contained in the large peptide precursor, preproenkephalin. Somewhat longer oligopeptide enkephalins have been

purified from various tissues, representing incomplete peptidase processing of the large precursore leu-enkephalin is also contained in the N-terminal sequence of dynorphins.

Entacapone

Synonyms
E-α-cyano-N,N-dietyl-3,4-dihydroxy-5-nitrocinnamamide

Definition
Entacapone (E-α-cyano-N,N-dietyl-3,4-dihydroxy-5-nitrocinnamamide) is a catechol-O-methyl transferase (► COMT) inhibitor, used for the treatment of Parkinson's disease in conjunction with L-DOPA. Entacapone prevents COMT from metabolizing L-DOPA, the dopamine precursor, in the periphery. Entacapone is always used in combination with ► L-DOPA for the treatment of Parkinson's disease, especially in those patients showing end-of-dose "wearing-off" signs. Entacapone is also available in a triple combination with L-DOPA and carbidopa, the DDC inhibitor, to further increase the half-life of L-DOPA.

► Anti-Parkinson Drugs

Entactogen

Synonyms
Empathogen

Definition
Entactogens are drugs, including MDMA (Ecstasy) and other MDxx structure compounds, that cause distinctive prosocial, emotional, and sensory effects in users. Most of them are substituted amphetamine compounds of the phenethylamine class.

Cross-References
► Ecstasy
► Methylenedioxymethamphetamine (MDMA)

Enterohepatic Cycling

Definition
Numerous drugs undergo elimination via the bile in the unchanged or conjugated form. Drugs eliminated in the bile are available for absorption in the gastrointestinal tract. This reentry into the body after "elimination" via the bile results in the "recycling" of drug and prolongs the time required for the drug to be irreversibly eliminated from the body.

Environmental Enrichment and Drug Action

Mary E. Cain[1], Michael T. Bardo[2]
[1]Department of Psychology, Kansas State University, Manhattan, KS, USA
[2]Department of Psychology and Center for Drug Abuse Research Translation (CDART), University of Kentucky, Lexington, KY, USA

Synonyms
Drug effect; Stimulus enrichment

Definition
Environmental enrichment is a manipulation in which subjects are exposed to different environments that vary

in the amount of stimulus novelty. In the typical preclinical procedure, rodents are housed in either an enriched condition (EC) with novel objects and social cohorts or an isolated condition (IC) without objects or cohorts. In order to determine the relative contribution of novel objects and social cohorts, a separate group can also be housed in a social condition (SC) with social cohorts, but without novel objects. While enrichment is applied typically during the periadolescent period of development, it produces effects across the life span and it is reversible.

Current Concepts and State of Knowledge

Effects on Learning and Memory

The amount of stimulation received during childhood and adolescence has profound effects on behavioral and neurobiological development (Renner and Rosenzweig 1987). In rats, enriched environments produce numerous neuroanatomical changes, including increases in cortical weight, cortical thickness, size of neuronal cell bodies and nuclei, number of glial cells, number of dendritic spines, and number of synapses per neuron. Most likely as a result of these neurobiological changes, enrichment also improves performance on several measures of learning and memory. Differences are evident in some of the most basic behaviors, including activity in an inescapable novel environment and startle reactivity. In general, as task complexity increases, the difference in performance increases between EC and IC rats (Renner and Rosenzweig 1987). For example, while EC and IC rats do not differ in the acquisition of operant lever press behavior, EC rats perform better than IC rats in tests of spatial memory. EC rats process contextual conditioning cues more rapidly and display better discrimination between conditioned stimuli when compared to SC rats (Barbelivien et al. 2006).

Early research on environmental enrichment examined a variety of control conditions to determine if any one component of enrichment was most critical for producing the neurobiological effects related to learning and memory. Social stimulation alone is not sufficient to produce neurobiological changes similar to those observed with enrichment. Overall, this research suggests that cohorts, novel objects, and handling are all essential for robust enrichment. While neurobiological effects of enrichment are evident after just four days of enrichment, the effects are more consistent and reliable when rats are assigned to their respective environments after weaning and housed for 30 or more days.

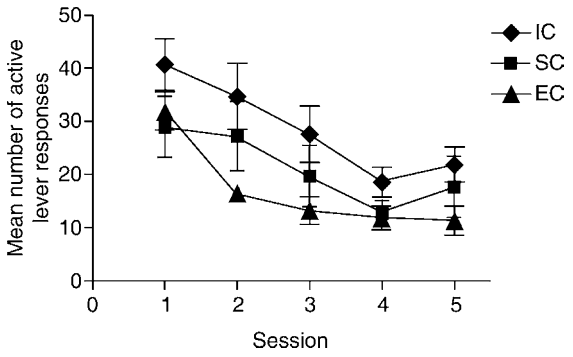
Effects on Drug Action

In addition to enrichment altering performance on a variety of measures of learning and memory, enrichment also alters the effects of a variety of drugs of abuse (Bardo and Dwoskin 2004). Several studies have examined the effects of enrichment on amphetamine-induced hyperactivity. EC rats display greater amphetamine-induced hyperactivity than IC rats following an acute injection of ▶ amphetamine. However, with repeated injections of amphetamine, IC rats display greater locomotor ▶ sensitization than EC rats. Similar results have been observed with cocaine and nicotine.

Interestingly, enrichment also appears to enhance conditioning to an amphetamine-paired context. Using the ▶ conditioned place preference (CPP) procedure, which is a measure of drug reward, EC rats display greater amphetamine CPP than IC rats. Similarly, using a low dose of amphetamine (0.3 mg/kg), context-dependent conditioned hyperactivity is obtained in EC rats, but not IC rats. Moreover, when the rate of ▶ extinction of conditioned hyperactivity is measured, EC rats extinguish at a faster rate than IC rats across a range of amphetamine doses. These results suggest that, in general, EC rats display a greater ability than IC rats to acquire and extinguish contextual conditioning of drug effects.

Numerous studies have examined the effects of enrichment on self-administration of stimulants, opiates, and sedatives. When drugs are available via the oral route, male EC rats increase their ▶ barbiturate consumption, but not their amphetamine consumption, when compared to male IC rats. Interestingly, female EC rats decrease their barbiturate consumption when compared to female IC rats, suggesting that sex can moderate the effects of enrichment. EC males also consume orally more ▶ cocaine and ▶ ethanol than male IC rats. The amount of oral ethanol consumption in male EC, SC, and IC rats also has been examined using a two-lever operant procedure in which one lever delivered 10% ethanol and the other lever had no programmed consequence. EC rats responded less than IC rats for oral 10% ethanol; SC rats were intermediate between EC and IC rats (Deehan et al. 2007, see Fig. 1), thus suggesting that enrichment may alter the reinforcing effects of oral ethanol itself.

Intravenous ▶ drug self-administration offers an advantage over the oral route because it eliminates the possibility that differences in taste reactivity may complicate interpretation of the results obtained. Several studies indicate that environmental enrichment decreases the self-administration of low unit doses of amphetamine and cocaine. In one initial study in which rats were trained to lever press for a low unit dose of amphetamine



Environmental Enrichment and Drug Action. Fig. 1. Mean number of active lever responses for oral 10% ethanol across five consecutive 30-min sessions in EC, SC and IC rats using a two-lever operant conditioning procedure. There was a main effect of group, with EC rats self-administering significantly less ethanol than IC rats; SC rats did not differ significantly from the two other groups. There was no difference between EC and IC rats in the number of responses on the inactive lever (which had no programmed consequence), although the number of inactive responses was negligible (~2 responses per session; results not shown). (From Deehan et al. 2007.)

(0.03 mg/kg/infusion) on a ► continuous reinforcement schedule, EC rats self-administered less amphetamine than IC rats; there were no differences between EC and IC rats at higher unit doses. A separate group of rats was trained to lever press for amphetamine on a ► progressive ratio schedule in which the number of lever presses required to earn a drug infusion increased until the rats stopped responding (i.e., breakpoint). As shown in Fig. 2, the ► breakpoint was significantly lower for EC than IC rats at the low unit dose, but not at the higher unit dose. These results suggest that enrichment decreases the reinforcing effect of amphetamine, but only at low unit doses.

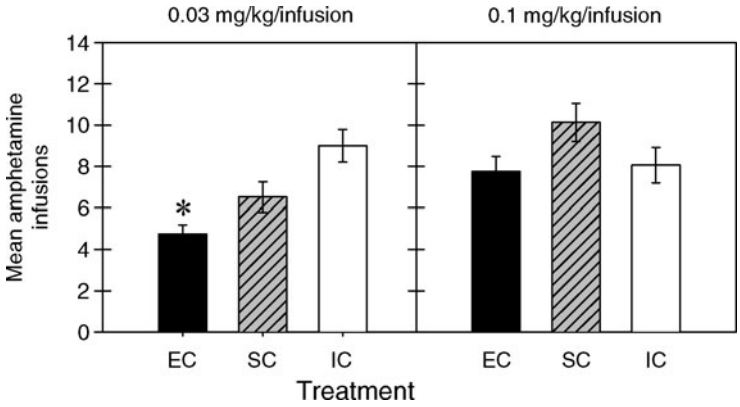
It is possible that the difference between EC and IC rats in amphetamine self-administration using low unit doses may reflect a difference in the rate of extinction or a difference in the ► reinstatement threshold. The rationale behind this possibility is that, at the beginning of each drug self-administration session, rats begin responding in a drug-free state. If a unit dose is too low, the responding may simply extinguish similar to what occurs when saline is substituted for drug. However, if several low dose infusions are earned in rapid succession, total drug intake may accumulate beyond some minimum threshold, thus engendering reliable responding within the session. Based on this notion, the decrease in amphetamine self-administration at a low unit dose in EC rats could represent either an accelerated rate of extinction within the session or an increase in the reinstatement threshold. A recent study using the reinstatement procedure found that EC rats extinguished responding faster than IC rats when amphetamine was replaced with saline (Stairs et al. 2006). When responding was reinstated following a noncontingent amphetamine priming injection, IC rats reinstated drug-seeking responses following a low dose prime, whereas EC rats only reinstated drug-seeking responses following a high dose prime. The higher reinstatement threshold in EC rats, taken together with a more rapid rate of extinction, may result in a loss of responding within the session, thus explaining the enrichment-induced reduction in drug intake.

Effects on Neurobiology Involved in Drug Action

Numerous studies have explored the neurobiological mechanisms that contribute to the ability of enrichment to decrease the reinforcing effect of drugs of abuse. Environmental enrichment increases thickness of the cortex, primarily by enlarging the size of neuronal cell bodies, increasing the density of dendritic spines and increasing the number of glial astrocytes. Metabolic activity is also enhanced, as revealed by an increase in the number of mitochondria and oxygenated capillary blood volume (Renner and Rosenzweig 1987). While these cellular changes also occur in subcortical regions such as the striatum, ► hippocampus, and ► nucleus accumbens, the ► prefrontal cortex appears to be especially sensitive to enrichment.

The ► medial prefrontal cortex (mPFC) has been implicated in the reinforcing effect of abused drugs, likely due to its inter-connections with limbic structures such as the anterior cingulate cortex and ► nucleus accumbens. Recent work has demonstrated that dopamine activity in mPFC is altered in EC rats compared to IC rats (Zhu et al. 2005). These investigators examined functional activity of the ► dopamine transporter (DAT). Compared to IC rats, EC rats have decreased DAT function as indexed by the velocity of uptake of [^{3}H] dopamine uptake into mPFC tissue slices. Measurements of DAT protein expression revealed that EC rats have less DAT than IC rats at the cell surface. Additionally, a recent study has shown that EC rats display a reduction in postsynaptic dopamine D1 receptors in mPFC (Del Arco et al. 2007). The enrichment-induced reduction in pre- and postsynaptic dopaminergic cellular processes in mPFC may reflect a compensatory decrease due to repeated stimulation of this cortical system by enriching stimulation.

Studies have shown that environmental enrichment also alters the neurochemical effects of various drugs of abuse. For example, when challenged with acute



Environmental Enrichment and Drug Action. Fig. 2. Mean number of amphetamine infusions earned by EC, SC and IC rats on a PR schedule of reinforcement using a unit dose of either 0.03 mg/kg/infusion (*left panel*) or 0.1 mg/kg/infusion (*right panel*). Asterisk (*) represents a significant difference from IC rats tested at the same unit dose, $p < 0.05$. (From Bardo and Dwoskin 2004.)

amphetamine, EC rats show a greater release of dopamine in the nucleus accumbens measured by in vivo ► microdialysis compared to IC rats. This enrichment-induced change is not specific to amphetamine, but appears to occur across various drugs of abuse. Alterations in reward-relevant brain regions likely play a role in the differential sensitivity of EC and IC rats to self-administer drugs of abuse.

In addition to dopamine, enrichment alters drug-induced glutamate release as measured by microdialysis (Rahman and Bardo 2008). ► Glutamate is an excitatory amino acid that has been implicated in drug reward. When challenged with amphetamine, EC rats show greater extracellular levels of glutamate in the nucleus accumbens compared to IC rats. Within the mPFC, EC rats also have increased glutamatergic tone compared to IC rats. This latter finding may be important from a drug abuse perspective because glutamatergic activity is not only important in drug reward, it may also be involved with behavioral inhibitory processes that become dysfunctional during the addiction cycle. While the effects of enrichment on the dopaminergic and glutamatergic systems contributes to the reinforcing effect of drugs of abuse, additional research is necessary to determine the interaction between these systems and the mechanism for the ability of environmental enrichment to decrease sensitivity to drugs of abuse.

Application to Humans

Teachers and educators are generally aware of the important role of enriching environments for promoting learning in children, adolescents, and young adults. In addition, there is considerable evidence that enriching stimulation, as provided by exercise and learning, protects against many neurodegenerative diseases that can occur later in life. While preclinical research indicates that enrichment also protects against drug abuse vulnerability, there is a paucity of information that addresses this issue specifically in humans. Nonetheless, genetic studies using twin concordance or familial assessment strategies indicate that the heritability of drug abuse is only around 40–60%, thus implicating a substantial role for environmental factors.

A recent study examined various summer programs implemented to promote healthy development among school-aged children and adolescents in order to determine the features that were important to demonstrate effectiveness (Bell and Carrillo, 2007). While a number of specific features were identified, a general conclusion was that the instructional techniques were most effective when academic learning was embedded in enriching activities. These results suggest that enrichment accelerates academic achievement and promotes positive development.

A more direct assessment of the effects of enrichment on human development and health-related risk was conducted by Raine et al. (2003). Children aged 3–5 years received enrichment or control treatment and were assessed subsequently in their young adulthood for personality disorders. Enrichment consisted of training in physical health, exercise, and multimodal enrichment provided by toys, art, handicrafts, drama, and music to improve verbal skills, visuospatial coordination, and memory. As young adults, enriched subjects had lower scores for schizotypal personality, antisocial behavior, and criminal

behavior (including drug-related charges) compared to control subjects. These results suggest that environmental enrichment during development protects against the emergence of drug abuse and associated personality disorders later in life. Further research is needed to determine what neurobiological alterations are associated with these long-term behavioral effects of enrichment.

Epigenetics

Lawrence S. Wilkinson, Anthony R. Isles
Behavioural Genetics Group, School of Psychology and MRC Centre for Neuropsychiatric Genetics and Genomics, School of Medicine, Cardiff University, Cardiff, UK

Synonyms

Chromatin remodeling; DNA-marking

Definition

The development of the idea and the first use of the term "epigenotype" occurred as far back as 1942 when Conrad H. Waddington suggested the existence of epigenetic mechanisms to explain the control of gene expression during cellular differentiation and maintenance of cellular identity. Implicit in the term epigenetics is that the mechanisms involved are labile (can be erased and reset), but also are heritable, in that they survive cell division. However, as the techniques required to directly analyze these epigenetic mechanisms have been developed and refined over the last two decades, it is now recognized that these same molecular processes can play an important information-coding role in post-mitotic tissues, such as occur in the brain. For the purposes of this review,

epigenetics can be loosely defined as the transmission and perpetuation of coding information that is not based on the alteration of the DNA sequence.

Principles and Role in Psychopharmacology

Mechanisms and Methods

The epigenetic code may be mediated via chemical marking of the DNA sequence itself (DNA methylation) and/or chemical tagging of ► histone proteins that bind DNA and are molecular tools by which gene expression levels are controlled. ► DNA methylation represents the simplest epigenetic process, and usually increased methylation levels at a gene loci equates to decreased expression of a gene. Most techniques to analyze DNA methylation rely on bisulfite treatment of the DNA. Here, bisulfite effectively deaminates methylated cytosines to uracils, providing a difference that can be detected by the direct assessment of the treated DNA sequence. Recently, methylated DNA immunoprecipitation (MeDIP) techniques, whereby an anti-5-methylcytosine monoclonal antibody is used to capture methylated genomic DNA fragments, have allowed a more global analysis of DNA-methylation.

Far more complex are the other epigenetic mechanisms related to ► chromatin modification. Differing histone protein modifications result in altered 3-D chromatin structures (open or closed), meaning the DNA sequences underneath are more or less accessible to transcription enzymes, which in turn leads to more or less gene expression. Applying ► chromatin immuno-precipitation (► ChIP) techniques, and utilizing recently developed antibodies that recognize specific histone modifications (acetylation, methylation, phosphorylation, etc.) to appropriately-processed tissue preparations, captures those stretches of DNA bound by these modified chromatin proteins. The relative abundance of a specific DNA sequence in a ChIP preparation allows the quantification of, for instance, Histone H3 acetylation at a given gene. However, unlike DNA methylation, the histone code is less easy to "read," due to the many different types of histone proteins and possible modifications.

The analysis of both DNA methylation and chromatin modification is likely to greatly benefit from the next-generation sequencing techniques (Mardis 2007). Previously, the final analysis of ChIP and MeDIP experiments was either target driven, using quantitative PCR measurements of specific genes, or coupled to microarray technologies (ChIP-on-chip) for a more global analysis of which genes were epigenetically modified. However, microarrays are limited by what is represented on the array itself. The next-generation sequencing technologies are capable of producing tens of millions of sequence reads during each instrument run, and identify *any* stretch of DNA that is marked by a given epigentic modification, effectively. Furthermore, ChIP-seq and MeDIP-seq offer other important advantages, including lower cost, minimal hands-on processing, and a requirement for fewer replicate experiments, which are of great importance in the analysis of epigenetic changes in discrete brain regions, and less input material.

Epigenetics and Neurodevelopment

As originally suggested, epigenetic mechanisms are crucial in determining cell programming and, consequently, development. Therefore, it is no surprise that epigenetic processes are implicated in a number of neurodevelopmental disorders. Some of these, such as Rett syndrome (altered DNA-methlyation and histone recruitment) and Rubinstein–Taybi syndrome (altered chromatin binding protein), are caused by a disruption of an epigenetic mechanism *per se* and consequently have greater effects on downstream genes thoughout development. Others are due to less global changes, but are caused by the disruption of the regulation of genes that are particularly sensitive to variations in epigenetic control. A good example of these are Angelman (AS) and Prader–Willi (PWS) syndromes, which are caused by mutations of a cluster of ► imprinted genes on Chr. 15q11-q13 that are particularly important for brain function (Wilkinson et al. 2007). The imprinted genes are subject to tight epigenetic regulation that results in expression of these genes from one parental allele (copy of gene) only; most genes are expressed from both the maternally and paternally inherited copies. The expression of imprinted genes is controlled by a combination of differential DNA methylation and histone recruitment to the parental chromosomes, and as a consequence any disruption of these epigenetic process leading to an inbalance in expression of these genes in turn results in abnormalities.

Many of these neurodevelopmental syndromes are quite severe, often resulting in mental retardation. However, there are also commonalities in terms of behavioral problems with other non-syndromic psychiatric illnesses, in particular autistic-like symptomology. These overlapping behavioral and cognitive problems may point to a common underlying mechanism (Wilkinson et al. 2007). This raises the possibility that more subtle alterations in the epigenome may contribute to the vulnerability to mental illness, particularly when in combination with an existing genetic predisposition (Isles and Wilkinson 2008).

Labile Epigenetic Mechanisms in the Brain

Although many epigenetic modifications are developmentally determined, there is also an inherent lability in some, and these provide a molecular mechanism by which environmental events may be integrated and translated into changes in the control of gene expression. A striking example of the epigenome's ability to alter has recently been shown by examining changes in DNA methylation and histone modification at the genome level over time. In monozygotic twins, where the DNA code is identical, the epigenome of twins diverged with age (Fraga et al. 2005), suggesting that this may be a molecular mechanism by which differing life experiences are encoded.

Although the idea of a role for epigenetic modifications in neural processes was posited many years ago (Crick 1984), it is only very recently that the tools and techniques have become available to investigators. One key area where the recently developed methods have been applied is in the study of molecular mechanisms underlying drug addiction. Work in animals models has examined the epigenetic processes involved in regulating the changes in control of expression of these genes by using behavioral neuroscience techniques combined with DNA-methylation and ChIP analysis on samples from key regions of the brain.

The expression of the Fos (*cFos, FosB*) family of transcription factors is correlated with the switch between acute and chronic ► cocaine exposure. Upon first exposure, these are highly expressed; however expression becomes desensitized upon repeated cocaine dosing. Conversely, chronic exposure results in the accumulation of *ΔFosB*, an alternative transcript from the *FosB* gene promoter. The control of this change in expresion is due, in part, to a subtle switch in chromatin modification at the *FosB* promoter (Kumar et al. 2005). Acute exposure results in increased acetylation of Histone H4, but upon repeated exposure (and indeed self-administration) there is increased acetylation of Histone H3. Interestingly, it seems that the accumulation of *ΔFosB* also mediates the desensitization and epigenetic silencing of another Fos transcription factor, *cFos*, following repeated simulant exposure (Pulipparacharuvil et al. 2008). Taken together, these data indicate that chromatin remodeling is an important mechanism underlying stimulant-induced neural and behavioral plasticity.

These techniques have now been applied to many other models of neuro- and psychopathology, and indicated that epigenetic factors such as DNA methlyation and chromatin remodeling may be important here too. These include the regulation of neural changes related to learning and memory (Miller and Sweatt 2007) and stress and depression (Tsankova et al. 2006).

Advantages and Limitations

The methods to examine DNA-methylation and chromatin modification that have been developed over the last decade or so allow us insight into the epigenetic control gene expression. Furthermore, these techniques have provided evidence for a biochemical system which can encode life events – environmental pressures and stressors being of particular importance to the vulnerability to psychiatric illness. However, in most cases, the existing techniques have been applied in animal models, as, in the majority of cases, the availability of suitable samples limits clinical studies of epigenetic changes to surrogate tissues such as blood and unlike sequence information (i.e., genetics), the extent to which surrogate tissues tell us anything about epigenetic changes occuring in brain is, at best, uncertain.

Additionally, although epigenetic mechanisms are clearly of potential clinical relevance, a key question is whether they are accessible to pharmacological intervention. There are a number of ► histone deacetylase (HDAC) inhibitors and ► DNA methyltransferase inhibitors that are currently being used and/or tested as anticancer drugs. However, how applicable these are in potentially treating neuropsychiatric disorders is not clear – although, ► valproate has HDAC inhibitor properties and may, in part, exert its action through epigenetic effects on the schizophrenia candidate gene *Reelin* (Guidotti et al. 2009). Currently, a major problem exists between the specificity of the epigenetic changes that may occur in response to a given environmental or developmental challenge in a specific population of brain cells, and the relative nonspecificity of the drug armory available to manipulate epigenetic mechanisms. Essentially, at present this is limited to HDAC and DNA methyltransferase inhibitors. Hence, experimentally, it can be difficult to prove causal significance between a change in behavior, or some other aspect of brain function, and a specific epigenetic change in a specific gene. Additionally, the current nonspecificity of the drugs available may limit therapeutic applications due to unwanted side effects. What is urgently needed are more selective drug agents able to interfere with particular epigenetic modifications that can be targeted somehow to particular genes. This would be a major step forward, not just for psychopharmacology, but for the use of such drugs across a wide range of other conditions, especially cancer. It is hoped that the ongoing epigenome project (http://www.epigenome.org/) and other

initiatives, focused on the structural and allied medicinal chemistry (for instance, see http://www.sgc.ox.ac.uk/chemicalprobes/) aspects of chromatin functioning will provide potential solutions to this limitation.

EPSPs and IPSPs

Synonyms

Excitatory postsynaptic potentials; Inhibitory postsynaptic potentials

Definition

An excitatory postsynaptic potential (EPSP) is the change in membrane voltage of a postsynaptic cell following the influx of positively charged ions into a cell (typically Na+) as a result of the activation of ligand-sensitive channels. This results in a depolarization of the postsynaptic cell, thus increasing the likelihood of action potential propagation. These excitatory synapses serve to increase excitability in neurones. Conversely, inhibitory postsynaptic potentials (IPSPs) result from the influx of negative ions (e.g., Cl−) into, or the efflux of positive ions (e.g., K+), out of the postsynaptic cell. This results in cell hyperpolarization and thus decreases the likelihood of action potential propagation, and therefore represent inhibitory synapses. Both types of postsynaptic potential are graded and therefore sum together to have a cumulative excitatory or inhibitory effect.

Equilibrium Dissociation Constant

Synonyms

K_D

Definition

Reciprocal of affinity. Equal to the ratio of the rate at which a ligand-receptor complex dissociates into the

separate reactants to the product of the reactants at equilibrium, $K_D = k_{off}/k_{on} = [L][R]/[LR]$.

Erectile Dysfunction

Definition

Erectile dysfunction is a sexual dysfunction characterized by the inability to develop or maintain an erection of the penis sufficient for satisfactory sexual performance. There are various and often multiple underlying causes. The most important physiological causes include cardiovascular disease, diabetes, and drug side effects. Often psychological or relational problems are implicated as well. Besides treating the underlying causes and psychological consequences, the first-line treatment of erectile dysfunction are PDE5 inhibitors, for example, sildenafil (Viagra), vardenafil (Levitra), or tadalafil (Cialis).

Definition

Ergot is the general name for the sclerotia from any of the species of the fungus *Claviceps* that infects grain crops. It produces the ergot alkaloids, which are very toxic, and in earlier times were responsible for outbreaks of ergotism, or St. Anthony's fire, where peripheral vasoconstriction could lead to gangrene and necrosis of the fingers or toes, and typically accompanied by hallucinations and bizarre behavior. Ergotism was caused by eating bread that had been made from ergot-contaminated flour. The ergot alkaloids have served as the starting materials for a number of valuable therapeutic agents such as ergonovine. Basic hydrolysis of ergot alkaloids leads to production of lysergic acid, the starting material for LSD.

Escitalopram

Definition

Escitalopram is a selective serotonin reuptake inhibitor (SSRI). It is commonly used in the treatment of depression and anxiety disorders (e.g., obsessive–compulsive disorder, panic disorder, social anxiety disorder, generalized anxiety disorder). As with other SSRIs, the most troublesome side effect of escitalopram is sexual dysfunction (dysorgasmia and erectile dysfunction); mild side effects include drowsiness, headache, and nausea. Escitalopram is the *S*-enantiomer of racemic citalopram, which is also marketed as an antidepressant.

Establishing Operation

Definition

Any operation that temporarily alters the effectiveness of a consequence as a reinforcer of behavior. The most commonly used establishing operation is deprivation. Establishing operations also temporarily increases the probability of behavior that has been reinforced previously by the event/stimulus whose reinforcing efficacy is increased.

Estazolam

Definition

Estazolam is a benzodiazepine derivative possesses anxiolytic, anticonvulsant, sedative, and skeletal muscle-relaxant properties. It is prescribed for the short-term treatment of certain sleep disorders. It is an effective hypnotic drug showing efficacy in increasing the time spent asleep as well as reducing awakenings during the night. Combination with non-pharmacological options for sleep management results in long-term improvements in sleep quality after discontinuation of short-term estazolam therapy. There are concerns that estazolam may have abuse potential when drug use is continued against medical advice.

Justifications; Morals; Philosophical basis

Definition

Justification for the care and use of animals in Psychopharmacology research is based on philosophical arguments, moral principles, and general consensus of reviewing boards and governing agencies.

Current Concepts and State of Knowledge

While the use of animals by humans for many purposes (e.g., food, labor, transportation) goes back to prehistoric times, and the use of animals for scientific research goes back several centuries; in the last several decades, the use of animals for research has generated controversy. Researchers have dedicated their lives to developing life-saving treatments through the use of animals, yet groups of activists believe that animals are not our property or subject to our control and experimentation. Thus, consideration of ► ethical issues is at the forefront of psychopharmacology research. This essay explores the ethical

use of animals in terms of whether animals should be used, how their use should be regulated, how their use has influenced psychopharmacological research, and what is the best animal to study. There are sources that have debated these ethical issues and provided examples of the ethical use of animals in psychopharmacological research to promote the health of humans and other animals (e.g., Carroll and Overmier 2001).

Ethical Considerations: Should Animals Be Used?

There have been several philosophers over the last few centuries who have addressed the issue of the use of animals in research. The use of animals for research can be traced back to the seventeenth century with René Descartes, a French philosopher/scientist (Descartes 1637). He established experimental methods for scientific investigation including his precepts never accept anything for true that is not clearly known to be such, divide difficulties into parts, analyze from simple to complex, and make complete descriptions of your experiments. His work became the basis of the Cartesian coordinate system and the histogram. He also dissected live animals and compared animals to machines without reason, soul, mind, or human intelligence. Descartes' dualistic beliefs divided the body and mind into separate entities.

In the eighteenth century, German philosopher, Immanuel Kant, addressed the issue of human rights and virtue (Kant 1785). He said that animals do not have rights or duties. Moral rights are given and received by humans, not among animals. Humans have obligations and can make moral claims with other humans, but nonhuman animals do not have moral obligations or rights. However, Kant recognized that animals have feelings and needs and that humans have a moral obligation to treat them well with human dignity.

Peter Singer is a utilitarian philosopher whose book entitled *Animal Liberation* (Singer 1975) ignited the animal liberation cause. ► Utilitarianism requires that a moral act should result in the greatest good (i.e., happiness) for the greatest number of people. Singer states that since humans and ► sentient animals can suffer, they are equally entitled to moral concern, and exclusion of animals from our moral concern is discriminatory (which he calls speciesism). Singer does allow for animal research only if its benefits greatly outweigh the harm done to animals. However, the question that remains is whether greater happiness is the only thing that matters when determining if something is morally correct?

Thomas Regan (1985) is another philosopher who is concerned with the moral status of nonhuman animals. He rejects the utilitarian claim on the basis of animals' ability to suffer, and states that nonhuman animals have rights simply because they have inherent value. He disagrees with Kant's idea that moral rights should only be ascribed to humans. However, he admits that when having to choose between a human and an animal's life, the human should take priority.

Carl Cohen is a philosopher who returned to Kant's ideas of moral rights for humans (Cohen 1986). He states that rights arise only among organisms (i.e., humans) who can make moral claims against one another. Animals cannot respond to moral claims and they cannot evaluate the conflict that may arise between their self-interest and what is just. He believes that we have obligations to animals to do no gratuitous harm (the principle of nonmaleficence) and to do good for animals within one's power (the principle of beneficence). He states that most people will agree that we should treat animals humanely, with decency and concern as sensitive human beings, but not as holders of human rights. In addition, morality is a basis for many of our laws, and when these laws are broken, a crime is committed. An animal cannot commit a crime because it does not understand morality or the concept of being guilty.

Adrian Morrison, a veterinarian and Professor Emeritus from the University of Pennsylvania, has thought and written extensively on the human–animal relationship. He has also endured attacks from animal activists for his defense of animal research. In a new book, Morrison (2009) points out the symbiotic nature of humans and nonhuman animals and the need for animal welfare laws that will maintain the health and well-being of both humans and nonhuman animals. He stresses that humans have a special obligation to provide excellent care for those animals under their control (e.g., pets, farm, zoo, research). He explains that animals used in research are supervised by veterinarians, protected by extensive legislation, and are housed and maintained by standards that far exceed any other form of animal husbandry.

How Should Animals Be Used?

The use of animals for research in the U.S.A. is highly regulated by the ► Animal Welfare Act (2006), the National Institutes of Health (NIH) regulations, Guide to Scientific Research, the National Research Council, and rules of the editorial boards of scientific journals. Before an animal can be used in research by a qualified and trained scientist, the care and use of the animals and the rationale for the research must be approved by a local ► Institutional Care and Use Committee (► IACUC) and the work is monitored by the US Department of Agriculture (USDA). There are frequent inspections, in some

cases unannounced (USDA), and follow-up visits if questions arise. IACUC applications must be resubmitted and reviewed every 3 years. Animal and research facilities must be maintained to extremely high standards and supervised by veterinarians who require strict compliance with the NIH and USDA rules for the care and use of the animals. In addition, the facilities that house animals are tested for temperature, humidity, and air quality and flow, and high standards are maintained. The NIH, major research centers (e.g., Sloan-Kettering Cancer Center, and St. Jude's Children's Research Hospital, the American Red Cross), and most large universities have accreditation from a review board, such as the American Association for the Assessment and Accreditation of Laboratory Animal Care (AAALAC), which reviews care, training, and physical plant issues regarding the care and use of animals in research. Animal research facilities have also become much more secure in recent years, due to the attacks and destruction of extremists. This prevents activists from releasing animals to a harmful environment and maintains the integrity of the research, but the downside is that the high level of security distances the research from the general public who funds most of the research and deserves to know about it.

The Use of Animals in Psychopharmacological Research

There are two main areas in which animal models are used for psychopharmacological research. The first is to study the etiology and neurobiology that underlies psychiatric disorders affecting humans. Research on these disorders is funded by the NIH institute, the National Institute on Mental Health (NIMH), and many other public and private organizations. Goals of these research institutes are to study brain disorders, some that develop early in life, such as ► attention deficit hyperactivity disorder, ► eating disorders, drug ► dependence, mood disorders such as ► anxiety and ► depression, personality disorders (e.g., antisocial), ► schizophrenia, and those occurring later in life such as Alzheimer's and other forms of ► dementia. Animal models that are reliable and have predictive validity have been developed to represent many of the DSM-IV (American Psychiatric Association 1994) diagnostic criteria for substance abuse, and animal studies have identified the underlying causes of these disorders and tested medications to treat them. Since many of these conditions involve a gene, environment, development, interaction, and ► neurobiological manipulations are necessary, they can only be conducted with animals, and those results have been most informative for advancing the treatment of mental illness. Animal research has been crucial to the development of many medications that allow mentally ill individuals to live normal, productive lives.

The second area is considered a subset of the first, but the problem (► drug abuse) is so immense that there are two other NIH institutes that represent it: the National Institute on Drug Abuse (NIDA) and The National Institute on Alcohol Abuse and Alcoholism (NIAAA). Deaths due to drug abuse, particularly tobacco use, approach nearly half a million a year; thus, understanding the etiology and neurobiology of drug abuse and developing effective treatment strategies is a national priority. Again, the abuse of drugs begins at an early age and involves factors (genetic, developmental, and environmental) that are difficult to prospectively study and experimentally control in humans; thus, animal models are essential to advance our knowledge. As is the case with the first area, there are critical scientific approaches that can only be done with animals, such as neurobiological assays, embryonic and developmental studies, and neuroimaging (PET), which cannot be done with children under 18.

It is also important to study factors that influence all phases of drug abuse, such as initiation, maintenance, escalation (binging), withdrawal, and relapse, as in humans drug abuse is a chronic relapsing disease. However, several of these phases are difficult to study prospectively in humans such as initiation and escalation or ► binge use of the drug, as it is unethical to introduce drugs to young teens or to encourage escalation of drug use in current users. Relapse is also difficult to control and study in humans, as it would be unethical to promote the reinstatement of drug use in abstinent individuals. While adult human drug users can be studied in the laboratory, it is difficult to interpret the data because their histories are varied and their self-report measures are unreliable. Furthermore, human subjects are not always compliant with instructions for medication use or nonuse of drugs of abuse prior to laboratory visits. They are often not available for extended periods of time that are required to study the variables related to the study, and absences are a problem for data collection.

The use of animals in drug abuse research has led to our recognition of the main transition phases associated with drug abuse (initiation, persistence, escalation, and relapse), and the efficacy of pharmacological and behavioral interventions may vary with phases of drug abuse (Carroll et al. 2009). Animal research has also informed us that individual factors such as age, sex, hormonal status, ► impulsivity, sweet preference, and a proclivity for exercise predict vulnerability to drug abuse. Recent studies with animals that have translated well to humans revealed the behavioral economics of drug abuse that describe the compulsive nature of this disorder. Emerging

evidence from animal research has also connected many common behavioral and neurobiological features of drug addiction with excessive eating in animals and humans, and principles resulting from these animal studies will be useful in understanding and treating the obesity epidemic. Rodent studies also identified environmental determinants such as stress and whether the individual is in an enriched versus impoverished environment are also critically important to the development of drug abuse and the chronically relapsing nature of it.

These vulnerability factors, which apply to drug abuse and other psychiatric disorders, were primarily identified through the use of animals in research. With rats, it was possible to discover that the sex differences in drug abuse and related disorders are accounted for by the ovarian hormones and to manipulate the hormonal milieu to compare behavior over phases of the estrous cycle in rodents or the menstrual cycle in nonhuman primates (NHP). Through ► selective breeding in rat or selection of high and low behavioral phenotypes in a large group of rats, it has been possible to relate sweet preference, impulsive behavior, or a proclivity for exercise for an avidity to self-administer drugs of abuse. Adolescence is a critical period when vulnerability to drug abuse is at its peak. We know that is true in humans, but is it cultural or developmental/physiological? Animal studies have indicated that in adolescence there is a confluence of hormonal surges, dietary influences, elevated impulsivity, risk taking, reactivity to stress, and aggression in adolescents, and these factors explain the vulnerability of adolescents to drug abuse, and other addictive behavior (e.g., food consumption), and their examination in animals will be important for developing prevention strategies for humans.

What Animals Should Be Used?

As animals are used in the evolution of research in psychopharmacology, more knowledge is gained about the species that provides the best representation of human behavior, both with respect to understanding the disorder and to the effectiveness of treatment. Mice, for example, have been invaluable for conducting gene knockout studies to elucidate the neurobiological bases of psychiatric disorders, and genetically altered mice have shown remarkable improvement in an animal model of Alzheimer's. Rat studies have been useful for developing animal models for depression, anxiety, drug abuse, and other disorders. Rat studies also allow for group comparisons including dose–response analyses and control conditions. Much of the behavioral pharmacology research that has been conducted in rodents has generalized well to results obtained in NHP and humans.

A disadvantage of rodent studies is that in some cases pharmacological agents that are efficacious in rodents are not always translatable to humans. For example, medications that prevent and reduce cocaine self-administration in rats (e.g., Prozac) have not always been successful to treat cocaine abuse in humans. It may be a species difference in metabolism or ► pharmacokinetics or the composition and distribution of receptors in rodent versus primate brains. NHP models offer access to the genetic, environment, early development, interaction that leads to the onset of mental illness in young adults. Psychopharmacology research in NHPs is closely translatable to humans, and there are several advantages of using NHP in this research; for example, NHPs have a similar, although condensed, developmental period, hormonal cycle, and life span compared to humans. Their long life span (up to 40 years) allows for examination of all ages and longitudinal studies. For drug abuse studies, NHPs are more amenable to being trained to drink or smoke drugs, modes of drug use that represent the most common forms of drug abuse in humans (Weerts et al. 2007). In contrast, rats are neophobic about drinking drugs; thus, self-administration studies are typically limited to the iv route.

It is important for researchers who use animals to recognize when an animal species is a good model for psychopharmacological research and when it is not, and the more animal models are used, more valuable feedback is provided about their validity in terms of what aspects of psychopharmacology can be successfully modeled in humans. For example, factors developed using rodent research on the relapse model have provided information about factors that trigger relapse and treatments that prevent it in humans (e.g., ► naltrexone for alcohol abuse). In contrast, mice may not be the best model for immunological research; thus, testing the newly developed ► vaccines for cocaine, methamphetamine, and nicotine may not be optimal in rodents. Thus, it is also important to recognize when we do not yet have a suitable animal model for the psychopharmacological research.

In conclusion, ethical issues in animal research have been discussed for centuries, and animal research is considered legal, and it is widely used but highly regulated. The US government sanctions and supports animal research, contingent upon adherence to strict guidelines and multiple forms of oversight from national and local boards. As a result, using animals over the last several decades, animal research in psychopharmacology has made important advancements in understanding underlying neurobiological mechanisms and in the development of psychotropic medications for psychiatric

disorders. Psychopharmacological research in the area of drug abuse has also gained important information from animal research regarding the genetic, neurobiological, and behavioral precursors of drug abuse. As a result, there are now successful treatments available for the most common forms of drug abuse (alcohol and tobacco use), and new treatments for psychostimulant drug abuse are on the horizon.

Synonyms

Ethics of placebo prescription; Ethics of prescription

Definition

The application of ethical issues to the development, research, production, approval, marketing and prescription of psychotropic drugs to be used with human beings.

Ethics (from the Greek *ethos* "character") is that branch of philosophy systematically studying the nature of values relating to human conduct, with respect to the rightness and wrongness of actions and to the goodness and badness of the motives and ends of such actions. It seeks to address questions about morality, such as what nature of ethics or morality is (meta-ethics), how moral values should be established (normative ethics) and how morals be attained in specific situations (applied ethics).

The word ethics also refers to a system of moral principles (i.e., the ethics of a culture) or rules of behavior

assumed or mandatory in respect to a particular class of human actions or a particular group (i.e., bioethics, medical ethics).

Current Concepts and State of Knowledge

Psychopharmacology is an achievement of many players. The indispensable performers are the industry, which produces drugs, the researchers, who conceive new substances and test them, the Administration, which gives the final approval to medicaments, the doctors, who prescribe them and the patients, who take them. There are also other secondary players such as the shareholders who expect profits from their investment, those who are involved continuous medical education and policy makers at national and international levels. Although the final goal may be common, namely, to improve the condition of patients and to increase the overall health, their values may be different and therefore conflicting.

The ethics of medicine has three main sources that are often considered as stages in its development although all of them are present nowadays: (1) the ethics of welfare, which are the traditional medical ethics. From this perspective, the duties of doctors are the wellbeing of the patients and the harm to be avoided; (2) the ► ethics of autonomy, which considers that the patient is an autonomous human being, adult, free and, able to take his or her own decisions. Consequently, doctors have to inform patients about all possible diagnoses and treatments so that patients are able to decide and (3) the ethics of equity, also known as the ethics of management, which are the consequence of the impact of economic factors in medicine. From this perspective, the goal of health care is the equal access to health care resources for all patients and a larger level health care is only one among several needs and rights of citizens.

These three forms of ethics are present in different proportions in the performers mentioned above. As a result, the disagreement among them is often profound and therefore the number of guidelines, recommendations, rules, consensus documents, and regulations is overwhelming.

It is not easy to deal with the conflicts of values mentioned above, yet the perspective of ► Values-Based Medicine (Fulford) can be very useful when faced with conflicts of interests and values. Values-Based Medicine is the theory and practice of effective healthcare decision-making for situations in which legitimately different, and hence potentially conflicting, value perspectives are in play. Values-Based Medicine is a response to the growing complexity of the relevant values and it is a skills-based counterpart of the currently dominant quasi-legal form of clinical bioethics. Quasi-legal ethics prescribes "good outcomes" in the form of increasingly complex ethical rules and regulations. Values-Based Medicine emphasizes the importance of good process in the form particularly of improved clinical practice skills.

The Prescription of Psychotropic Drugs

Prescription of medicines is a basic aspect of clinical practice and it is responsibility of every clinician, which cannot be hangover to anybody. The prescription should follow full information from the doctor on the consequences, opportunities and dangers of taking it, or of not taking it, and of the available alternatives.

Yet, there have been discussion on several issues such as the obligation of informing the patient having in mind the goal of committing suicide, about the possible lethality psychotropic drugs that can help them to choose a ► tricyclic antidepressant instead of an SSRI because of the higher lethality of the older drug. In spite of these difficulties, it seems that patients should know that with some drugs the risk of death by poisoning is very elevated and to control the risk of suicide by other means. The issue for the clinician is not lethality, it is suicidality.

Confidentiality is an essential component of patient–doctor relationship and it includes the prescription of drugs.

Prescription is not an exclusive act in the framework of patient–doctor relationship, as all the partners mentioned above may interfere with it or may have the right of some input or control over it. Family members, the public and private health care administration, institutions, and even the legal system may claim a say on prescription. For that reason, it is the obligation of the doctor to maintain a level of professional formation and independent information, to allow him or her to make, at any moment, a rational, free and ethical decision in the best interest of the patient.

The fact that psychiatric classifications since 1980 rely on symptoms to make the diagnosis of a mental disorders has strong ethical implications which are absent when dealing with diagnoses based on any sort of pathology. A psychiatric diagnosis is based on the presence of a number of criteria selected from a set. If the number or the presence of some important criteria are absent, then the patient may suffer from a subsyndromal condition. Should it they be treated?

In most of the cases, psychiatric symptoms are also present in non-psychiatric populations. Consequently, other secondary criteria had to be added, such as suffering and disability. Both, suffering and disability are value-based concepts impossible to define scientifically. The levels of suffering and disability can be manipulated as

well as the criteria for diagnosis, leaving the door open for possible abuses.

Informed Consent in Severe Psychiatric Cases

There are differences in the legislation and practice in different countries concerning the requirement of consent on the part of psychiatric patients, depending on their level of mental capacity. Some countries like the United Kingdom have laws that authorize doctors to implement treatment in such cases: the doctor must exert his power justly and exclusively in the best interests of the patient. In Spain the fact that a patient is legally admitted does not automatically permits a prescription against the will of the patient, therefore an informed consent should be looked for; if this is not possible, the clinician has to follow the rules of good clinical practice and, above all, fulfill his duties as a clinician. Other countries such as Italy are very strict with long acting antipsychotics without the consent of the patient. The fact that compulsory ambulatory treatment is becoming possible in many countries is helping very much in difficult cases. A few decades ago, the impact of antipsychiatric propaganda and the stigma of mental disorders prevented such kind of forced prescriptions. Yet, the importance given in the media to tragic cases of homicides by untreated psychiatric patient or by those who interpreted treatment on their own has changed the public perception and attitudes. Clinicians should be aware that again, conflicting values are in conflict in these problem and that their duty is to try to establish an inspired doctor–patient relationship and as a consequence to safeguard the dignity of patients.

Several studies show that a substantial number of hospitalized chronic mental patients do not have the capacity to appreciate the risks and the benefits of the anti-psychotic medication[2].

The Ethics of Placebo Prescription

The term "drug" conveys a magical element, which is clearly manifested in the power of the ▶ placebo, and not only in psychiatric settings. Sometimes, this form of behavior is due to the lack of an effective treatment for a specific disease, but in others, it is simply to be freed of the pressure of the patient and their relatives. Independently of the cost of such behavior, placebo prescription outside of research protocols is a violation of the doctor–patient relationship. A doctor acting as such can only behave as a doctor. The Madrid Declaration is clear about it. If circumstances force him or her to take decisions that a clinician should not undertake, he or she could nevertheless proceed with them in order to prevent important harms, but with the clear knowledge that this may be the end of the doctor–patient relationship. This is the case of some court expert witness declarations. Placebo prescription fall with this perspective, with the added ethical unacceptable consequence of the sensation of superiority that is produced by having the authority to prescribe is recognized as one of the greater instruments of professional domination.

The Misuses of Psychotropic Drugs

In English language the word drug refers both to a medicine and to a poison, the same happens in ancient Greek with the word pharmakos. In other languages, the word drug is reserved for illicit substances, but still the cutting edge between both meanings is far from clear. For instance, there are restrictions on the prescriptions of ▶ benzodiazepines because of the potential risk of dependence, although the restriction criteria are not the consequence of scientific evidence. Why there is a 2 months limit and not a 2-week or a 6 months one? The case of white cell control with ▶ clozapine use is another example. The evidence is that the danger for a severe leucopenia becomes minimal after a few weeks of intake. Every Country has a huge database of patients on ▶ clozapine and weekly or monthly white cell counts, and nobody has have the courage to analyze them to produce clear guidelines on the controls needed to proceed with such a drug, or with other which may share the same risk.

▶ Cosmetic psychopharmacology refers to the use of psychotropic medication by people who are not ill but intend to enhance well being and functioning. A futile prescription is something different, because this is a medical intervention which has no value for the patient (who may be severely ill), although it will produce some effect.

Healthy persons that are unhappy with their own personality traits because they may not be socially acceptable may turn their eyes to cosmetic psychopharmacology to achieve a more satisfactory level of normality. The fact is that psychotropic drugs can produce such benefits: ▶ Fluoxetine allows feeling energetic, bright and accepted; ▶ beta-blockers and ▶ paroxetine can change the life of shy people and improve the performance of artists who suffer from stage fear. This last use has been considered as a form of doping. There is also an increasing use of ▶ cognitive enhancers to improve performance and endurance, commonly by students and people in intellectually very competitive jobs, although the evidence of their usefulness is very scarce.

As in the case of cosmetic surgery, the intervention needs a doctor and there is the risk that healthy people receive a psychiatric diagnostic in order to get a prescription or that diagnostic criteria become less restrictive.

The Development of New Medicines for the Health Care Market

The development of new medicines has generated ethical problems that have been dealt with legal norms and strict regulations.

In spite of the fact that modern pharmacology has contributed to a better quality of life for many patients all over the world, the issue of the advantages of new (and expensive) drugs versus older (and cheaper) ones is today a hot one. This is a typical case of conflict of values between doctors on one side and the health care authorities on the other. Doctors are guided by the ethical principles of welfare, and therefore any medicament that may bring a benefit to a patient classic, even a minor one, should be prescribed. The administration, working on tight budgets, which more often than not are short in time (very often yearly) and constrained (to the department of Health) follows the principles of the ethics of management. In the case of psychiatry, the stigma of mental disease and of psychiatry itself plays a major role in this context.

Pharmaco-economy studies cannot rely exclusively in the daily cost of the medication, but they must contemplate direct costs (hospitalization and use of the health care services, treatment of adverse effects and overdoses, home care, psychosocial interventions, etc.), indirect costs (absenteeism, social issues, etc.) and intangibles costs, such as, suffering, disability for the patient and the relatives and patient's quality of life, and cost in planning and management (suicide prevention programs, anti-stigma interventions, etc.).

Defensive medicine is not only a matter of doctors or hospitals; it also an issue of the health care administration, as the clozapine case shows.

The Ethics of the Marketing Psychotropic Drugs

The ethical problems of psychotropic drugs do not disappear when the drug is marketed. Even when a medicine has been approved and commercialized ethical problems in its prescription can appear. Commercialized medicines quality is assured by the proceedings and exigencies imposed by health care that guarantee the drug as a remedy (effectiveness) and in addition delimit the possible adverse effects (safety). The guarantees comprise the use in specified indications, based on the research presented for the approval. Yet, it should be clear that the goal of this process is to assure that the drug has potential effects on some disease or syndrome and the level of potential side effects is within acceptable limits. The rest, how the drug compares with others, what is its niche within the therapeutic armamentarium, what are the benefits in populations not previously exposed to the drug (children, elderly patients, patients with co-morbid conditions, and so on), the benefits in other disorders or in sub-threshold conditions is another story.

The pharmaceutical industry considers itself as an essential element of health care and probably more than other sector it has recognized ethical issues. In any case, it is a highly regulated industry, contrary to what happens with some other medical interventions.

Several ethical problems exist in the area of marketing of drugs to health care professionals: (1) gifts offered to health professionals, where the consensus that they must be of little value and be related to the practice of medicine or pharmacy; (2) hospitality in professional meetings, which should not include "congress tourism" activities; (3) the quality of all the advertising material, which should be prepared the scientific department pharmaceutical companies and duly supervised by health care authorities. David Healy has called attention to some of marketing campaigns and strategies deprived of sufficient scientific support. The World Psychiatric Association has included an item on the ethical implications of the relationship of psychiatrists with the industry as a part of the Madrid Declaration and most of the national and international organizations in the field of neuropsychopharmacology or psychiatry have produced ethical recommendations aiming to curb abuses in this field. The same aims are regulated in the European Union.

The fact that there is something wrong in this field was clearly exposed by Palmisano and Edelstein in the United States. They compared the expenses in medicine promotion by the pharmaceutical industry during the 1970s with the expenses on health care for young people by the health authorities. The results were overwhelming; $3000 per doctor per year in medicine promotion, as opposed to $212 per person per year in health care.

Research

Research, in general, and clinical research, in particular, plays a significant although indirect role in the act of the prescription, filtered by measures imposed by regulating authorities, information conveyed by the pharmaceutical industry and by continuous medical education activities, often promoted by the pharmaceutical industry. In addition, the publishing of clinical research in scientific publications is greater every day. Nevertheless, from an ethical perspective, the financial support of these means of diffusion on the part of the pharmaceutical companies, although societies or scientific committees of an independent nature guarantee their content.

Other biases that can change the prescription habits for psychotropic drugs is the influence exerted by the so called "opinion leaders," Another aspect is "ghost writing,"

which means that a scientific paper may have been written by pharmaceutical companies employees or by special firms engaged in the business of writing scientific papers and reports, and not by researchers involved in the actual investigation.

In a meeting of the Permanent Committee of Doctors of the European Community, they recognized the problems caused by the rapid increase of health care costs and acknowledged that this concerns not only governments and citizens, but also the medical profession. However, they concluded, unanimously, that it is "the duty of the doctor to oppose all measures that, destined to control expenses, violate medical ethics." In addition, they mentioned in the document that "the health sector not only is an expense, but also a benefit for the state and for public health, and, therefore, it is correct to consider it from an economically positive point of view and not only in terms of expenses." Yet, on the other hand, without health care services supported by the Administration, only wealthy patient could afford what a doctor prescribes, and for sure, the number of jobs for doctors would be very much reduced.

The use of placebo in clinical research raises major ethical problems. In a strict sense the use of placebo in clinical trials could be considered as being against the spirit of the Helsinki Declaration. But on the other hand treatment is not just the prescription of a drug. Treatment is the result of pharmacological effects and of the doctor–patient interaction. In psychotherapeutic research novel approaches are confronted with "treatment as usual" interventions. The challenge is to design studies where the more or less unspecific role of the doctor–patient relationship and the treatment as usual approach are as controlled as the effects of the drug being tested. The fact is that in the particular case of psychopharmacology there is a high response rate in many psychiatric disorders.

Patients as Research Subjects

Although already Claude Bernard declared in 1874 that "the principle of medical morality is to never perform an experiment on a human being that may be harmful to some extent, although it may be very beneficial to science, namely for the health of others," this principle was repeatedly violated and in an extreme form in Germany during the Third Reich. The fact is that doctors at least passively accepted laws put forward by the Nazi regime declaring that the regulation was designed to benefit the nation and not the patient, an example of conflict of values. Nowadays the Madrid Declaration of the World Psychiatric Association clearly affirms the independence of the psychiatrists and their right to practice their profession free from external pressures. The first international code of ethics for research on human beings is the Nuremberg Code that follows the Hippocratic principle *primum non nocere* and puts particular emphasis on obtaining the person's voluntary consent.

The ethical and scientific models for conducting biomedical research on humans have been developed through various international guidelines: the Declaration of Helsinki (1964) and its subsequent amendments (Tokyo 1975; Venice 1983; Hong Kong 1989, Somerset West 1996; Edinburgh 2000) of the World Medical Association (WMA); the International Ethical Guidelines of the Council for International Organizations of Medical Sciences (CIOMS) and the International Conference of Harmonization (ICH) guides for good clinical practice (GCP), which are at the core of most national and international legal standards on medical research involving human subjects.

The Nuremberg Code, the Declaration of Helsinki and the ICH Guides have led to GCP, an international standard of ethics and scientific quality for the design, implementation, records and reports on investigations involving humans.

Later on, the United Nations and World Psychiatric Association (1996) produced codes specifically oriented to psychiatry and the care of mental patients (Resolution 211, Hawaii Declaration 1977; Madrid Declaration 1996).

Publications and the Dissemination of the Results of Research

The publication and the dissemination of the results of research projects is a major ethical concern. The selective publication of clinical trials occurs and distorts the body of evidence available for clinical decision-making. Thus, researchers and editors are often more enthusiastic about the publication of studies that show a very significant effect of a new treatment (positive test) or an equivalence between two therapeutic approaches (non-inferiority trials). On the contrary, researchers and editors tend to show little interest in trials that show that a new treatment is less effective than the standardized treatment for a specific disease (negative trials), let alone those that are not clearly positive or negative, because inconclusive studies do not change routine clinical practice.

The editors of a several major medical journals have demanded greater transparency in the implementation and publication of clinical trials, requiring, as a prerequisite for dissemination, the registration of the trial in a public database.

Yet the publishing business is not free of unethical behavior and there is a risk that the danger may increase

in the future. Scientific journals with high impact factor are major players in research, as the investigator's career stands on his or hers published output. Therefore, the policies or even ideologies of a journal can have an indirect influence on grants accorded to investigators. This may even be present in editorials: the publication of a paper on comparison between typical and atypical antipsychotics, which showed favorable results for the latter based on retention rates, was accompanied by an editorial which only commented that there were not differences in the scores of the PANSS scale, withholding that this was a secondary outcome measure and the study was not powered to find differences in the clinical scales. The issue becomes more important as some journals are now considering themselves as major players in the health care sector, assuming the power to correct injustices around the world.

Ethopharmacology

Berend Olivier
Department of Psychopharmacology, Utrecht University, Utrecht, The Netherlands

Synonyms

Ethological pharmacology; Pharmaco-ethology

Definition

Ethopharmacology can be described as the study of drug effects on behavior, relying on observations and descriptions of species-specific elements (acts and postures). It is therefore strongly rooted in principles derived from ethology, the biological approach to the study of animal and human behavior. The roots of ethology lie in evolutionary biology as defined by Darwin and others and, more specifically, by the studies of Lorenz, Tinbergen and Von Frisch. Of central concern in ethology are the functional aspects of behavior and its adaptive value in evolutionary terms where it contributes along with genetic and environmental factors to natural selection.

Current Concepts and State of Knowledge

Ethologically based behavioral models, therefore, tend to focus upon a species' entire behavioral repertoire,

which is divided into clearly identifiable units of behavior (acts and postures, e.g., eating, grooming, walking, exploring, and fleeing). The repertoire is defined in naturalistic settings by comprehensive, systematic observation and recording of the species' behavior (including gender and age-related differences) without resort to a priori theories or hypotheses which putatively might bias the objectivity of the observation. Having exhaustively defined the behavioral repertoire and the environmental circumstances (antecedent, concurrent, and consequential) in which it is found, systemic alteration of environmental conditions, including the administration of a drug, can be undertaken.

Kršiak (1991) defined ethopharmacology as "the study of behavioral and other effects of drugs through the application of ethological concepts" in an article describing the historical contexts of the field. In his view, ethopharmacology is a subspecialty of the broader field of behavioral pharmacology, which reflects the behavioral effects of drugs on species by all kind of methods.

The first "ethopharmacological" studies were performed in the early 1960s of the last century (Chance and coworkers) by scientists coming from an ethological background. This group did most of their groundbreaking work on social behavior in rodents and they were the first to describe ethograms of isolated behaviors and social interactions (Grant and Mackintosh 1963). An ethogram is a list of all acts and postures of an animal in a certain environmental situation.

Ethopharmacology has particularly blossomed in the area of ► social interactions and ► aggression research probably due to the availability of ethologically trained scientists, the rich agonistic repertoire of rodents, and the translational aspects of such research into human biomedical (psychiatric) problems (Miczek et al. 1994).

The ethopharmacological approach is illustrated here in the area of aggression or ► agonistic behavior. Before the 1960s, the effects of drugs were assessed in very simple aggression tests often measuring only one parameter (e.g., the number of bites, Yen et al. 1959). Such parameters did not unravel whether a drug was selectively antiaggressive or just sedative. Therefore, ethological approaches were introduced to better describe and interpret the effects of drugs on behavior. Agonistic behavior, as found in a variety of animal models, includes a number of behavioral components with complex functions that have been organized in certain patterns and sequences. The species-specific behavioral patterns, taken together, can be considered the species' agonistic behavioral repertoire. The diversity of the repertoire, that is the number and subtlety of behavioral options available, is smaller in more primitive species and becomes apparently larger and more complex in the higher orders. Investigators try to use "models" of agonistic behavior and mostly this is done in rodents. Depending upon the model used, as defined by the specific environmental situation constructed, a particular frequent and temporal distribution of the species' behavioral repertoire can be elicited. In a territorial (resident–intruder paradigm) model of agonistic behavior in rats, the resident male ordinarily takes the offensive role and the intruder, a defensive role. Although both rats have available identical behavioral repertoires, the two rats show a completely different frequency, sequence, and temporal distribution of behavioral elements. On the basis of these different distributions, the overall behavior of each contributor can be classified as either offensive or defensive. The ethopharmacological approach has been used in developing specific antiaggressive drugs, serenics (Olivier et al. 1984, 1990a, b). These compounds have highly selective effects on offensive components of agonistic behavior while not influencing defense and flight. Using extensive ethograms (Olivier, 1981) and describing drug effects on frequency and time distributions on the sequential structure and the timing of behavioral elements enabled the very precise and sophisticated development of antiaggressive drugs, where effects on offensive behaviors could be distinguished from sedative, sensory, or motor deficits or interfering other behaviors (Miczek et al. 1989; Mos et al. 1987; Olivier and Van Daalen 1982). By testing an extensive battery of drugs from various classes (anxiolytics, antidepressants, antipsychotics, anticonvulsants) in different agonistic models, including maternal aggression in female rats, territorial aggression in male rats and mice, brain-stimulation-induced aggression and others (cf. Olivier et al. 1994) and using the ethological approach, an extensive and subtle profile of these psychotropics could be generated that appeared to be extremely helpful in describing the basal effects of these drugs on various aspects of agonistic behavior.

Ethyl Loflazepate

Definition

Ethyl loflazepate is a benzodiazepine that has anxiolytic, anticonvulsant, sedative, and skeletal muscle-relaxant properties. Its elimination half-life is 51–103 h. It also produces an active metabolite that is stronger than the parent compound. The symptoms of an overdose of ethyl loflazepate include sleepiness, agitation, and ataxia. Hypotonia may also occur in severe cases. These symptoms occur much more frequently and severely in children. High doses of the antidepressant fluvoxamine may potentiate the adverse effects of ethyl loflazepate. Like most similar compounds, it is subject to dependence and abuse.

ERPs

Definition

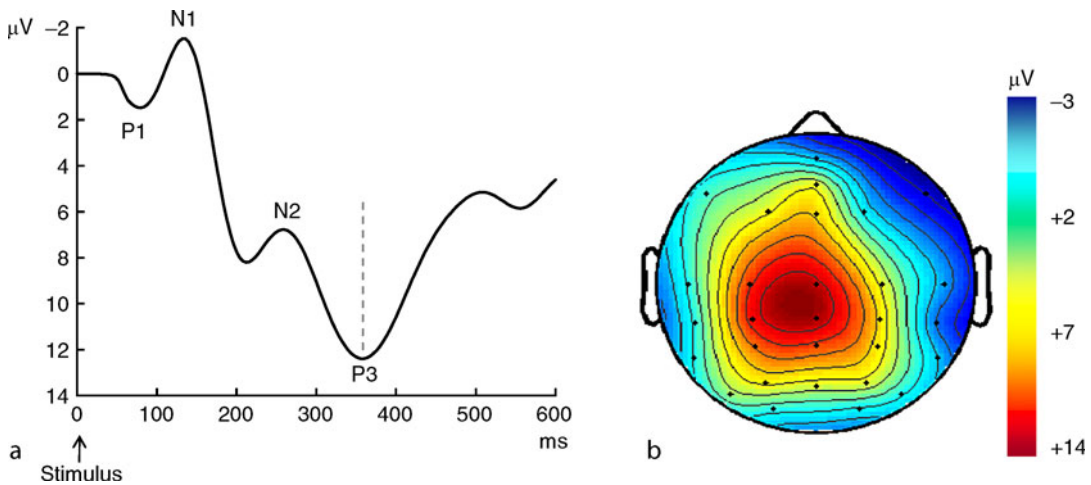
Event-related potentials are a general class of electrical brain potentials that are embedded in the ► electroencephalogram and that display a stable time relationship to a definable sensory, cognitive, or motor event.

Principles and Role in Psychopharmacology

► Electroencephalography is one of the most popular ► psychophysiological methods in clinical and preclinical research, and provides a recording that reflects the global electrical activity of the brain – the EEG. A limitation of the EEG is that it represents the summation of all the electrical activity at a given moment in time, making it difficult to isolate the activity associated with individual neurocognitive processes. A more powerful method for the study of isolated neurocognitive processes focuses on the specific EEG responses to particular sensory, cognitive, or motor events. Such specific responses are called event-related potentials (ERPs), to denote the fact that they are associated with specific events. The ERP is difficult to see in the EEG recorded for a single event. To isolate an ERP, one must collect the EEG of a large number of trials with the event-of-interest, time-lock the corresponding signals to the onset of this event, and then average the signals. The averaging process filters out all EEG activity that is not related to the event-of-interest, and isolates the ERP – the systematic response of the EEG to the event (Luck 2005).

Properties of ERP Components

ERPs consist of a series of peaks and troughs that are referred to as ► ERP components (Fig. 1a). The naming



Event-Related Potentials. Fig. 1. (**a**) Typical stimulus-evoked average ERP waveform. The abscissa indicates time from the onset of the stimulus, and the ordinate indicates the microvolt value for a specific electrode. Negative voltage is plotted upwards by convention. (**b**) Typical voltage distribution over the scalp, corresponding with the P3 peak latency.

of these components often reflects their polarity (P for positive, N for negative voltage) and their order of occurrence (e.g., P1 is usually the first negative component) or typical timing in milliseconds after the event (e.g., P300). Apart from their polarity and latency, ERP components can be characterized in terms of their general scalp distribution (Fig. 1b). The relationship between the voltage distribution observed over the scalp and the brain regions giving rise to this pattern is by no means transparent. This is because there is, in principle, an infinite number of cortical source configurations that can produce the same scalp distribution – a methodological problem known as the ► inverse problem. Nonetheless, the scalp distribution can be used to infer or test coarse hypotheses about a rather localized neuronal population or multiple, anatomically distributed populations that generate an ERP component. This can be achieved using ► source localization techniques, which limit the number of possible source configurations by making simplifying assumptions about the physics of the brain and head tissues, as well as the nature of the active neuronal populations (Handy 2005; Luck 2005).

One must exercise great caution when using ERP-component measures for drawing conclusions about underlying neural processes. One difficulty is that ERP components can reflect the combined activity of multiple, relatively independent, underlying or *latent* components that are overlapping in time and/or location. In that case, the neural process-of-interest typically corresponds with only one of those latent components. Furthermore, differences between experimental conditions or groups in the scalp distribution of a component need not necessarily represent the involvement of different neural sources, but may also reflect different relative contributions of the same sources. Techniques such as principal component analysis can sometimes be useful in identifying latent ERP components and their contributions to the observed ERP over the scalp. However, these techniques have significant limitations (Handy 2005; Luck 2005; Picton et al. 2000). Another potential pitfall concerns the variability in timing of some ERP components. Not only can there be large variability of the average component latency across individuals or groups, but also substantial variability in the timing of single-trial ERP components. Both cases may pose significant problems for the investigator, because an increase in latency variability results in a decrease in peak amplitude of the average (across individuals or trials). For example, two experimental conditions that differ in latency variability may appear to differ in component amplitude when examined in an average ERP, even when this is not the case in the single-trial waveforms. Investigators should take this possibility into account when examining and measuring ERP components (Picton et al. 2000). Indeed, sometimes it pays off to attempt to measure single-trial estimates of an ERP component and use the trial-to-trial variability in component latency or amplitude to address scientific questions.

In view of the above considerations, it is not useful to define a particular ERP component in terms of its polarity, latency, and scalp distribution. Peak latency and scalp distribution may differ between trials, conditions, and individuals, and even the polarity of a component may vary depending on the placement of the ► reference electrode. Modern definitions of ERP components acknowledge that a component may occur at different times under different conditions, and emphasize that two components are the same if they arise from the same neuroanatomical structure(s) and represent the same cognitive function (Luck 2005).

The Physiological Basis of ERP Components

Little is known about the physiological basis of ERP components. It is widely accepted that ERP components reflect the intracortical currents induced by excitatory and inhibitory postsynaptic potentials, which are triggered by the release of neurotransmitters. If many individual neighboring neurons with a similar orientation receive a similar excitatory or inhibitory input at approximately the same time, then the summation of the resulting postsynaptic potentials results in a measurable voltage at the scalp (Luck 2005). Thus, ERP components reflect the postsynaptic effects of neurotransmitters such as glutamate and GABA and indirect modulatory effects from neuromodulators such as norepinephrine, dopamine, and serotonin. Biophysical considerations suggest that the contribution of subcortical structures to the scalp-recorded EEG is small, and hence, most ERP components reflect primarily cortical activity. Whether an ERP component has a positive or negative polarity depends on many neurophysiological and nonphysiological factors and is little informative about the neural origin or functional significance of the component (Handy 2005).

With regard to the origin of ERP components, an important distinction can be made between traditional and synchronized oscillation theories of ERP generation (Klimesch et al. 2007). According to the traditional view, ERP components reflect phasic bursts of activity in one or more brain regions that are triggered by experimental events-of-interest. As explained above, this view treats the ongoing EEG as background noise that obscures the ERP signal-of-interest, and deals with that noise through data-averaging procedures. The synchronized oscillation

hypothesis challenges this approach and instead proposes that ERP components are generated when an event leads to the resetting of the phase of ongoing oscillations in the EEG, such that peaks and troughs in the oscillatory waveform become aligned to the resetting event. When aligned in this way, oscillatory peaks and troughs in the ongoing EEG are evident in the ERP waveform, even in the absence of transient bursts of neural activity. Empirically distinguishing between these two theories has proven difficult for a variety of methodological reasons.

ERP Components as Markers of Mental Processes

The study of ERPs has been of great importance for our understanding of mental processes, by augmenting traditional, behavioral measures such as reaction speed and accuracy (Rugg and Coles 1995). This approach is based on the assumption that changes in a certain cognitive process are selectively expressed in a particular component of the ERP. Then, if it has been established that ERP component X reflects cognitive process Y, one can investigate whether an experimental manipulation or mental state/trait (e.g., psychopathology) affects process Y by measuring its effect on component X. In particular, an effect on the component amplitude suggests a change in process Y or a change in the input to this process. For example, patients with obsessive–compulsive disorder exhibit an increased amplitude of the error-related negativity, an ERP marker of internal error detection. This finding confirms previous notions of a dysfunctional action-monitoring circuit in obsessive–compulsive disorder. Furthermore, an effect on the peak latency of component X suggests that the manipulation or mental state/trait has changed the duration of processes preceding and including process Y. In contrast, an effect on reaction speed in the absence of an effect on the peak latency of component X suggests a change in the duration of processes *following* process Y. For example, it is well known that the presentation of a warning signal can speed up the reaction to an imperative stimulus. ERP researchers have increased our understanding of this phenomenon by showing that the benefit in reaction speed is largely restricted to the time interval between an early ERP marker of spatial ▶ attention shifts and an ERP marker of hand-specific motor preparation, the lateralized readiness potential.

Of course, the logic outlined above depends on the validity of any given ERP component as a marker of a specific mental process. In the past decades, a large amount of research has focused on validating ERP components, and although there are many ongoing debates in the scientific literature, significant progress has been made in refining hypotheses about the functional significance and neural origin of ERP components (Key et al. 2005; Rugg and Coles 1995). This is particularly true for early ERP components such as the P1 and N1 (Fig. 1a). It is generally held that these components reflect aspects of stimulus encoding in modality-specific perceptual areas, such as visual or auditory cortex. Voluntary or involuntary changes in the amount of attention paid to a particular stimulus lead to amplitude modulations of the P1 and N1 components. Another prominent example of a "sensory" ERP component with a source in modality-specific perceptual areas is the mismatch negativity. This is a negative deflection with a typical latency of 100–250 ms that occurs in response to an odd stimulus in a sequence of stimuli, regardless of whether the subject is paying attention to the sequence.

Some other prominent ERP components are not sensory in nature, but reflect central cognitive processes. Important examples are the N2 and P3 components (Fig. 1a), both of which are sensitive to contextual variables, such as the relationship between the eliciting stimulus and the subject's goal of the task, and the subjective probability and novelty of the stimulus. The scalp distribution and latency of these components are highly variable across different task contexts. The N2 has been associated with various mental processes, including response inhibition and conflict detection. The P3 is thought to reflect updating of contextual memory representations or temporal filtering of motivationally significant stimuli and its latency is thought to index the end of stimulus-evaluation processes. Another cognitive ERP component is the error-related negativity, a negative deflection immediately following erroneous responses, that is clearly visible in the response-locked ERP. There is much evidence that the error-related negativity reflects the response of the dopamine system to unfavorable outcomes and events. Finally, there are a number of ERP components that are directly related to motor processes. The most important example is the Bereitschaftspotential or readiness potential, a measure of activity in the motor cortex that is leading to voluntary muscle movement. A derived measure, the lateralized readiness potential, reflects the relative activation of the left and right motor cortex and this has been very important for the study of covert aspects of motor preparation (Rugg and Coles 1995).

Investigating Drug Actions Using ERPs

One use of ERP methodology in psychopharmacology is to investigate the effects of a drug on specific neurocognitive processes (Carozzo et al. 2006; Pogarell et al. 2006). To that end, researchers examine whether and how the drug changes the corresponding ERP components. This

often allows for more detailed conclusions than examining behavioral measures alone. For example, ethanol, which has sedative effects, has been found to decrease P3 amplitude, whereas ► caffeine increases P3 amplitude, suggesting that these drugs affect high-level stimulus-encoding processes. Another example concerns the P50 wave, an ERP component that is used for the assessment of sensory gating – the habituation of responses to repeated stimuli. In healthy subjects there is an inhibition of responsiveness, that is, a diminished P50 to repetitive stimuli – an adaptive mechanism to prevent overstimulation. The NMDA receptor antagonist ► ketamine and the antipsychotic ► haloperidol disrupt P50 suppression, indicating that these drugs modulate sensory gating. Another ERP measure, the loudness dependence of the auditory evoked potential (LDAEP), has been proposed as a valid indicator of central serotonergic function in humans. This measure is assessed using the N1/P2-component of the auditory evoked potential and reflects the reactivity of the auditory cortex. Thus, this ERP measure is used as a marker of neuromodulatory function, rather than a cognitive function.

Investigating ERPs Using Drug Actions

Since ERPs reflect functional aspects of neurotransmitters and neuromodulators, drugs affecting particular neurotransmitter or neuromodulator systems are used to investigate the role of these systems in the generation of ERP components (Carozzo et al. 2006; Pogarell et al. 2006). A limitation of this approach is that most available drugs are not selective for a single system, which complicates the interpretation of the results. One exception is a class of drugs, ► serotonin reuptake inhibitors (SSRIs), which selectively increases the amount of serotonin in the brain. Accordingly, SSRIs have often been used to investigate the role of serotonin in the generation of different ERP components. Using this approach, it has been shown that serotonin affects the LDAEP strongly, but is not involved, for example, in the generation of the P3, which is modulated by cholinergic, dopaminergic, and noradrenergic drugs. The mismatch negativity is blocked by ► NMDA-receptor antagonists, indicating that the mismatch negativity critically depends on glutamatergic neurotransmission. These and many other findings have led to an increased understanding of the neural basis of ERP components. This, in turn, has informed theories of their functional significance. For example, the finding that the error-related negativity is modulated by dopaminergic drugs has strengthened existing views that link this ERP component to the literature on dopaminergic reward-prediction errors.

The Role of ERPs in Psychiatry: Sensitivity and Specificity

ERPs are not only important research instruments, but are also useful as clinical instruments in neuropsychiatry (Pogarell et al. 2007). ERPs can be used in the diagnostic workup of a wide range of neuropsychiatric disorders as well as in monitoring the course of the disorders and the prediction of treatment responses. To be useful in the diagnostic workup, an ERP component has to be sensitive enough to detect the disorder, but also sufficiently specific for the disorder to rule out alternative explanations.

► Alzheimer's disease is consistently related to smaller P3 amplitudes and prolonged P3 latencies. Using the P3 component, Alzheimer's patients can be diagnosed with high sensitivity and specificity (up to 88.5%). Furthermore, the P3 is effective in both monitoring and predicting the treatment response of Alzheimer's patients to cholinesterase inhibitors. Thus, the P3 may be an important instrument not only in the diagnostic workup, but also in the monitoring and prediction of the treatment response in Alzheimer's disease. This tool is still underutilized in the clinic, presumably because the P3 has not been generally accepted as a valid biomarker for Alzheimer's disease. Schizophrenic patients also show a decreased P3 amplitude. However, this is generally considered a trait marker rather than reflecting the neurological pathology causing ► schizophrenia, because the P3 amplitude reduction is not affected by neuroleptic medication and can also be found in remitted schizophrenics, relatives of schizophrenic patients, and other subjects at risk of developing schizophrenia. Thus, the P3 amplitude may be a sensitive marker, but is not a specific marker for schizophrenia and is therefore not used in the diagnostic workup. However, there are indications that in schizophrenic patients, the P3 may predict treatment response.

Advantages and Limitations of Event-Related Potentials

The major advantage of ERPs is their fine temporal resolution (on the order of milliseconds), indicating that ERPs reflect what is happening in the brain at the very same moment. Another advantage of ERPs is that electroencephalography is noninvasive and cheap compared with other brain-imaging methods. An additional convenience is that there are clear and widely agreed-upon guidelines for how ERP studies should be conducted, analyzed, and reported (Picton et al. 2000). The primary limitation of ERPs is that it is not possible to determine the neuroanatomical generator of an ERP component from the measured scalp potentials alone. Furthermore, the

geometrical orientation of neurons must be more or less parallel in order to detect the neural activity at the scalp. Signals from structures located deep within the brain are particularly hard to measure. Finally, during the averaging procedure for isolating the ERP from the EEG, all activity that is not time-locked to the event-of-interest is lost. In order to examine that information, other electrophysiological methods are needed.

Event-Related Potentials Components

Synonyms

ERP Components

Definition

Systematic response of the electroencephalogram to a particular sensory, cognitive, or motor event that is generated in a given neuroanatomical structure when a specific mental operation is performed. The naming of these components often reflects their polarity (P for positive, N for negative voltage) and their order of occurrence.

Evidence-Based Guidelines

Definition

A series of statements, based on systematic searching of relevant scientific literature and critical appraisal of relevant sources, usually reached through consensus and designed to guide clinical practice. Greatest weight is given to evidence at the top of the "hierarchy" (meta-analyses and randomized controlled trials) with stronger recommendations than are possible when evidence is derived solely from less well-designed studies.

Evidence-Based Medicine

Synonyms

EBM

Definition

Evidence-based medicine aims to apply evidence gained from the scientific method to certain parts of medical practice. It seeks to assess the quality of evidence relevant to the risks and benefits of treatments (including lack of treatment).

Ex Vivo

Definition

The term originates from Latin and means "out of the living"; it refers to an experiment that is done in or on living tissue, and at least partially outside the organism. For example, for the measurement of ex vivo receptor binding, an animal can be treated with a test compound *in vivo*, followed by removal of the brain, exposure of brain slices with a radioligand specific for that binding site *in vitro*, and subsequent quantification of the amount of radioactivity in brain areas of interest. The degree to which radioactivity is reduced due to competitive binding of the test substance can be taken as a measure of receptor occupancy.

Excessive Sleepiness

Synonyms

Excessive daytime sleepiness; Narcolepsy

Definition

A subjective report of difficulty in maintaining the alert awake state, usually accompanied by a rapid entrance into sleep when the person is sedentary.

Excitatory Amino acid Transmitters; Excitatory Neurotransmitters

Definition

There are more than 100 known *excitatory amino acids* (EAAs) and the large majority of them are non-protein-forming amino acids initially purified from algae or fungi (Lubec and Rosenthal 1990). The endogenous EAAs Glutamate (Glu) and Aspartate act in the nervous system as excitatory neurotransmitters; they are released from neurons and they induce neuronal excitation via ionotropic and metabotropic Glu receptors (iGluRs and mGluRs). Related endogenous molecules like N-acetylaspartylglutamate (NAAG) could also belong to the group of EAAs, but they have no demonstrated neurotransmitter properties. EAAs are usually grouped to distinguish them from AAs like GABA, Glycine, or Taurine exerting inhibitory effects on neuronal cells. Excitatory neurotransmission is present in central and peripheral nervous system, and in the periphery EAAs contribute to the regulation of gastrointestinal motility, pain sensation, as well as respiratory and cardiovascular functions. In non-neuronal cells, Glu receptors and transporters exert a role in the control of proliferation, immune response, and bone tissue dynamic (Gill and Pulido 2005).

Pharmacological Properties

History

Glu is the most abundant excitatory neurotransmitter in the brain. The first indications that Glu exerted excitatory actions on cerebral cortex were obtained by Hayashi in 1954, and later observations by Watkin and colleagues showed that Glu can depolarize and excite individual neurons in the cat spinal cord. However, it took the scientific community a long time to realize that Glu was functioning as a neurotransmitter, mainly due to its very high abundance in the brain and its involvement in important metabolic pathways. Full acceptance of the neurotransmitter role of Glu was achieved only with the characterization of selective agonists and antagonists for all Glu receptors (Roberts et al. 1981). The last decade has seen several attempts to exploit the therapeutic potential of Glu receptor ligands since molecular psychiatry and behavioral psychopharmacology have been instrumental in highlighting the possibilities of a pharmacological modulation of Glu in diseases like ► schizophrenia and ► treatment-resistant depression (► TRD).

EAA Receptors and Selective Agonists

Glu is a flexible chiral molecule that can adopt nine staggered conformations in physiological conditions by rotations around two of its carbon bonds. Because of the large flexibility of Glu, the characterization of the different subgroups of EAA receptors was only possible after the discovery of conformationally restricted Glu and Aspartate analogs. The observed selective binding properties of Glu analogs imply that Glu interacts with each receptor subtype in a distinct conformation (Krogsgaard-Larsen and Hansen 1992). Agents exerting a specific modulatory role on the effects of EAAs are also of therapeutic relevance in CNS disorders and are listed accordingly in Table 1.

EAA and iGluRs

iGluRs are ion channels which share a common genetic ancestor, and are divided into subclasses depending on their ability to interact with three different Glu analogues:

NMDA (N-methyl-D-aspartic-acid), AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), and Kainic acid (KA, 2-Carboxy-3-carboxymethyl-4-isopropenyl-pyrrolidine). Each iGluR consists of four protein subunits, and each subunit in turn contains a large extracellular domain withholding the orthosteric binding site (the binding site for the endogenous ligand), four transmembrane (TM) domains, and an intracellular C-terminal domain responsible for anchoring and trafficking. The TM2 in each subunit forms a loop inside the cell

membrane to create the lining of the pore of the ion channel. The ion permeability properties of iGluRs are therefore determined by the amino acids residues contained in TM2 (Squire et al. 2008). ► *AMPA receptors* (AMPAR) are Na^+/K^+ ion channels, known as the principal transducers of fast excitatory transmission in the brain. The native AMPAR contains different combinations of the four subunits: GluR1-4. In the predominantly expressed GluR2 subunit an ► RNA-editing site is present in the center of the TM2 loop. Such editing results in an amino acid substitution (a neutral Glutamine is changed to a positively charged Arginine residue) which reduces the permeability of Ca^{2+} ions through the channel. The functional diversity of AMPAR subunits is further enhanced by additional RNA-editing as well as alternative splicing. Together this causes a large variation in the

extracellular region of GluR subunits, e.g., the presence of a splice region referred to as flip/flop, and results in receptor isomers exhibiting different kinetic and pharmacological properties (Squire et al. 2008). The trafficking of AMPAR to and from synapses is controlled by a complex sequence of interactions with several proteins. Briefly, the AMPAR M1 domain is tightly interacting with regulatory proteins (TARPS), which specifically controls the incorporation of the receptor into the synapses in association with ► long-term potentiation (LTP) or long-term depression (LTD) events affecting the synaptic plasticity.

The first generation of selective AMPAR agonists (and antagonists) was based on the AMPA structure (isoxazol derivatives), and they were useful to demonstrate the most relevant features of AMPAR: (1) rapid deactivation (channel closure upon Glu removal), (2) desensitization (channel closure during continuous exposure to Glu) due to a conformational change of the extracellular domain, (3) less pH sensitivity than NMDA receptor, (4) the presence of phosphorylation sites for kinases (PKC, PKA, and CAMKII). More recently, AMPA potentiators or ampakines have been identified which modulate the AMPAR by interacting at allosteric sites. ► Ampakines (e.g., CX717) have been shown to stabilize the receptor in the channel-open state prolonging ion flux and reducing desensitization. Generally, ampakines exhibit cognitive-enhancing properties while compounds (e.g., CX614, CX929, and CX1837) specifically interacting at the cyclothiazide-binding site of the AMPAR also induce the expression of neurotrophins (such as BDNF) and exhibit antidepressant properties.

The ► *NMDA receptor* (NMDAR) consists of a heterotetramer assembled from seven different subunits: NMDAR1 contains the glycine-binding site; NMDAR2 (A–D) contains Glu, polyamine, Zn^{2+}, and proton-binding sites; and NMDAR3 (A and B) with modulatory role (Gereau and Swanson 2008). Subunit R1 is required for channel formation while R2A–R2D play an important role in determining the affinity for both Glu and coagonists Glycine or D-cycloserine, and modulating the receptor activity. The restricted NMDA analogue Homoquinolinic acid which displays some selectivity against the NR2B-containing receptors can also be included among receptor agonists.

In neurons, NMDARs are likely heterooligomers of R1 and R2 subunits forming functional channels with different physiological and pharmacological properties. NMDAR-containing subunit NRA2B exhibit for instance the highest affinity for glycine and is inhibited only by micromolar concentrations of Zn^{2+}. During membrane-resting potential conditions Mg^{2+} ions are binding to and blocking the NMDAR channels and membrane depolarization (usually by activation of AMPAR) is required to release the Mg^{2+} blockade. Activation of the NMDAR allows Ca^{2+} influx to initiate numerous intracellular processes responsible for synaptic plasticity. Hyperactivation of the NMDAR, on the other hand, causes *excitotoxicity* and this is why the activation process is strictly controlled by binding of several endogenous ligands and interaction partners. Binding of polyamines (spermine and spermidine) and ► neurosteroids (e.g., dehydroepiandrosterone) to allosteric sites on the NMDAR positively modulates current amplitude; and for this reason, several polyamines are also ► excitotoxins (e.g., Argiotoxin 636) (Krogsgaard-Larsen and Hansen 1992). In spite of the high concentrations of Glycine present in extracellular fluids, the Glycine site of the NMDAR is possibly not always saturated because of the presence of efficient Glycine transporters (GlyT1 and GlyT2). Clinical evidence of NMDA hypofunction in schizophrenia has triggered attention for the pharmacological modulation of GlyT1, and inhibitors are currently under development as antipsychotics.

The *KA receptors* (KAR) form heteromeric cationic ion channels assembled from five different subunits, GluK1–5 (according to the new IUPHAR nomenclature, GluR5–7 are now named GluK1–3 and KA1 and KA2 are named GluK4 and 5). Glu activity at different KAR subunits is exerted in the low μM range and they are involved in NMDA-independent LTP. Similar to the AMPAR, RNA-editing occurs in KAR (e.g., at the Q/R site in TM2 on subunits GluK1 and GluK2) and the C-terminal domains of GluK1-3 are edited by alternative splicing (Gereau and Swanson 2008). The fully edited (modified by both RNA-editing and splice variation) variant of GluK2 is the most abundantly expressed subunit in the adult CNS. High expression of the KARs is seen in the synaptic connection between hippocampal mossy fibers and CA3 pyramidal cells. Neurotransmitter release modulated by KARs facilitates presynaptic forms of short- and long-term synaptic plasticity. When expressed at postsynaptic locations KARs also induce synaptic currents of small amplitude with slow kinetics. The cellular subunit localization of KAR is dynamic and AMPAR stimulation is known to increase GluK2 postsynaptic localization, while both GluK2- and GluK5 expression are decreased at the presynapse. The understanding of the function of KARs is lacking behind mainly because of the relative shortage of selective pharmacological tools. Selective agonists for the KARs are all natural products isolated from seeweed or poisoning mushrooms. Domoate and Acromelic acid are both more potent agonists than the prototypic agonist KA (Krogsgaard-Larsen and Hansen 1992). KA and related

compounds exhibit also nondesensitizing agonist activity at the AMPA receptor, while Domoate selectively activate KARs at low concentrations. Quisqualic acid activates several Glu receptors: KARs, AMPARs, and mGluRs. AMPA is acting as a partial agonist at recombinant GluK1 receptors, with no effect on GluK2; and the AMPA analogue ATPA shows selectivity towards GluK1 over AMPAR. Also Willardiine analogs show selectivity for GluK1 over AMPA subunits.

EEA and mGluRs

mGluRs are ► G-protein-coupled receptors (GPCRs) and they are responsible for slow excitatory/inhibitory transmission. Distinct from the majority of GPCRs, mGluRs exist as functional homodimers where a cystein-rich domain connects the two monomers of the receptor. mGluRs are characterized by a large extracellular domain and seven TM domains. The extracellular domain of each mGluR monomer contains the Glu-binding site located in a so-called bi-lobed structure (usually referred to as the venus flytrap domain). The Venus flytrap can have an open or closed configuration in the absence or presence of an agonist, respectively. The molecular mechanism of activation of mGluRs is not completely understood, but agonist binding is known to stabilize the closed form of the venus flytrap domain and result in specific conformational changes in the extracellular and TM domains which recruits and activates specific G-proteins. Eight subtypes have been identified in the family of mGluRs (mGlu1–8), classified into three major groups (I–III) based on their sequence homology, second messenger coupling, and pharmacology. Splice variants of mGluRs are mainly found in the intracellular carboxyterminals affecting the G-protein coupling efficiency and have to date been identified for mGlu1, mGlu3 and mGlu5 (Gereau and Swanson 2008). Glu shows varying affinity for the different mGluRs, spanning from the μM to the mM range.

EAAs interacting with the mGluR ► orthosteric site exhibit fast K_{on}/K_{off} rate and a limited capacity of discrimination between the three subgroups. Among them, L-AP4 helped the pharmacological definition of mGluRs long before the cloning of the receptors and is probably the most characterized mGluR agonist. The restricted Glu analogue 1S,3R-ACPD (highest affinity for Group I and II) was the first identified mGluR ligand that did not interact with iGluRs (Gereau and Swanson 2008). Allosteric binding sites, which are located in the TM region, have allowed the characterization of functionally more selective ligands. mGluR enhancers can increase potency and/or efficacy of an agonist and are generally identified as positive allosteric modulators (PAM). Noncompetitive antagonists can be referred to as negative ► allosteric modulators (NAM) and are reducing the effects of an agonist. Ligands which bind to the allosteric site without apparent changes in receptor pharmacology are named silent allosteric modulators (SAM) (Lutz and Kenakin 1999). The search for allosteric ligands of mGluRs has allowed the discovery of compounds that are able to discriminate between very similar mGluRs, e.g., within Group II and Group III mGluRs. In the near future, the same effort might also result in the discovery of new classes of compounds with multiple PAM/NAM activities on different mGluRs.

Group I mGluRs (mGlu1 and mGlu5) are predominantly expressed postsynaptically where they are positioned by scaffold proteins (acts as regulators of signaling pathways by binding to and localizing its components to specific areas) in close contact with the postsynaptic density. Activation of these receptors stimulates phospholipase C, potentiates L-type Ca^{2+} channels, and stimulates ► GIRK channels (G-protein-activated inwardly rectifying K) in recombinant systems. L-Quisqualate, also activating AMPAR, is the most potent Group I agonist while (S)-3,5-DHPG is a moderately selective agonist at the mGlu5 and to date, no selective agonist has been identified for mGlu1. The very first PAMs identified for mGluRs were a class of compounds (e.g., RO674853) potentiating the agonist-induced response at mGlu1. Enhancing the mGlu1 receptor activity has been shown, both from animal model and genetic studies, to be beneficial in cerebellar ataxia.

A complex interaction can be demonstrated between mGlu5 and NMDA receptors. Coexpression of NMDA and mGlu5 receptors in vitro and in vivo has revealed the presence of a tonic mGlu5-mediated potentiation of NMDAR activity. This observation is the reason for the current search for mGlu5 PAM with predicted antipsychotic properties. The benzaldazine DFB molecule was earlier identified as a PAM on mGlu5; and among its derivatives we can also find both NAM and neutral ligands, all showing partly overlapping binding sites in the TM domain. Compounds like CPPHA, CDPPB, ADX47273, and VU-29 enhance mGlu5 activity, facilitate hippocampal synaptic plasticity and have therefore a potential use as ► antipsychotics and ► cognitive enhancers. The ADX63365 mGlu5 PAM is presently in development for the treatment of schizophrenia.

Group II (mGlu2 and mGlu3) and III (mGlu4, 6, 7, and 8) mGluRs are predominantly expressed at the presynaptic terminal or in glial cells (mGlu3). They inhibit adenylate cyclase, activate GIRK channels, and inhibit presynaptic Ca^{2+} with an overall inhibitory effect on

neurotransmitter release. The first high affinity in vivo active agonist selective for Group II was the Glu analogue LY354740 (bicyclic structure). Several modifications have been made on this scaffold, changing both its receptor affinity and functional properties. An agonist derivative from this class LY404039 (with the prodrug LY2140023) was recently shown to have antipsychotic and ▶ anxiolytic effects in Phase-II clinical trials. Several mGlu2 PAMs have been characterized in preclinical models trying to obtain an antipsychotic profile similar to the mGlu2/3 agonists. Compounds like LY487379, BINA, PTBE, AZ1007992, MRLSD-650, and ADX71149 are the results of this search, while selective mGlu3 PAMs are still lacking.

For the Group III receptors (S)-AP4, (S)-SOP, and (1S,2R)APCPr are the most potent agonists, and the (S)-3,4-DCPG ligand show some selectivity for mGlu8. Because of the lack of selective ligands the pharmacology of the Group III receptors are still the least developed of the mGluRs. The first mGlu4 PAMs, such as PHCCC, SIB1893, and MPEP, were originally identified as NAMs at Group I mGluRs. More potent and selective mGlu4 PAMs are the VU3423 and VU155041 compounds which, in preclinical models, have shown to have a function in neurodegenerative disorders, particularly on reversal of motor deficits in Parkinson's disease. For the mGlu7 receptor there are no available PAMs to date, but AMN082 was recently identified as a mGlu7-selective allosteric agonist. Initial studies with this compound show activation of mGlu7 to be linked to anxiolytic-like effects in rodents. Two PAMs for mGlu8, Thiomethylanilide A and B, were recently introduced but in vivo data are still awaited.

EAA Receptor Antagonists

iGluR Antagonists

NMDAR antagonists: D-α aminoadipate and D-2-amino phosphonovalerate were among the first competitive antagonists that are selective for the NMDAR described in the literature. More potent orally active compounds with anticonvulsant and neuroprotective properties (like AP-5, AP-7, and LY274614) were prepared in the 1990s. These competitive antagonists however produced psychotic reactions and were soon dismissed in favor of noncompetitive ligands. The discovery of two use-dependent, high-affinity, noncompetitive antagonists (MK-801 – dizocilpine and PCP) binding in the ionic pore only in the open channel (commonly referred to as the PCP-binding site) created in fact a lot of interest. However, also these channel blockers had to be dismissed because of the euphoric and dissociative central effects responsible for their abuse potential and the induction of memory loss. Few NMDA antagonists have found applications in clinical practice. The open-channel blocker ▶ memantine (interacting at the Mg^{2+}-binding site) is well tolerated in chronic treatment and has shown mild but positive effects on cognition and agitation in clinical trials in Alzheimer disease dementia. Dextromethorphan (and its metabolite dextrorphan) is a commonly used cough depressant that inhibits the NMDAR by binding inside the ion channel and might have a potential use for children with ▶ Rett's syndrome. ▶ Ketamine, also an open-channel blocker for the NMDAR, is commonly used as dissociative anesthetic and at low doses against neuropathic pain. In ▶ treatment-resistant depression (TRD), the acute administration of ketamine is able to improve mood and anxiety while reducing suicidal thoughts in matter of hours and with a long-lasting effect. The possibility to discriminate, in a pharmacological manner, between the antidepressant properties and dissociative/euphoric effects mediated by NMDA antagonists is currently investigated using selective and high-affinity NMDA2B antagonist (e.g., Ifenprodil and Felbamate) (Kew et al. 1998). These compounds (also called polyamine site antagonists) cause a relative selective blockade of the NR2B-receptor subunit (100-fold over NR2A and NR2C). RO256981 and CP-101,606 are among the best-known antagonists of this kind and the orally active compound of this class, EVT101, is undergoing development for TRD.

Kynurenic acid, derived from tryptophan catabolism, is an endogenous antagonist at the NMDAR with selectivity for the glycine site at low concentrations while blocking also AMPAR and KAR at higher concentrations. A more potent antagonist for the glycine site is the 7-chloro-kynurenic acid. Riluzole is also a glutamatergic modulator with anticonvulsant, neuroprotective, and plasticity-enhancing properties which is presently approved for treatment of ALS and a promising candidate for treatment of mood disorders. It has several effects on the brain glutamatergic system: inhibiting Glu release via Na^{+}-channels, increasing ▶ Glu transporter (EAAT1) activity and expression, and increasing the surface expression of AMPA subunits GluR1 and GluR2. No direct interaction with NMDA or KARs is established although inhibition of NMDAR to prevent Ca^{2+} entry is a possible mechanism of action.

AMPA and KARs antagonists: Much progress has been made in developing selective AMPAR antagonists while it is only recently that selective KAR antagonists have been disclosed. The cross reactivity of AMPA and kainate on GluK1 and AMPAR resulted in the initial development of antagonists with effect on both receptors. The most

commonly used AMPAR antagonists are the quinoxalinediones (such as DNQX and CNQX), which are potent non-NMDA antagonists with selectivity for AMPAR (20-fold) over KARs. Tezampanel is a competitive AMPA/GluK1 antagonist with increased potency, and its orally active prodrug NGX426 is the first AMPA/KAR antagonist to be studied in clinical trials for chronic pain, including migraine and neurophatic pain. Some derivatives of tezampanel are functioning as selective KAR GluK1 antagonists (LY382884 and LY466195). Selectivity for AMPAR over GluK1 was only achieved when developing noncompetitive antagonists, e.g., GYKI-53784 and CP-456,022. These AMPAR antagonists do not function as open-channel blockers but are instead binding in the linker regions between the extracellular and TM domains, affecting the conformational changes induced by the agonist. Another potent and highly selective, noncompetitive, AMPAR antagonist Perampanel was initially developed as an add-on therapy to L-Dopa in Parkinson's disease, but is presently under investigation for neuropathic pain and epilepsy. UBP203 and UBP316 are potent competitive antagonists with enhanced KAR GluK1 selectivity achieved by SAR studies of the natural product willardiine. Selective competitive antagonists for the other KAR subtypes are not yet available. Noncompetitive antagonists have so far been identified for the GluK1 and GluK2 subtypes (e.g., the AUBA compounds) and for the GluK1 homomeric KAR (NS3763). These compounds are likely to be the starting point of further development of noncompetitive antagonists. Other modulators include the Joro spider toxin (JSTX) – blocking the unedited GluK2, Arachidonic acid, primarily blocking homomeric GluK2 and GluK1/GluK2 receptors and Topiramate which inhibits excitatory neurotransmission also through actions on KAR (GluK1) and AMPARs (Lutz and Kenakin 1999).

mGluR Antagonists

Competitive antagonists acting on mGluRs prevent the closure of the two lobes of the extracellular binding pocket (the venus flytrap). Potent competitive antagonists for the Group I receptors (e.g., LY367366) are derived from the (S)-MCPG structure, while LY367385 is a selective mGlu1 antagonist. Most potent Group II antagonists are derived from L-CCG-I (e.g., LY341495) while antagonists with better selectivity could be obtained by derivatization of agonist LY354740, e.g., HYDIA and MGS0039. Extensive preclinical studies have been performed with the Group II selective antagonists showing antidepressant and anxiolytic-like effects. The Group III mGluRs still lack competitive antagonists with high potency and selectivity while compounds like MAP4, DCG-IV, and LY341495 function as antagonists with moderate potency. Due to the high similarity of the orthosteric binding site of the different mGluRs, the most promising strategy to selectively antagonize this group of receptors is by targeting the allosteric binding site(s) using NAMs.

Group I NAM mGlu1: The most commonly used mGlu1 antagonist is the noncompetitive antagonist CPCCOEt which is structurally unrelated to Glu and is binding in the TM domain of the receptor. More potent NAMs are YM-298198, BAY36-7620, and EM-TBPC, interacting in the same region of the receptor. Blockade of mGlu1, by ► antisense oligonucleotides, antibodies, and NAMs, has shown its involvement in modulation of nociception and chronic pain. A-841720 NAM, structurally different to previous mGlu1 NAMs, has also shown to be effective in models of ► nociception and is presently under development for pain treatment. Antagonists of mGlu1 have been postulated to have a therapeutic effect in ► anxiety disorders which has been confirmed by the potent mGlu1 NAM JNJ16259685.

Group I NAM mGlu5: Brain areas expressing mGlu5 receptors (limbic cortex, hippocampus, amygdala, and basal ganglia) are known to play an important role in emotion and motor controls, and mGlu5 was early recognized as a potential target for ► mood disorders and neurodegenerative diseases involving motor dysfunctions. SIB-1757 and SIB-1893 were the first selective mGlu5 NAMs to be identified. They were further developed and optimized into the more potent and selective MPEP which is the most widely used mGlu5 antagonist (a prototype for mGlu5 NAMs). mGlu5 NAMs, such as MPEP and its more selective derivative MTEP, show a clear anxiolytic and antidepressant-like profile in a wide range of preclinical behavioral models. In the search for mGlu5 NAMs, the known anxiolytic compound fenobam was identified, binding to the receptor at the same site as MPEP. After this observation several pharmaceutical companies have filed numerous patents on compounds acting as mGlu5 NAMs (divided into two major classes: acetylene- and nonacetylene-containing compounds). The mGlu5 NAM ADX-10059 recently completed a ► Phase-II trial in migraine with successful outcome. The same compound was also the first in class to show positive results in a Phase-II trial for gastroesophageal acid-reflux disease. Supported by mGlu5 expression in cortical and basal ganglia structures, mGlu5 NAMs have been shown to treat L-Dopa-induced ► dyskinesia in rodent and primate models. MPEP has also been shown to protect the nigrostriatal system against toxicity, thus having a neuroprotective function and a possibility to prevent disease development. Based on these indications, the AFQ-056

and ADX48621 compounds are in development for reducing L-Dopa-induced dyskinesias in ► Parkinson's disease. It has been suggested that the loss of FMRP (► Fragile X Mental Retardation Protein) will result in an enhanced mGlu5 signaling, and attenuation of mGlu5 activity is therefore believed to provide not only symptomatic relief but also disease modification in Fragile X syndrome. NPL-2009 (Fenobam), STX107, and AFQ-056 are all in development as potential therapies for this autistic disorder (Jaeschke et al. 2008).

Group II NAM: Preclinical studies in rodents are supportive of a therapeutic potential for mGlu2/3 NAM in mood disorders and as cognitive enhancers. A class of ► benzodiazepines (e.g., MNI135, RO676221, and RO718216) has been disclosed as potent and in vivo active mGlu2/3 NAM. The discovery of antagonists with selectivity for the two subtypes, mGlu2 and mGlu3, would also help to clarify the specific role of these receptors under physiological and pathological conditions.

Group III NAM: The recent identification of selective allosteric agonists for mGlu4, 7 and 8 will greatly help to facilitate the pharmacological characterization of these receptors and the discovery of selective NAMs. Very recently a class of pyridine compounds (MDIP and MMPIP) was identified as mGlu7 NAM. They are likely to help the clarification of the physiological role of mGlu7 in anxiety since controversial results were seen in mGlu7 knockout mice and in studies using the allosteric agonist AMN082.

Conclusions and Perspectives

The effort placed during the past decades on the characterization of the molecular properties of EEAs and their antagonists has been rewarded with the development of some of these ligands for different therapeutic opportunities. The field is however still challenging. Further basic research is required to understand the function of the glutamatergic synaptic cleft in its entirety, as well as to clarify the peculiarities and the plasticity of the glutamatergic control on ► GABA neurons. Moreover, a number of Glu receptors and subunits are still missing selective ligands, and the definition of molecular determinants of receptor cross talk for mGluRs (e.g., mGlu2/5-HT2A) could bring new challenges for medicinal chemists and new tools for behavioral pharmacologists. The clinical development of several EAA receptor ligands (included in Table 1) has also increased the need for suitable PET ligands (positron emission tomography; an imaging technique using short-lived radioactive substances to show uptake and distribution of the substances in tissue) that could be used during the preparation of the different clinical trials and possibly could be of help both in diagnostic terms and to identify responders.

Proof of concept clinical studies for the different pharmacological targets brought forward by the glutamatergic hypothesis are certainly long awaited. They will help to understand if efficacy and tolerability of the pharmacotherapy of both schizophrenia and depression (McArthur and Borsini 2008) will be substantially improved in future years.

If there is, however, an achievement that already stands out because of the long-term impact it will hopefully have on the quality of life of the patients, this must be the observation of the effects of mGlu5 antagonists in ► Fragile X. The concrete hope of a cure has increased also the interest for the early diagnosis and for a better understanding of the disease progression during the first years of life. This is certainly one of the best examples of a successful molecular approach to the therapy of neurodevelopmental brain disorders.

Excitotoxicity

Definition

This term was coined by Olney and colleagues in the 1970s to describe neuronal necrosis caused by the exposure of CNS tissue to EAAs. These neurotoxic lesions affect predominantly postsynaptic regions with swollen dendrites, dilated perykarial mitochondia, and endoplasmic reticulum while axons and presynaptic terminals are spared. In the late stage, nuclear pyknosis and vacuolations are apparent. EAA neurotoxic properties can be used in neurobiology to selectively lesion sensitive neuronal populations (eg., ibotenic acid).

Excitotoxins

Synonyms

Neurotoxin

Definition

Excitotoxins are agonists at the either of the glutamatergic receptor subtype (AMPA, NMDA or kainate) receptors and cause damage or cell death by permitting high levels of calcium ions to enter the cell. The calcium ions then activate a variety of enzymes including phospholipases, endonucleases, and proteases that can damage the internal structures of the cell, for example, DNA and cytoskeleton, potentially leading to cell death.

Excretion

Synonyms

Clearance; Elimination

Definition

Excretion is the elimination of the drug from the body.

Executive Functions

Synonyms
Cognitive control; Higher-order cognitive processing; Supervisory attentional system

Definition
Executive functions are mechanisms involved in the optimization of cognitive processing, monitoring, and coordinating the performance of lower-order cognitive processes during both the planning and the execution of behavioral output. Executive functions embrace, for example, cognitive flexibility, behavioral inhibition, and the regulation of attention. Preserved executive functioning depends primarily on intact frontal lobes and frontostriatal pathways in the brain.

Expectancies and Their Influence on Drug Effects

Amee B. Patel, Kim Fromme
Department of Psychology, The University of Texas at Austin, Austin, TX, USA

Synonyms
Expectations

Definition
Substance-related expectancies are anticipatory cognitions that explain drug-seeking behavior by providing information about whether a substance will produce a desired effect (contributing to behavioral activation) or an undesirable outcome (resulting in behavioral avoidance). Expectancies need not be accurate or explicit to guide behavior.

Impact of Psychoactive Drugs
Expectancies help explain how individuals initiate and maintain psychoactive drug use. Prior to their own first use of a substance, individuals develop beliefs about the effects of drugs based on information gathered from parents, peers, advertising, and media. As individuals associate psychoactive drug use with subjectively positive outcomes, they are more likely to try the substance. If the expected effect is achieved, the expectancy is reinforced. Expectancies, however, can be reinforced by observing the behavior and communication of others, allowing individuals to maintain expectancies without trying the drug. It should be noted that most of the extant literature on substance abuse has focused on alcohol-related expectancies, although studies evaluating expectancies for other psychoactive substances have demonstrated similar findings.

Expectancies gained attention as an explanation for the placebo effect after it was observed that questionable medications were effective in some individuals. It was hypothesized that creating an expectation that the medication would be successful was the key in separating mental processes from chemical processes, which was supported by the fact that the absence or misattribution of this expectation led to the failure of the placebo effect. This concept of expectation was also used to explain the disinhibitory effects of alcohol use (MacAndrew and Edgerton 1969). It was argued that disinhibition was a psychological manifestation of the sociocultural *belief* that alcohol caused a lack of inhibition, rather than an actual pharmacological effect.

Experimental procedures were subsequently developed to test pharmacological versus psychological explanations for drug effects. Clinical drug trials using placebos were used successfully to test the efficacy of different psychoactive medications, such as ► imipramine, ► diazepam, and ► haloperidol. In contrast, Penick and Fisher (1965) conducted a study to test expectancies in which students were administered epinephrine or placebo while being told that they had received a drug that was either sedating or stimulating; they found that there were moderate expectancy effects such that some students reported feeling sedated on the epinephrine. Despite the promise of this area of study, there were methodological limitations that called for a more rigorous experimental design.

The ► balanced placebo design corrected for these limitations and allowed researchers to separate true pharmacological effects from the effects induced by ► expectancy set, or instructions that one has consumed a substance. Applied to the effects of ► alcohol, individuals received either an alcoholic beverage or non-alcoholic beverage and were given information about whether or not their beverage contained alcohol (Marlatt and Rohsenow 1980). As illustrated in Fig. 1, four distinct groups were created; two groups were given correct information about the alcoholic content of their drink (i.e., received alcohol/told alcohol; received no alcohol/told no alcohol), whereas the other two groups were told that they were given the opposite of what they actually received (i.e., received placebo/told alcohol, received anti-placebo/told no alcohol). The placebo was a non-alcoholic beverage designed to mimic an alcoholic drink, whereas the anti-placebo was an alcoholic beverage disguised as a non-alcoholic beverage. By comparing the behavior of those individuals who believed they received alcohol and actually did to the behavior of those who believed they received alcohol but did not, researchers were able to disaggregate the effects caused by alcohol from the effects of simply expecting alcohol.

		Participants actually receive…	
		Alcohol	No alcohol
Participants expect to receive…	Alcohol	Both pharmacological and expectancy effects	Expectancy effects only (given placebo)
	No alcohol	Pharmacological effects only (given anti-placebo)	No effects

Expectancies and Their Influence on Drug Effects. Fig. 1. Balanced placebo design depicting the four groups and measurable effects of the experimental manipulation.

Early alcohol research with the balanced placebo design demonstrated that both pharmacological and expectancy effects affected overall behavior, but that expectancy effects have greater effects on social behaviors (Hull and Bond 1986). Likewise, studies evaluating the effects of placebo versus marijuana found that previous experience with marijuana and the subject's expectancies were predictive of difficulties differentiating placebo from active drug. It was hypothesized that frequent users were responding to marijuana-related cues (e.g., smell, taste) rather than the true potency of the drug. In studying chronic pain management, it was found that placebo effects constituted a significant proportion of pain reduction attributed to analgesics, but placebo was not effective for those who held negative expectancies about the utility of the drug. The application of the balanced placebo design to nicotine studies yielded results that suggested that the expectation of ► nicotine in gum increased abstinence among smokers trying to quit. Mixed results were found in a study of ► cocaine versus placebo effects, with some studies supporting placebo effects and others finding pharmacological effects to outweigh placebo (Earleywine 2005). These and other findings led to the reasoning that placebo effects were based on people's beliefs about the effects of the drug; therefore, these beliefs could be studied outside of experimental designs, leading to the study of outcome expectancies as unique predictors of psychoactive drug use.

Substance-related outcome expectancies, or beliefs about the expected outcomes of the substance, have been differentiated into explicit and implicit types based on whether or not the individual is aware of the expectancy. Explicit expectancies are higher-order cognitive processes that can be deliberately recalled, reflected upon, and discussed. Implicit expectancies are automatic processes that do not rely on the individual's awareness to motivate behavior. Although evidence is limited, the current research on explicit and implicit expectancies has shown that each provides a unique contribution in predicting substance use (Goldman et al. 1999; Wiers and Stacy 2006). This is further supported by the existence of divergent explicit and implicit expectancies. Because the individual is aware of his own explicit expectancies, these

expectancies are subjected to cortical processing and cognitive filters such as social desirability. Researchers have yet to determine the association between implicit and explicit expectancies, but current hypotheses are that they are different facets of the same cognitive construct, discrete cognitive processes, or temporally-related constructs (i.e., explicit cognitions precede implicit cognitions such that learning becomes more automated over time, Wiers and Stacy 2006).

Explicit Expectancies

Explicit expectancies are measured using surveys that ask individuals to report their expectations about the behavioral and affective outcomes of using a psychoactive drug. Expectancy measures have been developed for alcohol, marijuana, tobacco, and cocaine (Patel and Fromme 2009). Many assessments evaluate both positive, or activating, and negative, or inhibiting, expectancies. As each person has multiple beliefs about using psychoactive substances, it is important to assess both positive and negative expectancies to determine how these beliefs act together to predict behavior. Studies have suggested that positive expectancies are more closely aligned with the initiation and maintenance of substance use, whereas negative expectancies are associated with past or decreased drug use (Jones et al. 2001).

Among studies evaluating expectancy effects on alcohol use, explicit expectancies have been shown to influence both the frequency and quantity of alcohol consumption, binge drinking, and alcohol-related consequences (Jones et al. 2001). The relation between these distinct measures of alcohol use and explicit expectancies suggests that expectancies shape decisions about alcohol consumption at many levels. The literature on tobacco use and expectancies demonstrates that stronger expected outcomes are found among smokers and more robust expectancies predict smoking after abstinence. Marijuana- and cocaine-related expectancies are similarly associated with more frequent use of each respective drug (Patel and Fromme 2009).

Implicit Expectancies

The influence of implicit expectancies on substance use has been shown to be as robust as that of explicit expectancies (Wiers and Stacy 2006). Alcohol use can be predicted by implicit expectancies among college students, at-risk youth, and community samples. Implicit expectancies are also associated with greater tobacco use, increased cravings for tobacco, and a higher likelihood of relapse after smoking cessation. Preliminary studies evaluating implicit expectancy effects on marijuana, opiates, and cocaine suggest that implicit expectancies are important factors in predicting drug use (Rooke et al. 2008).

Implicit expectancies are measured using experimental tasks that attempt to isolate different aspects of implicit cognition. Measurable areas of implicit cognition include attentional bias, arousal, and memory associations. ▶ Attentional bias refers to the identification of drug-related cues faster than cues not typically associated with drugs. Drug abusers demonstrate greater attentional bias toward drug-related cues. Implicit arousal assesses the level of physiological arousal and/or the level of arousal-related cognitions in response to the presentation of drug-related cues. Increased cognitive or physiological arousal in response to substance-related cues is associated with higher levels of drug use. Associative memory tasks present individuals with ambiguous words or sentences, which elicit a free association response that may be related to drug use. It is hypothesized that repeated experiences with psychoactive drug use leads to the development of specific memory associations between the drug of choice and ambiguous cues. Endorsing a greater number of drug-related associations predicts heavier drug use (Rooke et al. 2008; Wiers and Stacy 2006).

Harnessing Expectancies for Therapeutic Change

Expectancies have long been used for therapeutic change using placebos in medical settings. Placebos can include sugar pills, non-therapeutic doses of medications, therapies that are not empirically-supported, and medications that have not yet been proven effective for a specific disorder or population. In relation to psychotropic medication, the latter is a common occurrence because of the number of new drugs available and limited efficacy research, particularly among children and adolescents. Research in the past three decades has increasingly focused on finding treatments that surpass placebo effects; however, the utility of placebo effects continues to be a source for effecting change.

▶ Expectancy challenge interventions are designed to identify inaccurate expectancies and provide correct information about the effects of drug use. Findings for the efficacy of this intervention have been mixed, although there is evidence that expectancy challenges lead to transient reductions in drug use (Jones et al. 2001). Another promising area for reducing substance use is strengthening negative expectancies, which are related to decisions to reduce drug use (Jones et al. 2001). ▶ The attentional retraining intervention was designed to specifically target and reduce attentional bias for drug-related stimuli (Wiers and Stacy 2006).

Interventions that target both types of expectancies may be more effective in achieving sustained changes in substance use. This is supported by the evidence that heavy drinkers endorse positive explicit expectancies but hold negative implicit expectancies (Wiers and Stacy 2006). Conversely, addicted individuals who enter recovery may find that the opposite holds true; they endorse negative explicit expectancies but continue to experience physiological arousal and attentional bias, which undermines their efforts. This dissociation of explicit and implicit expectancies may be explained by cognitive dissonance or self-justification (e.g., "If I use the drug, I must enjoy it;" "If I have stopped using the drug, it must be bad") or may represent internal conflict over the decision to engage in substance use. Regardless of the mechanism, it appears important to address both types of expectancies in efforts to understand or to change substance use.

Conclusion

The decision to use psychoactive substances is influenced by numerous internal and external factors, including biological, genetic, and social phenomena. Cognitive determinants alone do not explain substance use; however, it is apparent that both explicit and implicit expectancies play a significant role in the etiology, maintenance, and cessation of substance use. Given their individual contributions, both types of expectancies are necessary in understanding substance use and creating effective interventions.

Expectancy Challenge

Definition

An expectancy challenge is an intervention designed to provide experiential demonstrations of expectancy effects through the use of placebo and active drug effects. Early expectancy challenges provided individuals with placebos but stated that they received an active drug. After administration, information about expectancies and their influence on behavior was provided. Recent expectancy challenges have used attentional bias to activate expectancies prior to administration of the substance or placebo. Other procedures provide either psychoactive drugs or placebos to individuals in the same group and ask group members to determine who has received the actual drug.

Expectancy Set

Definition

Expectancy set refers to the belief that a psychoactive substance has been consumed, regardless of whether or not it has been. During experiments designed to evaluate expectancy and pharmacological effects, instructions are given that either accurately or incorrectly inform individuals about whether they received a placebo or psychoactive substance to activate the expectancy set.

Externalizing Disorders

Synonyms

Disruptive behavior disorders

Definition

Disorders characterized by disruptions in the ways that individuals interact with their environments. Examples include attention-deficit/hyperactivity disorder, substance use disorders, conduct disorder, pathological gambling, and kleptomania. Externalizing disorders are often diagnosed in late childhood and adolescence, at a time when impulsivity is high. Contrast to internalizing disorders, characterized by disruptions in the ways individuals deal with their emotions.

Extinction

Synonyms

Habituation

Definition

A process that becomes active in certain situations and that leads to a reduction in the expression of a learned behavioral response. In operant conditioning, extinction typically refers to a procedure that reduces the rate at

which a previously acquired operant response is emitted. The subjects (laboratory animals or humans) are first trained to make an operant response (e.g., lever press) to earn a reinforcer. Once stable responding is obtained, the reinforcer is no longer presented when the operant response occurs. The number of responses decreases with repeated extinction sessions. Conversely, punished responses are strengthened after a punishing stimulus is withheld. In Pavlovian (classical) conditioning, extinction typically refers to the continued presentation of the conditioned stimulus with the unconditioned stimulus withheld; this results in a decrease in the magnitude of the conditioned response across repeated presentations of the conditioned stimulus. Extinction appears not to be the complete erasure or destruction of old learning, but the acquisition of new learning that competes with or inhibits the expression of the previously learned operant or Pavlovian conditioned response. Recent research on extinction learning has identified behavioral processes and distinct neurobiological mechanisms that are distinct from those responsible for the original conditioning, involving active processes of relearning about changed contingencies.

Extracellular Recording

Victoria L. Harvey, Anthony H. Dickenson
Neuroscience, Physiology and Pharmacology, University College London, London, UK

Synonyms

Measurement of neuronal activity

Definition

Extracellular recordings are used to monitor neuronal activity from outside the cell. It provides a means to measure patterns of action potentials within many areas of the peripheral and central nervous systems. In addition, massed activity can also be recorded. The effects of pathology and drugs can be investigated over extended time-courses using this technique.

Principles and Role in Psychopharmacology

Principles of Extracellular Recording

Richard Caton (1842–1926), who performed ► electroencephalography (► EEG) from the surface of living brains in animals, first discovered the electrical nature of the brain (Caton 1875). These electrical impulses, in the form of ► action potentials, underlie the information processing capabilities of the central nervous system (CNS). The pattern, frequency, and coding of this activity allows messages to be transferred from one area to another of the CNS. Extracellular recordings represent a very powerful technique for investigating the function within CNS pathways, since it provides both high-resolution information from neural tissue in vivo and in vitro and information on the spiking (output) and synaptic activity (input) of neurons in a particular recorded area. Paired with our understanding of anatomy, recordings can reveal information on the input–output function in neuronal networks. In comparison, intracellular recordings and ► patch-clamp recordings, by their very nature, produce short lasting recordings of underlying events such as ► EPSPs (► excitatory postsynaptic potentials), ► IPSPs (► inhibitory postsynaptic potentials), and channel activity, whereas extracellular recordings can provide hours of recording, rendering the approach suitable for examining both detailed response characteristics and also pharmacological manipulations. The patterns of activity can be viewed and monitored in real time and so extracellular activity allows neuronal function to be studied in normal conditions and then be compared with pathological or dysfunctional states neuronal activity. Changes in neuronal activity in response to pharmacological manipulation can also be assessed. Importantly, neuronal activity provides an objective and unbiased way of observing changes in neuronal systems and these quantitative measures of firing of a neuron are less subjective than a behavioral response.

The general principle of extracellular recordings involves detecting the changes in the membrane potential of neurons, which occur during the firing of action potentials. Differences in the voltage fluctuations between the recording electrode (placed in the target tissue) and a reference wire (placed at a more distal site) are recorded. The firing of action potentials requires the transient opening of a sodium channel and since the concentration of sodium is greater outside of the neuron than inside, the sodium flows down its concentration gradient. This reduction of positive ions from the extracellular environment is observed as a negative voltage fluctuation with, respect to the reference electrode. Commonly, these

signals are small (<1 mV) and require signal amplification, and filtering with low- (<1 Hz) and high-pass (>3 kHz) filters, to produce a useful measurable output. Therefore, extracellular recording allows responses to be recorded and quantified as a result of controlled sensory or electrical stimulation, either as a means of activating neurons in one area to identify functional connections, or used as a conditioning stimulus or even simple ongoing activity. Once these responses have been measured, it is then possible to apply drugs by a wide range of routes, namely systemic, local (icv, by microinjection or spinal), or directly to the neuron.

Drugs can be used as agonists to activate either excitatory or inhibitory receptors, using their effects on action potentials as a measure of the existence of that receptor in the particular circuit. Antagonist studies, however, are likely to be the most powerful, since the physiological activation of a particular receptor, by release of the endogenous transmitter in the pathway under study, can be evidenced by the ability of a drug that blocks a receptor to alter activity in the neuron. This type of study can further be used to study the potential changes in transmitter systems in pathophysiological events by comparing responses between control and experimental groups. In this context, care is needed to ensure that similar populations of neurons are recorded in both groups to allow valid comparisons. In a similar way, the same measures can be made in wild-type and transgenic mice to allow functional roles of protein products to be ascertained in situations where pharmacological tools are lacking or insufficiently selective.

Technical Considerations

Extracellular activity is most often recorded in vivo under anesthesia throughout the study or, in the case of activity in unrestrained animals, have a recording device secured in place under surgical anesthesia. In the former case, volatile anesthetics such as isoflurane or halothane, often delivered in a gaseous mixture of N_2O:O_2, are used, with anesthesia maintained at a steady state throughout the recording period. Other approaches use urethane, pentobarbitone, etc. as anesthetics, but here fluctuations in levels with time may be issues. In most studies of this nature, the animals will be placed in a stereotaxic frame to maintain stability at the recording site during electrophysiological recordings and allow for defined brain areas to be located using coordinates found in a stereotaxic atlas; the placement of the electrode is confirmed histologically at the end of the experiment.

Electrodes of many types can be used, ranging from glass to parylene-coated tungsten. The ways in which action potentials or other forms of activity are monitored and measured are varied, but in general terms: a headstage will receive input from the recording electrode and often differential recordings are made where activity from the muscle, cardiovascular, and respiratory systems as well as an eventual electrical interference, from the surrounding environment, is subtracted from the main input. Efficient grounding of the recording system is necessary for high signal-to-noise recordings.

Equipment is needed to amplify and differentiate the input, to allow filtering between defined frequencies, and often the signal is monitored by both audible and then visible means on an oscilloscope. Neurones are differentiated according to their amplitude by use of a window discriminator with adjustable window height, to separate activity from the baseline background noise, or to discriminate a single neuron based on waveform and amplitude. The activity is then quantified and further analyzed, mostly online by use of an interface linked to a computer, where the captured data is quantified, analyzed, and displayed using software.

The ability to monitor action potentials in a dynamic fashion can be used in many ways. The recording of single unit activity allows an unequivocal measure of the integrated responses of a single neuron, but mass activity of neuronal populations can also be measured as ▶ field potentials or multiunit recordings and activity of more than one single unit in an area can be measured simultaneously using electrode arrays.

Single-unit Recordings

In vivo extracellular recordings can be performed with relatively little damage to the surrounding tissue. Single-unit recordings using an electrode with a small tip (<1 μm, microelectrode) can be used to monitor the electrical activity of a single cell. Neuronal activity is recorded once the microelectrode is positioned in proximity to a neuron. Current fields, generated by action potentials, are detected through the tip of a microelectrode and are displayed as small voltage deflections occurring in the millisecond range. Stimulation can be used to measure the postsynaptic effects of an afferent input to a neuron. Electrical pulses are applied to a stimulating electrode to activate neurons that project to where a target cell is recorded. For example, tungsten microelectrodes positioned in the dorsal horn of the spinal cord of rats, in an area receiving information from the hindpaw, can be used to measure the activity of second-order neurons receiving both afferent information from the periphery and descending modulation from the brain (Urch and Dickenson

2003). Neuronal activity is recorded in response to a wide range of stimuli applied at the periphery. Typically, post-stimulus time histograms (PSTHs) summating neuronal activity from a series of trials are compiled, allowing the measurement of even relatively weak responses. Together with pharmacology, this approach can be used to investigate the mechanisms involved in the transmission and processing of nociceptive information, for example (Suzuki et al. 2002).

Multi-unit Recordings

By increasing the diameter of the recording electrode, or by using multielectrode arrays, multi-unit recordings can be performed measuring the activity of several neurons simultaneously. Multi-unit recordings are often performed in conscious freely moving animals and can provide information on integrated systems facilitating the understanding of the transformation of sensory input to its functional behavioral output. Normally, the animals have been trained for a particular behavior and the aim is to look for a neuronal correlate to this behavior. This approach has proved particularly successful in the ▶ hippocampus where "place cells," which exhibit high-frequency firing in response to specific location, were first described (O'Keefe and Dostrovsky 1971). This technique can be used to observe both the synchronized activity of the neurons, within the locality of the recording electrode, and identify the number and type of cells responding to the stimulus in different brain areas. This process is known as spike sorting, where the time-course of a particular spike is defined by the size and shape of a neuron and its position relative to the recording electrode. Analysis based solely on changes in amplitude can be difficult to interpret as neurons are physiologically heterogeneous, such that the activity in one neuron may cancel out the activity in an opposing neuron. Thus, more sophisticated algorithms have been developed to separate and identify the activity produced by each individual neuron in the local vicinity.

In vivo recordings permit recordings from intact neuronal networks; however, it may be difficult to gain access to certain target structures. Recordings from in vitro studies, therefore, can be used to provide information from such areas and avoid any potential problems associated with anesthesia. In vitro electrophysiology can be performed on cell cultures, acute or cultured tissue slices, and isolated superfused structures (e.g., brainstem). Acutely isolated neurons, by mild enzymatic digestion of brain slices, and cultured neurons offer advantages over in vivo preparations, as they allow direct visualization using a microscope. The administration of ligands of defined concentrations can be applied rapidly and repeatedly, and molecular targets can be isolated by pharmacological manipulation using agents known to block undesired systems. However, these preparations lack the integrity of network interconnectivity and are devoid of the long-range targets that are present in in vivo recordings.

Similar to in vivo recordings, in vitro recordings can be performed extracellularly (as well as intracellularly). Because of the small signal, neuronal activity is often obtained using multi-unit recordings (field potentials) observing changes in the potentials of the neurons with respect to the recording electrode, visualized as a change in amplitude. The activity of individual neurons cannot be distinguished; rather the activity of a group of neurons is recorded as a field potential. This approach has been employed with great success in understanding the role of the hippocampus. For instance, the concept that learning and memory might be underpinned by persistent changes in the strength of synaptic contacts within the hippocampus, a structure with clearly defined pathways, laminae, and circuits, was borne out by the ability to activate a large number of synapses using an extracellular stimulator (e.g., perforant path) and record large responses of many cells simultaneously with an extracellular electrode placed in another area such as the granule cell layer or pyramidal layer (Bliss and Lømo 1973). This paved the way for the numerous studies of synaptic activity related to plasticity in the brain, with ▶ long-term potentiation (LTP) being the key proposed mechanism in this regard.

Carbon Fiber Amperometry

▶ Carbon fiber amperometry can be used to investigate exocytosis of neurotransmitters and hormones from presynaptic neurons and other secretory cells. Much of our current understanding of vesicular fusion and subsequent transmitter release has been gained by amperometric recordings (either alone or in combination with other techniques), such as the identification of the fusion pore (the initiating event of exocytosis), kiss-and-run fusion (fast vesicle recycling), and the understanding of the interplay between various parts of the synaptic machinery (e.g., Munc18-1/syntaxin) (Chow et al. 1992; Neher 1993).

The general principle involved relies on the measurement of amperometric spikes resulting from the electrochemical current elicited by the oxidation and reduction of certain molecules. This can be measured by placing a carbon fiber electrode held at a constant potential (amperometry) or cycling (voltammetry) close to the cell of interest. Certain neurotransmitters (namely monamines and catecholamines) lose (oxidation) or gain

(reduction) electrons at characteristic voltages, allowing the identification of particular brain chemicals. This approach provides information regarding the reuptake and metabolism of transmitters and vesicle release probability, but is limited to those cells that secrete a detectable substance. More recently, this technique has been developed by pairing it with other types of electrophysiology such as ► patch-clamping (patch amperometry) allowing the simultaneous determination of the fusion pore conductance, vesicle size, and the kinetics of transmitter release from the same vesicle. Fluorescence imaging is also employed, tagging proteins involved in the exocytotic machinery, thus allowing the investigation of the spatiotemporal dynamics of neurotransmission and secretion. Further advances have been made in the form of multielectrode arrays (MEAs) to study exocytotic events from multiple sites avoiding problems with micromanipulation, and this strategy has proved useful in the understanding of neuronal communication in brain slices, neuronal cultures, and has been used in drug discovery.

Extradimensional

Synonyms

ED

Definition

In the context of a ID/ED task, the extradimensional (ED) stage involves discriminating between two (generally novel) stimuli that differ from each other in at least two dimensions (e.g., color and shape), but for which the relevant discriminative dimension (e.g., shape) is unattended because the irrelevant dimension (e.g., color) has been primed by prior experience. In the ID/ED task, the critical comparison is between the ID and ED stages: although both are formally novel acquisitions, prior experience biases attention such that there is a benefit of ID over ED acquisition.

Extrapyramidal Motor Side Effects

Synonyms

EPS

Definition

The extrapyramidal system is a neural network located in the central nervous system, which is involved in the coordination of movement. Extrapyramidal symptoms refers most commonly to the side effects of many antipsychotics that affect movements. They include neurologic syndromes such as dystonia, dyskinesia, Parkinson-like disturbances including tremor, rigidity, and bradykinesia as well as akathisia. These adverse events can occur both during acute and the chronic treatment with antipsychotics. They are sequelae of the dopamine antagonist properties of antipsychotics. In general, they are dose-dependent and more severe and frequent with first-generation antipsychotics than with the newer drugs.

Eye Movement Tasks

Samuel B. Hutton
Department of Psychology, University of Sussex, Falmer, Brighton, UK

Synonyms

Oculomotor tasks; Eye tracking; Saccaddes; Smooth pursuit

Definition

Eye movement tasks are a powerful tool with which researchers can study the effects of pharmacological compounds on brain function. Although there are several different classes of eye movements (see Leigh and Zee 2006), two types are particularly relevant to psychopharmacological research. Saccadic eye movements are rapid, conjugate movements of the eyes, which serve to orient the high acuity foveal region of the retina onto a specific region of visual space. ▶ Smooth pursuit involves slower eye movements that serve to keep an object foveated if it moves across our field of vision. Both saccades and smooth pursuit eye movements are influenced by ▶ endogenous factors, such as our goals and expectations, as well as ▶ exogenous factors, such as the size, shape and luminance of an object in the visual field, and as such can provide important insights into the effects of pharmacological compounds on cognitive function. In addition, eye movements made to more complex stimuli, such as faces or scenes can also reveal important information concerning cognitive function.

Principles and Role in Psychopharmacology

The use of eye movement tasks as a tool with which to investigate the effects of pharmacological interventions on brain function has a number of distinct advantages. Firstly, sophisticated eye tracking technology means that eye movements can now be measured with exceptional accuracy and reliability. Secondly, the neural systems involved in eye movement control have been well established by neurophysiological studies in non-human primates and lesion studies in humans – it has been argued that the oculomotor system provides researchers with a "microcosm of the brain" (Carpenter 1994). Thirdly the neural systems involved in eye movement control overlap considerably with those that mediate important cognitive processes such as those involved in ▶ attention and ▶ working memory, and the simplicity of eye movement tasks enables them to be manipulated in ways that allow specific cognitive processes to be isolated. Finally pharmacological compounds have been shown to have replicable effects on a range of eye movements.

Eye Movement Tasks

The majority of research into the effects of pharmacological compounds on eye movement function has used two very simple paradigms. In the ▶ prosaccade task participants typically fixate a central stimulus (such as a small cross) for a short period of time and then make a saccade towards a sudden onset target which appears in the left or right hemifield. Key metrics include the latency of the saccade (e.g., its reaction time with respect to the target onset), its amplitude, duration and peak velocity. In a standard ▶ smooth pursuit task participants are asked to follow a moving target (typically a small circle) with their eyes. The target moves backwards and forwards along the horizontal axis, with either a constant or sinusoidal velocity. Key metrics include pursuit velocity gain (the ratio of the eye velocity to target velocity) and the number of saccades made during pursuit. Reductions in pursuit velocity gain are typically compensated for by in an increase in the number of corrective "catch-up" saccades.

The prosaccade task seems, on the surface, to require very little in the way of cognitive processing, but the average prosaccade latency (~190 ms) is around 100 ms longer than would be required if the response was simply a reflex. It has been argued that this extra time reflects a "decision" process – our brain needs to determine not just where to look, but whether it is worth looking there at all. This decision reflects the influences of both ▶ exogenous (bottom up) and endogenous (top down) factors, and is clearly related to the processes that determine where we allocate our attention. The precise nature of the relationship between saccades and visual attention remains a topic of considerable debate, but there is agreement that the neural mechanisms underpinning them overlap considerably. Following a target as it moves horizontally also seems to require relatively little in terms of cognitive effort. Again, though, research has demonstrated that smooth pursuit eye movements involve a surprisingly complex set of information processing stages, including the generation of an internal model of the target's velocity.

Other eye movement tasks that have a more obvious "cognitive" involvement are increasingly being used in psychopharmacological research. These tasks typically place a greater role on higher cognitive functions than the prosaccade and smooth pursuit tasks described above. The ▶ antisaccade task is an important variant of the prosaccade task. The stimulus timings and properties

are identical in the two tasks, but in the antisaccade task participants are instructed to saccade to the mirror image location of the sudden onset target rather than towards it. The task thus requires participants to inhibit a highly prepotent response (to saccade towards the sudden onset target) and initiate an internally generated response (to saccade to the mirror image location). Many neuropsychological tasks sensitive to damage to the prefrontal cortex (e.g., Stroop) share this requirement to respond on basis of an internal goal as opposed to an external stimulus, and patients with lesions to this area, as well as patients with psychiatric disorders such as ► schizophrenia, in which prefrontal dysfunction is implicated, make a large number of antisaccade errors (prosaccades made towards the target). The key metric of the antisaccade task is the proportion of trials in which antisaccade errors occur. However, the latency, amplitude and velocity of correct antisaccades can also be informative.

There are other simple eye movement tasks that are routinely used in other research settings, but which have yet to be widely adopted in psychopharmacological studies. These include remembered and predictive saccades, and predictive pursuit. Eye movement tasks that use more complex stimuli are also potentially informative, and can also exploit the close relationship between eye movements and attention. For example, in visual search tasks, participants are required to identify one or more target items (e.g., the letter "L") presented in an array of distractors (e.g., the letter "T"). Standard visual search tasks provide a single measure – reaction time. When combined with eye tracking, however, metrics such as the number of refixations on previously identified targets or the average angle between saccades can provide important information concerning the functionality of working memory and attentional processes, and the high level strategies participants are using to perform the task. Eye tracking can also be used to provide important insights into performance on other standard tasks of cognitive function. In the dot-probe task, for example, two images are presented simultaneously for a short period of time, and participants' reaction time to a dot that appears subsequently behind one or the other is measured. The task is typically used to measure ► attentional biases (e.g., towards drug related stimuli in a drug addict) but can also be used to index potentially subtle effects of psychopharmacological compounds on specific types of information processing – for example, whether ► alcohol biases attention towards negative or positive facial expressions. Recording eye movements during dot probe performance allows variables such as the time to first fixation, first fixation duration and total dwell time for each of the images to be measured. These measures can potentially reveal subtle effects of pharmacological compounds that a simple reaction time measure may be insensitive to.

Eye Tracking Techniques

Eye movements can be recorded using a variety of techniques (see Duchowski 2007 for a comprehensive discussion). Early research mainly used electro-oculography, in which pairs of electrodes placed near the eye record small changes in voltage that occur as it moves. Most current eye trackers are video based, and use high speed cameras and sophisticated image analysis systems to establish the location of the pupil and the corneal reflection of an infrared light source. After a simple calibration procedure the vector between these two points can be used to determine the location of gaze. In some eye tracking systems the camera recording the eye movement is mounted on a lightweight head-set, but increasingly remote optics are being used, with fixed cameras placed beneath the monitor on which stimuli are displayed.

Eye Movement Tasks in Psychopharmacological Research

There are two broad areas of psychopharmacological research in which eye movement tasks have been widely used. (1) investigations into the acute effects of pharmacological compounds on psychological functioning in healthy participants, and (2) investigations into the more chronic effects of pharmacological treatments in clinical (typically psychiatric) populations. Evidence from these two fields of research will be considered separately. A very thorough treatment of both literatures is provided by Reilly et al. (2008).

Acute Effects in Healthy Participants

The majority of studies into the acute effects of pharmacological compounds on eye movements have been done in the context of tolerability studies. A number of different psychopharmacological compounds have been shown to have replicable effects on eye movements. Early research established clear dose dependent relationships between serum concentrations of ► benzodiazepines such as ► diazepam and ► temazepam and saccade peak velocity – saccade velocity decreases as serum concentration of benzodiazepines increases. These effects are presumably mediated via GABA-ergic connections between the caudate nucleus and the substantia nigra pars reticular, and between the nigra and the superior colliculus – both regions that lesion studies have confirmed are critical for the generation of saccades. The clear relationship between saccade velocity and benzodiazepine dose led to the use of eye movement tasks as an index of the sedative effects of

psychopharmacological compounds. Recent studies have confirmed that saccade velocity is more sensitive to the sedative effects of benzodiazepines than other common measures of altertness such as rating scales or measures of psychomotor speed. Benzodiazepines also have consistent effects on smooth pursuit velocity. Again studies have demonstrated a dose dependent relationship such that increases in serum concentration of benzodiazepine are associated with a reduction in smooth pursuit velocity gain, and consequent increase in the number of corrective "catch-up" saccades.

Other pharmacological compounds, in particular ▶ first generation antipsychotics, whose primary action is the blockade of dopamine receptors and anticonvulsant/mood stabilizing compounds such as ▶ lithium have also been found to decrease prosaccade peak velocity, and disrupt smooth pursuit performance. In both cases, the effects likely reflect the sedative properties of these compounds on CNS function. The effects of ▶ second generation antipsychotics on eye movement tasks have not been well established, although reductions in prosaccade velocity have again been observed.

Stimulants, such as ▶ amphetamines and cholinergic agonists like ▶ nicotine, do not appear to improve performance on standard prosaccade or smooth pursuit tasks, possibly because performance on these simple tasks is typically already optimal. Interestingly, SSRIs and 5HT agonists have been found to impact on some eye movement metrics –most notably resulting in increases in saccade peak velocity and pursuit velocity gain. The underlying mechanism by which these improvements are mediated is not clear (they do not appear to reflect an increase in alertness), but there are known serotonergic pathways in brain-stem regions involved in saccade generation.

Despite the well established effects of benzodiazepines and antipsychotics on prosaccade and smooth pursuit function, comparatively few studies have explored the effects of these compounds on antisaccade performance, or other eye movement tasks requiring greater attentional and cognitive control. In one study ▶ lorazepam, but not ▶ chlorpromazine was found to increase antisaccade error rate (although not, surprisingly, antisaccade velocity). A larger number of studies have explored the effects of nicotine on antisaccade performance in healthy participants. Several studies have found that nicotine can increase correct antisaccade latencies and reduces the number of antisaccade errors. Nicotine has also been found to improve performance on visual search tasks in smokers, resulting in a reduction in the number of fixations on non-target items.

Treatment Effects in Patient Populations

As Reilly et al. (2008) note, given the potential advantages outlined earlier, it is perhaps surprising that the literature examining the effects of medication on eye movement function in patients with clinical disorders is comparatively limited. Whilst medication is often included as a factor in studies that have measured eye movement function in clinical populations, longitudinal randomized designs (which would allow direct inferences concerning the effects of different medications on oculomotor function) are rare. In addition, methodological differences between studies with respect to the eye movement tasks used make comparisons difficult. The effects of psychiatric and neurological disorders themselves (as opposed to medication effects) are reviewed comprehensively elsewhere (e.g., Leigh and Kennard 2004).

The effects of first and second generation antispsychotics on eye movement performance in patients with schizophrenia are perhaps the best characterized. In accordance with the findings of single dose studies in healthy participants, first and second generation antipsychotics have been found to reduce prosaccade velocity in patients with schizophrenia. Antipsychotic medications also result in a reduction in prosaccade amplitude – ▶ hypometria. This hypometria is particularly pronounced for endogenously generated saccades, such as occur in the remembered saccade task (in which participants initiate a saccade to a location based on their memory for where the target stimulus appeared) and the predictive saccade task (in which participants saccade to a target moving backwards and forwards between two locations at a predictable frequency). Interestingly saccade hypometria is a feature of patients with ▶ parkinson's disease, and thus may reflect decreased striatal dopamine availability. Performance on the antisaccade task does not appear to be effected by antipsychotic treatment, despite improvement in neuropsychological indices of cognitive function that can occur with treatment. Another important finding is that studies investigating changes in psychotic symptoms and eye movements as a result of treatment initiation in previously antipsychotic free patients have found that changes in both over time are unrelated.

Interestingly, mirroring their beneficial effects in healthy participants, nicotinic compounds have been shown to slightly ameliorate impairments in smooth pursuit and antisaccade performance in patients with schizophrenia. In contrast, anticholinergic compounds such as ▶ procyclidine have been found to impair performance on these tasks in this population.

The evidence concerning the effects of medication on eye movements in other disorders is sparse and often

contradictory. There is no consensus as to the effects of stimulants such as ► methylphenidate on eye movement task performance in patients with ► attention deficit hyperactivity disorder (ADHD). Some, but not all studies have found that treatment with dopamine agonists improves performance on some eye movement tasks in patients with parkinson's disease.

Limitations

Whilst one of the potential advantages of basic eye movement tasks such as prosaccades and smooth pursuit are their simplicity, there are a myriad of methodological variations in the ways in which these tasks are presented. It is becoming increasingly clear that small differences in apparently minor details such as the size of the target, its distance from the central fixation point or its temporal relationship with the offset of the central fixation stimulus, can all have a significant impact on metrics such as saccade latency and amplitude. These differences considerably complicate cross study comparisons. The situation is perhaps even more serious for more "cognitive" eye movement tasks such as antisaccades, in which differences in the way instructions are given has been shown to have an impact on the number of errors made (see Hutton 2008).

Future Directions

There have been comparatively few investigations into the effects of pharmacological compounds on variations on the standard eye movement tasks, such as the antisaccade task and predictive smooth pursuit. Even fewer studies have attempted to use eye tracking to explore the effects of pharmacological interventions on eye movements made to more complex stimuli (such as scenes or faces) or more complex tasks (such as visual search or matching familiar figures tests). Future research using these more complicated tasks, and related tasks that exploit the link between gaze and endogenous attentional processes, may provide important insights into the effects of pharmacological compounds on brain function.

Another important use of eye movement tasks in the future will be in pharmacogenetic studies. Researchers have already employed eye movements as intermediate phenotypic markers of schizophrenia in family genetic studies. In addition, several studies have established relationships between genotype and oculomotor function in patients with schizophrenia – for example, male patients with the Met/Met allele of the catechol-o-methyltransferase (COMT) Val/Met polymorphism had significantly better smooth pursuit performance compared to patients with other genotypes. Other research has found that the sensitivity of smooth pursuit velocity gain to benzodiazepines is moderated by genotype – carriers of the Ser385 allele, associated with alcoholism, demonstrated a smaller benzodiazepine induced reduction in pursuit velocity gain than non carriers. Such finding suggest that basic eye movement tasks such as prosaccade and smooth pursuit, as well as more complex eye movement tasks, will continue to provide researchers with important insights into the mechanisms through which pharmacological compounds impact on cognitive function.

Synonyms
Classical antipsychotics; Classical neuroleptics; Conventional antipsychotics; Conventional neuroleptics; Major tranquilizers; Old antipsychotics; Old neuroleptics; Traditional antipsychotics; Traditional neuroleptics; Typical antipsychotics; Typical neuroleptics

Definition
Antipsychotics introduced to the market in USA before ► Clozapine (before 1989).

Pharmacological Properties
► First-generation antipsychotics (FGA) is a heterogeneous group of ► dopamine D_2 receptor antagonists with different chemical, pharmacological and clinical profile. Main clinical characteristic of the FGA is more ► Extrapyramidal Motor Side-Effects (► EPSE), more frequent ► hyperprolactinaemia and less clinical efficacy if compared with the ► second-generation antipsychotics (SGA). There are, however, some exceptions from and inconsistencies in the definition above. For example ► amisulpride and ► risperidone, two SGA significantly increase prolactin levels and so some authors do not acknowledge hyperprolactinaemia as a good group differentiating factor. Moreover, clinical comparison of FGA and SGA gives ambiguous results. Today it is clearer that there are not sharp boundaries between FGA and SGA and maybe in the near feature more pertinent classification will be adopted.

Chemical Profile
Using chemical profiles FGA can be classified as ► butyrophenones (e.g., ► haloperidol, ► bromperidol, ► benperidol, droperidol, pipamperone, spiperone, trifluperidol).

Dibenzoxazepines: loxapine. Diphenylbuthylpiperidines: fluspirilene, penfluridol, ► pimozide. ► Phenothiazines (e.g., ► chlorpromazine, clopenthixole, ► fluphenazine, metophenazate, metotrimeprazine, periciazine, ► perphenazine, ► prochlorperazine, ► promazine, ► promethazine, prothipendyle, ► thioridazine, ► trifluoperazine, triflupromazine. Substituted benzamides: ► sulpiride. *Other tricyclic antipsychotics*: ► carpipramine, clorotepine, oxyprothepine. ► Thioxanthenes (e.g., chlorprothixene, cisclopenthixole, ► flupenthixole, ► thiothixene, ► zuclopenthixole).

Many of these compounds are no more on the market.

Low and High Potency Antipsychotics
From clinical as well as pharmacological point of view FGA can be classified as *high-potency* and *low-potency* antipsychotics. Potency refers to their affinity to dopamine D2 receptors and the average therapeutic dose, compared with a 100 mg of chlorpromazine (so called

chlorpromazine equivalent) (Baldessarini et al. 1988). The example of low-potency antipsychotics in light of ▶ evidence based medicine is chlorpromazine (Leucht et al. 2003). Low potency antipsychotics have been suggested to be more sedative than high potency antipsychotics but on the other hand induce less EPSE than high-potency antipsychotics. In sufficiently high doses, low potency antipsychotics are not, in principle, less effective than high potency antipsychotics such as haloperidol (Leucht et al. 2003). Low-potency antipsychotics induce more EPSE than ▶ clozapine, ▶ olanzapine and risperidone but not more than other SGA (Leucht et al. 2009). Low-potency antipsychotic are less sedative than ▶ clozapine, ▶ NNH (Number Need to Harm) 13 [7–220], but do not differ in this respect from other SGA (Leucht et al. 2009). Weight gain is similar to that after SGA and higher than after ▶ aripiprazole and ▶ ziprasidone (Leucht et al. 2009).

High-potency antipsychotics induce more EPSE than low-potency antipsychotics and SGA. The typical representative of this group is haloperidol. NNH for haloperidol to induce EPSE was between 2 for clozapine and 5 for ▶ zotepine (Leucht et al. 2009). On the other hand haloperidol was associated with less weight gain than most of SGA and was not different from aripiprazole and ziprasidone in this respect (Leucht et al. 2009). Haloperidol was significantly less sedating than clozapine (NNH 5 [3–14]), ▶ quetiapine (NNH 13 [8–20]), and zotepine (NNH not significant) but significantly more sedating than aripiprazole (NNH 33 [20–1,001]; (Leucht et al. 2009).

Efficacy of the FGA

The recent ▶ meta-analyzes concluded that the FGA as a group were less efficacious than some but not all antipsychotics from SGA (Leucht et al. 2009). In Leucht et al. (2009) meta-analysis 95 studies were included with haloperidol, 28 studies with chlorpromazine, five studies with perphenazine and less than five with other FGA. So results from this meta-analysis are more related to haloperidol or chlorpromazine than to other FGA. In the concrete, FGA was less effective in overall change of symptoms than ▶ amisulpride, ▶ clozapine, ▶ olanzapine, and ▶ risperidone; in the management of positive symptoms FGA were less effective than amisulpride, clozapine, olanzapine, quetiapine, and risperidone; in the management of negative symptoms FGA were less effective than amisulpride, clozapine, olanzapine and risperidone, and in alleviation of depression FGA were less effective than amisulpride, aripiprazole, clozapine, olanzapine and quetiapine (Leucht et al. 2009). FGA are less effective in long term treatment of schizophrenia than olanzapine (NNT 17 [8–100]), risperidone (NNT 11 [7–33]), and ▶ sertindole (NNT 14 [8–50]). FGA improve ▶ quality of life less than amisulpride, clozapine and sertindole (Leucht et al. 2009).

Naturalistic (Effectiveness) Studies

Results from real world effectiveness studies such as ▶ CATIE (Rosenheck et al. 2006), and ▶ CUtLASS (Jones et al. 2006) suggest that mid-potency FGA compounds would have been more appropriate, because they are less likely to cause EPSE and they are not associated with sedation and weight gain. The representatives of this group are ▶ perphenazine and ▶ sulpiride. Efficacy of SGA was not better than perphenazine on ▶ PANNS total score (Rosenheck et al. 2006), cognition (Keefe et al. 2007), cost (Rosenheck et al. 2006), quality of life, and psychosocial functioning (Swartz et al. 2007).

Another pragmatic trial (EUFEST) compared the effectiveness of SGA with that of a low dose of haloperidol (1–4 mg), in the first-episode schizophrenia (Kahn et al. 2008). This pragmatic trial found lower discontinuation rate with SGA than with haloperidol. However, symptom reductions were virtually the same (about 60%) in all groups. Despite the fact that the difference in discontinuation rates was the primary outcome variable one cannot definitively conclude that SGA are more efficacious than is the low dose haloperidol in first-episode schizophrenia, since discontinuation rates are not necessarily consistent with symptomatic improvement.

Other Side Effects of the FGA

There are other typical side effects of the FGA than only EPSE and hyperprolactinaemia. These side effects are observed mainly in low-potency antipsychotics and are related to anticholinergic, antiadrenergic and antihistaminic activity. Anticholinergic activity of low-potency antipsychotics leads to dry mouth, blurred vision, difficulty passing urine, urinary retention, constipation, glaucoma and rarely ileus. Antiadrenergic activity can induce postural hypotension, reflex tachycardia, and sexual dysfunction (particularly erectile dysfunction). Antihistaminic activity is responsible for sedative effect and weight gain. Idiosyncratic side effects are: leucopenia or agranulocytosis, cholestatic jaundice, altered glucose tolerance, skin photosensitivity (sun block is important in sunny weather), pigmentation to skin or to eye, ▶ neuroleptic malignant syndrome. Some FGA can lower seizure threshold (i.e., chlorpromazine) or could prolong ▶ QT interval (chlorpromazine, droperidol, pimozide, thioridazine).

First-Order Elimination Kinetics

Synonyms

Kel

Definition

First-order elimination kinetics depends on the concentration of only one reactant (drug) and a constant fraction of the drug in the body is eliminated per unit time. The rate of elimination is proportional to the amount of drug in the body. The majority of drugs are eliminated in this way.

First-Rank Schizophrenic Symptoms

Definition

Psychopathological symptoms like delusional perceptions, commenting auditory hallucinations, thought withdrawal,

thought broadcasting, etc., which are strongly associated with schizophrenia, if a somatic cause is not present.

Fischer (F344)/Lewis (LEW) Rat Strains

Definition

The Fischer and Lewis rat strains are inbred rat strains independently developed as models of cancer susceptibility and tissue transplantation, respectively. Many differences between the F344 and LEW rats have been identified, leading to direct comparisons in studies of genetic contributions to disease-relevant differences in physiology and behavior, for example, drug susceptibility.

Cross-References

► Inbred Strains

Five-Choice Serial Reaction Time Task

Synonyms

5-CSRT; 5-CSRTT

Definition

A cognitive task initially developed for use in the rat, capable of examining the effects of neural, pharmacological, and behavioral manipulations on aspects of impulse control, accuracy of discrimination, response times, and perseveration. Animals are trained to detect flashes of light presented at one of five holes and to make nose-pokes at the appropriate location to receive a food reward. The task necessitates withholding of responding until stimulus onset. Measures include premature responses (a measure of impulse control) and accuracy of stimulus discrimination (attentional capacity). The translational version of this task for humans is the CANTAB five-choice serial reaction time test.

Cross-References

Fixed Ratio

Definition

A fixed ratio (FR) is a schedule of reinforcement that sets the contingency for the delivery of a reinforcing stimulus (i.e., a drug injection in the case of a self-administration experiment) according to a predetermined number of responses. Under an FR1 (or continuous reinforcement) schedule, a reinforcer would be delivered immediately following a single response.

Floropipamide

Definition

Floropipamide is a first-generation (typical) antipsychotic drug that belongs to the butyrophenone type indicated for the treatment of schizophrenia. However, it possesses more potent antagonist properties at 5-HT_{2A} than D_2 receptors. It can induce extrapyramidal motor side effects, hypotension, and fatigue, but it displays generally low toxicity. Extrapyramidal side effects with floropipamide appear to be less common than with other butyrophenones.

Fludiazepam

Definition
Fludiazepam is an anxiolytic benzodiazepine medication used in the treatment of anxiety disorders. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Long-term use may induce dependence with withdrawal reactions. Recreational use and abuse can occur.

Cross-References

Flumazenil

Synonyms
Flumazepil; Ro-15-1788

Definition
Flumazenil was the first substance found to act as an antagonist at the benzodiazepine site of the $GABA_A$ receptor. It competitively inhibits the effects of benzodiazepines and is used clinically to reverse benzodiazepine-induced sedation, and to diagnose and treat benzodiazepine overdose. It may also be used with imaging techniques to visualize $GABA_A$ receptors in the brain and has been invaluable as a research tool in experimental psychopharmacology for determining whether drug effects involve benzodiazepine receptors. It is a weak ► partial agonist, although its action is very much weaker as an agonist than as an antagonist.

Cross-References
► Benzodiazepines
► Sedative, Hypnotic, and Anxiolytic Dependence

Flumazepil

► Flumazenil

Fluoxetine

Synonyms
Prozac

Definition
Fluoxetine is a selective serotonin reuptake inhibitor (SSRI). One of the earliest of these drugs to be developed, it is widely perceived in the popular culture to be paradigmatic of the class. It is commonly used in the treatment of depression and the more severe anxiety disorders (e.g., obsessive–compulsive disorder, panic disorder). Fluoxetine is also approved for the treatment of bulimia nervosa, anorexia nervosa, and premenstrual dysphoric disorder. A distinguishing pharmacokinetic feature of the drug is its long elimination half-life (up to 4–6 days during long-term use and up to 2 weeks for the major active metabolite norfluoxetine). As with other SSRIs, the most common troublesome side effect of fluoxetine is sexual dysfunction (dysorgasmia and erectile dysfunction); mild side effects include drowsiness, headache, and nausea. Some patients develop a syndrome of psychomotor activation upon starting the drug, which has been characterized as similar to akathisia.

Cross-References
► Antidepressants
► Selective Serotonin Reuptake Inhibitors

Flupenthixol

Definition
Flupenthixol is a typical thioxanthene antipsychotic, sharing similar profile to phenothiazines. It acts as an antagonist at D1 and D2 dopamine receptors, as well as α-adrenergic receptors. Its antipsychotic effects are

thought to result from postsynaptic D2 receptor blockade. Due to its long-acting nature (elimination half-life ranging from 5 to 113 days after depot injection), flupenthixol is often used for maintenance treatment of schizophrenia. As with other typical antipsychotics, flupenthixol is associated with a high incidence of extrapyramidal symptoms, but it has less anticholinergic effects. Like many other antipsychotic agonists, it has also been used in experimental psychopharmacology to test the importance of dopamine receptors in various physiological and psychological phenomena; the different selectivity of the (+)- and (−)-isomers has to be taken into account.

Cross-References
► Antipsychotics
► First-Generation Antipsychotics

Fluphenazine

Definition
Fluphenazine is a first-generation antipsychotic in the phenothiazine class, which is also available in a long-acting intramuscular preparation. It exerts its action mainly via dopamine D2 receptors blockade. It has a fairly long half-life (up to 60 h) and is metabolized mainly by 1A2 and 2D6 CYP450 isoenzymes.

Cross-References
► First-Generation Antipsychotics
► Phenothiazines

Flurazepam

Definition
Flurazepam is a benzodiazepine that has anxiolytic, sedative, and anticonvulsant properties. It has a very long duration of action, mainly due to a long elimination half-life (24–100 h), and conversion to the active benzodiazepine metabolites hydroxyethyl- and desalkyl-flurazepam. Flurazepam has been used to treat insomnia and is subject to tolerance, dependence, and abuse.

Flutoprazepam

Definition
Flutoprazepam is a benzodiazepine derivative that has anxiolytic, anticonvulsant, hypnotic, sedative, amnesic, and muscle-relaxant properties. It is used mostly in Japan and Asia and can be abused. It is four times more potent than diazepam.

Cross-References
► Anxiolytic
► Benzodiazepine

Fluvoxamine

Definition
Fluvoxamine is a selective serotonin reuptake inhibitor (SSRI). It was one of the earliest of these drugs to be developed and widely marketed. Although originally released as an antidepressant, it is now commonly used in the treatment of obsessive–compulsive disorder. Fluvoxamine is also used to treat other anxiety disorders (e.g., ► panic disorder, ► social anxiety disorder). As with other SSRIs, the most common troublesome side effect of fluvoxamine is sexual dysfunction (dysorgasmia and erectile dysfunction). Milder side effects include drowsiness and headache. Fluvoxamine may be somewhat more likely to cause nausea and vomiting than other SSRIs.

Foetal Alcohol Spectrum Disorders

Kieran O'Malley
TMR Health Professionals, Belfast, Northern Ireland

Synonyms

Alcohol-related neurodevelopmental disorder; FAS; FASDs; Foetal alcohol syndrome

Definition

Foetal Alcohol Spectrum Disorder(s) are umbrella terms used to describe conditions arising in the infant, child and, later, adult, resulting from a *confirmed* range of prenatal alcohol exposure be it acute or chronic or low, high, or binge dose variety.

There are two diagnostic categories:

1. ► *Foetal Alcohol Syndrome (the ► Facial Dysmorphology Disorder)*
   (a) Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (i.e., flat upper lip, flattened philtrum, and flat midface)
   (b) Evidence of growth retardations in at least one of the following forms:
   - Low birth weight
   - Decelerating weight over time not due to nutrition
   - Disproportional low weight to height (Ht and Wt below tenth percentile)

   (c) Evidence of CNS neurodevelopmental abnormalities, such as:
   - Structural brain abnormalities, i.e., decreased cranial size at birth, microcephaly (head circumference under third percentile), partial or complete agenesis of the corpus callosum, and cerebellar hypoplasia
   - Neurophysiological abnormalities, complex partial seizure disorder, absence seizure, and other seizures
   - Neurological hard or soft signs (age-appropriate):
     - Motor: gross motor function; poor tandem gait, positive Romberg test, balance problems with fine motor function, fine motor problems with evidence of constructional apraxia, poor hand–eye coordination, motorically disorganized in the under 5 years age group
     - Sensory: abnormal sensation in upper or lower limbs, neurosensory hearing loss, abnormal visual, auditory, gustatory, olfactory, or tactile sensations, including hallucinations, regulatory disorder in the under 5 years age group

   (d) Attentional, cognitive, and language problems can also be found as in ARND.

2. ► *Alcohol-Related Neurodevelopmental Disorder (the Non-Facial ► Dysmorphology Disorder)*
   (a) No characteristic pattern of facial anomalies
   (b) No or little growth retardation
   (c) CNS deficits as for FAS
   (d) Also deficits shown in:
   - **Behavior**, with visual or auditory attentional problems, distractibility, poor impulse control, poor organizational skills, and poor adaptive functioning
   - **Cognition** with complex learning disorders, which are often a mixture of verbal and nonverbal inabilities, inability to link cause and effect, mathematics disorder with dyscalculia, poor insight, and impaired judgment.
   - **Language** with deficits in higher level receptive and expressive language i.e., the patient does not understand the "gist" of a social situation, has an impairment in social communication and interaction, and has problems in understanding and expressing emotional feeling i.e., ► alexithymia.
   - **Gross and Fine Motor problems** may also be found, as in FAS.

(Sources: Hagerman 1999; Koren et al. 2003; O'Malley 2008; Stratton et al. 1996; Streissguth and Connor 2001; Streissguth and O'Malley 2000).

Epidemiology

Foetal Alcohol Spectrum Disorders (FASDs) are more common than have been initially thought and it was the

University of Washington group who first estimated a figure of 9.1 per 1,000 live births. Although some populations namely Aboriginal or Native American have been deemed more susceptible to the effects of prenatal alcohol exposure, international research continues to show that FASD is prevalent in all ethnic populations in which the mother drinks alcohol during pregnancy.

Pathophysiology of Foetal Alcohol Spectrum Disorders

Streissguth and Connor (2001) reviewed animal studies of over 25 years that have demonstrated that heavy doses of alcohol administered to a wide range of laboratory animals produced a spectrum of CNS effects starting with the cell death **seen in nerve cells**. Also, prenatal alcohol has been demonstrated in many animal studies to interfere with the embryological development of most of the **neurotransmitters**. This has been reported by Manteueffel (1996), Stratton et al. (1996), O'Malley and Hagerman (1998), and Hagerman (1999).Deficits have been found in the dopaminergic, noradrenergic, serotonergic, GABAergic, cholinergic, glutaminergic, and histaminergic systems.

The deficits in dopaminergic and noradrenergic systems most likely are connected with the ► attentional deficit hyperactivity disorder (ADHD presentation of patients with FAS or ARND. Previous animal research on rats has demonstrated that the D1 receptors of the mesolimbic dopamine system are affected by prenatal alcohol more than the nigrostriatal or tegmental dopamine D1 receptor system.

Ongoing neurological research is analyzing the clinical effect of the prenatal alcohol disruption of the balance between ► GABA the inhibitory and ► Glutamate the excitatory neurotransmitter in the brain. Scientists in the USA have shown the kindling of seizures due to the effect of prenatal alcohol on the GABAergic cells in the hippocampus which leads to a lower seizure threshold.

Recently, a research has studied the effect of alcohol on inhibiting L1, an immunoglobulin cell adhesion molecule that promotes cell–cell adhesion, neurite outgrowth, cell migration, and synaptic plasticity.

Role of Psychopharmacology

Although this is used quite extensively with children, adolescents, or adults with FASD, it is important to remember that there are no US Food and Drug Administration (FDA) or UK National Institute for Health and Clinical Excellence (NICE) approved medications for these conditions. Thus, the use of medication in FAS or ARND has not been properly evaluated, and as O'Malley and Hagerman (1998) have commented, the brain of a prenatally brain-damaged infant, young child, or adolescent is especially vulnerable to an atypical medication response or side effects.

The role of medication is one of symptom control in order to facilitate other modalities of treatment. There is extensive literature on the psychopharmacotherapy of patients with mental retardation and also with brain injury, both of which are relevant to this patient population. Only a small number of studies have been performed on children or adolescents with mental retardation and comorbid psychiatric disorder. They have been reviewed by O'Malley and Hagerman (1998), Hagerman (1999), Byrne (2008), and O'Malley (2008).

If medication is being considered, it is essential to have a recent complete medical examination by a family physician or pediatrician to rule out any alcohol-related birth defects (ARBD) such as kidney or cardiac problems, to name a few (Stratton et al. 1996).

ADHD Symptomatology

The animal research, coupled with the evidence from Hagerman (1999) and O'Malley (2008), has indicated that prenatal alcohol affects the developing ► mesolimbic and not the fronto-nigral dopamine neurotransmitter system.

In mental retardation/intellectual disability studies on children, ► Methylphenidate relieves ADHD symptoms, but is less effective if the IQ is under 50. The previous research on animals and humans, as reviewed by O'Malley and Hagerman (1998), Byrne (2008), and O'Malley (2008), has indicated that dextroamphetamine (short or long acting) may be a better first-line psychostimulant than methylphenidate (short or long acting) for FAS or ARND patients with ADHD symptoms, as it modulates the mesolimbic dopamine system, whereas methylphenidate modulates the fronto-nigral dopamine system. A dose of 1 mg/kg/day is a good ceiling dosage, and 2 mg/kg would be likely to cause side effects such as aggression, irritability, schizoid demeanor.

Methylphenidate still remains a reliable medication and is probably a good second-line choice.

The biphasic newer preparations such as Concerta and Equasym appear to be useful after initial stimulant response is established. Studies need to be done to clarify the ► pharmacokinetics in these preparations, as patients with FAS or ARND often metabolize psychotropic drugs at a faster rate than patients without this developmental neuropsychiatric disorder. It is worth remembering that prenatal alcohol can affect the developing heart, kidney, and even liver, so side effects are more unpredictable. Blood pressure, ECG, blood sugar, and thyroid function should be tested.

FAS is a growth retardation condition, and long-term stimulants run the risk of lowering the growth hormone. A number of patients have shown decreased bone age or decreased linear growth due to long-term high dose psychostimulants (usually, methylphenidate).

A clinically significant but also potentially negative side effect of psychostimulants in FAS or ARND is their ability to increase arousal and help the patient focus, but at the same time contribute to an increased level of ► perseveration especially in patients with pre-existing autistic or obsessive features.

► Atomoxetine (Strattera) seems to be more helpful in older children or teenagers with ADHD symptoms and has less risk of dependency. Liver function and ECG need to be tested if atomoxetine is given.

Impulse Control with ADHD

Impulsivity is a pervasive problem and is not always associated with physical hyperactivity. Sometime the inattention subtype of patients with ADHD can be pervasively impulsive.

► Fluoxetine is helpful as a treatment. It is better to start with the liquid preparation so that low initial dose can be given. This medication has also been shown to have positive effect in mental retardation of child population with the same symptoms.

► Valproic acid and ► carbamazepine are also useful especially if there is a mood instability associated with the impulsivity. The mood or affective instability frequently presents with a rapid cycling bipolar disorder picture.

Anxiety with ADHD

Guanfacine and clonidine are both useful and can be added to a psychostimulant. It is important to check BP and pulse while lying and sitting and do a pretreatment ECG. These patients frequently have a history of PTSD or developmental trauma disorder.

Conduct Disorder and/or Disruptive Behavioral Disorder and ADHD

There are no specific medications, but SSRIs are useful and atypical antipsychotics such as risperidone and olanzepine are both helpful with aggressive/disruptive behaviors. These medications can be used successfully if ADHD is present.

Intermittent explosiveness alone can respond to carbamazepine or valproic acid or GABA agents, such as ► gabapentin. This can be related to a complex partial seizure disorder or it can sometimes be seen in patients with "hyperactive" symptomatology who do not respond to dextroamphetamine, or methylphenidate, or may be precipitated by too long a treatment with an SSRI.

Depressive disorders are best treated with SSRI such as ► fluoxetine, ► sertraline, ► citalopram, or ► bupropion (as second-line agent). It is important to be aware that SSRIs may unmask a ► bipolar disorder or may precipitate ► extrapyramidal side effects in patients over 20 years of age, as this is a more neurologically sensitive brain-damaged population. Impulsive suicide risk may be increased by excessive activation or excitation in the first week as a response to SSRI; so this early period should be carefully monitored.

Psychotic features (such as auditory or visual hallucinations) respond to neuleptil oral drops alone or to ► anticonvulsants such as carbamazepine or valproic acid if the patient has an epileptic focus in the temporal lobe and clinical presentation of complex partial seizures.

The newer atypical antipsychotics (e.g., risperidone, olanzapine, seroquel, or clozaril) may have a use here (only after failed treatments with other antipsyhotics or in very ill hospitalized patients). Recent work on the atypical antipsychotics has shown that they can double the risk of abnormal glucose metabolism including diabetes, hyperprolactinaemia, and pancreatitis. The population of patients with FAS or ARND is also more likely to need benztropine as they develop extrapyramidal symptoms (EPS) easier. Parenteral medication such as fluanxol has proven effective in once a month regime, useful in noncompliant older patients with ► schizoaffective symptomatology.

Panic attacks and generalized anxiety disorder respond to ► lorazepam (short acting), ► buspirone (longer onset of action and less risk of drug dependency) or bupropion if mood symptoms are present. GABAergic agents such as gabapentin should be used if mood instability like bipolar disorder is present.

Bipolar disorders or more correctly affective/mood instability may be precipitated/ unmasked by too long administration or too high dose of SSRI agents. Often the symptoms decrease with change of dosage of SSRI or discontinuation of the drug. The symptoms can include rather disarming pathological laughing or crying akin to **emotional incontinence** seen in brain-injured patients.

The affective/mood instability unrelated to medication can respond to carbamazepine, valproic acid, or GABA agents (e.g., gabapentin).

Sleep disorders respond to ► melatonin (liquid or tablet form), ► trazodone, or l-tryptophan (safe if the patient is pregnant).

Alcohol dependence is still a poorly understood phenomenon in adolescents and young adults with

FAS or ARND. Research with animals and humans have shown that ► prenatal alcohol exposure increases the risk for alcohol craving probably via its effects on the developing brain, specifically the nucleus accumbens. Narcotic antagonists, such as ► naltrexone, have proven useful in curbing this alcohol craving and subsequent dependence (O'Malley 2008.)

► **Autistic spectrum disorder** or ► **Asperger's disorder** can be the primary clinical presentation of FAS or ARND, and explosiveness with or without ADHD symptomatology is the key clinical feature.

There are a number of **medications that should be used with caution** in children and adolescents with FAS or ARND

- ► Lithium carbonate causes cardiac, renal, and thyroid problems.
- ► Tricyclic antidepessants (amitriptyline, imipramine, desipramine, clomipramine) cause cardiac toxicity, sudden death, and lower seizure threshold and are lethal in overdose.
- New antidepressants affecting serotonergic and noradrenergic systems. (Effexor) may cause cardiotoxicity due to noradrenergic activity.
- ► First generation antipsychotics (chlorpromazine,* stelazine, nozinan, and haldol) cause excess sedation, increased risk of EPS and possible liver toxicity, and sun sensitivity*.
- ► Second generation atypical antipsychotics can affect weight and glucose metabolism.
- Paroxetine (SSRI) has now been recommended by FDA not to be used in under 18 year old patients. It causes increased interaction with other psychotropics because of its inhibition of **cytochrome P450 2D6 isoenzyme** liver pathway.

Future Considerations for Psychopharmacology

Increasingly, researchers and clinicians show that patients exposed to prenatal alcohol are frequently exposed to stress at many different levels i.e., domestic violence, abandonment by partner, and physical or sexual abuse which predates pregnancy. The role of the ► hypothalamic–pituitary axis is being reconsidered in the population of patients with FAS or ARND who have been born into environments of high stress (Meewisse et al. 2007).

Excess cortisol has been shown to stop many metabolic, neuronal, and immune systems, including potential nerve growth factor. It remains to be seen if psychopharmacological agents affecting the balance of the HPA axis have an ameliorating or neuroprotective role in FAS or ARND.

Some neuroprotective agents have already been used to counterbalance the effect of prenatal alcohol on the developing fetus. They include folate, vitamin B12, thiamin, Vitamin B6, and choline (reviewed in O'Malley 2008).

Foetal Alcohol Syndrome

Definition
A developmental neuropsychiatric disorder with characteristic facial dysmorphology resulting from prenatal exposure to alcohol.

Cross-References
► Foetal Alcohol Spectrum Disorders

Folate

Definition
Folate is one of the 13 essential vitamins. Dihydrofolate is the form of folate obtained from dietary intake, while folic acid is the synthetic form of folate contained in over-the-counter and prescription vitamin supplements. Dihydrofolate and folic acid are ultimately converted by the body to L-5-methyl-tetrahydrofolate (MTHF); the only form of folate that passes into the brain and is utilized by trimonoamine neurons to facilitate neurotransmitter synthesis.

Force Platform

► Force-Plate Actometer

Forced Swimming Test

► Behavioral Despair

Force-Plate Actometer

Synonyms
Force platform

Definition
A force-plate actometer consists of a rigid, low mass floor supported by force sensors whose force-proportional electronic signals are processed by a computer to allow the computation of a subject's x–y location in the horizontal plane, and, at the same time, to record the time series of reactive forces as the subject moves on the plate. It is especially useful for quantifying the rhythms of rodent movements concurrent with the recording of distance traveled, rotations, wall rears, and other features of behavior.

Cross-References
► Motor Activity and Stereotypy

Forgetting

Definition
The inability to retrieve one or a number of memory items. Is usually understood as the time-dependent erosion or loss of memory traces.

Formal Thought Disorder

Definition
Disorder of the mechanisms of thinking as characterized descriptively.

Forward Genetics – Random Mutagenesis

► Forward Genetics/Reverse Genetics

Forward Genetics/Reverse Genetics

Synonyms
Forward genetics – random mutagenesis; Reverse genetics – targeted mutagenesis

Definition
Forward genetics is the examination of the genetic cause of an altered or abnormal phenotype introduced by a chemical mutagenesis or mutation by irradiation (e.g., phenotype → genotype). In reverse genetics, a particular gene is altered and the phenotype is investigated (e.g., genotype → phenotype).

Cross-References
► Genetically Modified Animals
► Phenotyping of Behavioral Characteristics

Fostering

Synonyms
Cross fostering

Definition
A procedure used in animal studies to control for potential residual effects of drug exposure during pregnancy on subsequent maternal behavior that involves placement of prenatally drug-exposed offspring with nondrug-exposed foster mothers.

Fourier Analysis of Time Series

► Power Spectral Analysis

Fourier Spectrum

► Spectrograms

Fourier Transform

Fovea

Definition
The small portion of the retina (subtending 2–3° of visual angle) that contains the highest density of cone cells, and thus is responsible for the clearest, most acute vision.

Fragile X

Definition
Fragile X is the most common cause of inherited mental impairment and the most known genetic cause of autism. Elongated face and large and protruding ears are characteristics physical features for the disease. Males are more severely and more often affected (1:4000) than females (1:8000). The disease is caused by an expansion of CGG repeats upstream of the FMR1 gene leading to hypermethylation of the promoter region, reducing the transcription of the FMR1 gene and consequently the expression of the FMRP (fragile X metal retardation protein).

Free Radicals

Synonyms
Reactive oxygen species

Definition
Free radicals are chemical compounds that contain one, or more, unpaired electrons in the outer orbits. This has the effect of making the atom or molecule more reactive than its non-radical relation. Such compounds can capture electrons from other molecules thereby oxidizing such molecules.

Cross-References
► Oxygen and Nitrogen Reactive Species

Freebase

Definition
Freebase cocaine or amphetamine is the active drug without the chemical component that makes these drugs soluble in water (e.g., hydrochloride or HCl). This "base" or "freebase" form of the drug is prepared by dissolving the hydrochloride form of the stimulant with a strong alkali, and drawing out the cocaine from its impurities. The preparation of freebase cocaine involves the use of highly explosive solvents such as ether.

Cross-References
► Amphetamine
► Cocaine

Function of Delta Waves

Synonyms
Delta activity; Slow waves

Definition
Signals in the human EEG in the frequency range from near-DC to ~4 Hz are considered as part delta activity. Consensus on the functional correlate exists; it reflects the amount of sleep pressure. Indeed, its amplitude fluctuates dramatically comparing waking state and, for example, stage N3, deep or slow-wave sleep.

Cross-References
► Electroencephalography
► Polysomnography

Function of Slow and Fast Alpha Waves

Synonyms
Alpha waves; Eyes closed occipital waves; Spindles; Thalamocortical 10 Hz rhythm

Definition
Signals in the human EEG in the frequency range from 8 to 13 Hz are considered to be part of the alpha activity. As simplest functional correlate, one can describe it as an "idling" wave, which much like a screensaver keeps neurons at a minimum alertness. Indeed, the amplitude fluctuates with attention and arousal and, for example, stimulants can switch the balance from slow to fast alpha or increase both, interpreted as an altered vigilance state.

Cross-References
► Electroencephalography

Functional Magnetic Resonance Imaging

Synonyms
Magnetic resonance imaging (functional)

Definition
Functional magnetic resonance imaging (fMRI) is a method for measuring hemodynamic (brain blood flow/oxygenation) responses related to neural activity in the brain. This technique has been used in conjunction with neurocognitive tasks to measure brain activation during discrete cognitive processes and effects of pharmacological agents on such processes. It is a recently developed form of neuroimaging. The advantages of fMRI include its low invasiveness, lack of radiation exposure, and relatively wide availability.

Functional Outcome

Definition
Functional outcome distinguishes itself from clinical outcome, focused instead of an individual's recovery in areas such as vocational and social functioning rather than symptom resolution. Its measurement speaks to the impact of severe and chronic illnesses, such as ► schizophrenia, and a growing awareness that functional and clinical recovery do not necessarily parallel each other.

With schizophrenia, it was held for many years that the positive symptoms (e.g., delusions, hallucinations) were central to the gradual decline in functioning commonly seen over the course of the illness. However, more recent evidence suggests that other features of this illness, for example, deficit (negative) symptoms and

neurocognitive changes, may play a more critical role in compromising functional recovery. This has diminished focus on positive symptoms and the implicit assumption that their resolution ensures a return to premorbid level of functioning and, in so doing, has forced a reconceptualization of schizophrenia and expanded current treatment/research strategies.

Functional Selectivity

Synonyms

Biased agonism; Ligand-directed trafficking; Stimulus trafficking

Definition

According to the classical receptor-occupancy theory of receptor, activation receptors are in equilibrium between one active and one inactive state. In correspondence with this model, the ability of a given ligand to modulate either one of the receptor's signaling pathways should be similar. Experimental observations have provided an important lesson though: a receptor is not just either on or off, and ligands can display distinct efficacies toward different effector systems. The ability of a ligand to preferentially stabilize specific GPCR conformations, each associated with its own repertoire of signaling behavior, is called functional selectivity.

G

G protein-Coupled Receptors

Definition

A family of metabotropic receptors (formed by seven transmembrane hydrophobic domains linked by hydrophilic groups) coupled with a heterotrimeric protein named G-protein (consisting of α, β, and γ subunits), that, upon binding guanosine phosphates (GTP or GDP) in response to extracellular signals (e.g., neurotransmission), activate or inactivate specific intracellular effectors systems.

GABA

Definition

An abbreviation for gamma-aminobutyric acid, the principal inhibitory neurotransmitter, ubiquitous throughout the mammalian brain. GABA-bearing neurons constitute inhibitory interneuronal populations in the cortex and projection neurons in subcortical (e.g., striatal) regions. GABA released from axonal presynaptic terminals typically dampens electrical excitation and suppresses axon potential generation in postsynaptic neurons. GABA-ergic neurotransmission is thought to tightly regulate excitatory neurotransmission, information processing, and neuroplastic events via polysynaptic connectivity with glutamatergic neurons.

$GABA_A$ Receptor

Definition

The GABA receptors are a class of receptors that respond to the neurotransmitter gamma-aminobutyric acid (GABA), the most common inhibitory neurotransmitter in the central nervous system. $GABA_A$ and $GABA_C$ receptors are ligand-gated ion channels, whereas $GABA_B$ receptors are G protein-coupled (metabotropic) metabotropic receptors. Each receptor comprises five subunits arranged around a central pore. Binding of GABA molecules to extracellular binding sites triggers a conformational change that opens the pore to allow chloride ions to pass down an electrochemical gradient into the cell, resulting in hyperpolarization of the postsynaptic membrane. In addition to the GABA binding site, $GABA_A$ receptors appears to have distinct binding sites for ▶ benzodiazepines and many anesthetic agents such as ▶ barbiturates, inhaled anesthetics, and propofol.

Galantamine

Definition

Galantamine is a drug marketed for treating the cognitive impairments (learning, memory, and attention) in Alzheimer's disease. It has mainly been used in patients in the mild to moderate stages of the disease and like the drug ► donepezil works by enhancing brain levels of ► acetylcholine, a chemical that is reduced in Alzheimer's disease and is known to be relevant to cognition. It has been suggested that galantamine also acts as a positive ► allosteric modulator of neuronal nicotinic receptors, which are also the target of nicotine found in tobacco. Since nicotine has been shown to have some cognitive benefits, and various drugs being developed are targeting nicotinic receptors in the brain, it has been proposed that this additional mechanism is relevant to the use of galantamine in Alzheimer's disease.

General Anesthesia

Synonyms

Anesthesia

Definition

General anesthesia is a temporary, drug-induced state in which a patient is rendered unconscious and insensible to noxious stimuli such as surgery. Anesthesia is considered adequate if the patient shows no sign of consciousness, exhibits no cardiovascular stress responses to surgery (such as rising heart rate and blood pressure), and on recovery from anesthesia has no recall of intraoperative events.

Generalized Anxiety Disorder

David S. Baldwin[1,2]
[1]Clinical Neuroscience Division, School of Medicine, University of Southampton, Southampton, Hampshire, UK
[2]University Department of Mental Health, RSH Hospital, Southampton, UK

Synonyms

Anxiety neurosis; Free-floating anxiety; GAD

Definition

Generalized anxiety disorder (GAD) is characterized by an excessive and inappropriate worrying that is persistent and not restricted to particular circumstances. Patients have physical anxiety symptoms (such as tachycardia and tremor) and key psychological symptoms, including restlessness, fatigue, difficulty in concentrating, irritability, and disturbed sleep. The disorder is common and disabling: a recent review of epidemiological studies in Europe suggests a lifetime prevalence of approximately 5%, and the associated functional impairment is similar to that with major depression. However, many of those who might benefit from treatment are not recognized or treated, which is disappointing, as a range of evidence-based treatments are available.

Role of Pharmacotherapy

Efficacy in Acute Treatment

Current ► Evidence-Based Guidelines for the pharmacological management of patients with GAD recommend initial treatment with either a ► selective serotonin reuptake inhibitor (SSRI) or a serotonin–norepinephrine reuptake inhibitor (► SNRI), on the basis of proven efficacy and reasonable tolerability in randomized placebo-controlled trials (Baldwin et al. 2005; Bandelow et al. 2008). Approximately, 40–60% of patients will "respond" to placebo and 60–75% to the SSRIs ► escitalopram, ► paroxetine, or ► sertraline, when using global measures of improvement, and similar findings are seen for the SNRIs ► duloxetine or ► venlafaxine and for the novel anxiolytic drug ► pregabalin (Baldwin and Ajel 2007). Symptom severity on the primary outcome measure, traditionally the ► Hamilton Rating Scale for Anxiety, HAMA, can be reduced markedly, but many patients remain troubled by distressing anxiety symptoms at study end-point, despite seemingly making a good overall "response" to treatment.

Benzodiazepines are also efficacious (and can provide a rapid reduction in symptoms) in many patients and have similar overall efficacy to the psychological treatment cognitive therapy. However, they are usually ineffective in relieving comorbid depressive symptoms, and unwanted effects include sedation, disturbance of memory, and psychomotor function; other potential problems include development of ► tolerance, abuse and dependence, and distressing withdrawal symptoms. Because of these, it is advisable to use benzodiazepines only for short-term treatment (up to 4 weeks) or in patients who have not

responded to at least two previous treatments and who remain troubled by severe and impairing anxiety symptoms (Baldwin et al. 2005; Tyrer and Baldwin 2006).

Only few randomized controlled trials (RCTs) have allowed the assessment of the relative efficacy of different drugs, when compared with placebo. A recent analysis of RCT findings found an overall mean effect size of 0.39, with pregabalin having the highest effect (0.50) and the azapirone anxiolytic ▶ buspirone the lowest effect (0.17) (Hidalgo et al. 2007). However, this represents a *post hoc* analysis of pooled data, derived from RCTs that differ in design and which were not powered for this comparison. Nevertheless, there is much scope for improvement in developing pharmacological treatments with greater overall efficacy (Baldwin 2008).

Prediction of Response to Treatment

It is hard to predict reliably which patients will make a good response to treatment. Greater severity but shorter duration of symptoms, more pronounced impairment, and the presence of comorbid depressive disorders may predict a greater likelihood of response to antidepressant medications. Lower symptom severity, a history of benzodiazepine treatment, and the presence of comorbid personality disorders may be associated with a lesser chance of responding. Similar difficulties are seen when deciding how long the initial drug treatment in GAD should continue, before it is reasonable to conclude that the chance of responding is too low to justify proceeding with the current approach, although recent analyses shows that an onset of efficacy (defined as a reduction in HAMA score by 20% or more) after 2 weeks of treatment is strongly predictive of response at the study endpoint for duloxetine (Pollack et al. 2008; Baldwin et al. 2009).

Prevention of Relapse

GAD is usually regarded as a chronic disorder, waxing and waning in severity, over many years, although many patients have a more episodic course, with periods of anxiety symptoms and intervening better health. Unlike the situation in recurrent unipolar depression, where continuation of antidepressant treatment beyond initial response substantially reduces the risk of early relapse and later recurrence of depressive symptoms, the value of long-term treatment in GAD is less well established due to the limited number of ▶ Relapse Prevention Studies. Four studies with this design demonstrate the value of continuing pharmacological treatment, with escitalopram, paroxetine, pregabalin, or duloxetine. A formal relapse prevention study with venlafaxine did not reveal efficacy, but significantly fewer patients relapsed during venlafaxine treatment in a separate prolonged randomized double-blind placebo-controlled trial. A currently (November 2009) unpublished relapse prevention study with the second-generation antipsychotic drug quetiapine suggests that it has some efficacy in relapse prevention.

Further Management After Nonresponse to Initial Treatment

There is much uncertainty about subsequent stages in patient management after a poor response to first-line treatment. Commonly employed interventions include an increase in dosage, a switch to another evidence-based drug treatment, augmentation with an additional psychotropic agent, and the combination of medication with a psychological treatment. There is no published dosage escalation study in GAD, in which patients either continue with the initial low dose or switched to a subsequent higher dose, and the findings of fixed-dose randomized placebo-controlled studies do not provide consistent evidence that higher doses are more efficacious. Most guidelines recommend an SSRI for first-line pharmacological treatment; so, common second-line approaches include an SNRI, buspirone, the tricyclic antidepressant imipramine, pregabalin, or a benzodiazepine. Buspirone is more efficacious when GAD patients have not previously been treated with a benzodiazepine; so, it makes sense to consider the use of buspirone before prescribing benzodiazepine anxiolytic (Chessick et al. 2006).

Some doctors recommend an antipsychotic drug after nonresponse to SSRI or SNRI treatment, perhaps fearing the development of tolerance or dependence with the use of benzodiazepines. The conventional neuroleptic drug ▶ trifluoperazine has proven efficacy in acute treatment, and more recently, the second-generation antipsychotic drug ▶ quetiapine has also been found efficacious in placebo- and comparator-controlled studies. However, the adverse effect profile and potential long-term risks of antipsychotics should usually lead them to be reserved for patients who have not responded to earlier SSRI treatment, perhaps followed by an SNRI treatment. Both ▶ risperidone and ▶ olanzapine can enhance the efficacy of SSRI treatment, on at least some measures, and other potential alternative augmentation approaches include the use of ▶ pregabalin, or the novel antidepressant drug ▶ agomelatine, which has recently been found efficacious (Stein et al. 2008). Combining pharmacological interventions with psychological interventions is often advocated for patients with anxiety disorders, but in GAD, it is uncertain whether the combination treatment is superior to psychological or drug treatment given alone (Bandelow et al. 2007).

Tolerability of Current Treatments

The acceptability to patients of prescribed medication is an important consideration, particularly when recommending long-term treatment. The adverse effects of SSRIs and SNRIs including headache, nausea, and increased nervousness and the drowsiness associated with benzodiazepines and pregabalin, usually diminish after a few weeks, though other side effects can become more important over subsequent months. Common concerns during longer-term treatment with SSRIs or SNRIs include the development of sexual dysfunction, weight gain, persistent disturbed sleep, and the potential for experiencing ► Discontinuation Symptoms on stopping the treatment.

The latter are common with many classes of psychotropic drugs, including SSRIs, SNRIs, and benzodiazepines. Symptoms are typically mild and only transient, but many patients report severe and distressing symptoms, despite gradual discontinuation by tapering the prescribed dose of medication. Compounds differ in their propensity to cause discontinuation symptoms (Baldwin et al. 2007), but it is hard to predict which patients will be the most affected. Gradual withdrawal ("tapering") is often advised in the hope of minimizing symptoms, but this is not fully established and there is a need for withdrawal studies with a randomized double-blind staggered design, in which patients and doctors are unsure of whether treatment ends slowly or swiftly, or when the dosage reduction has occurred.

Genetically Engineered Animal

► Genetically Modified Animals

Genetically Modified Animals

Nicole Edgar, Etienne Sibille
Center for Neuroscience, Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Genetically engineered animal; Genetically modified organism; GMO; Transgenic animal

Definition

A genetically modified animal is one whose genetic material has been altered by the use of genetic engineering or recombinant DNA technology. In biomedical sciences, genetically modified animals are typically generated for the purpose of studying the function of a particular gene.

Principles and Role in Psychopharmacology

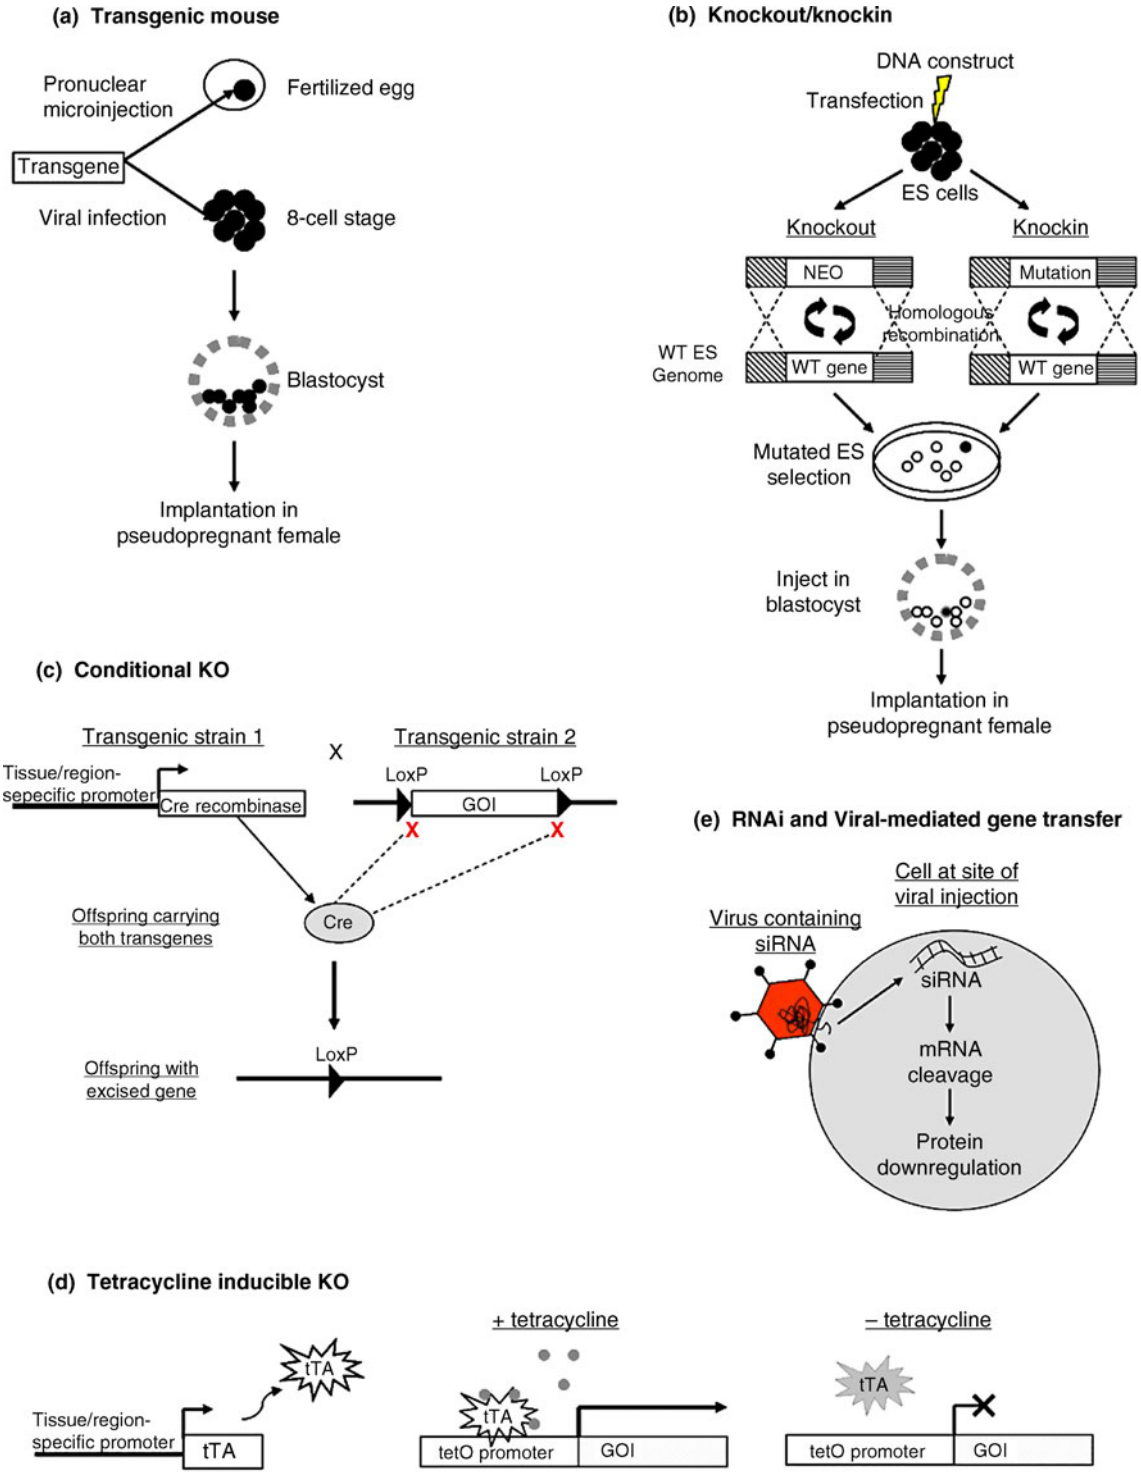
One of the main goals of the field of genetics is to classify and functionally characterize individual genes. The investigative approach to studying genes in living organisms has principally been divided into three strategies: (1) analysis of natural variation, (2) random mutagenesis, and (3) targeted mutagenesis and transgenesis (Rudolph and Mohler 1999). Analysis of natural variation (e.g., spontaneous mutations) and random mutagenesis (e.g., chemical or irradiation) are the primary approaches of ▶ forward genetics in which the genetic cause (▶ genotype) of an altered or abnormal ▶ phenotype is investigated. However, with random mutagenesis, many chromosomal loci are often targeted and it is difficult to trace any phenotype back to a specific genetic origin. The development of ▶ reverse genetic approaches, in which a particular gene is altered and the phenotype is investigated, provided tools to investigate specific gene function in a more targeted manner (Brusa 1999). Since the development of these tools in the 1980s and 1990s, their use in the field of biomedical research and pharmacology has been substantial owing to the ability to develop suitable animal models of specific diseases, to genetically dissect the underlying mechanisms of disease, and to identify and verify molecular targets of pharmacological agents.

In the past two decades, a variety of techniques have been developed to introduce genetic modifications in various species for specific research purposes. Among the most targeted species are *Drosophila melanogaster*, *Caenorhabditis elegans*, and mice, which have each played integral roles in identifying genes involved in development, aging, cell differentiation, and other major biological functions. Other genetically modified animals that have been developed include xenopus, zebrafish, rabbits, pigs, and cows. More recently, transgenic and ▶ knockout rats have been developed, which will allow more extensive research in the neurosciences because of their extensive use in behavioral paradigms (Abbott 2004). In addition, the first transgenic primate disease model (for Huntington's disease) was recently created (Yang et al. 2008). While a wide variety of genetically modified organisms have been created to date for numerous research purposes, techniques for genetically modifying mice are the most advanced and the most applicable to the field of psychopharmacology, which represent the main focus of the remainder of this article.

Transgenic Technology

While the term "transgenic" has grown to include any type of genetically modified animal, the traditional definition of a ▶ transgenic organism is one containing foreign DNA, whether from the same species or a different one. The expression of foreign DNA in a mouse is a valuable technique, since it allows for the investigation of the functional role of this gene in a living organism. For instance, transgenic mice overexpressing a particular gene are often generated to analyze exaggerated phenotypes. The expression of a human gene or a mutated gene in mice is also often used to explore gene function, particularly in the context of a specific disease.

There are several ways to create a transgenic mouse; however, all methods consist of first designing a DNA fragment, or "genetic construct," which contains the gene of interest (GOI) and other features necessary for the expression of this gene in a mammalian system (e.g., gene promoter, enhancer, polyA signal, etc.). The traditional transgenic method consists of physically injecting the transgenic construct into the nucleus of a fertilized egg (pronuclear microinjection), allowing it to develop in vitro to the blastocyst stage, and then implanting the egg into a ▶ pseudopregnant female (Fig 1a). The embryos must then be screened for the presence of the transgene and unlike the production of knockouts, the transgene typically occurs in an all or none fashion, with the embryo either containing the transgene in every cell or in no cells at all. Alternatively, transgenic animals can be produced by viral infection of the fertilized embryo (see below) or transfection of embryonic stem cells (ES) with the gene of interest (Dale and von Schantz 2002). While the transgenic approach is fast and efficient, limitations of the technology include: (1) The GOI may randomly integrate into the genome, which can result in expression in ectopic sites, interference with the endogenous gene, or severe



Genetically Modified Animals. Fig. 1. Diagrams of methods for producing genetically modified animals.

disruption of the homeostasis of the cells and organism; (2) The level of ► gene expression is unable to be controlled and is dependent upon where the gene inserts into the host genome and on the number of copies inserted. Overexpression of the gene could have unexpected detrimental effects, including lethality; (3) Mosaic or chimeric animals are sometimes produced, particularly when the transgenic animal is generated with the viral method, owing to infection of only a subset of cells within the blastocyst; (4) The genetic background of mice can considerably influence the ability of the manipulated egg to survive microinjection, implant in the uterus, and develop to term (Brusa 1999; Dale and von Schantz 2002).

Gene Knockout Technology

The creation of a traditional knockout (i.e., removal of a gene) mouse consists of disrupting all or part of the coding sequence of the GOI, with the purpose of exploring the phenotype in the absence of the gene. The exact locus of the GOI can be targeted by creating a genetic construct that is homologous to the region of the GOI on a particular chromosome. The genetic construct is injected into embryonic stem cells where rare homologous recombination events can occur with the endogenous GOI at the intended chromosomal locus. In the knockout approach, the GOI is often replaced with neomycin (Neo) or another selectable marker, which allows for in vitro selection and identification of the stem cell colonies that have undergone appropriate recombination (Fig. 1b). Selection against random integration into the genome is often attained by using a second selectable marker outside the inserted region. Once the mutated stem cells are identified and verified, they are microinjected into a blastocyst and implanted into a pseudopregnant female as in a transgenic mouse. Most of the offspring produced using this technique are ► chimeras (or mosaics),which is the result of the presence of both mutated and nonmutated stem cells within the blastocyst. Embryonic stem cells from a different color strain of mice than the fertilized egg are often used because the chimeric mice are then easily identifiable due to bi-colored fur. The next step consists of breeding chimeric mice to identify individuals with germ cells that have undergone homologous recombination. These founder mice will then be bred to produce homozygous mutant animals (Dale and von Schantz 2002) (except when homozygous are lethal, in which case heterozygous breeding may be the preferred approach). Similar to knockout mice, ► knockin technology, where one or more exons of a certain gene are replaced with an altered version (Fig. 1b), is often used to study specific polymorphisms, or the human equivalent of the GOI.

While knockout organisms have been paramount in the goal to elucidate the function of specific genes, problems associated with knockout technology include that removal of a gene is often lethal or that the absence of the gene product during development leads to compensatory events that can obscure the analysis of the function of the missing gene. Specifically, these compensatory developments likely differ from the disease mechanisms that the knockout animal is intended to model, as disease processes rarely include full loss of gene function.

Conditional Knockout Technology

The desire for greater specificity and the need to bypass potential developmental compensations and occasional lethality has led to the development of ► conditional or inducible knockouts, where the experimenter has either temporal or regional control over expression of the GOI. Several systems have been developed for this purpose including the Cre-LoxP system, Flp-FRT system, and the tetracycline-inducible system. The Cre-LoxP system of bacterial origin employs Cre recombinase, which mediates site-specific recombination by targeting a DNA sequence called LoxP (Houdebine 2007). To implement this system, one strain of mice is engineered to express Cre under a tissue- or developmental stage-specific promoter and these mice are bred to a second strain of mice in which the GOI has been flanked with LoxP sites. The resulting offspring then have the GOI removed only in the tissues (or at the developmental time point) where/when Cre is expressed (Fig. 1c). The Flp-FRT system originated in yeast and is used in the same manner as the Cre-LoxP system with Flp recombinase excising the GOI flanked by FRT DNA sequences (Houdebine 2007). Importantly, these two systems can be used together to allow for a range of additional approaches.

The tetracycline-inducible system is based on the tetracycline-resistant gene from bacteria and has been modified for use in mammals to essentially act as a switch to initiate or terminate gene expression. In bacteria, the tetracycline-resistance gene is typically kept in the off position by a repressor bound to a specialized DNA sequence in the promoter of the gene, the tetracycline operator (*tetO*) sequence. For use in mammalian transgenics, the repressor protein was modified into a transactivator (tTA), which allows constitutive expression of genes bound to *tetO*. Thus, in the presence of tetracycline, gene expression is terminated when the drug binds to tTA, removing it or preventing its binding to *tet*O. A modified version of tTA (rtTA) requires the presence of tetracycline to bind to *tetO*, thereby allowing activation of a gene in the presence of tetracycline. For these systems

to work, two transgenes in a single animal are needed; one expressing tTA under the control of a site- or temporal-specific promoter and the GOI under control of the *tetO* (Fig. 1d) (Brusa 1999).

RNAi and Gene Transfer In Vivo

The recent discovery and exploitation of the endogenous ► RNA interference (► RNAi) mechanism has aided in the development of loss of function models. The endogenous mechanism consists of short sequences of double-stranded RNA, which bind and cleave complementary mRNA sequences, thereby silencing or inducing downregulation of the specific gene (Dunn et al. 2005). Short sequences of double-stranded RNA (~22 nucleotides), termed small interfering RNA (siRNA), are easily synthesized and can be delivered in vivo using a variety of gene transfer techniques (see below and Fig. 1e). Interestingly, in vivo manipulations using siRNA result in rather limited downregulation of the GOI (when compared with the global KO); yet, they seem to produce marked functional effects (Thakker et al. 2005). Similar to RNAi, antisense technology is the expression of the reverse complement of mRNA, which interferes with normal translation, thereby reducing protein synthesis (Dale and von Schantz 2002).

While conditional and inducible knockouts provide certain level of site and temporal specificity, they are dependent on the availability of promoters that provide the desired specificity. The development of viral-mediated gene transfer has allowed more flexibility in producing the desired manipulations. In addition to an alternative method of producing transgenic animals (discussed above), viral vectors can be used to transfer genetic material in a temporal and site-specific manner in both neonatal and adult mice. Modified virons such as herpes, lenti-, adeno-, and adeno-associated viruses can be engineered to carry a transgene, siRNA, or other genetic material. These viral vectors are then able to infect cells and transmit the desired genetic material. Viral-mediated gene transfer has the additional advantage over conditional mutants that the genetic manipulation occurs only at the site of infection and cell-type-specific promoters can be used for additional specificity. Depending on the type of virus used, the genetic material may be integrated into the genome or may remain epichromosomal. The type of virus also influences the infection rate, type of cells infected, and the size of DNA insert (Dunn et al. 2005). While viral-mediated gene transfer technology is widespread, nonviral gene transfer to the central nervous system has also been achieved using in vivo electroporation and both intracerebroventricular and intrathecal infusion (Gilmore et al. 2006).

Roles of Genetically Modified Animals in Psychopharmacology

The creation of the first knockout mouse in 1989 led to a Nobel prize for Sir Martin Evans (Cardiff University in Wales), Oliver Smithies (University of North Carolina at Chapel Hill), and Mario Capecchi (University of Utah in Salt Lake City) in 2007. Since the development of the technology, using knockout mice along with other types of mutants to investigate critical questions in psychopharmacology has become a standard practice. In particular, genetically modified mice have been essential in psychopharmacology for (1) elucidating both the function of a gene and the molecular elements associated with a gene; (2) creating animal models of human disease; (3) identifying and validating drug targets and drug specificity, and (4) examining temporal aspects of gene function.

One of the first major breakthroughs in the field of neuroscience using targeted mutagenesis came from Eric Kandel's group at Columbia University. In a series experiments using the tetracycline-inducible system, they were able to express a calcium-independent form of the forebrain-specific calcium-dependent kinase, calcium-calmodulin kinase II (CaMKII), and found deficits in ► spatial memory and hippocampal ► long-term potentiation (LTP) (Mayford et al. 1996). These groundbreaking experiments provide a classic example of the power of how spatial and temporal control over molecular elements can aid in elucidating the function of specific genes and their role in higher brain function. The CaMKII promoter still remains one of the most popular promoters to express numerous genetic constructs in the mouse forebrain.

Another critical role for transgenic animals is the development of animal models for human disease, by either the introduction of a mutated gene or the elimination of a gene putatively involved in the illness. In the field of neuroscience, this has been particularly useful in modeling a wide variety of disorders, including ► Alzheimer's disease (AD), Huntington's disease, neuropsychiatric disorders, and cerebral ischemia. In particular, AD is characterized by the formation of ► neurofibrillary tangles of hyper-phosphorylated tau protein and by ► amyloid β-peptide (Aβ) plaques. Mutations in the amyloid precursor protein (APP), presenilin 1 and 2 (PS1, PS2), and apolipoprotein E (APOE) are all implicated in the disease. Studies now show that mice overexpressing APP and PS1 form Aβ plaques and display memory deficits, both characteristic symptoms of AD (Brusa 1999), consequently highlighting the important role of genetically modified animals in testing potentially causal mechanisms involved in human disease. In some cases, it is

necessary to replace the murine gene with the human gene because of distinct structural differences between the human gene and mouse homolog at the molecular level (Rudolph and Mohler 1999), or simply to replicate the human pharmacological signature (e.g., 5-HT_{1B}, NK_1...).

The development of genetic animal models for human diseases has provided a solid foundation for drug discovery and for the identification of drug targets. The specificity of the genetic manipulation (i.e., removing a gene coding for a particular receptor subtype) ensures virtually absolute selectivity, thereby offering a great advantage over classical pharmacological approaches. For instance, the function of receptor subtypes can be examined using both knockin and knockout approaches. A particularly relevant example is that of the utilization of transgenic mice in determining the role of specific ► $GABA_A$ receptor subunits in distinct actions of the benzodiazepine, ► diazepam. Diazepam is known to act on $GABA_A$ receptors containing the α1-, α2-, α3-, or α5- subunits. By examining mice carrying point mutations in the benzodiazepine binding sites of each subunit, investigators were able to genetically dissect the different functions of diazepam (e.g., sedative vs. anxiolytic) acting at otherwise similar $GABA_A$ receptors (Rudolph and Mohler 1999).

Other critical uses of genetically modified animals are the dissection of second messenger signaling pathways and the determination of critical developmental time-windows for gene function. The latter was elegantly demonstrated by the use of a tetracycline-inducible knockout of the serotonin 1A (5-HT_{1A}) receptor. Gross et al. (2002) showed that when the 5-HT_{1A} receptor was knocked out during development, it resulted in behavior similar to the knockout mouse (increased anxiety). However, when the receptor was knocked out in adults, the phenotype was absent (anxiety levels were normal), thereby implicating the 5-HT_{1A} receptor as a critical developmental factor for normal emotional behavior (Gross et al. 2002).

In summary, the primary goal of reverse genetics is to create a targeted mutation and then investigate the resulting phenotype. We briefly discussed several methods of targeted mutagenesis, including the development of transgenic animals and the techniques for developing global, conditional, and inducible knockouts. The values of this technology have been far-reaching and have played a considerable role in psychopharmacology. We have highlighted some of the most common uses for genetically modified animals in this field, including the dissection of molecular mechanisms, modeling human disease, drug discovery and validation, and the investigation of critical time windows in gene function. While several other approaches for creating genetically modified animals exist (e.g., the use of modified male gametes) along with other applications for these animals (e.g., pharming), we focused on the role of genetically modified mice in psychopharmacology, as their impact on this field has been substantial. New approaches to developing and using genetically modified organisms are quickly evolving, including modifications and combinations of the discussed systems, which will likely further impact psychopharmacology.

GIRK Channels

Definition

GIRK channels are G-protein coupled inwardly rectifying K^+ channel (also known as $K_{ir}3$ channels) causing membrane hyperpolarization and plays a very important role in reducing neuronal excitability in most brain regions and in the heart. Four subunits have been identified in mammals, and neuronal GIRK channels are predominantly heteromultimers of GIRK1 and GIRK2. The channels are activated through the G-protein βγ dimer, derived mainly from $G_{i/o}$ heterotrimers.

Glucocorticoid Hormones

Definition

Steroid hormones synthesized and secreted from the zona fasciculata of the adrenal gland in response to ACTH after exposure to a stressor or during the diurnal peak. The main endogenous glucocorticoids are corticosterone in rodents and cortisol in humans.

Glucocorticoid Receptor

Definition

A transcription factor regulating the CRF gene. Glucocorticoid receptors (GR) are stabilized in the cytosol by various chaperones before homodimerizing and translocating into the nucleus. Childhood abuse and polymorphisms in FKBP5, a chaperone for GR, are associated with posttraumatic stress disorder.

Glutamate

Definition

The principal excitatory neurotransmitter in the central nervous system, ubiquitous throughout the cortex and subcortical regions of the mammalian brain. Glutamate released from axonal presynaptic terminals generates electrical excitation and action potentials in postsynaptic neurons. It is a key molecule in learning, memory, and cellular metabolism. Different glutamate receptor systems play differential roles in information transfer, neuroplasticity, and maintenance of synaptic strength. There are four distinct glutamate receptors: ► NMDA, ► AMPA, and kainate, all ion channel receptors, and a ► metabotropic receptor. The NMDA receptor, in particular, has been linked to a long-term potentiation of neuronal activity, which may be a basis for synaptic plasticity and learning.

Glutamate and EAA Transporters

Synonyms

EAAT

Definition

Glutamate (Glu) and EAA transporters (EAAT) are membrane transport proteins responsible for removing Glu from the synapse into glial cells (EAAT1-3) or neurons (EAAT4). They belong to the larger family of neurotransmitter transporters including GABA transporters, glycine transporters, and the different monoamine transporters. Glu transporters play a crucial role in regulating the amount of synaptic Glu and are therefore responsible for terminating synaptic transmission. By reducing the

exposure to Glu, they further serve to protect the cell from excitotoxicity. Known EAAT inhibitors are WAY213613 and dihydrokainic acid.

Glutamate Microelectrode Arrays

Definition

To measure glutamate, a selective and highly active glutamate oxidase from *Streptomyces* sp. X-119-6 is applied to two microelectrode recording sites (Hascup et al., 2007). Reference or "sentinel" microelectrode sites are created by applying a chemically inactive protein (bovine serum albumin) to other recording sites. All recordings are performed using amperometry at +0.7 V versus an Ag/AgCl reference with a FAST16mkII electrochemical recording system (Quanteon LLC, Nicholasville, Kentucky). Drugs are locally applied from micropipettes or cannulae between the recording sites using pressure ejection or volume displacement, respectively. Subtraction algorithms are used to remove the background and interfering signals by using the responses from the sentinel or self-referencing recording sites.

Glutamate Receptors

Definition

Glutamate receptors are transmembrane receptors located on neuronal membranes. There are several receptor subtypes including the ► NMDA (*N*-methyl-*d*-aspartate glutamate receptor), kainate, ► AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate acid glutamate receptor) and mGluR receptors. Glutamate is one of the major excitatory transmitter systems in the central nervous system and many of these systems have been implicated in learning and memory processes. ► Alcohol acts as a weak antagonist of glutamate receptors during initial exposure to alcohol. However, chronic exposure to alcohol can result in an increase in the number of glutamate receptors (upregulation); such an effect has been reported with NMDA receptors. An increase in glutamate receptors may lead to a neuronal circuit that is hyper-excitable. This hyper-excitability is more pronounced in the absence of alcohol and may be a critical component in the underlying neurobiology of alcohol withdrawal.

Glycine Transporter 1

Definition

Glycine transporter 1 is widely expressed in astroglial cells throughout the mammalian central nervous system and has been implicated in the regulation of N-methyl-D-aspartate (NMDA) receptor activity. Glycine transporter 1 plays a pivotal role in maintaining the glycine level at the glutamatergic synapse.

Go/No-Go Task

Synonyms

Response conflict task

Definition

Behavioral tests in which subjects respond in the presence of a *Go* signal or cue and inhibit responding in the presence of a *No-Go* signal or cue. For example, in a rodent version, responding in the presence of the *Go* stimulus is reinforced but in the presence of the *No-Go* stimulus it is not (although in some "symmetrically reinforced"

versions withholding the response in the presence of the *No-Go* stimulus is also reinforced). Response accuracy can be examined using ► signal detection theory, which uses a 2 × 2 matrix of signal (*Go* or *No-Go*) and response (occurred or omitted). Responses occurring during the *Go* signal are called hits. Responses occurring during the *No-Go* signal are false alarms. Trials on which there are no responses during the *Go* signal are misses. Trials on which there are no responses during the *No-Go* signal are correct rejections.

Goal Tracking

Synonyms
Anticipatory food seeking; Anticipatory goal seeking

Definition
Goal tracking refers to orientation and approach behavior to the source or location of a rewarding (appetitive) stimulus such as food, water, sex, etc. In rats, this may be operationalized as head-entries into the receptacle where sucrose is delivered. For nonhuman primates, this could be measured as hand entries in a recessed container where food or treats are provided. Goal tracking is a widely used behavioral measure of associative learning.

GPCR

Definition
G-protein-coupled receptor. This is the largest group of transmembrane receptors, including all opioid receptors, that predominantly transducer intracellular signals via G-proteins or trimeric GTP binding proteins. A large number of psychoactive drugs act on GPCRs.

G-Protein-Coupled Inwardly Rectifying Potassium Channels

Synonyms
GIRK channel

Definition
A group (Kir 3.1 – 3.4) of inwardly rectifying (so-named because they have a higher conductance for potassium entering than leaving the cell) potassium channels that are activated by G-protein βγ-subunits. When activated, they hyperpolarize membranes to reduce excitability.

Gradient-Echo EPI

► Echo-Planar Imaging

Gradient-Echo Images

Synonyms

Gradient-echo MRI; Gradient-recalled-echo (GRE) planar images

Definition

Gradient-echo imaging is one of the two most frequently used pulse sequences in modern day MRI as distinct from spin-echo (SE) MRI. There are many variations of the basic gradient-echo (GE) sequence. It is the most common form of fMRI pulse sequence, typically with echo-planar imaging (EPI) or more recently, spiral imaging.

Guard Column

Definition

In ► high-pressure liquid chromatography, this guard column is a short column (typically 1–5 cm), normally packed with the same stationary phase as the analytical column, and placed immediately before the analytical column. It serves two main purposes: first as a filter to remove any fine particulate material from the mobile phase before it reaches the analytical column and second to pre-saturate the mobile phase before it reaches the analytical column, thus protecting the analytical column from dissolving.

H

Habit Reversal Therapy

Synonyms

CBIT; Cognitive behavioral therapy for trichotillomania; Comprehensive behavioral intervention for tics or trichotillomania; HRT

Definition

Habit reversal therapy (HRT) is an evidence-based behavioral therapy used in the treatment of tics, trichotillomania, and other body-focused impulse control disorder. HRT involves several different components – self-monitoring, awareness training, stimulus control, and competing response training.

Habit Reversal Training

Synonyms

HRT

Definition

A behavioral intervention that attempts to replace a tic with a voluntary movement or sound that can then be discarded. The premonitory urge that subsides following the performance of the tic suggests that the relief of the premonitory sensation reinforces the performance of the tic. In HRT, subjects are taught to initiate an alternative movement (or sound) upon detection of the premonitory urge and to continue the voluntary movement until the urge subsides.

Habituation

Mark A. Geyer
Department of Psychiatry, University of California San Diego, La Jolla, CA, USA

Synonyms

Extinction

Definition

Habituation is a decrement in responding that results from repeated presentations of an initially novel stimulus in the absence of sensory adaptation and motor fatigue. Experimentally, habituation can be distinguished from sensory adaptation or motor fatigue by the demonstration of ▶ dishabituation or by demonstrating stimulus specificity (i.e., the response still occurs to other stimuli). Habituation is considered to be the simplest form of learning. More specifically, habituation refers to a nonassociative form of learning insofar as it occurs in the absence of any contingency associated with the stimulus. Habituation is a prerequisite to selective attention; in the absence of habituation, an organism would continue to respond to all stimuli depending upon its inherent characteristics.

Characteristics of Habituation

As detailed elsewhere (Thompson and Spencer 1966; Rankin et al. 2009), habituation is a general phenomenon that can be observed across species, stimulus modalities, and response systems. Although habituation typically refers to behaviors, some use the term to refer to decrements in responses, such as neuronal firing, ▶ event-related potentials, or even biochemical responses. In theory, the process of habituation is expected to exhibit a progressive exponential decay to an asymptotic level of the frequency and/or magnitude of the given response. In practice, the decrement is commonly linear or may exhibit facilitation prior to decrementing because of the simultaneous process of ▶ sensitization. Sensitization, in the Pavlovian sense of the term, is an incremental change in the response to a stimulus in the absence of any associated contingency. Dual-process theory suggests that the observed response in an experimental study of habituation reflects the summed effects of the two independent underlying processes of habituation and sensitization, with sensitization typically being most evident in response to the first several stimulus presentations, and habituation becoming the dominant process as the presentations continue (Groves and Thompson 1970). Sensitization is expected to be directly proportional to stimulus strength. In contrast, the less intense the stimulus, the more rapid and more pronounced the behavioral response decrement, i.e., the habituation.

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

Presentation of a different stimulus in the same or different modality may lead to an increase of the habituated response to the original stimulus, a phenomenon called "dishabituation." The experimental test required to demonstrate dishabituation is to show an increase in response to the original stimulus, not the response to the dishabituating stimulus, which may not even elicit an observable response on its own. Spontaneous recovery is a related phenomenon in which the habituated response recovers at least partially if the stimulus is withheld and then presented again.

Habituation typically refers to relatively short-term changes within a series of repeated stimuli, but can also refer to longer-term reductions in response frequency and/or magnitude that may last for hours, days, or weeks. This distinction is sometimes described as within- versus between-session habituation. In analogy with short- and long-term memory, short- and long-term habituation phenomena appear to be subserved by somewhat different underlying mechanisms, the latter presumably involving changes in protein synthesis (Rankin et al. 2009). Furthermore, pharmacological effects on short-term habituation are not reliably predictive of parallel changes in long-term habituation. A related consequence of exposure to a within-session habituation protocol is the phenomenon of latent inhibition, in which it becomes more difficult to learn an association to a previously habituated stimulus than to a novel (i.e., nonpreexposed) stimulus. As with ▶ extinction learning, latent inhibition can be shown to differ from simple long-term habituation, but only when an intervention can be interposed between the original habituation protocol and the acquisition training of the new association. Thus, in studies of genetically modified animals or psychiatric populations, the effects on habituation versus latent inhibition are fundamentally confounded.

Impact of Psychoactive Drugs

As noted, habituation affects many, if not all, stimulus-response systems. In human psychophysiology, the most common stimuli are visual, auditory, or tactile, and the most common measures are motor reflexes or skin conductance orienting responses (Bernstein 1987; Groves and Thompson 1970). In the field of psychopharmacology, however, the most common measures are based on motoric ▶ startle responses, in part, because skin conductance responses are variable, quite transient, and highly sensitive to peripheral autonomic changes. When mammals are exposed to a sudden stimulus, typically a rapid-onset acoustic noise or tactile (e.g., airpuff or shock) stimulus, a startle response is elicited (Davis 1980). In both rodents and humans, habituation can be quantified by measuring the magnitude of the startle response to repeated presentations of startling stimuli. Using startle habituation measures is advantageous in psychopharmacologic research for a number of reasons (Geyer and Braff 1987). First, startle habituation in rodents has some face, predictive, and construct validity for startle habituation in humans. Second, startle habituation exhibits some stability across repeated testing sessions, enabling one to use longitudinal designs to explore developmental and environmental perturbations on habituation over time and across experience. Third, startle habituation involves fairly rapid tests that do not involve complex stimuli, increasing their ease of use and their reliability. Since startle relies on a simple reflex measure, its reliability and reproducibility are greater than more complex behavioral measures that are modulated by competing behaviors or motivations (e.g., approach/avoidance behavior), and increases the chances of translation of these effects to humans.

Startle habituation has been found to be reduced in ▶ schizophrenia and schizotypal patients, and also in patients with panic disorder (Geyer and Braff 1987; Ludewig et al. 2003). Attentional and information processing dysfunctions have long been considered important in understanding schizophrenia and other psychiatric disorders. The deficit in habituation seen in schizophrenia is thought to reflect an inability to filter or "gate" sensory (and, theoretically, cognitive) information. Theoretically, impairments in basic information processing functions such as habituation contribute to difficulties in maintaining selective attention, which, in turn, leads to disordered thought and cognitive fragmentation observed in psychotic disorders such as schizophrenia. Given the cross-species comparability of startle habituation protocols, identification of genetic contributions to startle habituation in humans can be extended to parallel studies, using genetically engineered mice or other relevant strains of rats or mice (Geyer and Braff 1987; Halberstadt and Geyer 2009).

The psychopharmacology literature is not rich in definitive studies of habituation. Many studies have reported putative changes in the habituation of the exploratory response of rodents to novel environments. Nevertheless, the fundamental difficulties in quantifying the initial response to the stimulus, and in even defining the discrete stimulus itself, have complicated the interpretation of drug effects as being related to the process of habituation *per se*. As noted above, measures of startle habituation have proven more tractable to study in rodents as well as humans. It should be noted, however, that typical habituation protocols in

rodents involve tests of 30–60 min in duration. Hence, it is critical to consider potential confounding of the time after drug administration with changes in the process of habituation. Furthermore, despite the long-standing acceptance of the dual-process theory, empirical approaches to separating effects on sensitization versus habituation remain weakly based upon the premise that sensitization effects are short-lived, relative to habituation effects (Meincke et al. 2004; Halberstadt and Geyer 2009). These complications have contributed to the lack of clarity in the literature on the psychopharmacology of habituation. Among the most robust observations is that deficits in startle habituation can be induced in rodents and, apparently, in humans, by treatment with serotonergic agonists, including ► hallucinogenic drugs such as mescaline or LSD (Geyer and Braff 1987; Dulawa and Geyer 2000). Evidence suggests that these deficits in habituation are attributable to the agonist actions of these drugs at 5-HT_{2A} receptors. Conversely, 5-HT_{2A} antagonists can accelerate habituation in a manner that is not due to the time-course of the drug action. Similarly, psychotomimetic glutamate antagonists such as ► phencyclidine or ► ketamine have been reported to attenuate startle habituation, although some of these effects may be complicated by effects of the drugs on the initial level of responding, prior to any influence of habituation. There is also evidence of phenotypic differences in sensitization and habituation of startle in mutant mice, in which specific subtypes of serotonin or dopamine receptors have been deleted (Dulawa and Geyer 2000; Halberstadt and Geyer 2009).

Half-Life

Synonyms

Biological half-life; Elimination half-life

Definition

Half-life is defined as the time interval required for a quantity undergoing exponential decay to reach half of its initial value. In the context of a drug injection, half-life refers to the interval required for drug levels from a single drug administration to decline to half of the peak value. Half-life is governed by ► pharmacokinetic variables such as drug degradation and clearance from the body.

Hallucinations

[2]Institute of Cognitive Neuroscience, University College London, London, UK

Definition

Hallucinations are perceptions without objective reality; that is, in the waking state, sensory events are experienced,

which are unfounded but appear to emanate from external space. Hallucinations can develop in any sensory modality but most commonly are visual or auditory in nature. They can be simple, for example patterns or noises, or complex, for example images of people, objects and scenes, voices of people speaking in coherent sentences, or musical recitals.

Hallucinations normally develop in association with other mental state abnormalities, when there is a medical condition adversely affecting brain function. However, they can also occur as isolated phenomena in people who are otherwise normal. For example, it is not uncommon to experience the physical presence or voice of a deceased loved one in the early stages of bereavement. Auditory or visual hallucinations can also be experienced when waking-up or falling asleep and are known as hypnopompic and hypnagogic hallucinations, respectively. Even a small percentage of the general public report hearing voices on a fairly regular basis when going about their daily routine. In these circumstances, hallucinatory experiences are usually transient or mild and do not give rise to significant distress. When people who experience hallucinations come to medical attention, it is usually because they are vivid, frequent and intrusive, and when insight into their veracity is lost.

Hallucinations can arise during the course of an organic disorder, usually in the context of diffuse cerebral cortical dysfunction, as in states of delirium where consciousness is impaired due to a metabolic derangement or a toxic influence. Notable examples are the alcohol withdrawal states of ► delirium tremens, when vivid visual hallucinations of animals are commonly experienced ("pink elephants") as well as tactile hallucinations of insects burrowing into the skin (formication), and alcoholic hallucinosis, when intense persecutory voices are heard. Hallucinations also commonly develop in organic disorders where consciousness is not impaired but when there is a widespread neurodegeneration of the cerebral cortex, as in ► Lewy body dementia or ► Alzheimer's disease. However, it is the study of hallucinations occurring in more rare circumstances, when there is specific focal pathology, which has provided important information concerning their neural basis. This has shown that hallucinations can arise when there is an abnormality in the sensory pathway corresponding to the modality of the hallucination itself which can be located anywhere from the primary sensory organ to the secondary sensory association cortex. Hence, the Charles Bonnet syndrome, in which vivid visual hallucinations of people, animals, or scenery are experienced, is most often associated with acquired damage to the retina or optic nerve. An auditory equivalent, musical hallucinosis, has been described in acquired deafness. Subcortical lesions of the thalamus, cerebral peduncles, and brainstem, due to tumor or infarction, can also give rise to complex visual or auditory hallucinations, presumably due to the transection of modality-specific ascending sensory nerve fibers (Braun et al. 2003). A common finding in functional neuroimaging studies of these disorders is that, even when the pathological locus is "downstream," there is increased activity in the corresponding modality-specific secondary association cortex (Allen et al. 2008). Secondary sensory association cortex is the area in which sensory stimuli are organized into coherent percepts, having been processed in fragmented form in primary sensory cortex. Thus, one explanation is that secondary association cortex spontaneously generates images or false perceptions using "top down" input from memory circuitry in an attempt to make sense of reduced or aberrant sensory input (Allen et al. 2008; Braun et al. 2003; Frith and Dolan 1997).

In the lesion cases described above, insight into the hallucinatory nature of experiences is often retained. When insight is disturbed and hallucinations are regarded as real, a disturbance of supra-modal association cortex is implicated, especially that of the frontal lobe. This has largely been demonstrated by the study of hallucinations in mental illnesses (Allen et al. 2008) known as "functional psychoses" because there is no obvious associated organic pathology. Schizophrenia is the most prominent example of such a disorder in which hallucinations of voices discussing the person in a derogatory fashion or commenting on their actions are core symptoms. One view is that neural processing in circuitry, critically involving dorsolateral prefrontal and anterior cingulate cortexes, is weakened as part of the neurobiology of the disorder. This circuitry is considered to be involved in monitoring and assigning significance to information being processed elsewhere and instigating actions accordingly. Central to this function is distinguishing whether events or actions, e.g., images or thoughts, are generated by the self or not. This is consistent with an influential psychological explanation of hallucinations by Frith (1995) as being the product of a failure of ► self-monitoring. That is, the failure to recognize that actions such as inner speech are initiated by the self results in them being misattributed to external agencies.

► Delusions are false beliefs that are held with complete conviction, unaffected by clear evidence to the contrary and implausible or bizarre. For a belief to be considered a delusion, it should additionally not be shared by other members of the culture from which the individual who holds it originates.

Delusions commonly occur alongside hallucinations as part of the spectrum of psychotic phenomena. Like hallucinations, they can arise in the context of organic disorders affecting cerebral function or mental illness. Again, like hallucinations, there are different forms of delusions typified by their content and sometimes associated with specific disorders.

The most frequent type of delusion is self-referential in nature. Paranoid delusions are the most common, witnessed in many organic or functional ▶ psychoses, and characteristically are imbued with fear and anxiety. Thus, persecutory delusions include beliefs about being threatened, deceived, or conspired against, and delusions of reference are beliefs that every day events, such as those reported on the TV or in newspapers, are about them. Delusions associated with an abnormally elevated or depressed mood are seen in the affective psychoses. Hence, grandiose delusions are typical of the manic state in ▶ bipolar disorder and concern an inflated sense of self-importance such as having special powers or being chosen by God for a special purpose. In psychotic depression, delusions of guilt, that one has committed a heinous crime or is responsible for some disaster; hypochondriasis, that body parts are failing or rotting; and nihilistic delusions, that the self or other people do not exist, are characteristic.

Another set of delusions known as "first rank symptoms" (Sims 1991) are more characteristic of ▶ schizophrenia. These cannot be understood to arise from ordinary life experience and, so long as there is accompanying social or occupational dysfunction, are alone sufficient for the diagnosis. These concern the belief that thoughts, feelings, or actions are under the control of outside forces. For example, thoughts may be inserted, withdrawn, or broadcast to the outside world and actions may be "made" or externally directed (also known as somatic passivity).

Current Concepts and State of Knowledge

The Neurochemistry of Hallucinations and Delusions

Insight into the neurochemical basis of hallucinations comes from the study of ▶ Parkinson's disease (PD) in which the primary pathology is degeneration of the ascending midbrain ▶ dopamine projections to basal ganglia and cortex. Hallucinations develop in up to 40% of patients and are mainly visual. In most cases, these are directly attributable to the dose of ▶ antiparkinsonian medication as they recede when this is reduced. Studies have shown that the direct dopamine D_2 receptor agonists are most likely to induce hallucinations in susceptible individuals but hallucinations have also been reported with other antiparkinsonian drugs, including 3,4-dihydroxy-L-phenylalanine ▶ L-DOPA, anticholinergic compounds, ▶ amantadine, monoamine oxidase-B inhibitors, and catechol-methyltransferase inhibitors, all of which have the common action of enhancing dopamine neurotransmission. One explanation is that in some cases, doses that are effective in treating the PD movement disorder, which is due to nigrostriatal dopamine depletion, may cause overstimulation of the mesolimbic/mesocortical dopamine system and that this mediates the emergence of hallucinations.

Other evidence supports a central role of abnormal dopamine neurotransmission not only in the development of hallucinations but also delusions. Indirect dopamine agonists, such as ▶ amphetamine and ▶ methylphenidate, administered at doses that are ineffective in healthy subjects, have been found to worsen both of these psychotic phenomena in schizophrenia (Lieberman et al. 1990). In addition, it has been known for several decades that drugs that block dopamine D_2 receptors, for example the typical or ▶ first-generation antipsychotics, such as ▶ haloperidol, are efficacious in the treatment of hallucinations and delusions, regardless of the context in which they occur. The atypical or ▶ second-generation antipsychotics are also efficacious in this respect. Although these have heterogeneous pharmacological profiles including the blockade of serotonin receptors or other dopamine receptors, they share the common mechanism of D_2 receptor blockade.

Other neurotransmitters have also been implicated as mediators of psychotic symptoms but less strongly than dopamine. This is based on self-reports of individuals under the influence of psychoactive drugs. Specifically, the so-called ▶ hallucinogens, lysergic acid diethylamide (LSD), psilocybin, and mescaline, are all 5-hydroxytryptamine 2A ($5\text{-}HT_{2A}$) receptor agonists suggesting a role for serotonin; the anesthetic drugs ▶ ketamine and ▶ phencyclidine are both ▶ *N*-methyl D-aspartate (NMDA) antagonists suggesting glutamate neurotransmission also plays a part. These compounds most often produce dissociated states and altered perceptions in the form of visual illusions or simple hallucinations rather than the more complex hallucinations and delusions experienced in organic and mental illness. Nevertheless, the known interactions between ▶ dopamine, ▶ serotonin, and ▶ glutamate in the modulation of neural processing in circuitry involving frontal cortex, thought to be abnormal in patients experiencing psychotic symptoms, substantiates the involvement of neurotransmitters other than dopamine in psychosis.

The Dopamine Hypothesis of Psychosis

Two variants of the dopamine hypothesis have been proposed: the postsynaptic variant proposes that abnormal dopamine transmission is related to hypersensitive D_2 receptors; the presynaptic variant holds that abnormal dopamine transmission is related to elevated dopamine synthesis or release.

While initial molecular imaging studies using [^{123}I] IBZM-SPECT (single-photon emission computed tomography, ► SPECT) were suggestive of abnormally elevated D_2 receptor binding in schizophrenia, later studies that included unmedicated patients produced negative findings, suggesting that antipsychotic medication may have been an important confound in early work. However, several positron emission tomography (► PET) studies, for example using [^{18}F]-DOPA, have provided evidence for elevations in presynaptic dopamine availability, even in antipsychotic-naïve patients and patients in the prodrome for psychosis (Howes et al. 2007). Furthermore, studies that measured stimulant-induced dopamine release in antipsychotic-naïve patients with schizophrenia have reported not only that dopamine release is elevated in these patients, but that the extent of dopamine release is strongly related to the increase in psychotic symptoms following stimulant administration. Together, these findings reinforce the importance of dopamine in the generation of psychotic symptoms, particularly delusions. However, there remains a gap in understanding the mechanism by which increased dopamine release might cause an individual to develop such persistent and irrational false beliefs.

In order to fill this gap, a number of theorists have sought to explain the link between dopamine and delusions by appealing to the function of dopamine in the healthy brain. Many studies have suggested that while dopamine is not necessarily released when rewards (e.g., food) are actually delivered, it is released when rewards are expected. Others have suggested that dopamine may act as a teaching signal during reward learning. In particular, it has been suggested that dopamine release mediates motivational salience in the brain, i.e., the ability of stimuli associated with reward to drive goal-directed behavior. Salient stimuli are those that stand out from their surroundings and automatically capture attention due to some distinguishing characteristics, be it perceptual contrast, novelty, surprise, or emotional association. Recent evidence suggests that novelty salience may also trigger dopamine neuron firing, raising the possibility that dopamine may play a more general role in encoding salience in the brain.

Appealing to this notion of dopamine as a general signal for salience, a recent hypothesis suggested that psychosis and, in particular, delusions might be related to a state of "aberrant salience," driven by poorly regulated dopamine release (Kapur 2003). In this framework, the release of dopamine out-of-context with the environmental surroundings leads to the tagging of irrelevant stimuli as salient, leading individuals to attribute to them some importance or relevance. In this framework, a delusion is conceptualized as the post-hoc rationalization of accumulated aberrant salience experiences. One of the strengths of this hypothesis is that it explains why delusions take some time to resolve following the onset of antipsychotic medication. It suggests that ► antipsychotics do not treat delusions directly, but instead limit the aberrant salience experiences that cultivate them, allowing delusions to extinguish gradually. It also explains why patients dislike taking antipsychotic medication, since both aberrant and normal motivational salience processes will be affected by D_2 blockade, resulting in a state in which individuals experience a lack of motivation or energy. However, further work is required to test the numerous predictions made by this influential hypothesis.

Definition

► Hallucinogen abuse and dependence are known complications resulting from the illicit use of drugs in this category, such as LSD and psilocybin. Users do not experience withdrawal symptoms, but the general criteria for ► substance abuse and ► dependence otherwise apply. Dependence is estimated in approximately 2% of recent-onset users in the United States. Acute hallucinogen intoxication may induce a plethora of physical and psychological effects that can become so overwhelming to the user as to result in seeking emergency psychiatric care. Providing supportive psychotherapy usually proves effective, though sometimes the use of a sedative hypnotic for anxiety is indicated in addition. No randomized controlled trials have examined treatments of hallucinogen abuse or dependence, but standard treatments (motivational interviewing, relapse prevention, outpatient counseling, participation in self-help groups, family therapy) should still be offered.

Role of Pharmacotherapy

Both hallucinogen abuse and ► hallucinogen dependence are characterized by patterns of compulsive and repeated drug use despite the knowledge of significant harm caused by the activity. However, it is important to point out that hallucinogen use very rarely leads to the development of classic dependence syndromes, such as those seen with opiates or alcohol. As a class, the ► hallucinogens lack significant direct effect on the dopamine-mediated reward system, and studies to date have failed to train animals to ► self-administer these compounds as is typical for dependence-inducing drugs (Nichols 2004). In contrast to the users of other substances of abuse, hallucinogen users do not experience withdrawal symptoms and, therefore, this trait is not a criterion for diagnosing hallucinogen dependence. It should also be noted that, in general, ► tolerance rapidly increases when hallucinogens are used frequently, and exponentially so with daily use.

Overall rates of abuse and dependence are thought to be low when compared with other substances (Wright et al. 2007). In the USA, hallucinogen dependence has been estimated in 2% of recent-onset users (first use within 24 months of survey) and 5% of past-onset users (first use 24+ months, last use within 12 months), with a relative risk of dependence apparently greater in users with very early age of onset of hallucinogen use (10–11 years old) (Stone et al. 2007). These figures are likely to be an overestimate, as the survey included the non-hallucinogenic structured amphetamine ► methylenedioxymethamphetamine (► MDMA) (that does have entactogenic properties) and the ► dissociative anesthetic PCP within their definition of hallucinogen.

Similar to other substances of abuse, hallucinogens may induce specific, related disorders. These include hallucinogen intoxication, hallucinogen-induced psychotic, mood, anxiety, delirium, or not otherwise specified (NOS) disorder, and the very rare ► hallucinogen persisting perceptual disorder (HPPD). These disorders arise in the context of substance use and may manifest during intoxication, after the acute effects have subsided, or in the days that follow (APA 2000). The diagnosis of a hallucinogen-induced psychotic, mood, anxiety, or delirium disorder is made only if the symptoms are in excess of what is expected from intoxication (APA 2000).

Symptoms, Diagnosis, and Treatment

Hallucinogen ingestion is the central component of hallucinogen abuse and hallucinogen dependence. It is therefore necessary to first discuss the effects, evaluation, and treatment of patients suffering from acute pathological cases of hallucinogen intoxication.

Physical and Psychological Effects of Acute Hallucinogen Intoxication

The typical syndrome of psychological alterations associated with the ingestion of hallucinogens, commonly referred to as "tripping," may induce a wide variety of emotional, cognitive, and behavioral effects (Table 1) (Hollister 1984). The visual components are typically not true hallucinations but illusions, such as the perception of geometric patterns or scenic dream-like visions appearing before closed eyes, perception of movement in stationary objects, and ► synesthesias. Content of visual and most emotional phenomena typically reflect the psychodynamics of the user (Leuner 1962). Colors may appear intensified, and altered human and animal forms may appear in the visual field. Hallucinogens activate affectivity and may cause significant changes in mood, where users may change from euphoria to depression or anxiety or vice versa. In some cases, psychotic-like reactions may also be experienced. In short, the psychological effects of hallucinogens are highly variable and strongly influenced by both the individual's mind-set (► expectancies and their influence on drug effects), and their physical surroundings and social setting. Toxicity of LSD, psilocybin, and other classical hallucinogens is very low (see Passie et al. 2008). Overdosing is possible with respect to psychological reactions, but no case of lethal overdose is known, and there is no evidence of long-term neurocognitive toxicity (► neurotoxicity) (Halpern and Pope 1999).

Diagnosis of Acute Hallucinogen Intoxication

Patients present for treatment most often because they experience a panic or depressive reaction, commonly referred to as a "bad trip." Such reactions can begin any time

Hallucinogen Abuse and Dependence. Table 1. Hallucinogen[a] intoxication may include a cluster of the following.

Physical effects[b]	Psychological effects
Typical (mild to very mild): Tachycardia Cardiac palpitation Hypertension or hypotension Diaphoresis Hyperthermia Motor incoordination Tremor Hyperreflexia Altered neuroendocrine functioning	Typical: Intensification and lability of affect with euphoria, anxiety, depression and/or cathartic expressions Dream-like state Sensory activation with illusion, ► pseudo-hallucination, hallucination, and/or synesthesia Altered experience of time and space Altered body image Increased suggestibility Lassitude/indifference/detachment Acute cognitive alterations with loosening of association, inability for goal-directed thinking, and memory disturbance
Typical (mild to strong): Mydriasis Arousal Insomnia	"Positive": Sense of perceiving deeper layers of the world, oneself, and others ("consciousness expansion") Mystical experience Sense of profound discovery/healing (See ► ritual uses of psychoactive drugs)
Occasional: Nausea Vomiting Diarrhea Blurred vision Nystagmus Piloerection Salivation	"Negative": Psychosomatic complaint Impaired judgment Derealization Depersonalization Megalomania Impulsivity Odd behavior Paranoid ideation Suicidal ideation

[a]Indolealkylamine and phenylalkylamine hallucinogens only

[b]Some effects are reactionary to psychological content (e.g., increased heart rate and nausea due to anxiety), and complaints can be dependent on factors such as mindset, setting, dose, and supervision. Intoxicated individuals may also deny physical impairment or claim increased energy, sharpened mental acuity, and improved sensory perception

after the onset of effects and may include fears of "going insane" (Strassman 1984). There may also be paranoid ideation, feelings of being manipulated, or being in a situation without any escape. The acute syndrome of hallucinogen intoxication should be suspected when a patient (or companion) reports recent ingestion of a hallucinogen, and presents with a characteristic constellation of sympathomimetic findings with a clear sensorium (unlike NMDA antagonist dissociative anesthetics like PCP that induce a clouding of consciousness). Since laboratory testing is generally not available in most acute settings, obtaining an accurate history and clinical examination is critical in establishing the diagnosis. Street drugs often contain various adulterants; therefore, the actual identity of the ingested substance may not be known. However, the hallucinogens typically produce similar effects, which should be carefully assessed. Signs and symptoms of hallucinogen intoxication are reviewed in the previous section (see Table 1). Physical examination will also provide important clues that can support the diagnosis of hallucinogen intoxication (in particular, widely dilated pupils that do not rapidly/tightly constrict to accommodate bright light). Hallucinogens have varying duration of action; nevertheless, the acute reaction typically lasts less than 10 h (maximum 12–24 h), and reactions lasting longer will require further investigation to rule out other etiologies.

Treatment of Acute Hallucinogen Intoxication

The "talk down" (more accurately the "talk through") is usually the primary effective intervention indicated in these situations (Taylor et al. 1970). This consists of keeping the patient in a low-stimulus environment (i.e., a quiet space with dimmed lights and minimal distractions) and providing emotional support. Arranging for a reliable sitter (a non-intoxicated companion) to look after the patient is recommended. The sitter can help in keeping the patient calm and oriented by providing a sympathetic presence. In addition, the sitter can also provide reassurance to the patient that the experience is generally non-hazardous, drug-induced, and time-limited, which will resolve with full recovery. The patient should not be left alone until the effects of the drug wear off.

If severe agitation does not respond to redirection and concerns for safety of the patient or others remain, ▶ benzodiazepines are quite effective in reducing anxiety and panic. Many authorities recommend oral ▶ diazepam or ▶ lorazepam, although intramuscular and intravenous routes are more immediately effective. Avoid physical restraints if possible and limit the use of ▶ antipsychotics since paradoxical effects have been reported (Strassman 1984). While no controlled trials have examined the efficacy of antipsychotic drugs for hallucinogen-induced agitation, rare cases may require such an intervention after benzodiazepines have not proven sufficient. However, great caution must be exercised, since ▶ first generation antipsychotics lower the seizure threshold and may also induce hypotension.

Once the acute symptoms subside, patients are usually able to go home accompanied by a companion (Strassman 1984). It is important to advise patients that subsequent ingestion of hallucinogens may precipitate similar reactions. If symptoms persist for longer than 24 h or there are accompanying severe mood or psychotic symptoms that warrant independent clinical attention, hospitalization may be considered.

Gastric lavage should be avoided as it is not effective in removing substances that were usually ingested several hours prior to hospital presentation. Moreover, gastric lavage will invariably worsen the patient's mental state.

Diagnosis of Hallucinogen Abuse and Dependence

Multiple drug use is common; the differential must always contain other substance use or substance-induced disorders. ▶ Alcohol abuse and dependence frequently occurs comorbid to hallucinogen abuse and should therefore also be assessed carefully in this population. ▶ Schizophrenia, schizophreniform, ▶ bipolar, and ▶ schizoaffective disorders must also be ruled out in these patients by assessing the longitudinal course of the symptom constellation and their temporal relation to hallucinogen ingestion.

Treatment of Hallucinogen Abuse and Dependence

There are no ▶ randomized controlled trials that have examined the treatment of hallucinogen abuse or dependence. However, general principles that apply to other substances of abuse should be employed in treating these patients. Motivational interviewing, detoxification, relapse prevention, intensive outpatient counseling, involvement with self-help groups, and family therapies are examples of interventions that need to be individualized for each particular patient.

Since polysubstance abuse and dependence is common, treatment should also target other substance abuse and dependence that are thought to be contributing to the disturbances. Furthermore, treatment should be provided with a dual diagnosis approach, and any underlying psychiatric disorder should be treated concurrently. No controlled trials have been conducted to evaluate the efficacy of pharmacotherapies.

Hallucinogen Dependence

Definition

Dependence should be considered when a chronic pattern of abuse appears to be out of control, such as using larger amounts than was intended or the inability to cut down the use, and continues despite awareness of social, psychological, or physical harms related to hallucinogen use.

Hallucinogen Intoxication

- ▶ Hallucinogen Abuse and Dependence

Hallucinogen Persisting Perception Disorder

Synonyms

HPPD

Definition

A rare condition in which some sensory element of hallucinogen intoxication is evocatively reexperienced in the days to weeks to months (and rarely years) after intoxication has ceased. Sometimes referred to as "flashbacks," HPPD is diagnosed when clinically significant impairments occur related to the symptoms.

Entheogens; Psychedelics; Psychotomimetics

Definition

Hallucinogens are drugs that are characterized principally by their ability to produce alterations in perceptual processes. They can effect profound changes in consciousness that involve all of the sensory modalities. At lower doses they produce alterations and distortions in sensory processing, often including ▶ synesthesias, or mixing of the senses, where, as an example, music may be perceived as colorful kaleidoscopic patterns. They produce changes in mood and affect, and can alter perception of time, space, and self in ways that ordinarily occur only during dreaming, or at times of religious exaltation. They increase the intensity and lability of affective responses, and engender a feeling of portentousness, e.g., a sense that the

experience is highly meaningful and momentous. Alterations in consciousness can range from feelings of bliss and a sense of oneness with the universe, to fear, paranoia, and psychotic reactions. Hallucinogens also produce ► cognitive impairments, such as deficits in ► working memory and associative learning, yet leave executive functions largely intact. They also impair high-level motion perception and reduce binocular rivalry rate and rhythmicity. The user's expectations (mind-set) and the environment (setting) fundamentally alter the nature of the experience.

Pharmacological Properties

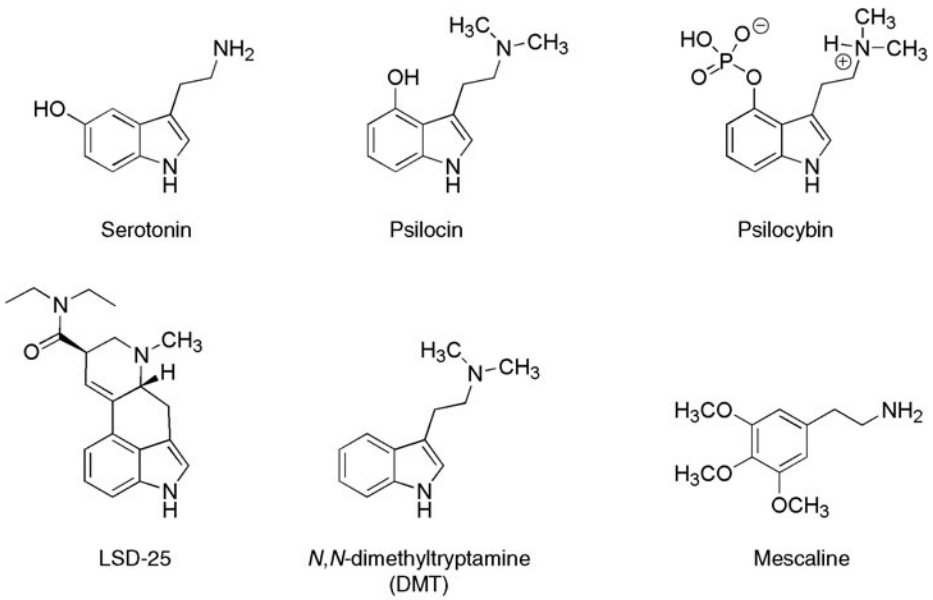
History

For the purposes of this discussion we shall consider hallucinogens to be those compounds, primarily natural or semi-synthetic, that share a common pharmacological mechanism of action and similar human psychopharmacology. This discussion will not cover substances like anticholinergic atropine-like compounds, or glutamate antagonists, which also can produce profound disruptions of consciousness, but have different mechanisms of action and are not generally accepted to have psychopharmacology similar to the classic hallucinogens.

The use of hallucinogens, in the form of natural plant substances and plant decoctions, stretches back into antiquity, with written records indicating the use of these materials in ancient India (e.g., *Soma*), Greece (*kykeon*), and by indigenous Mesoamerican peoples (*peyotl*, *teonanacatl*) (Schultes and Hofmann 1992). As powerful modifiers of consciousness, they were often tools of the shaman, or tribal healer, but also found a place in certain religious rituals and social events. Largely unknown to Western man until the end of the nineteenth century, they were dramatically "rediscovered" in the late twentieth century, becoming popular with college students, artists, and musicians in the 1960s, a phenomenon that ultimately led to strict legal control and proscriptions on their use.

The first "modern" study of a hallucinogen occurred in the late 1890s, when Arthur Heffter, a highly respected German pharmacologist, physician, and chemist, isolated and identified mescaline as the active principle in *peyotl*, the "peyote" cactus (*lophophora williamsii*), used by the Aztecs. A number of books and essays were written in the twentieth century describing the effects of mescaline, and as an outstanding example one might cite Aldous Huxley's 1954 book *The Doors of Perception*.

Chemically, mescaline is the simplest of the hallucinogens (Fig. 1). As noted above, it was originally isolated from the peyote cactus, and is the prototype of the phenethylamine class of hallucinogens, i.e., a substituted



Hallucinogens. Fig. 1. The structures of the natural neurotransmitter serotonin, and the hallucinogens, psilocin, psilocybin, LSD-25, DMT, and mescaline. The chemical similarity between serotonin, psilocin, and LSD is the underlying basis for the interaction between tryptamines and serotonin receptors.

phenyl ring separated by two carbon atoms from a basic amino group.

The second major class of hallucinogens is comprised of the ► tryptamines, represented by DMT and psilocybin, also shown in Fig. 1. The natural neurotransmitter ► serotonin is a tryptamine, and is shown for comparison. Although structurally more complex, close examination reveals that LSD (LSD-25) also contains a tryptamine fragment within its structure; thus it can be considered to be a special case of a tryptamine.

Popularity of these substances began to increase dramatically in the early 1960s, when LSD became easily available and inexpensive. This story began in 1943, when Swiss natural product chemist Albert Hofmann, working at the Sandoz laboratories in Basel, Switzerland, accidentally discovered the very powerful hallucinogenic effects of a semi-synthetic ► ergot derivative he had first prepared in 1938. This substance, lysergic acid-*N*, *N*-diethylamide, became known as LSD (or LSD-25), or simply "acid." The extremely potent effects of LSD were manifest following oral doses as low as 25–50 μg. Sandoz initially made LSD available to psychologists and clinical investigators in the belief that it produced a model psychosis, so that psychiatrists might gain insight into the nature of mental illness, although it is now recognized that the effects of LSD have distinct differences from the symptoms of ► schizophrenia.

It should be noted that the discovery of LSD preceded only by a few years the isolation and identification of the neurotransmitter ► serotonin from gut tissue, and its subsequent detection in mammalian brain. It was quickly observed that LSD incorporated a tryptamine moiety in its structure, which also was the essential core template of serotonin itself. The relative temporal conjunction of these two events catalyzed an intense research focus on the role of serotonin in the brain and its involvement in brain functioning. That interest by the neuroscience community continues to the present time and has led to several new types of therapeutics, including the SSRI class of ► antidepressants, and treatments for migraine headache, among others. It is rarely appreciated that the discovery of LSD had such a direct and profound effect on the neurosciences.

Following his discovery of LSD, Dr. Albert Hofmann then studied a number of natural plant materials that were employed in religious rituals by South American Indians. The first of these was the mushroom *Psilocybe Mexicana* ("teonanacatl," or flesh of the gods), which had been used by the Aztecs. He was able to isolate and characterize the active principle, a substituted tryptamine derivative that he named psilocybin. A minor product in this mushroom is the non-phosphorylated molecule, known as psilocin. It is now known that psilocybin is hydrolyzed by phosphatases after ingestion, and that psilocin is the active hallucinogenic substance.

Dr. Hofmann then proceeded to isolate and identify the active principle in *Ololuiqui*, obtained from the seeds of a species of morning glory also employed by the Aztecs. In that case the active substance surprisingly proved to be lysergic acid amide, a molecule chemically very closely related to LSD.

These substances largely remained academic curiosities until the 1960s, when Harvard psychology professor Timothy Leary began to promote and encourage the widespread use of LSD, particularly among the college age population with his mantra, "turn on, tune in, drop out." A strong governmental and law enforcement response resulted, and interest in these substances among scientists and clinicians fell off for many decades as a result of increased restrictions on their availability and use, as well as a sort of widespread social taboo that discouraged their further exploration. In addition, government funding agencies were no longer interested in supporting work on these substances unless it was related to understanding their abuse properties. These factors all came into a confluence that stifled research on hallucinogens for nearly four decades. Fortunately, that situation has slowly begun to improve, and there are now several clinical studies underway in the USA and elsewhere that are assessing the medical value of hallucinogens in carefully controlled settings.

Mechanisms of Action

Very early animal studies of LSD demonstrated that it markedly affected brain serotonin systems. Indeed, the fact that LSD incorporated a tryptamine fragment within its structure reinforced early experimental results indicating an effect on brain serotonin systems. There was much initial debate as to whether LSD "blocked" serotonin systems, or enhanced the activity of serotonin systems, and it took about 30 years before a consensus emerged that LSD, and other hallucinogens, acted as agonists or partial agonists at serotonin receptors. At the present time there is a scientific consensus that hallucinogens have, as their primary site of action, agonist activity at cortical serotonin receptors of the 5-HT_{2A} subtype (Nichols 2004). Although numerous animal behavioral studies had strongly supported that conclusion, the definitive study was carried out by Franz Vollenweider, where pre-administration of the serotonin ► 5-HT2A receptor

antagonist ketanserin was able to block the hallucinogenic effects of psilocybin in man (Vollenweider et al. 1998). ► PET studies also have demonstrated that hallucinogens produce a global increase in rate of cerebral glucose metabolism with significant and most marked increases in the frontomedial and frontolateral cortex, temporomedial and anterior cingulate cortex, and a somewhat lesser response in the basal ganglia.

Although the 5-HT_{2A} receptor appears to be the essential target for hallucinogens, it may not provide the entire explanation for their pharmacology. That is, activation of this receptor may be a necessary, but not sufficient action to understand all of their effects. For example, the phenethylamine-type of hallucinogens have nearly comparable affinity and efficacy at both the 5-HT_{2A} and 5-HT_{2C} receptor types, and there has been no drug available that is a specific agonist only for the 5-HT_{2A} receptor. The tryptamines and LSD present a similar pharmacological profile with respect to these two receptor subtypes, but in addition also have high affinity and efficacy at the serotonin 5-HT_{1A} receptor subtype. Activation of this receptor in the brainstem raphe nuclei suppresses their firing, which would have profound consequences for serotonin tone throughout the brain. These receptors also are expressed at high density in regions of the limbic system, and one would expect activation of the receptors in these brain areas also to have behavioral consequences. Nevertheless, a contribution of the 5-HT_{1A} receptor to the psychopharmacology of tryptamine hallucinogens has not been elucidated.

LSD presents the most complex pharmacology of all of the known hallucinogens, and its effects may not be simply explained by a serotonergic mechanism. In addition to its high affinity and efficacy at the 5-HT_{2A}, 5-HT_{2C}, and 5-HT_{1A} receptors, it acts at a variety of additional serotonin receptors. It also has activity at alpha-2 adrenergic receptors, as well as dopamine receptors, particularly the D_2-like family of dopamine receptors. It is presently unclear, how, or if, any of these other interactions might account for the unique psychopharmacology and potency of LSD.

Interestingly, the pioneer LSD researcher Dr. Daniel X. Freedman described the psychopharmacological effects of LSD in man as occurring in two temporal phases. The initial phase was considered psychedelic and euphoric, whereas after this initial phase, the effects of LSD in many subjects resembled paranoid psychosis, with ideas of reference and paranoid ideation. Temporally dependent pharmacology has not been reported for any of the other hallucinogens. Recent studies in rats have shown that the effects of LSD in rats also occur in two temporal phases. Nevertheless, there is good evidence that LSD does activate brain dopamine systems, and this action of LSD may be relevant to its human psychopharmacology (Marona-Lewicka et al. 2008). In particular, there is some evidence that the dopamine D4 receptor may play a role in the action of LSD, at least in rat behavior models (Marona-Lewicka et al. 2008).

Recent studies also have pointed to a role of ► glutamate in the action of hallucinogens. Administration of hallucinogens to rats or mice leads to increased extracellular levels of glutamate (Benneyworth et al. 2007).

Animal Models

The most useful and widely employed animal model for studying hallucinogens is the ► drug discrimination paradigm, an operant procedure that has been used in rats, mice, monkeys and pigeons. This method is very sensitive, so that doses of drugs can be used that do not produce overt behavioral effects. Typically, rats (or mice) are trained in a two-lever operant chamber using positive reinforcement, to discriminate between injections of saline and a particular drug, such as LSD. Animals are taught to associate one lever with the saline injection, and the other with the injection of the "training drug," e.g., LSD. Emitting a response on the appropriate lever results in reinforcement. Over a period of 2–3 months rats reliably learn this discrimination task so that administration of either saline or the drug results in a preponderance of lever pressing responses only on the lever associated with that treatment condition. Various treatments can then be employed in attempts to antagonize the response, or drugs can be administered that are thought to have a similar pharmacology, so that conclusions can be drawn about the mechanism of action. In the absence of human clinical trials, this method has been used to predict whether a novel molecule may have hallucinogenic effects in man.

Hallucinogens do not produce many other behavioral responses in animal models that are particularly useful. They generally do not affect locomotor activity per se, except at high doses, although they may alter patterns of locomotor and exploratory activity in rodents. They are not self-administered, and are not considered to be reinforcing. Hallucinogens do disrupt ► prepulse inhibition (PPI), which is based on the finding that a weak prepulse reduces the startle reflex to a given, usually acoustic, stimulus.

Pharmacokinetics

Most of the hallucinogens are well absorbed. LSD, mescaline, and psilocybin are all active after oral

administration, with effects lasting about 8–10 h for the first two, and 4–6 h for the latter. A number of substituted tryptamines also are orally active. Very few studies of the ► pharmacokinetics of hallucinogens have been reported. Early studies studied the formation and identification of major metabolites, but the work in this area is sparse. The best pharmacokinetic study for a hallucinogen was reported for psilocybin (Hasler et al. 1997).

Efficacy

Up until the early 1960s, LSD was hailed as a powerful new type of technology that had the potential to revolutionize psychiatry. More than 40,000 subjects were administered LSD in studies described in more than a thousand published clinical studies. Sadly, poor clinical designs, poor controls, and inadequate follow-up resulted in data that are, for the most part, useless in assessing the true medical value of hallucinogens. There are certainly hints from case reports, and trends in several studies suggesting possible utility in treating difficult to treat conditions such as alcoholism.

By contrast, the use of LSD to reduce anxiety and improve mood in dying patients is an indication that has been relatively well documented in studies carried out at the Baltimore State Hospital in the late 1960s. Inclusion of LSD in a program that only had a modest amount of counseling gave some degree of benefit in 60–70% of patients, seen as improved mood and a reduced need for pain medication.

More recently, in 2006 it was reported by a team led by Roland Griffiths at Johns Hopkins University that administration of psilocybin to normal volunteers engendered mystical experiences in a large percentage of subjects, with a majority reporting the experience as one of the five most meaningful experiences of their lives (Griffiths et al. 2006). Significant positive personality improvements induced by the experience were maintained at the 14-month follow-up (Griffiths et al. 2008). Another study of the efficacy of psilocybin in treating depression and anxiety in a small number of end-stage cancer patients has just been completed at UCLA Harbor Medical Center, with promising trends obtained.

Safety/Tolerability

From a physiological standpoint, hallucinogens are very safe. Their safety can be understood by the fact that 5-HT_{2A} receptors are not involved in essential vegetative functions. The only deaths associated with the direct actions of these drugs have occurred in a few individuals who had access to relatively large amounts of pure crystalline LSD tartrate. The author argues that it is not possible to become dependent on hallucinogens due to a process called ► tachyphylaxis, or rapid development of ► tolerance. In contrast to drugs that produce dependence and addiction, the repeated use of hallucinogens leads to a loss of their effect within 3 or 4 days, even with increasing dosages.

Conclusion

In summary, hallucinogens are a very old class of psychoactive substance that have profound effects on consciousness. They were important in a variety of social and religious contexts in older cultures. Their targets in the brain are 5-HT_{2A} receptors, which modulate function of cortical cells. They are presently being reinvestigated for potential medical value after a research hiatus of some four decades. In addition, they would seem to be very powerful tools to study consciousness.

Haloperidol

Definition
Antipsychotic drug of the older, first generation category (mainly dopamine D2 receptor blocker/antagonist).

Haloxazepam

► Benzodiazepines

Haloxazolam

Definition
Haloxazolam is a benzodiazepine derivative with hypnotic properties similar to those of the benzodiazepines triazolam and flunitrazepam.

Cross-References
► Anxiolytic
► Benzodiazepines
► Hypnotic

Hamilton Rating Scale for Anxiety, HAMA

Definition
A 14-item observer-rated scale designed to assess the severity of psychological and somatic symptoms in patients with anxiety disorders. Some items are rather insensitive to change, and this has encouraged the development of shorter and more sensitive scales, but the HAMA is still regarded by many as the "gold standard" for assessing efficacy of treatment in randomized placebo-controlled studies.

Haploid Genotype

► Haplotype

Haplotype

Synonyms
Haploid genotype

Definition
Haplotype is a set of single-nucleotide polymorphisms (SNPs) on a single chromatid that are statistically associated on one chromosome or a part of a chromosome (i.e., one set of alleles of linked genes).

Hemostasis

Definition

Hemostasis is a complex process that causes bleeding to stop. Usually, this includes the changing of blood from a fluid to a solid state, by the formation of a blood clot (thrombus). Intact blood vessels and platelets are central to modulate blood's tendency to clot; the disruption of the correct balance between the involved regulators may result in different diseases. In physiology, the process of thrombus formation starts when damage to the endothelium of blood vessels occurs.

Hepatotoxicity

Synonyms

Liver toxicity

Definition

Hepatotoxicity in pharmacology refers to chemically driven liver damage.

Herbal

► Herbal Medicinal Product

Herbal Ecstasy

Definition

Herbal ecstasy tablets, legally sold in many countries, usually contain the sympathomimetic herb Ephedra (*Ma Huang*) rather than the drug Ecstasy (MDMA).

Definition

Herbal medicines are increasingly popular. It is therefore relevant to evaluate their efficacy, safety, quality, and cost. Numerous clinical trials have tested the efficacy of herbal medicines, and several systematic reviews of these data are now available. They demonstrate that, for a relatively small minority of herbal medicines, efficacy is well established; for others, it is likely, but the vast majority has not yet been adequately tested. Herbal medicines are associated with complex safety issues. They are related to adverse effects of herbal ingredients, interactions with conventional drugs, contamination and adulteration of herbal preparations, and misidentification of herbs within herbal mixtures. In most countries, herbal medicines are marketed as (largely unregulated) dietary supplements, and the quality of some has been shown to be suboptimal.

Economic analyses of herbal medicines would be desirable, but are currently scarce. Thus, it is uncertain whether their use saves or costs extra money. It is concluded that each herbal medicine should be judged on its own merits on the basis of the evidence from rigorous investigations. Where such data are currently not available, we cannot make assumptions but should initiate research to fill the sizable gaps in our present knowledge.

Pharmacological Properties

Introduction

Many of today's synthetic drugs originated from the plant kingdom, and only 200 years ago, our pharmacopeia was dominated by herbal medicines. Medical herbalism (i.e., the medicinal use of preparations that contain exclusively plant material) went into rapid decline when pharmacology established itself as a leading branch of therapeutics. In much of the English-speaking world, herbalism virtually vanished from the therapeutic map during the last part of the 19th century and early part of the 20th century. In contrast, many developing countries never abandoned medical herbalism (e.g., Ayurvedic medicine in India, Kampo medicine in Japan, and Chinese herbalism in China), and in other countries (e.g., Germany and France), medical herbalism continued to co-exist with modern pharmacology, albeit on an increasingly lower key.

In recent years, this situation has started to change again. Herbal medicine is most commonly employed for allergies, insomnia, respiratory problems, and digestive problems. The total out-of-pocket expenditure amounted to $5.1 billion in 1997, and the total number of herbal medicines currently available in the USA has been estimated to exceed 20,000.

Herbal medicines usually contain a range of pharmacologically active compounds; in some cases, we do not even know which constituents are (the most) important for the therapeutic effect. This situation can render efficacy testing more complex than with synthetic drugs. One approach is to view the entire herbal extract as the active principle. To optimize the reproducibility of such studies, extracts need to be sufficiently characterized. This is often achieved through standardization based on a key constituent of the extract (e.g., a pharmacologically active ingredient or, if such an ingredient is not known, a marker substance). Adequate product characterization and quality control are essential for the reproducibility of scientific tests of herbal remedies.

If these rules are observed, clinical trials of herbal medicines are feasible much in the same way as for other drugs. Numerous randomized clinical trials of herbal medicines have been published and systematic reviews/meta-analyses of these studies have become available (Barnes et al. 1998). Table 1 provides examples of such papers. Their conclusions are often limited by the varied methodological quality of the primary studies. High-quality trials are, of course, expensive and research funds in this area are generally scarce, not least because plants are not patentable.

Generalizations about the efficacy of herbal medicines are not possible. Each herbal medicine has to be judged on its own merits; some have been demonstrated to be efficacious for certain indications, others may not be efficacious and by far, most of them have not been submitted to extensive clinical testing (Barnes et al. 1998).

Efficacy of Traditional Herbalism

The use of an extract of a single plant to treat one conditions (e.g., St. John's wort for ▶ depression) is dramatically different from what actually happens when patients consult herbal practitioners. These clinicians, regardless of which tradition they may subscribe to (e.g., traditional Chinese herbalist or herbalist in the European tradition) would investigate their patients according to the criteria of their tradition and subsequently prescribe a mixture of herbs that is "tailor-made" for their constitution and individual set of symptoms. Thus, 10 patients with depression might receive 10 different herbal mixtures, which may or may not contain St. John's wort.

This individualized form of prescribing is more difficult to submit to rigorous scientific testing, but such investigations are undoubtedly possible. To date, only very few randomized clinical trials of this type of herbalism have been published. Those that are available have recently been reviewed. The results demonstrated that there is currently no good evidence to suggest that individualized herbalism is efficacious (Canter et al. 2005).

Safety

Consumers are attracted to herbal medicines not least because they equate "natural" with "safe" (Barnes et al. 1998). Yet some herbal medicines are associated with serious risks (Carlo et al. 2001). These risks relate to a range of circumstances.

First, the active principles in herbal medicines can, of course, cause desirable as well as undesirable effects. Table 2 lists examples of commonly used herbal medicines that have been associated with serious adverse effects (Barnes et al. 1998). Traditional use does not guarantee for safety and is not an acceptable substitute for data. A poignant example is kava (*Piper methysticum*), a herbal remedy that has been used for centuries apparently without problems. During the last decades, it was shown to be a powerful

Herbal Remedies. Table 1. Examples of systematic reviews and meta-analysis of herbal remedies.

Common (Latin) name	Pharmacologically active ingredients [1]	Indications	Number of trials included(total sample size)	Average methodological quality of primary studies	Efficacy	Main result	Reference
Feverfew (*Tanacetum parthenium*)[2]	Parthenolide	Migraine prevention	5	Good	Likely	3 trials were positive, 2 were negative	Vogler (1998)
Garlic (*Allium sativum*)[3]	Alliin	Hypercholesterolemia	13	Good(some excellent)	certain but effect small	Overall effect is significant but of debatable clinical relevance	Stevinson (2000)

Herbal Remedies. Table 2. Examples of herbal medicines associated with serious risks.

Common (Latin) name	Indication	Adverse effects (examples)
Aloe vera (*Aloe barbadensis*)	Various	Juice may cause intestinal pain and electrolyte loss
Feverfew (*Tanacetum parthenium*)	Migraine prevention	"Post-fever syndrome" after discontinuation (migraine, anxiety, insomnia, muscle stiffness)
Hawthorn (*Crataegus*)	Congestive heart failure	Additive effects with other cardiac glycosides
Kava (*Piper methysticum*)	Anxiety	Toxic liver damage
St. John's wort (*Hypericum perforatum*)	Depression	Increased clearance of a range of prescribed drugs
Tea tree oil (*Malaleuca alternifolia*)	Skin problems (external)	Allergic reactions
Valerian (*Valeriana officinalis*)	Insomnia	Morning hangover

► anxiolytic medicine in rigorous clinical trials (Barnes et al. 1998). Recently, it has been associated with several cases of serious liver damage. Hence, it has been withdrawn from the markets of several European countries.

Second, the active principles in herbal medicines might interact with prescription drugs. A classic example of this scenario is provided by St. John's wort (*Hypericum perforatum*). One or several constituents of St. John's wort (most likely hypericin) act as an enzyme inducer on the ► cytochrome P450 system and increase the activity of the P-glycoprotein transmembrane transporter mechanism. Both mechanisms lead to a reduction of the plasma level of several conventional drugs (De Smet PAGM 2002). This can lead to a range of serious adverse effects.

Third, some herbal medicines (particularly Asian herbal mixtures) have been demonstrated repeatedly to be contaminated with heavy metals or adulterated, e.g., with prescription drugs. Because, in many countries (e.g., the USA and UK), most herbal medicines continue to be marketed as dietary supplements, their quality is not adequately controlled and suboptimal quality may put consumers at risk.

Finally, substitutions of one (innocent) herb from a herbal mixture with a toxic herb may occur either inadvertently or fraudulently. A famous example of such a scenario was the introduction of *Aristolochia* into a Chinese herbal mixture used for body weight reduction. This caused serious kidney damage and subsequent malignancies in many Belgian consumers (Ernst 2002).

Because positive safety data are usually not available, herbal remedies should be viewed as contra-indicated during pregnancy and lactation (Barnes et al. 1998). Our present post-marketing surveillance systems are likely to register only a minute proportion of all the adverse effects of herbal medicines. Consumers are less prone to report adverse effects of herbal medicines than those of other OTC medications (Ernst et al. 2006). As herbal medicines become more and more popular, we should find better ways of minimizing the risks that may be associated with them.

Quality

Commercially available herbal products have repeatedly been found to be of varying and at times suboptimal quality (Guo et al. 2007). As pointed out earlier, poor quality can cause harm, for instance, in the case of contamination with toxic substances. Any clinical trial of insufficient herbal product would generate a negative result, even if the herb tested is *per se* efficacious.

In most countries, herbal medicines are marketed as dietary supplements with no need to demonstrate efficacy, safety, or quality in the way of licensed medicines. Thus, many products available to patients may be of inadequate quality, for example, they may be underdosed. For consumers, it is notoriously difficult to identify products of high quality. Table 3 lists some manufacturers known for their experience, quality, and investment into research.

Cost

Very few economic analyses of complementary/alternative medicines exist. The few that have been published are methodologically weak and, therefore, far from convincing.

Herbal Remedies. Table 3. Examples of manufacturers who market high-quality standardized products and invest in research.

Name of the company	Country	Main herbal medicine
Bionorica	Germany	Sinupret[1]
Lichtwer	Germany	Garlic
Madaus	Germany	Echinacea
Pharmaton	Switzerland	Ginseng
Schwabe	Germany	Ginkgo biloba

[1]herbal mixture

Interestingly, retrospective analyses tend to suggest that complementary/alternative medicine can reduce costs, whereas (the more rigorous) prospective analyses tend to imply that the use of complementary/alternative medicine is associated with an increase in cost (Nortier and Muniz Martinez 2000). The situation with herbal medicines is much the same as with other complementary/alternative medicines.

Comment

Investigations of the efficacy, safety, quality, and cost of herbal medicines are feasible and, vis-à-vis, the popularity of such preparations is highly desirable. For some, but by no means all herbal medicines, efficacy data are now emerging (Barnes et al. 1998). They show that some herbal medicines are efficacious for certain indications. All herbal medicines are associated with safety issues which, in some instances, can be complex. Economic evaluations of herbal medicines are still extremely scarce.

Research into herbal medicines is much less active than research into conventional drugs. Lack of commercial impetus, owing to lack of patent protection, is one obvious reason. The legal status of herbal medicines might be another: as for dietary supplements, there is no formal obligation to prove efficacy. If we want to find the answers for many open questions in herbal medicine, we should consider other means of finding adequate funds for research in this area.

Herbal Remedy

► Herbal Medicinal Product

Heritability

Definition

The proportion of variance in a particular phenotype that is attributable to genetic, as opposed to environmental, factors.

Heroin

► Diamorphine

Heroin Addiction

► Opioid Dependence and Its Treatment

Hetero-Oligomers

Definition

Functional protein complexes formed by oligomerization of similar subunits. Functional opioid receptors and many other GPCRs are almost certainly formed from multiple identical (hom-oligomers) or closely related (e.g., MOR and DOR subunits can form a single functional receptor) receptor proteins. Hetero-oligomeric receptors may have pharmacological properties that are distinct from either of the subunits that make them up.

Heterosynaptic

Definition

When neural activity involving one of a neuron's synapse or synapses causes the strength of another neuron's synapse or synapses to change.

High Performance Liquid Chromatography

Definition

High pressure liquid chromatography (HPLC) is a means of separating constituent chemical compounds in a mixed solution in a chromatographic column. They can then be purified (preparative HPLC) or identified and quantified (analytical HPLC).

Principles and Role in Psychopharmacology

In the context of psychopharmacology the most common application of HPLC is analytical: that is for identifying and quantifying endogenous chemicals in brain perfusates in vivo (e.g., from ► microdialysis), in vitro (e.g., from brain slices) and in post mortem tissue. Compounds normally measured include endogenous neurotransmitters, synthesis and metabolic products, and exogenously applied chemicals, such as drugs. It can also be used to measure these compounds in blood, as indirect indicators of brain levels, and to measure the pharmacokinetic and pharmacodynamic profile of drug action.

Principles

There are two principle stages in HPLC analysis: separation, in which the sample is resolved into its constituent compounds; and detection, where these compounds are identified and quantified.

The sample to be analyzed is introduced into the mobile phase, which is continuously pumped through the ► analytical column under high pressure, without disrupting the flow or changing the pressure. This is achieved using a high pressure switching valve which may be a manual valve, where the experimenter "injects" each individual sample into the fluid stream, or it may be an autoinjector, where the valve is incorporated in an autosampler, such that batches of samples can be injected without the need for the experimenter to be present. The latter approach has advantages where large numbers of samples are to be analysed, but can have disadvantages in the amount of sample required to make an injection. If using an autoinjector, it is wise to include a chilled sample tray, to reduce degradation of the sample while waiting to be injected.

Chromatographic Separation

Separation is achieved in the analytical column and is dependent on the interaction of the constituent components in the sample with the mobile and stationary phases, which can be manipulated using different choices of solvents and column packing. These interactions are dependent on the size, the ionization, the polarity and the sterioisometry of the molecule (see Table 1).

Of these methods, reverse phase partition HPLC (RP-HPLC) is the most common HPLC method used in psychopharmacology, primarily due to its versatility and its relative ease of use. In RP-HPLC, separation is achieved by a partition of the compounds in the sample between the hydrophobic (non-polar) stationary phase and the hydrophilic (polar) mobile phase, and is dependant on a compound's relative affinity for each: this in turn is dependent on the hydrophobic/hydrophilic nature of the compound itself. Generally, compounds that are more hydrophilic, and so more similar to the mobile phase,

High Pressure Liquid Chromatography. Table 1. The main categories of separation types used for preparative or analytical HPLC.

Type	Mechanism	Uses
Adsorption	Separation based on differences between adsorption affinities of the sample components for the surface of the stationary phase (often alumina).	Mainly used for preparative or purification HPLC.
Partition	Separation based on the differences between the solubility of components in the mobile and stationary phases. There are two distinct types of partition. chromatography:	Reverse phase chromatography widely used for separating many different classes of chemical compounds. It is the most versatile and widely used analytical HPLC technique.
	Normal phase – partition between a polar stationary phase and a non-polar mobile phase	
	Reverse phase – partition between a non-polar stationary phase and a polar mobile phase	
Ion exchange	Separation based on differences between ionic charge of sample components. A charged stationary phase attracts molecules of opposite charge, which are retained on the column. These are then eluted off the column by introducing another ion of similar charge. Either anion or cation exchange columns can be used depending on the charge of the compound to be separated.	Mainly used for preparative and purification HPLC. Principles of ion-pair chromatography can be incorporated into reverse phase chromatography, by the use of ion-pairing agents.
Molecular exclusion	Separation based on the hydrodynamic volume of the molecule to be separated, relative to the pores in the non-adsorbing stationary phase.	Mainly used for purification.
Affinity	Separation based on the unique and highly specific biological interaction between the analyte and a ligand (e.g. enzyme-substrate interaction; antigen-antibody interaction).	Mainly used for purification: for example nucleic acid purification, protein purification, antibody purification.
Chiral	Stereoisomers separated by using chiral phases.	Separation of stereoisomers of a compound.

will pass through the column more quickly that those which are more hydrophobic, and so more like the stationary phase.

The mobile phase in PR-HPLC is based on an aqueous (polar) solution, typically also containing a proportion of an organic solvent (e.g., methanol or acetonitrile). The organic content of the mobile phase is an important determinant of retention in the column. Retention will be greater (i.e., longer retention times) when mobile phases of low organic content are used, while higher organic content will result in less retention in the column, and shorter retention times.

In RP-HPLC, a major factor in determining the retention of a compound in the column, is the ionization of the compound, since the more polar a compound is, the less it will be retained in the column, and so the more quickly it will pass through. Therefore, the degree of ionization of analytes will have a major impact on the speed they pass through the column, and thus the pH at which the chromatography is carried out is a crucial factor in determining the separation. At low pH, acidic molecules will be essentially unionized, and so will be retained, while basic molecules will essentially be ionized and will pass through the column quickly. At high pH, the opposite will be true: unionized basic molecules will be retained, and charged acidic molecules will not.

Ion-pair HPLC may be seen as a hybrid of RP-HPLC and ion-exchange HPLC. An ion pairing agent, a molecule with one non-polar terminal, which binds to the stationary phase, and a polar (ionized) terminal which is in contact with the mobile phase, is used. The principle effect of the ion pairing agent is to increase the retention in the column of compounds in the sample with an ionic charge opposite to that of the ion pair (since opposite charges attract): it may also have a small effect of decreasing the retention of similarly charges molecules, although the effect is minimal, and is of little use in changing separation characteristics.

From this it can be seen that adjusting the pH, and the use of ion-pairing agents have differential effects on the retention times (that is they have different effects on different compounds), whereas changing the organic content of the mobile phase, affects the retention of all compounds in an indiscriminate manner.

For many separations, it is adequate to use an isocratic buffer system: that is continuous perfusion with a single buffer. One drawback with this approach is that, in order to achieve good separation of compounds which elute more quickly from the column, those which elute more slowly are often retained for an unacceptably long time. This has two adverse effects: first, it can make the run time excessively long and therefore reduce the throughput of samples to an unacceptably low level; and second, the longer the peak is retained on the column, the wider and lower the peak appears, such that small peaks with long retention times may become impossible to measure.

To overcome this problem, gradient elution is often used. For this type of elution the content of the mobile phase changes steadily over the duration of a chromatographic run, such that the strongly retained components of the sample elute more quickly, whilst the separation of the least retained compounds is maintained. The two most common gradient elutions used are a pH gradient (i.e., the pH changes over the duration of the run) or an organic gradient (i.e., the organic content of the buffer changes over the duration of the run). Thus, for example, with an organic gradient, the run starts with a low content of organic component (e.g., methanol) in the mobile phase, allowing good separation of the least retained compounds, while the strongly retained compounds move very slowly through the column. As the organic content of the mobile phase increases in the gradient, these retained compounds move through the column faster, thus giving a more rapid elution than under isocratic conditions. In order to implement a gradient elution, two buffers of different organic content are used, and are mixed automatically in appropriate proportions to create a gradient. With a pH gradient, the same principles hold, but the change in retention is brought about by changing the pH, and thus the degree of ionization of the strongly retained compounds.

In order to achieve stable and reproducible measurements, it is essential to use a high purity mobile phase which has been filtered and degassed, as particulate material in the buffer will block the analytical column. It should be noted that even after filtration, some very fine particulate material may remain in the buffer, and so it is still beneficial to include a ▶ guard column. This is a shorter column, packed with similar stationary phase to the analytical column, which is installed immediately before the analytical column. Its purpose is to protect the analytical column, thus maintaining optimal separation and prolonging its usable life.

Detection

Once separated, the components of the sample must be measured and quantified. There are three main types of detection used in psychopharmacology; ultraviolet (UV) absorption, fluorometric and electrochemical detection. Of these, UV absorption is applicable to the widest variety of compounds, since most organic molecules show at least some degree of absorption of UV radiation. However, since different molecules absorb optimally at different wavelengths, optimizing the wavelength for one compound will mean suboptimal or even zero absorption for other compounds. The use of diode array UV detectors enables simultaneous measurement of UV absorption at different wavelengths, allowing several compounds to be measured simultaneously. Although UV detection is the most versatile, in terms of the number of compounds which can be detected, it has the disadvantage that the signals measured are not always very large, and so it has limited sensitivity. In psychopharmacology, this UV detection is primarily used for measuring drug concentrations, which are typically relatively high, although it can also be used for measuring endogenous neurochemicals under some circumstances.

Some organic molecules have natural luminescence (e.g., tryptophan, serotonin), which can be detected fluorometrically. Absorption of light at specific wavelengths, causes excitation of the molecule and subsequent emission of light at a longer wavelength: this emission is measured in fluorescence spectroscopy. For compounds which exhibit fluorescence, fluorometric detection is 10–1000-fold more sensitive than UV detection. However, individual chemicals have optimal excitation and emission wavelengths, so although measurement at one excitation/emission wavelength combination may be optimized for one molecule, it may completely fail to detect other molecules. While this is appropriate in some applications (see below), for other applications, it is beneficial to use ▶ detectors which switch rapidly between different excitation and emission wavelengths.

Many molecules do not themselves exhibit fluorescence, but can be conjugated to a fluorescent molecule, to create a fluorescent derivative (e.g., amino acids). Although some amino acids do exhibit a degree of innate fluorescence, all amino acids can be conjugated with a fluorescent "tag," for example orthophthalaldehyde (OPA), to produce a fluorescent derivative, which can

then be measured by fluorescence spectroscopy. In this situation, since one is essentially measuring the same fluorescent molecule, albeit "tagging" different amino acids, a single optimal excitation and emission combination is appropriate, and so a fixed wavelength detector is adequate.

Electrochemical detection depends on the redox equilibrium reaction of molecules (e.g., $A \leftrightarrow A^+ + e^-$). Application of a positive potential drives the oxidation reaction, and application of a negative current drives the reduction reaction. In electrochemical detection, a positive potential is applied and the current produced by the oxidation is measured at the working electrode. Although many compounds will oxidize if a high enough potential is applied, only a few oxidize at usable potentials. Notable among these are amine transmitters, such as dopamine, serotonin, and noradrenalin, and many of their metabolites. Most amino acids are not electrochemically active within a useful potential range, but their OPA derivatives (see above) do show electrochemical activity. Therefore it is also possible to use electrochemical detection for amino acids. While this has not been widely used for most amino acids, it is useful for GABA, which has often proved difficult to measure fluorometrically.

Enzymatic Modification

Some neuroactive compounds, notably ► acetylcholine, are difficult to detect using any of these methods. However, enzymatic treatment yields an electrochemically active product, which can be detected. Thus for acetylcholine, an additional column is placed after the analytical column, which has the enzymes acetylcholine esterase and choline oxidase immobilized onto the stationary phase. These enzymes break acetylcholine down, and produce hydrogen peroxide as a bi-product: hydrogen peroxide can be measured with an electrochemical detector. Any choline in the sample will also produce hydrogen peroxide, but can be distinguished from acetylcholine because the two have first been separated chromatographically on the analytical column.

The output from the detector feeds to a recording device, such as a chart recorder, or more commonly, an integrator: changes in current, representing the presence of a detectable entity, are displayed as peaks on a current versus time plot (the chromatogram). The area under the curve of these peaks is proportional to the concentration of the compound, and can be quantified by reference to standards of known concentration, run under identical conditions. Similarly, for a given ► mobile phase and ► stationary phase combination, individual compounds will have a constant retention time, and thus component compounds in a mixture can be identified by comparison with standards.

Thus, HPLC is an extremely versatile technique, and methods can be devised for separation, identification and quantification of a wide variety of chemical compounds. It is widely used in psychopharmacology to measure endogenous compounds, such as neurotransmitters, and metabolites, and exogenous compounds such as drugs, in post mortem brain tissue, in vitro, and in vivo procedures. It can also be used to measure these compounds in CSF and blood, as indicators of brain levels, and to measure the pharmacokinetic and pharmacodynamic profile of drug action.

Definition

Histaminic agonists and antagonists are drugs that mimic or antagonize the actions of histamine at one of its four ► G protein-coupled receptors (H_1–H_4).

Pharmacological Properties

Histamine is a biogenic amine that is widely distributed in the body and is involved in a number of physiological and pathophysiological functions (Hill et al. 1997; Parsons and Ganellin 2006). These include allergic inflammation, cardiovascular regulation, gastric acid secretion, and neuromodulatory functions within the central nervous system (CNS). Histamine is produced by decarboxylation of the amino acid L-histidine and is metabolized by histamine N^{τ}-methyltransferase (HMT) and diaminoxidases. In the case of its neurotransmitter role within the CNS, histamine-containing neurons are characterized by a high level of histidine decarboxylase activity and removal of synaptic histamine is mainly via metabolism (as a consequence of HMT activity). The actions of histamine are mediated by four different G-protein-coupled receptors (Thurmond et al. 2008). These G-protein-coupled receptors have all been cloned and interact with specific heterotrimeric G-proteins to trigger a variety of intracellular processes by altering the levels of intracellular messengers (e.g., cyclic AMP and Ca^{2+} ions) or by influencing the opening of cell surface ion channels.

Histamine H_1-Receptor

The human histamine H_1-receptor was the first of the histamine receptors that was identified and successfully targeted with therapeutically active drugs (i.e., by antihistamines for the treatment of allergic inflammation). It is a 487 amino acid receptor that has the characteristic seven transmembrane spanning domains of a G-protein-coupled receptor. It is characterized by a very large third intracellular loop (208 amino acids; through which it mediates interactions with G-proteins) and a short (17 amino acids) intracellular C terminal tail. The H_1-receptor couples to $G_{q/11}$-G-proteins and mediates responses primarily via the activation of phospholipase Cβ, which hydrolyzes phosphatidylinositol-4,5-bisphosphate into the intracellular second messengers inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol. The water soluble IP_3 then acts on its own ligand-gated ion channel in the endoplasmic reticulum to release intracellular free Ca^{2+} ions, while diacylglycerol is retained in the plasma membrane and can activate various isoforms of protein kinase C. Activation of this receptor has also been shown to affect other signaling pathways including stimulation of phospholipase A2 and stimulation of p42/44 MAP kinase (Hill et al. 1997; Bakker et al. 2004).

Histamine H_1-receptors are found throughout the body. Histamine acting via this receptor is a potent smooth muscle spasmogen (particularly in vascular, airway, and gastrointestinal smooth muscle). In the endothelial cells lining blood vessels, H_1-receptor-stimulation also leads to increased vascular permeability (which generates the classic "weal" response observed in the skin in response to intradermal injection of histamine) and increased synthesis of mediators (prostacyclin and nitric oxide) that can relax vascular smooth muscle. Intradermal injection of histamine also activated H_1-receptors on peripheral sensory nerve endings leading to itching and a surrounding vasodilatation due to an axonal reflex involving release of peptide neurotransmitters from collateral nerve endings. In the brain, H_1-receptors are present in the cerebral cortex, hippocampus, nucleus accumbens, thalamus, and posterior hypothalamus where they predominantly excite neuronal activity (Hill et al. 1997).

H_1-Agonists

Several derivatives of histamine have now been identified, which are more potent as agonists than histamine and are relatively selective for the H_1-receptor. These include 2-(3-(trifluoromethyl)phenyl)-histamine, 2-(3-bromophenyl)-histamine, histaprodifen, and N-methylhistaprodifen. The role of these compounds is, however, restricted to a use as pharmacological tools. Compounds originally developed as drugs for completely different classes of receptors have also been identified as H_1-receptor agonists. For example, the dopamine/serotonin receptor agonist 8R-lisuride is probably the most potent and stereospecific partial agonist for the H_1-receptor yet reported (Bakker et al. 2004).

H_1-Antagonists

Antagonists of the histamine H_1-receptor include mepyramine, chlorpheniramine, ▶ promethazine, triprolidine, diphenhydramine, cyclizine, loratidine, and cetirizine (Hill et al. 1997). All of them have proved useful in the treatment of hay fever, allergic rhinitis, insect bites, and anaphylactic reactions (Thurmond et al. 2008). However, at therapeutic doses, many of the older generations of H_1-antagonists (particularly promethazine, diphenhydramine, mepyramine, etc.) give rise to sedation as a consequence of H_1-receptor antagonism in the brain. More recently, a second generation of nonsedating H_1-antihistamines have been developed, which are much less able to cross the ▶ blood brain barrier. These include temelastine, terfenadine, acrivastine, astemizole, cetirizine, fexofenadine, and loratidine. Cetirizine is one of the antihistamines that exists as stereoisomers and the active levo-isomer is now available for clinical use. Many H_1-receptor antagonists also possess marked muscarinic receptor antagonist properties (e.g., promethazine, diphenhydramine, cyclizine) and this "side-effect" is exploited for the treatment of nausea and motion sickness. Several other classes of drugs, such as the ▶ antidepressants ▶ doxepin and ▶ amitriptyline, are also potent H_1-antihistamines. Interestingly, all of the H_1-antihistamines in current clinical practice are ▶ inverse agonists i.e., they are able to reduce agonist-independent constitutive receptor activity in cells where H_1-receptor-overexpression allows spontaneous receptor-G-protein coupling and functional activity.

Histamine H_2-Receptor

The human histamine H_2-receptor is best known for its ability to stimulate gastric acid secretion and this physiological action underpins the use of H_2-receptor antagonists in the treatment of duodenal and gastric ulcers (Parsons and Ganellin 2006). It is a Gs-coupled receptor that has a short third intracellular loop (30 amino acids) and a much longer C-terminal tail (70 amino acids) than the H_1-receptor. The H_2-receptor stimulates adenylyl cyclase and stimulates intracellular responses via the formation of the second messenger cyclic AMP. In the heart, H_2-receptor-mediated activation of adenylyl cyclase leads to positive chronotropic and inotropic effects while in smooth muscle (e.g., airway and vascular) H_2-receptors produce relaxation via cyclic AMP-dependent mechanisms. H_2-receptors in the brain generally mediate inhibitory effects on neuronal activity, although in hippocampal neurons they produce a block of the long-lasting after-hyperpolarization and accommodation of firing, which results in potentiation of excitatory stimuli.

H_2-Agonists

A number of potent and selective agonists are available for the histamine H_2-receptor. These include impromidine, arpromidine, dimaprit, and amthamine. In the case of impromidine and apromidine, the compounds are 48 and 100 times more potent, respectively, than histamine itself. However, while acting as agonists at the H_2-receptor, some of these compounds act as antagonists at other histamine receptors, e.g., arpromidine is an H_1-receptor antagonist, and impromidine and dimaprit are H_3-receptor antagonists (Lim et al. 2005).

H_2-Antagonists

Burimamide was the first compound to be described as an H_2-antagoinst that demonstrated selectivity for H_2- over H_1-receptors. However, with the discovery of the H_3- and H_4-receptors (see below), this compound was subsequently found to be a more potent H_3-receptor antagonist and to have H_4-agonist activity (Lim et al. 2005). Cimetidine was developed directly from burimamide and proved to be an effective agent in the treatment of gastric and duodenal ulceration because of its ability to inhibit basal and gastrin-stimulated gastric acid secretion via antagonism of the actions of endogenous histamine. A wide range of highly selective H_2-receptor antagonists are now available and are in regular clinical use including ranitidine, titotidine, famotidine, and mifentidine. Studies in transfected cells overexpressing the H_2-receptor have shown that cimetidine and ranitidine are both inverse agonists at the H_2-receptors, while burimamide behaves as a neutral H_2-antagonist. It remains to be established, however, whether inverse agonism is a property that contributes to the therapeutic effect of these compounds.

Histamine H_3-Receptor

The human histamine H_3-receptor (445 amino acids) couples to the Gi/o family of G-proteins that can inhibit adenylyl cyclase activity and inhibit neurotransmitter release (Bongers et al. 2007). It has a long third intracellular loop (142 amino acids) and a short C-terminal tail (29 amino acids). It was first identified as a presynaptic autoreceptor, inhibiting the synthesis and release of histamine from histaminergic nerves in the CNS. Histaminergic nerves originate in a small number of cell bodies in the posterior hypothalamus that innervate most areas of the forebrain. However, H_3-receptors have also been identified on the terminals of nerves containing other neurotransmitters in both the peripheral and central nervous systems. For example, in the brain H_3-receptors are present on nerve terminals that use acetylcholine, 5-HT, dopamine, and noradrenaline as neurotransmitters. In the periphery, H_3-receptors inhibit the release of sympathetic neurotransmitters in human saphenous vein, heart, bronchi, and trachea.

Unlike the genes for human H_1- and H_2-receptors, the H_3-receptor-gene contains introns and as a consequence, at least 20 splice variants have been identified for the human receptor and additional isoforms have been described for rodent and guinea-pig H_3-receptors (Bongers et al. 2007; Sander et al. 2008).

H_3-Agonist

Agonists with good selectivity for H_3-receptors (relative to H_1- and H_2-receptors) have been developed and these include R-α-methylhistamine, imetit, and immepip. However, a number of them also affect the histamine H_4-receptor (see below).

H_3-Antagonists

The initial compounds developed as selective H_3-receptor antagonists (relative to the H_1- and H_2-receptors) included thioperamide, clobenpropit, iodoproxyfan, ciproxifan, and impentamine and these all have substantially lower affinity for H_1- and H_2-receptors. However, the discovery of the histamine H_4-receptor subsequently revealed that there is considerable overlap in the pharmacology of some of these compounds for the H_3- and H_4-receptors. The existence of species H_3-receptor heterogeneity also revealed unexpected but significant variability in the affinity of certain of the prototypical H_3-receptor ligands (particularly thioperamide and ciproxifan). For example, thioperamide revealed similar affinity for the human H_3 (pKi 7.4) and H_4 (pKi 7.4) receptors, but a much higher affinity for the rat H_3-receptor (pKi 8.4). Clobenpropit turned out to be a high affinity H_4-agonist but also a high affinity inverse H_3-agonist, while ciproxifan does possess some preference for the human H_3-receptor over the H_4-receptor (Sander et al. 2008; Thurmond et al. 2008).

The H_3-receptor appears to be naturally expressed in a constitutively active form in the CNS providing a means for pharmacological interference by inverse agonists as well as agonists and neutral antagonists (Arrang et al. 2007). This natural constitutive H_3-receptor activity appears to be due to the sequence similarity of the C-terminal end of the third intracellular loop of the receptor and the mutations required in other G-protein coupled receptors to produce constitutively active mutant receptors. Many of the compounds developed as H_3-receptor antagonists have been shown to behave as inverse agonists in cell lines expressing recombinant H_3-receptors. These include thioperamide, clobenpropit, and iodophenpropit. Proxyfan was originally described as a neutral antagonist, but it has since been reclassified as a protean agonist that can act as an agonist or inverse agonist depending on the signal transduction pathway measured and the degree of constitutive receptor activity present (Arrang et al. 2007).

More recent emphasis has been placed on the development of nonimidazole-based antagonists and inverse agonists as clinical candidates. Some of the first lead compounds came from the natural ligands aplysamine-1 (extracted from the marine sponge Aplysina sp. (verongidae)) and conessine (a nonaromatic steroid-related alkaloid), which have pKi values of 7.5 and 7.2 for the human H_3-receptor, respectively. Nonimidazole and selective H_3-receptor antagonists have now been developed that have high affinity for the H_3-receptor and these include ABT-239 (pKi 9.4), GSK 189354 (pKi 9.9), JNJ 10181457 (pKi 8.9), and tiprolisant (pKi 8.6) (Sander et al. 2008).

Potential Therapeutic Indications for H_3-Antagonists

A number of H_3-receptor antagonists are currently in clinical trials (Phases I and II) for a range of potential CNS disorders including ▶ cognitive impairment and ▶ narcolepsy (Sander et al. 2008). Histamine has been long thought to have a role in maintaining the waking state because of its diffuse innervation of much of the forebrain from discrete nuclei within the tuberomammillary nucleus of the ▶ hypothalamus, and the well-known sedative side effects that have been associated with the classical H_1-receptor antihistamines. In keeping with this wake-enhancing role for histamine, the first preclinical and clinical data with nonimidazole H_3-antagonists

(which act by antagonizing presynaptic H_3-receptors leading to increased levels of postsynaptic histamine in distinct brain regions) has shown that they have marked wake-promoting actions accompanied with enhanced cortical EEG rhythm. The histamine-mediated increase in ► attention and vigilance associated with postsynaptic H_1- and H_2-receptor stimulation in the CNS that would follow H_3-receptor antagonism has also led to an evaluation of these compounds in conditions of impaired cognition (e.g. ► attention deficit/hyperactivity disorder).

Histamine H_4-Receptor

The H_4-receptor (390 amino acids) is the most recently identified histamine receptor and unlike the H_3-receptor appears to be exclusively expressed in the periphery. It is encoded by an intron-containing gene on chromosome 18. Like the H_3-receptor, it couples to the Gi/o family of G-proteins and can inhibit adenylyl cyclase activity. The H_4-receptor has been identified in a number of inflammatory cells including mast cells, eosinophils, dendritic cells, T lympohcytes, monocytes, and macrophages (Zhang et al. 2007; Thurmond et al. 2008). This distribution of the H_4-receptor has suggested that it may be an important target for drugs in inflammation, allergy, and autoimmune disease (Thurmond et al. 2008). There is also some overlap with H_1-receptor function in certain allergic conditions, which suggests that a combined H_1- and H_4-receptor antagonist may provide added benefit over the existing H_1-antagonist monotherapy.

H_4-Agonists

A wide range of ligands that act on $H_{1\text{-}3}$ receptors have been evaluated as agonists of the histamine H_4-receptor. The H_4-receptor shares the highest sequence homology with the H_3-receptor and it is therefore not surprising that a number of H_3-ligands have been identified as high-affinity H_4-agonists. These include R-α-methylhistamine (full), N-α-methylhistamine (full), immepip (partial), clobenprobit (partial), proxyfan (partial), and imetit (partial) (Lim et al. 2005). However, it is notable the H_3-agonist R-α-methylhistamine is several hundred-fold less effective as an H_4-receptor agonist than it is as a H_3-receptor agonist. Other potent H_4-agonists include burimamide (partial), the atypical antipsychotic drug clozapine (full) and 4-methylhistamine (full). In the case of 4-methylhistamine, this is probably the most selective and potent H_4-agonist available at present (Lim et al. 2005).

H_4-Antagonists

The H_3-receptor antagonists thioperamide, iodophenpropit, and clobenpropit all bind with high affinity to H_4-receptors, but clobenpropit also possesses weak H_4-agonist activity. Two compounds have emerged from high throughput screening programs as selective H_4-antagonists with very low affinity at H_3-receptors. These are JNJ 7777120 and VUF 6002 and these should prove useful in evaluating the potential anti-inflammatory actions of H_4-antagonists (Thurmond et al. 2004).

Conclusions

Histamine appears to play a key role in many physiological processes and the first two receptors (H_1 and H_2) discovered to respond to this biogenic amine have proved to be major and successful targets for drug development in the fields of allergic and gastrointestinal disease. The more recent discovery of the histamine H_3- and H_4-receptors and their differential distribution in the CNS and inflammatory cells has provided the potential for these two histamine receptors to also become the target for highly selective blockbuster drug candidates.

Histone

Definition
Histones are the main protein components of chromatin. They act as spools around which DNA winds, and they play a role in gene regulation. There are a total of six classes of histones (H1, H2A, H2B, H3, H4, and H5). Covalent modification of histones (e.g., their acetylation, methylation, phosphorylation, etc.) controls the degree to which chromatin is active or inactive.

Synonyms
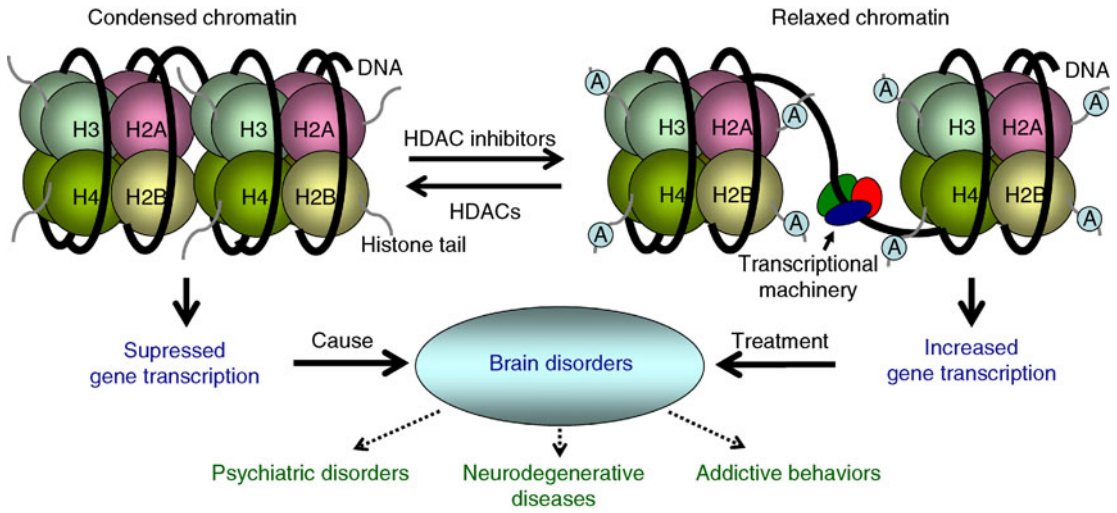
HDACs inhibitors

Definition
► Histone deacetylase (HDAC) inhibitors are compounds that have the ability to prevent the deacetylation of lysine residues found within the N-terminal tails of histone proteins (Nuclear proteins that DNA wraps around to form the chromatin structure which organizes into the nucleosome; see Fig. 1). These compounds were initially developed to treat cancers (Lee et al. 2008), but have recently been used to treat various brain disorders in animal models, suggesting that HDAC inhibitors may potentially develop into novel therapeutic agents (Abel and Zukin 2008; Kazantsev and Thompson 2008).

Pharmacological Properties

Role in Chromatin Remodeling
Chromatin architecture consists of DNA, histones, and nonhistone proteins. The nucleosome represents the basic repeating unit of chromatin and consists of DNA wrapped around a histone octamer that contains H2A, H2B, H3, and H4 histones. ► Chromatin remodeling occurs due to covalent histone modifications (acetylation, methylation, phosphorylation, ubiquitination, and sumoylation) and ► DNA methylation (Tsankova et al. 2007). Two major enzymes, ► histone acetyltransferases (HATs) and HDACs, regulate histone acetylation and deacetylation, respectively. The acetylation of histones leads to a relaxed chromatin state, which allows the DNA to interact more easily with various components of transcriptional machinery, such as transcription factors, transcriptional regulatory protein complexes, and RNA polymerases, resulting in increased gene transcription (Renthal and Nestler 2008). The removal of acetyl groups from histones (deacetylation) by the activation of HDACs condenses the chromatin structure, causing a decrease in gene transcription. HDAC inhibitors can increase overall gene expression by inhibiting HDAC activity, thus preventing the condensation of the chromatin structure (see Fig. 1). Therefore, HDAC-induced chromatin remodeling plays



Histone Deacetylase Inhibitors. Fig. 1. Hypothetical model of histone deacetylases (HDACs)-induced chromatin remodeling via histone deacetylation (condensed chromatin). HDAC inhibitors cause the opening of the chromatin structure (relaxed chromatin) due to its ability to increase histone acetylation (A). HDAC inhibition may serve as a potential therapeutic remedy for the treatment of brain disorders.

a fundamental role in regulating gene expression (► Epigenetics; ► Gene expression and transcription).

HDAC Inhibitors and Therapeutic Implications

Mammalian HDACs have been classified into four classes based on their homology to yeast HDACs and subcellular localization (Xu et al. 2007; Kazantsev and Thompson 2008). Class I HDACs are mostly nuclear and include HDAC 1, 2, 3, and 8. Class II HDACs can be either cytosolic and/or nuclear and include HDAC 4, 5, 6, 7, 9, and 10. Class IV HDACs include only HDAC 11, which display properties that are closely related to class I HDACs and are mainly localized in the nucleus. Class I, II, and IV HDACs require Zn^{2+} for activation and are therefore referred to as Zn^{2+}-dependent HDACs. On the other hand, class III HDACs are NAD^{+} -dependent enzymes that are collectively called sirtuins. Sirtuins are not structurally related to either class I, II, or IV HDACs. HDAC inhibitors that are specific to the Zn^{2+}-dependent class I and II HDACs and their clinical implications are described below.

A number of HDAC inhibitors belonging to different classes (hydroxamates, aliphatic acids, benzamides, and cyclic peptides) have been developed during the last decade and are currently in phase I and II clinical trials for the treatment of various cancers. Recently, the HDAC inhibitor Vorinostat (*SAHA* suberoylanilide hydroxamic acid), has been approved by the US Food and Drug Administration to be used for the treatment of cutaneous T-cell lymphoma (Xu et al. 2007; Lee et al. 2008). Despite the tremendous amount of progress regarding the clinical use of HDAC inhibitors to treat cancers, these compounds can display some forms of toxicity. These include fatigue, nausea, vomiting, thrombocytopenia, neutropenia, and cardiac irregularities (Balasubramanian et al. 2009). Drug development efforts have been diverted to synthesize HDAC isoform-specific inhibitory compounds with some success in the cancer field (Lee et al. 2008) and this approach may overcome the problems associated with drug toxicity (Balasubramanian et al. 2009). The HDAC inhibitors: ► Trichostatin A (TSA), sodium butyrate, SAHA, and ► valproic acid have been used in animal models to treat neurodegenerative (► Neurodegeneration and its prevention; ► Learning & Memory: Molecular Mechanisms) and psychiatric disorders (► Schizophrenia; ► Generalized Anxiety Disorder; ► Anxiety: animal models; ► Depression: animal models) (Tsankova et al. 2007; Kazantsev and Thompson 2008; Abel and Zukin 2008; Guidotti et al. 2009). Using an animal model for depression, it has been suggested that hippocampal chromatin remodeling may play a role in the pathophysiology of depression (► Animal models for psychiatric states; ► Antidepressants), and HDAC inhibitors may be beneficial in treating depression (Tsankova et al. 2006). Genetic and pharmacological manipulations of HDACs in the ► nucleus accumbens (NAc) brain region have been

shown to modify the behavioral sensitivity to ► cocaine, and TSA treatment can decrease cocaine self-administration (► Cocaine; ► Cocaine dependence) in rats (Renthal and Nestler 2008; Romieu et al. 2008). Acute ethanol has been shown to inhibit HDAC activity, and ethanol withdrawal after chronic ethanol exposure has been shown to increase HDAC activity in the ► amygdala of rats. Blocking HDAC activity by TSA treatment during ethanol withdrawal has prevented the development of anxiety-like behaviors (► Alcohol; ► Alcohol abuse and dependence) and has also corrected deficits in histone acetylation in amygdaloid brain regions of rats (Pandey et al. 2008). Collectively, these results suggest that HDAC inhibitors may represent potential therapeutic agents for the treatment of various brain disorders. Given that several HDAC isoforms exist and previous studies have used pan-HDAC inhibitors, it is important to investigate the role of specific HDAC isoforms in different brain disorders using both pharmacological and genetic approaches to block the action of specific HDACs that may lead to development of HDAC isoform-specific pharmacotherapy of brain diseases.

History of Psychopharmacology

Aldo Badiani
Department of Physiology and Pharmacology, Sapienza University of Rome, Rome, Italy

The field of psychopharmacology may be regarded as the point of confluence of theories, lines of inquiry, and methodologies pertaining to pharmacology, psychology, and psychiatry. Other disciplines, including ethology, genetics, and anthropology also contributed to the growth of psychopharmacology. The diversity of the roots of psychopharmacology goes a long way toward explaining the different definitions given to this term and why it means different things to different practitioners in the field. The goal of this essay is to briefly review the family tree of psychopharmacology and with it the development of the discipline.

The Origins of the Term Psychopharmacology

There is little doubt that psychopharmacology came of age in the 1950s with the ascent of behavioral pharmacology and the appearance of the first ► antidepressants and ► antipsychotic drugs. The first textbook of psychopharmacology (Wolfgang de Boor's *Pharmakopsycologie und Psychopathologie*) was published in 1956. Experimentation with psychotropic drugs, however, had been going on for many years before. The term "psychopharmacology" was used for the first time by David I. Macht in a paper titled "Contributions to Psychopharmacology," published in 1920 in the Bulletin of the Johns Hopkins Hospital. In the following year, Macht would write: "The effect of drugs on psychological functions and animal

behavior has been the subject of remarkably little investigation on the part of either psychologists or pharmacologists. With the exception of two substances – alcohol and caffeine – the contributions to this subject have until very recently been few and meager, so that the field of what may be termed 'psychopharmacology' is virgin soil, full of possibilities." The "little" that had been done until then was largely the work of Emil Kraepelin who had introduced the term *Pharmakopsychologie* in an 1892 monograph (*Über the Beeinflussung einfacher psychischer Vorgänge durch einige Arzneimittel* 1892). Even before the terms psychopharmacology and pharmacopsychology were coined, however, there had been sparse scholarly studies on opium, hashish, coca, and other natural substances. Furthermore, attempts at finding medications for mental disorders had began well before the pharmacotherapeutic revolution of the 1950s. A study on the early history of psychopharmacology should therefore be articulated in various phases.

Psychopharmacology Before Experimental Psychology

Although it is customary to start any history of psychopharmacology by mentioning the use of drugs in ancient times, the truth is that the ancients had very little understanding of the psychological effects of drugs except for the fact that some of these effects could be exploited for recreational or ritual purposes. It was only with the advent of evidence-based medicine in the nineteenth century that the scientific exploration of the psychoactive effects of drugs would begin, owing to the isolated efforts of physicians based in France, Germany, Great Britain, and Italy. The work of some of these scientists was quite innovative. The French physician Pierre-Alexandre Charvet was the first to conduct studies of comparative psychopharmacology by administering opium to a variety of species (*De l'action comparée de l'opium et de ses principes constituans sur l'economie animale* 1826). Another French physician, Jacques-Joseph Moreau (also known as Moreau de Tours) was the first to suggest a drug model of psychosis by comparing the mental status induced by hashish to that of mentally ill patients (*Du haschich e de l'aliénation mentale* 1845). Paolo Mantegazza, professor of *Materia Medica* (loosely corresponding to present day pharmacology) at the University of Pavia, was the first to report on the euphoriant effect of coca and to propose a comprehensive classification of psychoactive plants and plant extracts (*Sulle virtù igieniche e medicinali della coca e sugli alimenti nervosi in generale* 1859). The scope of these pioneering efforts was, however, hampered by the lack of quantitative methodologies as well as by inadequate conceptual frameworks of mental functions. Both of these obstacles began to be overcome in the second half of the nineteenth century with the acquisitions of sensory physiology and the rise of experimental psychology.

Psychology and Psychopharmacology

Experimental Psychology and the Scientific Study of Psychological Drug Effects

The role of experimental psychology in the development of early psychopharmacology is often forgotten or belittled. Yet it was in the Leipzig laboratory of Wilhelm Wundt, the founder of experimental psychology, that Emil Kraepelin began his investigation of the psychological effects of drugs (including ▶ alcohol, ▶ caffeine, tea, amyl nitrite, ▶ chloral hydrate, chloroform, ethyl ether, ▶ morphine, and paraldehyde) using "strict" methodologies and with the support of a working theory of the mind. The methodologies employed in Wundt's laboratory were largely based on self-experimentation and in particular, on the procedure of *selbst-beobachtung*, which unfortunately has been rendered in English mainly as "introspection" instead of "self-observation," the literal and more accurate translation of the term. Self-observation allowed the experimenters to turn themselves into experimental subjects. It has been calculated that 50% of studies conducted in Wundt's laboratory were concerned with sensation and perception. Not surprisingly, among the tasks used by Kraepelin were: simple reaction time (67 experiments), choice reaction time (58 experiments), differentiation reaction time (31 experiments), word reaction time (6 experiments), time estimation (12 experiments), associations (14 experiments), serial addition (10 experiments), and reading (7 experiments). Psychometric testing after drug administration was not an absolute novelty in itself, the effects of caffeine, alcohol, and opium on reaction times having been previously investigated by Sigmund Exner (1873), and by Michael J. Dietl and Maximilian von Vintschgau (1877). However, Kraepelin was the first to include in the experimental design healthy volunteers and controls, to employ high precision chronographs (in the millisecond range), to investigate dose-response relationships, and to conduct rudimentary statistical analyses. Although Kraepelin's goals were ambitious ("to recognize the true nature of certain psychological processes from the special effects of an already accurately known drug") the data he collected were plagued by exceedingly high variability and could be regarded, by today's standards, as having more to do with physiology than with psychology.

In the following years, psychometric studies continued to be conducted in European and American universities.

The most important advances were due to William H. R. Rivers at Cambridge University, who introduced ► placebo pills, and to Harry L. Hollingworth at Barnard College, who abandoned the technique of self-observation, adopting group averages calculated on a number of experimental subjects. Hollingworth's name is linked to the Chattanooga Trial of 1911 against the Coca Cola Company. Hired as an expert witness by the defense, on the condition that he would be allowed to publish the results of his research regardless of the outcome, Hollingworth adopted an extremely sophisticated design (the first ► double-blind clinical trial in the history of psychopharmacology), demonstrating that the caffeine content of Coca Cola was not harmful.

Another line of inquiry based on introspection was represented by the studies carried out at the turn of the century by Edmund B. Delabarre (1899), Edward W. Scripture (1893), and others on the effects of ► cannabis on consciousness and will, which somewhat echoed the work done half a century earlier by Moreau de Tours.

Comparative Psychology, Pavlov's Conditioned Responses, and the Ascent of Behavioral Psychology

Before, during, and after the emergence of experimental psychology other, more fundamental currents were developing in the field of psychology, which would have great importance for the shaping of modern psychopharmacology. In the first place, Charles Darwin's *The Descent of Man* (1871) and *Expression of Emotions in Man and Animals* (1872) provided the theoretical basis for comparative psychology. By breaking the separation between human and animal mental processes ("mental continuity doctrine") it became possible to turn the latter into bona fide subjects of psychological investigation. In the following years, Douglas A. Spalding began the scientific study of imprint and instinct and Conwy Lloyd Morgan developed, on the basis of experiments conducted in both humans and animals, a learning theory centered on the association between behavior and its pleasant or unpleasant consequences. These developments would coalesce in the departments of philosophy of North American universities, where functionalism and then behaviorism became the dominant paradigms in psychology.

In 1896–1897, Edward Lee Thorndike, at Columbia University, probably inspired by early research of Lloyd Morgan and John Lubbock, conducted a classical series of experiments with cats and chickens using puzzle boxes. Thorndike's theory of learning, based on the "law of effect" (whereby "satisfiers" would "stamp-in" whereas "annoyers" would "stamp-out" certain stimulus-response connections), would dominate the field of learning theory for over 30 years. The late 1890s also saw Pavlov's discovery of conditioned responses, which would be at the core of the behaviorist revolution promoted by John B. Watson. As a PhD student in Henry Donaldson's laboratory at the University of Chicago, Watson, had at his disposal the experimental subjects (albino rats) and the apparatuses (including the mazes, invented, in 1899, by Willard Small at Clark University) necessary for a rigorous investigation of animal learning. Building on Thorndike's learning theory and Pavlov's work, Watson developed a manifesto (*Psychology as the Behaviorist Views it*, 1913) in which psychology was reduced to the study of behavior "in terms of stimulus and response, in terms of habit formation, habit integrations and the like." Psychology's theoretical aim was defined as "the prediction and control of behavior" whereas the investigation of hypothetical psychological constructs and the study of the central nervous system's "mystery box" were placed outside its boundaries. Within 10 years, Watson's approach would come to dominate American psychology and in the 1930s various brands of behaviorism would emerge, including Edward C. Tolman's cognitive behaviorism, Edwin R. Guthrie's contiguity theory of learning, Clark L. Hull's drive-reduction theory of learning, and, most influential of all, Burrhus F. Skinner's behaviorism. Skinner not only pushed Watson's theoretical approach to its most radical formulation but also developed a procedure, based on Thorndike's "law of effect" and on ► Pavlovian conditioning, which would become central to psychopharmacological research in the following decades. In his "► operant conditioning apparatus" (Skinner box), reminiscent of Thorndike's puzzle box, the behavior of the experimental subject could be "shaped" into performing a given action so as to obtain a "reinforcing" stimulus. In the 1940s, Skinner and his associates embarked on a massive investigation of the effect of the ► schedule of reinforcement on responding, which, according to Skinner's own appraisal, represented his most important contribution to psychology.

Surprisingly, the developments outlined above had a relatively minor impact on the growth of psychopharmacology, at least in the short term. In Pavlov's laboratory, Igor Zavdaskii investigated the effect of ► morphine, ► cocaine, ► alcohol, and ► caffeine on the conditioned salivary reflex of the dog (1917). Among the behaviorists, Watson (who in his 1913 manifesto had mentioned the "psychology of drugs" as a field in "vigorous growth") studied the effect of strychnine and caffeine on rat learning and Skinner the effects of caffeine, ► amphetamine, and ► phenobarbital on conditioning and extinction (1937). More remarkable was a series of studies

concerning the effects of morphine and other ▶ opioids on rat behavior conducted, in the mid-1930s, by, Nathan B. Eddy of the University of Michigan Medical School. While Macht in his 1921 study had used a circular maze, Eddy and colleagues (Report of Committee on Drug ▶ Addiction, National Research Council, 1929–1941) used an elevated maze previously developed by Walter R. Morris to study "Drug effects measured by acquired patterns of response" (1929). Overall, however, it is fair to say that between the 1920s and the 1950s, psychopharmacology had entered a phase of relative quiescence.

Behavioral Pharmacology

Behavioral pharmacology originated in the 1950s in the department of pharmacology of Harvard University, where the freshly hired Peter B. Dews was introduced to behavioral psychology by Skinner. ▶ Operant conditioning procedures were promptly grafted onto pharmacology by Dews and his Harvard colleagues, Roger T. Kelleher and Will H. Morse. Behaviorism's preoccupation with the practical aspects of psychology found an ideal application in the systematic study of the revolutionary ▶ antidepressant and ▶ antipsychotic drugs that had just entered the market. In the following decades, the methodologies developed at Harvard would be extended to the study of the discriminative and ▶ reinforcing stimulus effects of drugs. ▶ Drug-discrimination procedures were pioneered by J. Conger, Don Overton, and Jane Stewart, but the earliest studies employing a two-lever operant conditioning chamber were published in the late 1960s. In 1962, James R. Weeks described a new technique allowing for the first time the study of intravenous morphine ▶ self-administration in the rat. More than two decades earlier, Sidney D.S. Spragg had shown that chimpanzee would work to obtain a shot of morphine but until Weeks's report the notion that a non-primate could become addicted was highly contentious. Drug-discrimination and drug self-administration procedures became standard paradigms for investigating the ▶ abuse potential of drugs.

In retrospect, it is not easy to evaluate the contribution of Dews, Kelleher, and Morse to psychopharmacology. On the one hand, they contributed to this discipline a wealth of methodologies based on conditioned ▶ operant behavior in animals that are still at the core of psychopharmacological research, especially of addiction research. On the other hand, it can be argued that the lack of interest (to put it mildly) of these most orthodox behavioral pharmacologists in the psychological phenomena and the neurobiological mechanisms underlying the behavioral effects of drugs somewhat hampered the growth of psychopharmacology.

Biological Psychology and Psychopharmacology

While behavioral pharmacology was establishing a cultural hegemony in North American departments of pharmacology, a different brand of psychopharmacology was brewing in the departments of psychology. In spite of the edicts by Watson and Skinner, the majority of animal psychologists remained interested in the neurobiological basis of fundamental psychological processes such as reward and motivation, learning and memory, aggression, emotions, and the like. Biological psychology brought to psychopharmacology an impressive range of techniques developed from within (e.g., chemical and electrolytic lesions, ▶ brain stimulation reward, in vivo ▶ microdialysis, in vivo ▶ voltammetry) or imported from related disciplines (e.g., operant conditioning procedures, ▶ conditioned preference/aversion procedures, ethological methods, ▶ spatial learning, social learning, electrophysiological techniques, ▶ fMRI, functional neuroanatomy, genetic manipulations, etc.) as well as powerful theoretical constructs. On the other hand, drugs provided biological psychologists with new tools for manipulating brain activity in a relatively selective manner. Drugs could even be microinjected into discrete brain regions, thus activating or blocking specific neural pathways. Drugs also provided biological psychologists with new areas of investigation, concerning in particular, the phenomenon of drug addiction. This line of research has been steadily growing in the last two decades and more than 50% of all papers published in the last volumes of the journal *Psychopharmacology* are concerned with addictive drugs. From a certain point of view, a large majority of biological psychologists can be considered as psychopharmacologists.

Psychiatry and Psychopharmacology

Early Pharmacotherapy of Psychiatric Disorders (1860s–1930s)

Beginning with the 1860s, and completely independently from the developments summarized above, a number of drugs were introduced for the treatment of mentally ill patients (see Table 1). In this early phase of psychiatric pharmacotherapy, drugs were used to achieve three main effects: sedation, deep sleep, and convulsions. Morphine, potassium bromide, ▶ chloral hydrate, atropine, hyoscyamine, and ▶ scopolamine were used, alone or in combination, for the control of agitated, aggressive patients, thereby reducing the need for physical restraint. Morphine was isolated from opium (which had been used for centuries to control "frenzy") by Friedrich Wilhelm Adam Sertürner in 1804 but its widespread use in

History of Psychopharmacology. Table 1. Milestones in psychopharmacotherapy.

Drug	Isolation or synthesis	Introduction in therapy	Therapeutic use
Morphine	1804	1850s	Sedation
Potassium bromide	1826	1850s	Sedation
		1900s	Sleep therapy
Atropine/hyoscyamine	1931	1860s	Drowsiness
Chloral hydrate	1832	1860s	Hypnosis
Scopolamine	1881	1880s	Drowsiness
Barbital	1903	1910s	Hypnosis
		1910s	Sleep therapy
Insulin	1921	1920s	Sedation
		1930s	Coma therapy
		1930s	Convulsive therapy
Amphetamine	1887/1929	1930s	Antidepressant effect
		1930s	Therapy of narcolepsia
		1930s	Therapy of ADHD
		1930s	Appetite suppression
Camphor	1903[a]	1930s	Convulsive therapy
Penthylenetetrazol	1925	1930s	Convulsive therapy
Lithium	1817	1949[b]	Antimanic effect
Iproniazide	1951	1951	Antidepressant effect
Chlorpromazine	1950	1952	Antipsychotic effect
Reserpine	1953	1953	Antipsychotic effect
Meprobamate	1950	1955	Anxiolytic effect
Imipramine	1940s	1957	Antidepressant effect
Haloperidol	1958	1958	Antipsychotic effect
Chlordiazepoxide	1955	1960	Anxiolytic effect
Clozapine	1961	1971	Antipsychotic effect

[a]Naturally occurring camphor was obtained from *Cinnamomum camphora* since ancient times
[b]In 1871, there was the first recorded use of lithium for the treatment of mania and in 1886 lithium carbonate was used for the first time to prevent depression

psychiatry began in the 1850s, with the invention of the hypodermic needle. Potassium bromide, first isolated from seawater in 1826, was initially used to treat scrofula and only later as an anticonvulsant. Its sedative effects began to be widely exploited in psychiatry in the 1850s. Chloral hydrate was synthesized in 1832 by Justus von Liebig and first used as an hypnotic by Otto Liebreich in the late 1860s, based on the wrong assumption that it would be metabolized to chloroform in the body. The awful taste of chloral hydrate did not prevent this drug from becoming a very popular hypnotic even outside the lunatic asylum. The anticholinergic alkaloids atropine (and its levorotary isomer hyoscyamine) and scopolamine were isolated from plants of the Solanaceae family in 1831 and 1881, respectively. Their ability to induce a state of drowsiness led to their wide use in psychiatric institutions.

In the first decades of the twentieth century, many psychiatrists advocated the use of bromides and ▶ barbiturates to induce a prolonged state of hypnosis (sleep-therapy). A variant of sleep-therapy was represented by coma-therapy induced with barbiturates and later with insulin. Indeed, the lack of effective psychiatric treatments made the psychiatrists ready to try the riskiest procedures (heroic treatments). In the late 1930s, Ladislas Von Meduna popularized the use of camphor and then of pentylenetetrazol to induce convulsions for the treatment of ▶ schizophrenia. Paracelsum (sixteenth century), Robert Whytt (1751), Leopold von Auenbbrugger (1776), and William

Oliver (1785) had previously advocated the use of camphor for the convulsive therapy of the mentally ill. In the 1930s, Manfred Sakel developed another type of convulsive therapy, based on the use of insulin. In 1939, with the introduction of ► electroconvulsive therapy by the Italian psychiatrists Ugo Cerletti and Lucio Bini, camphor and pentylenetetrazol were rapidly abandoned, whereas insulin therapy remained in fashion at the fringes of mainstream psychiatry.

It should be noticed that the pharmacotherapeutic approaches outlined earlier were initially used to treat virtually all types of mental disorders and did not lead to any "chemical" theory of mental function. Drugs were seen mostly as tools to restrain the patients or to produce dramatic changes in the state of brain activity (convulsions or coma) that might help "resetting" mental functions.

Experimenting with Hallucinogenic Drugs (1880s–1940s)

One of the most fascinating aspects of early psychopharmacology is represented by the great deal of interest in ► hallucinogens in both academic and industrial environments. This phenomenon is perfectly exemplified by the book *Phantastica* (1931), into which the German pharmacologist Louis Lewin poured his life-long interest in the ► classification of psychoactive substances, based on their subjective and behavioral effects. He identified *Inebriantia* (e.g., ► alcohol and ether), *Exitantia* (e.g., ► cocaine and ► Khat), *Euphorica* (e.g., ► opiates), *Hypnotica* (e.g., Kava), and *Phantastica* (e.g., Peyote or Ayahuasca). As early as 1887, the pharmaceutical company Parke Davis became interested in the active principle of peyote and other cactuses used by native Americans of the southwest for ritual purposes. Arthur Heffter finally isolated mescaline in 1897. In the following three decades, a number of psychologists and psychiatrists investigated the strange effects of mescaline hoping to find a lead into the nature of psychotic hallucinations. The interest in hallucinogens had almost died out when, in 1938, a chemist working at Sandoz, Albert Hofmann, isolated ergonovine from *Claviceps purpurea,* an ► ergot fungus growing on rye, and subjected it to a number of chemical modifications. Hofmann's aim was to find a drug could induce labor without endangering mother and child, as was the case with the ergot preparations used by midwives since the Middle Ages. Five years later, Hofmann tested lysergic acid diethylamide-25 (LSD-25) on himself, with spectacular results.

The psychedelic effects of LSD brought, for the first time in history, psychoactive substances to center stage of public discourse in North America and Europe, originating a subculture oriented toward spiritual enlightenment. Even the military became interested in LSD, in view of its possible use for manipulating mental functions. At a therapeutic level, LSD was used to facilitate psychotherapy, supposedly by reducing ego defenses (psycholytic therapy), the 1950s and 1960s being the heydays of psychoanalysis. More level-headed research was aimed at understanding the mechanisms of action of LSD in the hope of finding the neurobiological substrate of mental insanity. In 1953, John Gaddum discovered that LSD had anti-serotonin effects and in the same year, Betty Twarog found serotonin in the brain. In 1954, Gaddum proposed that serotonin was required for normal mental functions. It was later discovered that at recreational doses, LSD acted as a partial agonist at various subtypes of serotonin receptors (which is compatible with the anti-serotonin effect described by Gaddum, given that partial agonists act as antagonists in the presence of full agonists), including ► 5-HT2A receptors. The serotoninergic hypothesis of schizophrenia would gain further support with the discovery that many ► antipsychotics could block 5-HT_{2A} receptors.

The First "Antidepressant": Amphetamine (1930s–1950s)

It is often forgotten that ► amphetamine was the first antidepressant drug to enter the psychiatric outpatient market. Phenylisopropylamine (which received the name amphetamine only in 1939) was synthesized for the first time in 1887 by Lazar Edeleanu and then again in 1928–1929 by Gordon Alles, who was searching for an epinephrine analog that could be administered orally for the therapy of asthma. Amphetamine proved to be a failure as an antiasthma medication and in 1934 Alles sold the patent to Smith, Kline and French, which initially marketed it as a decongestant (Benzedrine). Soon it became clear that there was much more to amphetamine than its decongestant effect. In 1935, Benzedrine came to the attention of Abraham Myerson, a prominent American psychiatrist, who thought that its "energizing" effects could be beneficial in minor ("neurotic") depression. Myerson obtained clinical data supporting his hypothesis, and in 1937 SKF began pursuing the psychiatric market with a circular sent to virtually all American doctors stating that "the main field for Benzedrine Sulfate will be its use in improving mood." In 1939–1940, there was a first major campaign in nonspecialist medical journals advertising Benzedrine's effectiveness in "neurotic" depression. Further advertising runs throughout the 1940s reinforced the notion that amphetamine could serve as a stand-alone therapy for those mild forms of ► depression

that were most likely to fall within the scope of family doctors' practice. In the 1950s, with the ascent of psychoanalysis in the USA, amphetamine began to be marketed as an adjuvant to psychotherapy and it was only in the 1960s that its popularity among psychiatrists declined. For about two decades, amphetamine represented the only antidepressant available and was widely prescribed by psychiatrists and general practitioners alike. It was also used for the therapy of ▶ narcolepsy and of ▶ attention deficit disorders. In the mid-1940s, about one million daily doses of amphetamine were used for the therapy of mood disturbances and another one million for weight loss. Other uses of amphetamine, linked to its addictive and performance-enhancing effects (exploited to the full during WWII by civilian and army personnel alike), are beyond the scope of this essay. An important aspect of the amphetamine story was its role in advancing theoretical thinking in biological psychiatry. Myerson thought that the central feature of "neurotic" depression consisted of a state of anhedonia caused by an abnormal dominance of the, supposedly cholinergic, brain circuits responsible for sleep and restfulness over the supposedly adrenergic, brain circuits responsible for activity and wakefulness. Myerson was clearly ahead of his time because when he expounded his theory, in the late 1930s, the notion of chemical transmission in the brain was still highly speculative. In any case, amphetamine may be regarded not only as the first mass-marketed psychoactive drug but also as the first drug whose psychoactive and therapeutic effects could be framed in the context of a neurobiological theory of mental functions.

The Revolutionary Decade: Antipsychotic, Antidepressant, Anxiolytic, and Antimanic Drugs (1949–1958)

The clinical efficacy of the prototypical psychotherapeutic drugs was discovered in a serendipitous manner during a 10-year span, from 1949 to 1958. The starting point of this psychotherapeutic revolution was the substituted ethylamine group at the core of the phenothiazines, an ethylamine group present not only in histamine, but also in ▶ norepinephrine, ▶ dopamine, and serotonin.

Antipsychotic ▶ phenothiazines were first synthesized in 1883 by August Bernthsen, who, as many other industrial chemists of the time, was searching for synthetic dies that could replace the expensive natural dyes. However, in the first half of the twentieth century, it was common practice, given the dearth of effective medications, to screen the biological actions of available compounds in the hope of finding something with potential therapeutic value. In the 1940s, Rhône-Poulenc researchers found that phenothiazines were effective antihistamines, and therefore could be useful for the therapy of allergic reactions. It was later discovered that phenothiazines had many other effects, such as the ability to induce hypothermia, muscle relaxation, sedation, and mild euphoria. The French surgeon Henry Laborit thought that these effects might help in reducing the risk of postsurgical shock, a potentially fatal complication of surgical stress, and included one of these compounds, ▶ promethazine, in his preanesthetic "lytic" cocktail. Laborit was sufficiently impressed by the central nervous system effects of promethazine to ask Rhône-Poulenc for a more potent analog. Such a compound was already available: ▶ chlorpromazine (halogens such as chlorine are known to increase the biological potency of organic molecules). Chlorpromazine exhibited additional effects relative to other phenothiazines, including the ability to induce a state of detachment and to reduce hallucinatory and delusional symptoms in psychotic patients. The large spectrum of chlorpromazine actions led Rhône-Poulenc to market the drug under the name of Largactil. In 1952 and 1953, the French psychiatrists Jean Delay and Pierre Deniker published a series of papers reporting on the possible use of chlorpromazine in the treatment of severe depression, mania, and, most importantly, of ▶ schizophrenia. The hope was that because of its ability to induce drowsiness, chlorpromazine could be used in sleep therapy. The almost miraculous antipsychotic effect of chlorpromazine went beyond the wildest dreams of the psychiatrists, unlocking the doors of psychiatric wards to schizophrenics who had been considered hopeless until then. The frequent appearance of symptoms reminiscent of ▶ Parkinson's disease and other "extrapyramidal" side effects did not dampen the enthusiasm of psychiatrists for the first "▶ neuroleptic" (a term introduced by Delay) and chlorpromazine soon became a blockbuster.

In 1953, another antipsychotic drug, ▶ reserpine, made its appearance in the psychiatric wards. For centuries, traditional Indian medicine had made use of extracts from *Rauwolfia serpentina* for the treatment on insanity, hypertension, and other conditions. In 1931, G. Sen and K.C. Bose reported on the effectiveness of Rauwolfia in calming psychotic patients and lowering blood pressure, but their paper was published in an Indian medical journal and received little attention in Europe and North America. Nonetheless, in the early 1950s, pharmaceutical companies such as Squibb and Ciba become interested in Rauwolfia and in 1953 Ciba's chemist Hugo Bein found that its active principle was reserpine. In 1954, Nathan S. Kline reported on the antipsychotic effect of reserpine and the drug remained in use throughout the 1950s before it

became apparent that it was less effective and more toxic than chlorpromazine and other neuroleptics.

In the 1960s and 1970s, the search for new antipsychotic drugs followed two main paths. The first one (the "me-too" approach) consisted in altering the structure of phenothiazine; e.g., by adding a trifluoromethyl group to promethazine to obtain ► trifluoperazine. A slightly different approach consisted in using, instead of the phenothiazine rings, other tricyclic (e.g., thioxanthine) or heterocyclic rings as starting points for chemical modifications. A striking example of the latter case was the synthesis, in 1961, of ► clozapine, the first, and, according to many, the only truly atypical antipsychotic (that is, an antipsychotic with little extrapyramidal toxicity). A second line of development originated in the late 1950s with the synthesis by Paul Janssen, of a compound that exhibited both opioid-like analgesic effects and neuroleptic-like sedative and motor effects. Further structural modifications, aimed at boosting the antipsychotic effect, led to the synthesis of first butyrophenone, ► haloperidol, another blockbuster antipsychotic drug.

The discovery of effective antipsychotic drugs did not lead to an immediate understanding of their mechanism of action. It was known, however, that chlorpromazine and other antipsychotic phenothiazines could affect monoaminergic transmission in various ways: alpha-receptor blockade, norepinephrine reuptake inhibition, and norepinephrine release inhibition. Furthermore, tests in the rat had shown that antipsychotic phenothiazines were able to block the motor stereotypies induced by amphetamine, which was a notorious psychotomimetic drug. Although the mechanism of action of amphetamine was still uncertain, it was widely thought that it could be related to adrenergic mechanisms. Finally, it was shown that reserpine reduced ► norepinephrine levels in the brain. Even so, other pharmacological actions of chlorpromazine, such as the ability to block serotonin reuptake and to induce the formation of free radicals through oxidoreduction, were still considered potentially relevant for the antipsychotic effect. Then, in the early 1960s, the focus shifted to ► dopamine. In 1958–1959 Arvid Carlsson and colleagues demonstrated that dopamine was not a mere precursor of noradrenaline and adrenaline but a neurotransmitter in its own right, and soon afterward Oleh Hornykiewicz, Theodore Surkes, and colleagues demonstrated that dopamine depletion was at the basis of Parkinson's disease. In 1963, Carlsson and Margit Lindquist suggested the existence of dopamine receptors with high affinity for chlorpromazine and haloperidol, but the first to hypothesize that the antipsychotic effect was due to the blockade of dopamine receptors was Jacques van Rossum, in 1967. Finally, in 1975, Philip Seeman and Solomon H. Snyder demonstrated the existence of dopamine receptors. A striking correlation between the potency of antipsychotic drugs and their affinity for dopamine D2 receptors was found immediately thereafter. For the first time in history, there was a robust neurobiological hypothesis for a mental disorder as well for its symptomatic therapy. It is fair to say that the "► dopamine hypothesis" of schizophrenia represents a mere *ex-adjuvantibus* outcome of the serendipitous discovery of the antipsychotic effects of phenothiazines and reserpine.

Despite all efforts, none of the antipsychotics synthesized after chlorpromazine represented a significant improvement in effectiveness. The only important progress has consisted in developing antipsychotics with lesser autonomic and extrapyramidal toxicity or with better dispositional profiles (e.g., esterified compounds for depot preparations). Indeed, it is somewhat sobering to realize that the last breakthrough in the therapy of psychosis was achieved about 50 years ago with the synthesis of clozapine, and that the only pharmacological target that has yielded effective antipsychotics is still represented by the blockade of D2 receptors.

The high affinity of many neuroleptics for the 5-HT_{2A} receptors, as well as the serotoninergic mechanism of action of LSD and naturally occurring hallucinogens, has been at the base of much research for selectively serotonin antipsychotic drugs. Another potential target was identified in the glutamate receptors, given the ability of ► NMDA receptor antagonists, such as PCP and ketamine, to produce psychotic episodes. Yet, all attempts at developing antipsychotics with selective serotoninergic or glutamatergic mechanisms of action have been unsuccessful, at least so far. The excitement aroused in 2007 by reports of the antipsychotic efficacy of LY2140023, a prodrug of the mGlu2/3 receptors agonist LY404039, has been considerably dampened by Seeman and colleagues' demonstration of the affinity of a structural congener of these drugs for dopamine D2 receptors.

Antidepressants. Besides promethazine, promazine, and chlorpromazine, other drugs with a substituted ethylamine group were tried in the 1950s with the aim to improve sleep therapy. In 1899, Johannes Thiele and Otto Holzinger of the Bavarian Academy of Sciences in Munich synthesized an iminodibenzyl nucleus that differed from phenothiazines for having an ethylene bridge instead of a sulfur bridge and in the late 1940s, Geigy's chemists synthesized a number of derivatives of this basic structure while searching for new antihistamines. Ronald Kuhn, a Swiss psychiatrist, tried compound G22150 (► imipramine) on more than five hundred psychiatric

patients and found a dramatic improvement only in individuals with severe ► depression and only after many days or weeks of treatment. In 1957, Kuhn communicated his findings to a half-empty room at the Second World Congress of Psychiatry in Zurich, encountering general skepticism, even from Geigy's headquarters. Among the few who took notice, there was Heinz Lehmann, who conducted the first clinical trial in North America, reporting on the antidepressant effect of imipramine in 1958.

Even before imipramine, other drugs with antidepressant effect were available but it took some time before their efficacy could be proved conclusively. Isoniazid and iproniazid were synthesized by Hoffman-La Roche's chemists through the modification of hydrazine, a rocket fuel, of which large stores remained at end of WWII. The goal was to obtain drugs against tuberculosis, still a worldwide scourge at the time. These drugs were also tested, according to a well-established tradition, in psychiatric patients. The first report concerning isoniazid, by Jean Delay and colleagues, appeared in 1952 whereas the first report concerning iproniazid, by R. G. Bloch, appeared in 1954. The putative antidepressant effect of isoniazid was not confirmed by subsequent studies and was probably due more to the enthusiasm with which TB patients received the new treatment than to its pharmacological usefulness. It took several more years before it was understood that the apparent vagaries in the clinical effectiveness of iproniazid depended on the short duration of the treatment regimens. In 1957, Nathan Kline and colleagues of the Rockland State Hospital in Orangeburg, New York, reported that iproniazid seemed to work as a "psychic energizer" in depressed in- and outpatients.

The antidepressant effect of imipramine was readily attributed to its ability to block norepinephrine reuptake whereas that of iproniazid to the ability to block ► monoamine-oxidase, the enzyme that degrades norepinephrine and other monoamines. As seen for the antipsychotics, a relatively straightforward *ex-adjuvantibus* line of reasoning resulted in the "noradrenergic" hypothesis of depression. This hypothesis sat well with the finding that, when administered to rats, reserpine produced effects reminiscent of depression, such as immobility.

The "me-too" approach, which had been so successful with neuroleptics, was immediately adopted to obtain drugs with a pharmacological profile similar to, or better than, that of imipramine. For example, the halogen substitution strategy that had yielded chlorpromazine led to the synthesis of ► clomipramine. Contrary to the other ► antidepressants then available, clomipramine exhibited elevated serotonin reuptake blocking capabilities but its metabolite desmethylclomipramine, was a selective inhibitor of norepinephrine reuptake. Not everybody, however, subscribed to the noradrenergic hypothesis of depression. In the late 1960s, some researchers, including Carlsson, Lindqvist, G. F. Oxenkrug, and I. P. Lapin, proposed, on the strength of sparse lines of evidence, that the most important effect of antidepressants was the inhibition of serotonin reuptake. The ► serotonin hypothesis was pursued by Carlsson and Hans Corrodi, who modified the structure of the antihistamine pheniramines to obtain, after many years of work at Astra, zimelidine, the first selective serotonin reuptake inhibitor (► SSRI). Zimelidine was marketed in 1982 but was soon withdrawn because of neurological toxicity. Two other SSRIs were marketed in 1983 (indalpine, later withdrawn because of hematological toxicity) and 1984 (► fluvoxamine), but it was ► fluoxetine (marketed in 1986) that became a byword for SSRI and the most spectacular blockbuster in the history of psychopharmacotherapy, also because of an aggressive marketing campaign by Ely Lilly. However, no consistent relationship has been shown between the therapeutic efficacy of antidepressants and their selectivity for the ► norepinephrine transporter vs. the ► serotonin transporter. Despite all efforts, none of the antidepressants synthesized in the last 50 years exhibited a better therapeutic profile than imipramine, the most important advantage of the newer antidepressants being represented by lesser toxicity, cardiac toxicity in particular.

Anxiolytics. The first drugs with selective ► anxiolytic effects were the ► barbiturates. Barbital (diethylbarbituric acid) was first synthesized in 1902 by Bayer's chemists Emil Fischer and Joseph von Mering, who discovered that it was a very effective hypnotic. ► Barbital was marketed as Veronal in 1904 and along with ► phenobarbital (marketed in 1912 as Luminal) dominated the market of anxiolytic and hypnotic medication until the mid-1950s. Barbiturates, however, become known for the risk of potentially lethal overdosing, their habit-forming properties, and their ability to induce severe ► physical dependence. Thus, it is not difficult to see why, in 1955, the arrival on the market of ► meprobamate (described by Wallace Laboratories as a safe non-addictive alternative to barbiturates) took the medical establishment by storm. Meprobamate was derived from mephenesin, a drug that was developed as a would-be antibiotic but that turned out to have muscle relaxant, sedative and anxiolytic effects. For 10 years, meprobamate was a worldwide best-seller, under the trade names Miltown and Equanil, until it was understood that its toxicity and ► abuse potential was not much different from that of barbiturates. By that time, a much safer alternative to both meprobamate and

barbiturates had become available. The precursors of ▶ benzodiazepines were synthesized in the mid-1930s by Leo Sternbach, a Polish post-doctoral fellow in Krakow who was actually interested in finding new artificial dyes with quinazolinic structure. In 1954, Sternbach, now a chemist at Hoffman-La Roche, resumed working on the quinazolinic structure with the hope of finding a compound that could compete with meprobamate. All derivatives but one were tested and proved to be inactive. Three years later, the last compound, RO5-0690, was found sitting on a shelf by an assistant during a clean up. The results of testing in mice indicated that RO5-0690 had hypnotic and sedative effects similar to that of meprobamate and structural analysis indicated that it was not a quinazoline but a 1, 4 benzodiazepine, which explained why it differed so markedly from the other derivatives. After a further mishap due to the use of extremely high dosages in the first human trial, RO5-0690 (▶ chlordiazepoxide) turned out to be a very promising drug and in 1959 the first meeting focusing on a benzodiazepine was held in Galveston, Texas. Chlordiazepoxide proved to be extremely safe, although it exhibited habit-forming properties and induced physical dependence. In the last 50 years, the me-too strategy has led to the synthesis of more than 100 benzodiazepine analogs, which seem to differ predominantly in terms of ▶ pharmacokinetics. The risk of inducing severe ▶ sedative–hypnotic–anxiolytic dependence has represented the major shortcoming of all anxiolytic treatments until the introduction of ▶ buspirone (a partial agonist to 5-HT_{1A} receptors) in the mid-1980s.

▶ Lithium. Of all psychotherapeutic drugs, lithium has the most bizarre story. During the nineteenth century, lithium bromide was used, like other bromides, to sedate agitated patients although a more specific use as an antimanic drug was advocated as early as 1871 by the American neurologist William A. Hammond. Lithium was also used as an antirheumatic drug and, given the association that was believed to exist between rheumatism and depression, many physicians in Europe recommended it for the therapy of ▶ mania and depression. However, by the early 1940s, the widespread use of lithium chloride, instead of sodium chloride, by hypertensive patients, unveiled its serious neurological and cardiac toxicity, which led the Food and Drug Administration to ban it. Not surprisingly, the 1949 report by John Cade, a previously unknown Australian physician, claiming that lithium was highly effective in manic patients was met with a high degree of skepticism, not to say outright hostility. The naive pathogenic theory proposed by Cade to explain his findings did not help either. Finally, yet importantly, pharmaceutical companies had little or no interest in developing medications that no patent could protect. Mogens Schou, a Danish psychiatrist, and his collaborators, in a series of studies published between 1954 and 1970, demonstrated, beyond any reasonable doubt, that lithium carbonate was indeed an effective antimanic drug. Despite the recent introduction of "▶ mood stabilizers" such as ▶ lamotrigine, ▶ valproic acid, and ▶ carbamazepine, lithium remains the first-line treatment for mania.

Conclusions

The discovery of antipsychotic and antidepressant drugs in the 1950s, albeit of a largely serendipitous nature, powerfully catalyzed the research on chemical neurotransmission that had been going on since the early twentieth century, culminating in the identification of neurotransmitters. Another consequence of the interaction between psychiatry and pharmacology has been the development of ▶ animal models of schizophrenia (e.g., ▶ startle response, ▶ prepulse inhibition), ▶ animal models of depression (e.g., ▶ social stress, ▶ chronic mild stress, and other types of stress), and a variety of other ▶ animal models (e.g., attention hyperactivity disorders, eating disorders, anxiety, addictive disorders). These models have been increasingly employed in conjunction with techniques from molecular biology involving genetically modified animals. As a result, spectacular advances in our understanding of the neurobiology of normal and abnormal mental functions have occurred in the last 50 years and it seems reasonable to expect that this increment in knowledge will eventually lead to major therapeutic discoveries. Some limited success has already been achieved, as in the pharmacotherapy of heroin, alcohol, and tobacco addiction (e.g., ▶ methadone and ▶ buprenorphine for heroinism; ▶ varenicline, tobacco-free nicotine delivery devices, and ▶ bupropion for tobacco addiction; benzodiazepines, ▶ naltrexone, ▶ disulfiram, and ▶ acamprosate for alcoholism). Yet, the fact remains that the last major breakthrough in the pharmacotherapy of psychiatric disorders occurred about 50 years ago and that relatively little is presently available for the pharmacological therapy of obsessive–compulsive disorders, autism, eating disorders, aggressive behavior, dementia, etc.

Homeothermy

Definition

It refers to the maintenance of a constant body temperature in warm-blooded animals. This is typically achieved by the use of physiological processes to compensate for heat loss or gain when environmental temperatures change. Strategies typically recruited include generation of heat by metabolism, muscle contraction, and heat radiation by sweating or panting. Homeotherms generally have an insulating material to retain heat such as fur or fat. Infants of some species including rats and mice achieve homeothermy postnatally.

Homosynaptic

Definition

When events at a single synapse or group of synapses occur but do not involve interactions between synapses or groups of synapses.

Hormones

Definition

Hormones are substances produced by an organ and released into the bloodstream to have their effect on a target organ some distance away.

HPA

▶ Hypothalamic–Pituitary–Adrenal Axis

HPLC

Synonyms

High pressure liquid chromatography

Definition
High pressure liquid chromatography (HPLC) is a form of column chromatography used frequently in biochemistry and analytical chemistry in order to separate, identify, and quantify compounds. HPLC utilizes a column that holds chromatographic packing material (stationary phase), a pump that moves the mobile phase(s) through the column, and a detector that shows the retention times of the molecules. Retention time varies depending on the interactions between the stationary phase, the molecules being analyzed, and the solvent(s) used.

5-HT2A Receptor

Definition
A member of the serotonin 5-HT_2 receptor family – one of the Type A family of G-protein-coupled receptors. It is a seven-transmembrane helical bundle that responds to binding of serotonin by activating second messengers within the cell. Typically, one of the major signals is generation by coupling to Gaq, which leads to phosphoinositide hydrolysis. The receptors are highly expressed on apical dendrites of cortical pyramidal cells, where their activation enhances the gain of cortical cell signaling.

Hunger

Definition
A subjective feeling, comprising the visceral and emotional components associated with the desire to eat. Occurs in response to energy need (such as after fasting), or may be stimulated in response to external food stimuli irrespective of bodily need. Commonly occurs as a conditioned response to the expected delivery of food at regular, predictable mealtimes. The term is also used to refer to an inferred drive to consume food. Hunger is not purely biologically driven but is also context- and time-specific. At certain times and in certain situations, organisms expect to eat and hunger may be a conditioned response. Hunger is also stimulated by food cues and food availability.

Huntington's Disease

Synonyms
HD

Definition
An autosomal-dominant neurodegenerative disease due to a single mutation involving polyglutamine expansion

of >38 CAG repeats in exon 1 of the *huntingtin* gene on chromosome 4. HD is associated with a complex of motor cognitive and psychiatric symptoms, with a mean age of onset around 40 years (the actual age in individual patients correlates inversely with the CAG repeat length), and progressing to death over a course of 15–20 years. The huntingtin protein is involved in multiple subcellular processes including protein trafficking, nuclear uptake, and energy metabolism. The mutation results in intracellular aggregation and formation of nuclear inclusions of fragments of the mutant huntingtin protein and degeneration of the affected cells. ► Neurodegeneration is focused initially in the neostriatum (caudate nucleus and putamen), but spreads to associated cortical areas as the disease progresses, ultimately resulting in widespread neurodegeneration and brain atrophy. HD is most usually modeled in experimental animals by neurotoxic lesions of the neostriatum and more recently in a number of strains of transgenic mice and rats carrying the expanded CAG mutation in the huntingtin gene.

Hydrocodone

Synonyms
Dihydrocodeinone

Definition
Hydrocodone belongs to the opioid (narcotic) analgesic medication class as well to the antitussive medications class. It is a semisynthetic opioid derived from two natural opioids: ► codeine and thebaine. Hydrocodone is available only in combination with other ingredients and different product combinations are prescribed for different uses. Some hydrocodone products are used to relieve moderate to severe pain, whereas others are used for cough relief. Hydrocodone may cause side effects typical of opiate drugs such as nausea, vomiting, constipation, drowsiness, dry throat, itching, and constriction of the pupils.

Hydromorphone

Synonyms
Dihydromorphinone; Dimorphone

Definition
Hydromorphone is an opioid narcotic medication acting mainly on μ-opioid receptors. It is used in the treatment of pain in emergency situations and in patients suffering from chronic long-term pain. Like ► morphine, it has the potential to lead to abuse and long-term dependence on the drug, but some studies show that hydromorphone has a lesser tendency for these actions compared to morphine. Like morphine, it can produce physical dependence and a ► withdrawal syndrome.

6-Hydroxydopamine

Synonyms
6-OHDA

Definition
6-hydroxydopamine (6-OHDA), a hydroxylated analog of dopamine, is a neurotoxin commonly used in neurobiological research to lesion dopaminergic and/or noradrenergic pathways. Its biological effects were initially described in the hearts of mice in the early 1960s. 6-OHDA was subsequently shown to produce anterograde degeneration of the nigrostriatal dopaminergic system when injected in the substantia nigra pars compacta. It has since extensively been used to produce animal models of Parkinson's disease and, more recently, of ADHD and other neurobehavioral deficits.

Hyperactive Delirium

Definition

The hyperactive delirium is a subtype of delirium that is commonly characterized by restlessness, agitation, hypervigilance, hallucinations, and delusions. Hyperactive delirium is correlated with alcohol and drug withdrawal, drug intoxication, or medication adverse effects.

Hyperactivity

Synonyms

Hyperkinesias; Hyperlocomotion; Restlessness

Definition

In behavioral neuroscience, hyperactivity is a state of abnormally elevated locomotor and muscular activity. Especially in children, hyperactivity is often accompanied by impulsiveness, aggressive tendencies, and difficulties to concentrate. These and other symptoms are usually found together in the combined type of the ► ADHD syndrome. Paradoxically, psychomotor stimulants are widely used to reduce pathological hyperactivity in both humans and animal models of ADHD.

Hyperlocomotion

► Hyperactivity

Hyperphagia

Synonyms

Overconsumption; Polyphagia

Definition

An excessive consumption of food beyond that needed for basic energy requirements, which may occur in

association with central nervous system disorders. In animals, overeating or over consumption of calories is usually produced when an animal is given prolonged access to a highly palatable energy-dense diet. It can also be induced by administration of ► appetite stimulant drugs (orexigens). Hyperphagia is essential in animal models of dietary-induced obesity. Hyperphagia is more difficult to induce through pharmacological intervention than hypophagia.

Cross-References
► Appetite
► Appetite Stimulants
► Hunger
► Hypophagia

Hyperphagics

► Appetite Stimulants

Hyperpolarization

Definition
A transient increase in the relative negativity of the intracellular potential, usually causing a reduced excitability of the neurone.

Hyperprolactinemia

Synonyms
Elevated prolactin; Elevated luteotropic hormone

Definition
The presence of abnormally high levels of prolactin in the blood. Prolactin is primarily produced and secreted by lactotrope cells of the anterior pituitary gland (adenohypophysis), which in turn is regulated by neuroendocrine neurons in the ► hypothalamus. Specifically, dopamine released from the median eminence into hypophysial portal blood acts on dopamine D_2 receptors to inhibit prolactin release. Conversely, blockade of dopamine D_2 receptors, as can occur with ► antipsychotics, leads to hyperprolactinemia. All ► first-generation antipsychotics are associated with elevated prolactin. As a class, the ► second-generation antipsychotics demonstrate a decreased risk in this regard, with the exception of the substituted benzamides (e.g., amisulpride, sulpiride), risperidone, and paliperidone (9-hydroxy-risperidone). That these agents represent exceptions appears related to a combination of factors including ► elimination half-life and ► blood–brain barrier permeability. For example, substituted benzamides are administered in higher doses as they cross the barrier relatively poorly; however, the median eminence is termed a "circumventricular organ" that allows for permeability in this region.

Symptoms related to elevated prolactin in women include amenorrhea, oligomenorrhea, galactorrhea, infertility, and decreased libido. In males, symptoms include gynecomastia, galactorrhea, infertility, decreased libido, and reduced muscle mass. Hyperprolactinemia has also been linked to several types of cancer (breast, endometrial), increased platelet aggregation, and osteopenia with sustained elevations. At present, treatment of hyperprolactinemia generally involves switching to one of the atypical antipsychotics not linked to this particular side effect.

Hypersomnias

Michel Billiard
Department of Neurology, School of Medicine, Gui de Chauliac Hospital, Montpellier, France

Synonyms
Excessive daytime sleepiness; Excessive sleep; Hypersomnia; Narcolepsy

Definition

The hypersomnia disorders, or hypersomnias of central origin, are those in which the primary complaint is daytime sleepiness and in which the cause of the primary symptom is neither a circadian rhythm sleep disorder nor a sleep related breathing disorder nor any other cause of disturbed nocturnal sleep (ICSD-2). Daytime sleepiness is defined as the inability to stay awake and alert during the major waking episode of the day, resulting in unintended lapses into drowsiness or sleep.

Role of Pharmacotherapy

Daytime sleepiness is not a homogeneous concept. It can manifest itself as bouts of sleepiness building up into irresistible and refreshing sleep episodes. In other cases, it is associated with large increases in total daily amount of sleep with a major difficulty waking up at the end of the night or of a nap and no feeling of restoration. Rarely it can consist of periods of a week or so of almost continuous sleep, recurring at several months' interval. More frequently the pattern is one of sleepiness most apparent in the afternoon and early evening and awakening later on weekends or on days off.

The occurrence of excessive daytime sleepiness in the general population ranges from 5 (severe) to 15% (moderate) (Ohayon et al. 1997).

Daytime sleepiness has a clear impact on the life of the patient with the risk of automobile or work accidents, impaired academic or work performance, disruption of family life, and impaired cognitive function.

The severity of daytime sleepiness can be quantified subjectively, using the Epworth Sleepiness Scale, a scale rating the probability of dozing in eight more or less soporific daily situations (Johns 1994), and objectively, using the Multiple Sleep Latency Test, a test measuring the tendency to fall asleep in a quiet situation, repeated five times throughout the day (Littner et al. 2005).

Diagnostic Categories

The ICSD-2 includes ten diagnostic categories under the heading of hypersomnia of central origin:

- Narcolepsy with cataplexy is characterized by two cardinal symptoms – excessive daytime sleepiness/sleep attacks and cataplexy, and other clinical features, hypnagogic and hypnopompic hallucinations, sleep paralysis and disturbed nocturnal sleep, that are not necessarily part of the actual clinical picture.
- Narcolepsy without cataplexy includes the same symptoms except cataplexy.
- Narcolepsy due to medical condition. The distinctive feature of this subtype of narcolepsy is the existence of a significant underlying medical or neurological disorder accounting for the excessive daytime sleepiness/sleep attacks and/or cataplexy.
- Recurrent hypersomnia, most classically the Kleine–Levin syndrome, characterized by recurrent episodes of hypersomnia associated with behavioral and cognitive abnormalities.
- Idiopathic hypersomnia with long sleep time. In this condition, the patient has a complaint of excessive daytime sleepiness associated with prolonged nocturnal sleep and major difficulty in awakening at the end of night sleep or of a nap.
- Idiopathic hypersomnia without long sleep time is remarkable for excessive daytime sleepiness only.
- Behaviorally induced insufficient sleep syndrome occurs when a subject persistently fails to obtain the amount of sleep required to maintain normal levels of alertness and wakefulness.
- Hypersomnia due to medical condition depends on a coexisting medical or neurological disorder that produces hypersomnia.
- Hypersomnia due to drug or substance covers hypersomnias associated with tolerance to or withdrawal from various prescribed or street drugs.
- Hypersomnia that is not due to substance or known physiological condition (psychiatric hypersomnia) is a type of hypersomnia temporally associated with a psychiatric disorder.

According to a recent study that reviewed the diagnoses of 1,243 patients referred to a Japanese outpatient clinic for complaint of excessive daytime sleepiness, the most frequent diagnosis (34.7%) was obstructive sleep apnea syndrome (not a disorder of hypersomnia of central origin), followed by idiopathic hypersomnia (10.9%), narcolepsy (8.8%), behaviorally induced insufficient sleep syndrome (7.1%), ▶ circadian rhythm sleep disorders (6.1%) (not a disorder of hypersomnia of central origin), and hypersomnia not due to substance or known physiological condition (4.3%) (Komoda et al. 2008). Hypersomnia due to medical condition and hypersomnia due to drug or substance were not listed and recurrent hypersomnia accounted only for 0.2% of the diagnoses.

Prior to committing to long-term therapy of hypersomnia, an accurate diagnosis is important in order to choose an appropriate therapy. The ICSD-2 specifies necessary diagnostic tests and criteria for each disorder of hypersomnia of central origin. Treatment objectives should include control of excessive daytime sleepiness

and other sleep-related symptoms, such as cataplexy in the case of narcolepsy or the underlying condition in case of hypersomnia due to medical condition. A range of drugs is available to treat hypersomnia (Table 1).

Efficacy

All the listed drugs have been systematically studied in narcoleptic patients. Moreover only the new drugs, ► modafinil and sodium ► oxybate, have been subjected to a series of randomized, double blind, placebo-controlled trials (The US Xyrem Multicentre Study Group 2002; The Xyrem International Study Group 2005; US Modafinil in Narcolepsy Multicenter Study Group 1998; US Modafinil in Narcolepsy Multicenter Study Group 2000). Modafinil and sodium oxybate have been approved by the European Medicines Agency (EMEA) and the US Food and Drug administration (US FDA), and ► methylphenidate by some European countries (Belgium, Denmark, France, Germany, and Switzerland) and the US FDA.

Hypersomnias. Table 1. Drugs used as stimulants.

Drugs	Mechanisms	Starting/ maximum dose	Adverse effects/remarks
Long used drugs			
Amphetamines			
D-amphetamine	Induces dopamine release and, to a lesser extent, norepinephrine and serotonin	5 mg/60 mg	Increase in heart rate and blood pressure Irritability, nervousness Anorexia, nausea
Methamphetamine	Induces dopamine release and, to a lesser extent, norepinephrine and serotonin	5 mg/60 mg	Increase in heart rate and blood pressure Irritability, nervousness Anorexia, nausea
Amphetamine-like drugs			
Methylphenidate	Induces dopamine release	10 mg/60 mg	Same as with amphetamines but less marked
Pemoline	Blocks dopamine reuptake	37.5 mg/75 mg	Minimal sympathomimetic effects Potential hepatotoxicity (withdrawn from the market)
Mazindol	Induces a weak dopamine release Also blocks dopamine and norepinephrine reuptake	2 mg/8 mg	Sympathomimetic effects Rare cases of pulmonary hypertension and valvular abnormalities (withdrawn from the market in several countries)
Selegiline	Selective monoamine oxidase B Inhibitor (metabolically converted to amphetamine and methamphetamine)	10 mg/40 mg	Sympathomimetic effects Interaction with other drugs (tryptophan, serotonin) (only occasionally used)
Newer drugs			
Modafinil	Unknown mechanism but presumably involves dopamine reuptake inhibition	100 mg/400 mg	Headache, nausea, nervousness, rhinitis Induction of human hepatic cytochrome P450 enzymes
Sodium oxybate	The sodium salt of GHB, a neuromodulator of GABA, serotonin, dopamine and endogenous opioids	4.5 g/9 g	Headache, nausea, dizziness, enuresis

If one considers the most recent drugs, modafinil and sodium oxybate, the first has been approved in France in 1994 and in the USA in late 1998, while sodium oxybate has been approved more recently in 2005.

A conservative therapy, based on the well-tested efficacy of the drug and its limited adverse effects, consists in using modafinil first, in a split dose strategy with 200 mg in the morning and 200 mg at 12:00. In case of insufficient efficacy or of a secondary relapse, modafinil is supplemented with either methylphenidate (on an as-needed basis) or sodium oxybate at a dose of 4.5 g in two divided doses at night (Billiard 2008).

A more recent therapeutic approach consists in using sodium oxybate as a first-line treatment, based on the efficacy of the drug on the three main symptoms of narcolepsy, excessive daytime sleepiness/sleep attacks, cataplexy, and disturbed nocturnal sleep. The initial dose is 4.5 g in two divided doses at night, one at bedtime and another one 2.5–4 h later. The dose may be increased to a maximum of 9 g/night, divided into two equal doses of 4.5 g (Billiard 2008). Most patients will start to feel better within the first few days, but optimal response at any given dose may take as long as 8–12 weeks. In case of insufficient efficacy, sodium oxybate is supplemented with either modafinil or methylphenidate. In either case, the place for other stimulants, ► amphetamines and amphetamine-like drugs, has become extremely limited, due to potential adverse effects.

In addition to pharmacotherapy, behavioral treatment measures are always advisable in the case of narcolepsy. Essentially, the studies available support the recommendation for planned naps during the day, as naps decrease sleep tendency and shorten reaction time. Because of limitations on work or home times, naps are best scheduled on a patient-by-patient basis.

As concerns the other hypersomnias of central origin, pharmacotherapy depends on the disorder. In the case of recurrent hypersomnias, all attempted therapies have been disappointing. Idiopathic hypersomnia with or without long sleep time is treated by modafinil or methylphenidate. Results range from good to poor. Behaviorally induced insufficient sleep syndrome is best treated in encouraging patients to increase their time in bed either at night and/or in taking naps. The treatment of hypersomnia due to a medical condition, such as stroke, encephalitis, tumor, and neurodegenerative disease, is always challenging because excessive daytime sleepiness is often a multifactorial phenomenon including poor sleep at night, depression, effects of medication(s), and the effect of the disease itself. Hypersomnia due to drug or substance is to be treated by withdrawal of these, which is most often difficult to achieve. Psychological supportive therapy is required. Hypersomnia not due to substance or known physiological condition comes under the treatment of the psychiatric condition. However, the addition of modafinil is often necessary (Morgenthaler et al. 2007).

Tolerability

The different possible adverse effects of the various stimulants are listed on Table 1. Modafinil is probably the drug with the least adverse effects. As far as sodium oxybate is concerned, if one follows the titration rules strictly, that is, an initial prescription of 4.5 g divided into two equal doses of 2.25 g/night, and then increase to a maximum dosage of 9 g/night, by increments of 1.5 g at a 2-week interval, the likelihood of adverse effects is relatively limited.

Risks of tolerance and dependence

► Tolerance to amphetamine and amphetamine-like stimulants. may develop in up to one-third of patients, but abuse potential is generally low in narcoleptic patients. There is no evidence of tolerance and ► dependence with modafinil. In the case of sodium oxybate, the most problematic adverse effect was expected to be drug abuse. However, the monitored prescription program in the USA revealed that this is a very low risk in narcoleptic patients.

Future treatments

At present, there is not much research oriented toward the treatment of the different categories of hypersomnias, except for narcolepsy. In this case, the major development in understanding the neurobiological basis of the condition has led to several focuses for future treatments, namely symptomatic neurotransmitters, endocrine therapy, immunotherapy, and hypocretin-based therapies (Mignot and Nishino 2007).

Novel compounds currently in development include armodafinil, the R-enantiomer of the racemic compound modafinil, and an inverse H-3 receptor agonist (tiprolisant). The first one has already been evaluated in humans and seems promising, while the second has been tested with success in canine and murine models of narcolepsy and in a pilot single-blind trial of narcoleptic patients receiving a placebo followed by tiprolisant, both for one week. Thyrotrophin-releasing hormone has been shown to increase wakefulness in canine narcolepsy.

Based on the not yet confirmed autoimmune hypothesis of narcolepsy, treatments such as intravenous immunoglobulins have been tried in children with some uncontrolled but promising results.

Now, as ► hypocretin/orexin deficiency is the cause of most narcolepsy in humans, the best standard for narcolepsy treatment is likely to aim at replacing the missing neurotransmitter. Various approaches are being considered including administration of hypocretin-1, cell transplantation, and gene therapy.

Conclusion

The treatment of hypersomnias of central origin varies with the actual disorder. The most advanced treatment is the one for narcolepsy, due to the fact that the approved drugs have undergone several randomized, double blind, placebo-controlled clinical trials. Moreover, due to major advances in the understanding of the neurobiological basis of narcolepsy, new treatments are being tested in animal models and some of them in humans. Other hypersomnias have not benefited from systematic pharmacological trials and there is a need for studies testing commonly used stimulants in these disorders.

Hypersomnias of Central Origin

Definition

Hypersomnias in which the primary complaint is daytime sleepiness and the cause of this symptom neither a circadian rhythm sleep disorder nor a sleep-related breathing disorder or another cause of disturbed nocturnal sleep.

Hyperventilation

Definition

Hyperventilation is when a person breathes abnormally, both too quickly and too deeply.

Cross-References

► Agoraphobia
► Panic

Hypnagogic Hallucination

Definition

A vivid, dream-like sensation of seeing, hearing, or feeling something that occurs just before sleep onset. Although described as one of the symptoms of narcolepsy, taken alone is considered a normal phenomenon.

Hypnotic Dependence

► Sedative, Hypnotic, and Anxiolytic Dependence

Hypnotics

Definition

Drugs used for the treatment of insomnia.

Hypoactive Delirium

Definition

Hypoactive delirium is a subtype of ► delirium that is characterized by psychomotor retardation, lethargy, sedation, and reduced awareness of surroundings. The hypoactive subtype of delirium is commonly misdiagnosed as depression. Hypoactive delirium has generally been found to occur due to hypoxia, metabolic disturbances, and hepatic encephalopathies.

Hypochondria

► Somatoform and Body Dysmorphic Disorders

Hypocretins

Luis de Lecea
Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA, USA

Synonyms

Orexins

Definition

The hypocretins (Hcrt1 and Hcrt2), also known as orexin A and orexin B, are two ► neuropeptides expressed in a few thousand neurons in the lateral hypothalamus (de Lecea et al. 1998; Sakurai et al. 1998), which are critical for arousal stability. Lack of Hcrt neurons or peptides leads to narcolepsy with or without cataplexy.

Pharmacological Properties

Hcrt peptides are derivatives of a longer precursor of 130 residues, with an apparent signal sequence.

The C-terminal 19 residues of these two putative peptides – Hcrt2 (28 residues; RPGPPGLQGRLQRLLQA NGNHAAGILTM-amide) and Hcrt1 (33 residues; EPL PDCCRQKTCSCRLYELLHGAGNHAAGILTL-amide) – share 13 amino-acid identities, suggesting that the peptides have related structures and functions. This region of Hcrt2 contains a seven-amino acid match with secretin. Hcrt1 contains two intrachain disulfide bonds. Human Hcrt1 is identical to the rodent peptide, whereas human Hcrt2 differs from rodent Hcrt2 at two residues. The non-amidated forms of the peptides are electrophysiologically inactive.

Receptors and Signaling Cascades

The initial orphan GPCR, Hcrtr1, binds Hcrt1 with high affinity, but Hcrt2 with 100–1,000-fold lower affinity (Sakurai et al. 1998). A related GPCR, Hcrtr2, sharing 64% identity with Hcrtr1, was identified by searching database entries with the Hcrtr1 sequence and has a high affinity for both Hcrt2 and Hcrt1. These two receptors are highly conserved (95%) across species. Radioligand-binding studies and calcium flux measurements have shown Hcrt1 to have equal affinity for Hcrtr1 and Hcrtr2, whereas Hcrt2 has ~10-fold greater affinity for Hcrtr2 than Hcrtr1.

The mRNAs that encode the two Hcrt receptors and the receptor proteins themselves, detected by immunohistochemistry, are both enriched in the brain and moderately abundant in the hypothalamus, but have different distributions within the brain.

Hcrt receptors are also widely expressed in the periphery, especially in endocrine tissues including the pituitary, adrenal gland, testis, gastrointestinal tract, pancreas, and pineal gland.

Both Hcrtr1 and Hcrtr2 act through a family of GTP-binding proteins (Gq) that activate protein kinase C (PKC) and mobilization of intracellular calcium. Gq-activated signaling cascades result in phosphorylation of Ca^{2+} channels, which can increase Ca^{2+} conductance and neuronal excitability.

Biological Actions Within the Brain

Experimental administration of Hcrt peptides to animals stimulates food intake, affects motivation and rewarding behavior, and modifies arousal.

Feeding and Metabolism

Sakurai et al. (1998) found that intracerebroventricular (ICV) administration of either Hcrt1 or Hcrt2 increased short-term food consumption in rats. Other findings suggest that the hypocretins are not critical players in feeding activities, but rather play roles in increasing arousal and motivation. Continuous administration of Hcrt1 for seven days in rats does not significantly alter daily food intake, body weight, blood glucose, total cholesterol, or free fatty acid levels, suggesting that many of hypocretin's effects may be limited to short-term, immediate stimulation of feeding behavior consequent to the increased wakefulness. Hcrt deficient mice show very modest, if significant, differences in food intake. Hypocretin-► ataxin 3 transgenic mice, which are genetically depleted of hcrt

neurons and would be expected to be lean, show obesity, and hypolocomotion, and this effect appears to be dependent on diet and genetic background. During fasting, Hcrt1 accumulation in the CSF does not exceed concentrations normal for the waking period. In addition, hcrt ataxin-3 mice, unlike wild-type animals, do not show an increase in locomotor activity after fasting. All these data suggest that some of the food-uptake effect may result from arousal rather than direct feeding pressure.

Motivation and Addiction

Hcrt neurons are highly responsive to ► morphine and their activation is linked to preferences for cues associated with drug and food reward and also naltrexone-precipitated withdrawal. Moreover, Hcrt reinstates extinguished drug-seeking behavior, an effect blocked by an Hcrt1 antagonist (Boutrel et al. 2005) (► Addictive disorder: animal models). Hcrt1 infusion into the ventricle or the VTA leads to a dose-dependent reinstatement of alcohol and cocaine-seeking behavior (► Alcohol abuse and dependence; ► Cocaine dependence; ► Reinstatment of self administration; ► Operant behavior in animals) and it also increases intracranial self-stimulation thresholds. Hcrt-induced reinstatement of cocaine-seeking was prevented by the blockade of noradrenergic and corticotropin-releasing factor systems. Accordingly, a Hcrt1 receptor antagonist blocks footshock-induced reinstatement of previously extinguished cocaine-seeking behavior leading to the conclusion that Hcrt is a major gate in driving stress-mediated drug seeking behavior.

Arousal

In vivo recordings of Hcrt neurons have revealed that these cells do not fire tonically, but rather show bursts of activity at the transitions between sleep and wakefulness, and during exploratory or consummatory behavior (Mileykovskiy et al. 2005). More recently, Adamantidis et al. (2007) used ► optogenetic methods to demonstrate that activation of Hcrt neurons is sufficient to induce wakefulness (Adamantidis et al. 2007).

(a) Rodent models

Continuous recording of the behavior of Hcrt gene deleted mice (Hcrt knockout mice) revealed periods of ataxia, which were especially frequent during the dark period. (Chemelli et al. 1999) EEG recordings showed that these episodes were not related to epilepsy, and that the mice suffered from cataplexy-like attacks with their EEGs showing episodes of direct transition from wakefulness to REM sleep, the hallmarks of narcolepsy (Chemelli et al. 1999). Similar observations were made in rats in which the hypocretin neurons of the lateral hypothalamus were inactivated by ► saporin targeting, although in this model, cataplexy was not observed. Mice with an inactivated Hcrtr 2 gene have a milder narcoleptic phenotype than the Hcrt knockouts; Hcrtr 1 knockouts exhibit only a sleep fragmentation phenotype, whereas double Hcrtr 1 and Hcrtr 2 mutants recapitulates (almost) the full Hcrt knockout phenotype, suggesting that signaling through both receptors contributes to normal arousal, although the role of Hcrtr 2 is greater than that of Hcrtr 1.

Mouse and rat models of ► narcolepsy have been generated by expressing a mutant form of ataxin 3. These transgenic animals show progressive depletion of Hcrt neurons, and display a narcolepsy-like phenotype.

(b) Human narcolepsy

Nishino et al. (2000) studied Hcrt-1 concentrations in the cerebral spinal fluid (CSF) of normal controls and patients with narcolepsy by radioimmunoassay. Hcrt-1 was undetectable in 37 of 42 narcoleptics and in a few cases of Guillain-Barré syndrome. CSF Hcrt-1 was in the normal range for most neurological diseases, but was low, although detectable, in some cases of CNS infections, brain trauma and brain tumors (► Hypersomnias). The absence or very low levels of CSF Hcrt-1 have been replicated independently in narcolepsy patients with or without cataplexy.

Peyron, Thannikal and their teams of collaborators (Peyron et al. 2000; Thannickal et al. 2000) found that, in the brains of patients with narcolepsy, only few or no Hcrt-producing neurons could be detected. Hcrt neurons are likely selectively depleted, as other markers that colocalize in these neurons such as preprodynorphin are also absent in the hypothalamus of narcoleptic patients, whereas co-distributed MCH neurons are unaffected. Furthermore, a single patient with a non-HLA-linked narcolepsy carries a mutation within the Hcrt gene itself. The mutation results in a dominant negative amino acid substitution in the secretion signal sequence that sequesters both the mutant and heterozygous wild-type Hcrt nonproductively to the smooth endoplasmic reticulum. These findings leave no doubt as to the central role of the Hcrt system in narcolepsy. Because most cases are sporadic, mutations in the Hcrt gene or those for its receptors can account for no more than a small subset of the human narcolepsies. The HLA association, loss of neurons with signs of gliosis, and age of disease onset are consistent with autoimmune destruction of the Hcrt neurons accounting for the majority of narcolepsy, although a nonimmune-mediated degenerative process has not been ruled out.

Current treatment of narcolepsy includes ► modafinil and psychostimulants to promote alertness during the day and sodium oxybate to consolidate sleep during the rest period. Modafinil has been shown to activate Hcrt neurons in the hypothalamus, although this effect is not selective.

Several Hcrtr 1 selective antagonists have been reported. Recently, a nonselective orally bioavailable Hcrt receptor antagonist (almorexant) has been shown to promote sleep in dogs and humans (Brisbare-Roch et al. 2007). This small molecule Hcrt receptor antagonist has great promise in the treatment of insomnia (► Hypnotics) as well as prevention of relapse of drug seeking and modulation of metabolism.

Hypocretins/Orexins

Definition

The hypocretin peptides, hypocretins 1 and 2, were discovered and named in 1998. The name "hypocretin" was derived to reflect the primary localization of hypocretin-producing cells in the hypothalamus and a sequence similarity with the hormone secretin.

In parallel, endogenous ligands to two orphan receptors with homologous structures had been identified and called orexins A and B because of their stimulating effects on appetite.

The orexin peptides turned out to be the same as hypocretins.

Hypometria

Definition

An undershoot in saccade amplitude, that occurs most acutely for internally generated saccades, often observed in patients with Parkinson's disease or medicated patients with schizophrenia.

Hypophagia

Definition

The suppression of caloric intake in animals usually resulting from a reduction in feeding behavior brought about by drug administration or other biological (e.g., surgical) or environmental interventions (such as change in diet). This is usually the first indication of a drug's

appetite-suppressing potential. However, drugs can reduce caloric intake through a variety of non-appetite mechanisms such as nausea, behavioral disruption (sedation or hyperactivity), or malaise.

Hypothalamic–Pituitary–Adrenal Axis

Synonyms

HPA

Definition

Refers to a coordinated pattern of stimulation and feedback interaction between hypothalamic paraventricular neurons, pituitary corticotrophs, and the adrenal cortex with the aim to facilitate adaptation to stress and synchronize daily and sleep-related events.

Hypothalamus

Definition

A portion of the brain that contains a number of small nuclei with a variety of functions. The main function of the hypothalamus is to maintain homeostasis. Some cells of the hypothalamus detect changes in the levels of metabolites and hormones and participate in the control of metabolic and neuroendocrine functions.

Hypothermia

Definition

The situation where the body temperature of a warm-blooded creature is reduced to being lower than normal for that species. Hypothermia can be produced by either exposure of the animal to low ambient conditions or can be induced by administration of certain chemical compounds.

Hypovase®

► Prazosin

I

IACUC

Synonyms

Imaging Mass Spectrometry

Synonyms
IMS; Mass spectrometry imaging; MSI

Definition
IMS allows an image of a brain tissue section to be acquired at a specific molecular weight and provides the investigator with spatial and quantitative information of proteins and peptides. It is commonly possible to generate individual maps to verify the presence, the molecular weight, and the location of proteins. IMS can produce hundreds of image maps each at a discrete molecular weight value. Applications range from low-resolution images of peptides, proteins, drugs, and their metabolites in selected areas of tissue to high-resolution images of tissue cross sections.

Imipramine

Definition
Imipramine is a ► tricyclic antidepressant with a tertiary amine chemical structure. The first tricyclic to be developed, it acts by inhibiting the reuptake of ► norepinephrine and ► serotonin. Its primary use is in the treatment of depression. It is metabolized to desmethylimipramine (desipramine), a tricyclic associated with relatively selective norepinephrine reuptake inhibition, which is itself marketed as an antidepressant. Usage of imipramine has declined in recent years in conjunction with the general decline in the use of tricyclics. Imipramine has a side-effect profile similar to that of other tricyclics, including drowsiness, cardiovascular effects, and anticholinergic

Impairment of Functioning; Measurement Scales

Johannes Wancata
Department of Psychiatry and Psychotherapy, Medical University of Vienna, Vienna, Austria

Synonyms

Activities of living scales; Disability scales; Impairment of functioning scales; Quality of life scales

Definition

Psychiatric disorders can have a variety of negative psychosocial consequences such as unemployment, homelessness, or difficulties in communicating with others. Recently, the World Health Organization (WHO) developed a new scheme for the description and classification of these negative consequences (International Classification of Functioning, Disability, and Health – ICF; WHO 2001). In this context, "disorders of activity/capacity" means the ability of what an individual can do or not do. "Disorder of participation" means the degree in which an individual can fulfill role requirements in the job, the family, or in leisure times.

Principles and Role in Psychopharmacology

Assessments of the outcome of morbidity focused traditionally on deaths and reduction of symptoms. While mortality data or data on symptoms are important in their own right, they do not adequately capture health outcomes of individuals. Especially when analysing psychiatric interventions, symptom assessment alone does not explain what patients can do, what they need, and what their prognosis will be (Üstün et al. 2004).

Psychiatric disorders are an important cause of long-term disability. The most recent report of the WHO attributed about 29% of all years lived-with-disability to psychiatric disorders: the five major were unipolar affective disorders (10%), substance use and alcohol-use disorder (4%), ► schizophrenia (2%), ► bipolar affective disorders (2%), and ► dementia (2%). However, the interaction between mental disorder and disability is more complex than what the WHO report suggests. For example, ► depression is an important predictor for the onset and progression of both physical and social disability. In contrast, disability due to physical diseases is an important risk factor for depression in older adults (Mathers and Loncar 2006; Prince et al. 2007). A variety of studies have shown that psychiatric disorders frequently result in impairment of functioning, such as keeping social contacts, living independently, or to stay in the job (Rössler et al. 2005). The distinctions of the in-part similar and sometimes overlapping constructs such as impairment of functioning, disability, impaired activities of living, and quality of life are not fully clear (Katschnig et al. 1997).

When investigating the effects of psychiatric treatment such as psychotropics, psychotherapy, or social interventions, clinicians usually focus on the reduction of symptoms and avoiding relapses (usually defined as recurrence of symptoms). For this purpose, a variety of condition-specific assessment tools had been developed (e.g., ► Hamilton Rating Scale for Anxiety (Hamilton 1959), Positive and Negative Syndrome Scale (Kay et al. 1987)). Nevertheless, it has been shown that psychiatric treatment might reduce symptoms but does not have an impact on functioning. Thus, several authors suggested analysing the effects of treatment not only on symptoms, but also on functioning.

The idea of measuring functioning, disability, or similar concepts is not new in psychiatry. There are a lot of assessment tools, but many have been criticized because they are not comprehensive or mix functions with symptoms. Considering these aspects, the WHO adopted a new scheme in 2001 for the description and classification of illnesses, including disability and functioning, called the the International Classification of Functioning, Disability, and Health (ICF; WHO 2001). The ICF aims to provide a unified and standard language and framework for the description and classification of health and health-related states. It belongs

to the group of classifications developed by the WHO, such as the International Classification of Diseases (Baron and Linden 2008).

In addition to symptoms, the ICF describes disorders of activity/capacity (i.e., what an individual can do or not do). Of course, symptoms essentially influence what an individual can do. Disorders of activity/capacity can result in disorders of participation (i.e., the degree in which an individual can fulfill role requirements in the job, the family, or in leisure times). For example, reduced drive is typical for persons with depressive episodes (=symptom). Reduced drive impairs the ability to leave the apartment (=disorder of activity/capacity). If somebody cannot leave the apartment, he/she will not be able to work resulting in sick leave or unemployment (=disorder of participation). Further, we must not forget that the ability to fulfill role requirements can also be influenced by environmental factors (Baron and Linden 2008). The risk for unemployment will be increased for this person suffering from depression if the unemployment rate in the city is overall high.

Nevertheless, there is a complex interrelationship between symptoms, capacities, and participation. Different symptoms can lead to the same or different disorders of capacity. For example, reduced drive, negativism, ► hallucinations, or ► anxiety symptoms can impair an individual's ability to leave his/her apartment. Similarly, different disorders of capacity can lead to the same or different disorders of participation, and context factors might have an essential influence on the ability to fulfill role requirements. A person whose anxiety reduced his/her ability to communicate with other persons might be able to work as a data typist, but may be incapable to work as a salesperson in a supermarket.

A classification considering such complex interrelationship becomes very impractical for daily clinical use. For this reason, the WHO developed several instruments based on the ICF, like the ICF-Checklist (WHO, 2002) and the WHO Disability Assessment Schedule II (Üstün et al. in press). The ICF-Checklist is a short selection of items for everyday clinical practice. Its items were selected by experts to cover the most frequently used aspects. The WHO Disability Assessment Schedule II is a scale that gives a total score of disability based on the activities and participation domains of the ICF (Üstün et al. 2004). While the theoretical framework of ICF is a sound basis to understand the complex interactions between symptoms, capacities, and participation, it is not widely used in clinical practice or research. For these reasons, the following types of scales are often used for these purposes.

Impairment of Functioning and Disability

Both concepts mix impairments in capacities and impairments in participation. Instruments covering these domains are often used to describe the consequences of psychiatric disorders. It has been criticised that the number of randomized controlled trials using such scales is much smaller (Burns and Patrick 2007). Among others, the "Personal and Social Performance" (PSP; Morosini et al. 2000) scale, the "Global Assessment of Functioning" (GAF; Hall 1995) scale and the "Groningen Social Disability Schedule" (GSDS; Wiersma 1986) scale are frequently used.

Activities of Living

The theoretical concept of activities of daily living is focussing on activity/capacity, but scales often include items covering impairments in participation. Examples are the "Katz Index of Activities of Daily Living" (ADL; Katz et al. 1963) or the "Instrumental Activities of Daily Living" (IADL; Lawton and Brody 1969) scales (Baron and Linden 2008). These scales are frequently used in dementia research and studies investigating other mental disorders among the elderly.

Quality of Life

Quality of life is conceptualized by some authors as the opposite to impairment of functioning and disability. There is no clear distinction between activity/capacity and participation. In addition, often aspects of well-being, happiness, or satisfaction with treatment are included (Katschnig et al. 1997). While some instruments assess the subjective views of patients, others focus on the expert views. Since subjective well-being and happiness are diminished in depressive disorders, some authors discussed if there is a systematic error in the assessment of quality of life among persons suffering from depression. Nevertheless, a recently published study revealed no evidence for a globally biased negative evaluation of subjective quality of life by depressed patients (Kuehner 2002). Instruments were developed in order to cover all types of psychiatric and physical disorders (e.g., "WHO Quality of Life" scale – WHOQOL (The WHOQOL Group 1998), Medical Outcome Study Approach – MOS-SF-36 (Ware and Sherbourne 1992)), and others were developed specifically for those with psychiatric disorders (e.g., "Lancashire Quality of Life Profile" (Becker et al. 1993), "Quality of Life Index for Mental Health" (Becker et al. 1993)).

Impairment of Functioning Scales

► Impairment of Functioning; Measurement Scales

Implicit Expectancies

Definition

Implicit expectancies are automatic anticipatory cognitions about the effect of some phenomenon. Related to the use of psychoactive substances, expectancies describe an individual's beliefs about the expected outcomes of consuming the substance. Implicit expectancies are automatic and unconscious. Individuals are often unaware of implicit expectancies.

Synonyms

Behavioral addictions; Impulsivity; Urge-driven behaviors

Definition

In the fourth edition of the Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV-TR), the category "impulse control disorders not elsewhere classified" includes kleptomania, intermittent explosive disorder, pyromania, pathological gambling, and ▶ trichotillomania. The impulse control disorders share common core qualities: (1) repetitive or compulsive engagement in a behavior despite adverse consequences; (2) diminished control over the problematic behavior; (3) an appetitive (▶ urge) or craving state prior to engagement in the problematic behavior; and (4) a hedonic quality during the performance of the problematic behavior (▶ impulsivity).

Despite being fairly common among adolescents and adults, impulse control disorders (ICDs) have been relatively understudied (Grant 2008). Currently in the USA, for example, there are no Food and Drug Administration (FDA)-approved medications for the treatment of any of the impulse control disorders. These essays review the available research on the pharmacological treatments of kleptomania, intermittent explosive disorder, and pyromania (pathological gambling and trichotillomania are discussed elsewhere), the advantages and disadvantages of different agents, as well as the reason for the preference of one medication over another.

Role of Pharmacotherapy

Kleptomania

Kleptomania is characterized by repetitive, uncontrollable stealing of items not needed for one's personal use, and is associated with significant morbidity and morality. The onset of this disorder occurs typically in early adulthood but has been reported in cases as young as four and as old as 77. The course of the illness is generally chronic, with waxing and waning of symptoms. Women appear twice as likely to suffer from kleptomania as men. Individuals with kleptomania frequently hoard, discard, or return stolen items. Less than half of the married kleptomaniacs disclose their behavior to their spouses.

Most individuals with kleptomania try unsuccessfully to stop stealing. The inability to stop this behavior often leads to feelings of shame and guilt. The majority of individuals with kleptomania have been apprehended at some time due to their stealing behavior. High rates of co-occurring psychiatric disorders (e.g., depression, anxiety, and other impulse control disorders) are common in individuals with kleptomania (McElroy et al. 1991).

Pharmacological Treatments

There is a very limited amount of data regarding treatment for kleptomania. Most of the available data are confined to one (▶ double-blind) study, two (▶ open label) studies, and case reports. Although there are no medications approved to treat kleptomania, pharmacotherapy has shown some early promise in treating this disorder.

Opioid Antagonists

Since subjects with ICDs, such as kleptomania often report uncontrollable cravings and excitement upon stealing an item, the hypothesis of a reward-triggered release of dopamine has been implicated as underlying these symptoms. Alterations in dopaminergic pathways may produce the feelings of pleasure often associated with kleptomania. As a result, ▶ opioid antagonist, such as ▶ naltrexone, which are thought to decrease dopamine neurotransmission in the ▶ nucleus accumbens and the corresponding linked motivational neurocircuitry, have been proposed as beneficial agents in dampening the excitement and cravings often reported in kleptomania.

The first (open-label) study for kleptomania involved the use of the (opioid antagonist) naltrexone. Ten subjects with kleptomania were treated over 12 weeks with escalating doses of naltrexone (50 to 200 mg/day) in an open-label design. A mean dose of 145 mg/d resulted in a significant decline in the intensity of urges to steal, stealing thoughts, and stealing behavior in nine of the ten subjects compared to baseline symptoms. A naturalistic study of naltrexone produced similar results. Seventeen subjects were followed over a 3-year period while being treated with naltrexone (mean dose of 135.3 mg/day). The study showed that 41% of the subjects reported complete abstinence from stealing and 76% of the subjects reported significant reductions in their urges to steal.

In the only placebo-controlled, double-blind study of kleptomania, 25 subjects were randomized in a 1:1 fashion to either naltrexone or placebo for 8 weeks (Grant et al. 2009). By study endpoint, 66.7% of the naltrexone group compared to 7.7% of the placebo group ($p<0.001$) demonstrated symptom remission. The mean effective dose of naltrexone was 116.7 mg/day.

Although the double-blind study of naltrexone did not report any elevations of liver enzymes, (opioid antagonists), particularly at doses higher than 50mg/day, have been associated with ▶ hepatotoxicity. Other common side effects of opioid antagonists include nausea, dizziness, insomnia, headaches, and loose stools.

Antidepressants

Because low levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) and blunted serotonergic response within the ▶ ventromedial prefrontal cortex have been associated with impulsive behaviors,

serotonergic antidepressants have also been examined in the treatment of kleptomania.

The only controlled study of an antidepressant involved 7 weeks of open-label ▶ escitalopram treatment followed by having the responders randomized to either escitalopram continuation or placebo for an additional 16 weeks (Koran et al. 2007). When the responders were randomized, 43% of those on escitalopram relapsed compared to 50% on placebo, thereby showing no drug effect in terms of response. Although escitalopram is generally well tolerated, the selective serotonin reuptake inhibitors may cause sedation, constipation, weight gain, headache, sexual dysfunction, and dry mouth.

Other Agents

Case series and case reports have also illustrated the benefit of mono- or combination pharmacotherapy for the treatment of kleptomania. In the case of monotherapy, the following medications have shown benefit: ▶ topiramate, ▶ paroxetine, ▶ fluoxetine, ▶ valproic acid, and ▶ fluvoxamine.

In terms of combination therapy, the following have been reported as successful in treating kleptomania: paroxetine plus valproic acid plus naltrexone; topiramate plus paroxetine; naltrexone plus ▶ venlafaxine; ▶ lithium plus fluoxetine; ▶ trazodone plus ▶ tranylcypromine; ▶ sertraline plus ▶ methylphenidate; and ▶ imipramine plus fluoxetine.

Conclusions

Kleptomania, a largely unrecognized disorder, presents as a chronic illness for many individuals and causes significant psychological, social, and legal repercussions. Since presentation specifically of kleptomania is quite rare, it is important that clinicians recognize the disorder and screen patients appropriately. Treatment recommendations are difficult to make, given the extremely limited amount of information regarding pharmacotherapy of kleptomania. The opioid antagonist naltrexone has demonstrated benefit in a placebo-controlled, double-blind study and therefore should be considered a first-line treatment. There is a substantial need for systematic studies in the treatment of this disorder.

Intermittent Explosive Disorder (IED)

Intermittent explosive disorder (IED) involves recurrent, significant outbursts of (aggression), often leading to assaultive acts against people or property, which are disproportionate to outside stressors and not better explained by another psychiatric diagnosis. Recent research suggests IED may be common, with 6.3% of a community sample meeting criteria for lifetime IED (Coccaro et al. 2004).

IED appears as early as childhood (i.e., prepubertal) and peaks in mid-adolescence with a mean age of onset ranging from about 13 to 18 years. The average duration of symptomatic IED has variably been reported to range from nearly 12 to 20 years to nearly the entire lifetime. Individuals suffering from IED regard their behavior as distressing and problematic. Aggressive outbursts in IED have a rapid onset, often without a recognizable prodromal period. They are short-lived (<30 min) and involve verbal assaults, destructive and nondestructive property assaults, or physical assaults. Aggressive outbursts most commonly occur in response to a minor provocation by a close intimate or associate and individuals may have less severe episodes of verbal and nondestructive property assault in between more severe assaultive/destructive episodes. Episodes are associated with substantial distress, impairment in social functioning, occupational difficulty, and legal or financial problems.

Pharmacological Treatments

While there are no approved medications for the treatment of IED, several psychopharmacologic agents appear to have effects on aggression. Classes of agents shown to have "anti-aggressive" effects in double-blind, placebo-controlled trials of individuals with "primary" aggression (i.e., not secondary to psychosis, severe mood disorder, or organic brain syndromes) include mood stabilizers (e.g., ▶ lithium), 5-HT uptake inhibitors (e.g., fluoxetine), and anticonvulsants (e.g., diphenylhydantoin, ▶ carbamazepine). Findings from (double-blind), placebo-controlled, clinical trials suggest that anti-aggressive efficacy is specific to *impulsive*, rather than non-impulsive, aggression.

Although pharmacotherapies have been studied in the treatment of aggression, there is only one controlled study specific to IED. In a 12-week study in the treatment of impulsive aggression, 96 subjects with Cluster B personality disorders, 116 subjects with IED, and 34 subjects with post-traumatic stress disorder were randomized to receive either divalproex sodium or placebo (Hollander et al. 2003). In the intent-to-treat analysis, the study found that divalproex had no significant influence on aggression in the subjects with IED. Although divalproex is generally well tolerated, it can cause somnolence, nausea, weight gain, hair loss, and (hepatotoxicity).

Several other medications have shown efficacy in treating IED in case reports, including lithium, ► clozapine, carbamazepine, and ► propranolol.

Conclusions

Given the paucity of treatment studies for IED, no empirically supported pharmacological treatment recommendations can be offered. The only pharmacological study to date failed to demonstrate benefit. Given the personal and publics health issues of IED, treatment studies are of immediate and inevitable need.

Pyromania

Pyromania is considered to be a rare psychiatric condition characterized by (1) deliberate and purposeful fire-setting on more than one occasion; (2) tension or affective arousal before the act; (3) fascination with, interest in, curiosity about, or attraction to fire and its situational contexts; and (4) pleasure, gratification, or relief when setting fires or when witnessing or participating in their aftermath.

Although thought for a long time to be a disorder primarily affecting men, recent research suggests that the gender ratio is equal in adults and may be slightly higher among females in adolescence. The mean age of pyromania onset is generally late adolescence, and the behavior appears chronic if left untreated. Urges to set fires are common in individuals with this behavior and the fire setting is almost always reported as pleasurable. Severe distress follows the fire-setting, and individuals with pyromania report significant functional impairment (Grant and Kim 2007). High rates of co-occurring psychiatric disorders (e.g., ► depression, ► substance use disorders, and other ► impulse control disorders) are common in individuals with pyromania.

Pharmacological Treatments

There are no randomized, controlled clinical trials examining pharmacotherapy for the treatment of pyromania, and no medications have been approved for its treatment.

Medications that have been described in case reports have shown benefit in the treatment of pyromania include ► topiramate, ► escitalopram, ► sertraline, ► fluoxetine, ► lithium, and a combination of ► olanzapine and sodium ► valproate. An equal number of medications have also shown no benefit in the treatment of pyromania in case reports, including fluoxetine, valproic acid, lithium, sertraline, olanzapine, escitalopram, citalopram, and clonazepam.

Pyromania is a largely unrecognized disorder that causes significant psychological, social, and legal repercussions. Because few individuals volunteer information regarding their fire-setting, it is important that clinicians recognize the disorder and screen patients appropriately. Various treatments have been helpful in case studies but more research on examining etiology and treatment is needed.

Recommendations for Pharmacological Treatment of Impulse Control Disorders

In the area of ICDs, the systematic study of pharmacotherapy is in its infancy. With few studies published, it is not possible to make treatment recommendations with a substantial degree of confidence for most ICDs. No drugs are currently approved by the US FDA for the treatment of any of these disorders. Nonetheless, specific drug therapies may offer promise. Although naltrexone might be considered a promising treatment for kleptomania, the data are limited to one small placebo-controlled study. For IED and pyromania, there are even less available data to generate empirically supported treatment recommendations. For all of these disorders, issues such as which medication to use and for whom, or the duration of pharmacotherapy, cannot be sufficiently addressed with the available data. In conjunction with emerging epidemiological data supporting a relatively high prevalence of impulse control disorders, the small amount of data in the area of effective treatments highlights the clinical need for additional research in this area.

Inability to delay gratification; Failure of response inhibition or behavioral inhibition; Self-control failure

Definition

The term impulsivity is used in two distinct ways. First, it is used to indicate a lack of inhibition, or a tendency to behave without regard to the potential negative consequences of the action. Second, it is used to indicate a failure of self-control or inability to delay gratification, and refers to selecting an outcome that occurs sooner rather than an outcome that is objectively larger but will occur later.

Impact of Psychoactive Drugs

Contexts in Which the Impulsivity Construct is Used

Impulsivity is a multifaceted construct that is used in psychology, psychiatry, and economics. It can refer to both normal and abnormal functions, and to both a stable ► trait of an individual and a transient ► affective state. In the healthy population, impulsivity changes throughout development, with peak levels during childhood and adolescence, and there is also considerable variability in the trait among healthy adults. In psychiatric populations, impulsivity is a common symptom of several psychiatric disorders, including, but not limited to, the category of "Impulse Control Disorders."

In a clinical context, heightened levels of impulsivity are a diagnostic symptom for a number of psychiatric disorders in the DSM-IV TR (APA, 2000) and ICD-10 (WHO, 1990). These disorders are commonly classified as ► externalizing disorders, e.g., ► Attention-Deficit/Hyperactivity Disorder, Substance Use Disorders, Conduct Disorder, and Pathological ► Gambling. There is also some speculation that abnormally low levels of impulsivity may be associated with psychiatric conditions. For example, obsessive-compulsive behavior is characterized by repetitive behaviors and intrusive thoughts, which may reflect an exaggerated focus on the potential negative consequences of behavior and heightened behavioral inhibition.

In the normal population, inter-individual variation in impulsivity is a key element of most personality theories. Within this context, impulsivity is viewed as a stable trait loosely related to sensation or novelty seeking, boredom susceptibility, ► risk taking, unreliability, disorderliness, and sometimes even sensitivity to reward. For example, in the Five-Factor Model of personality, impulsivity is assessed through three of the five factors: It is a component of the domains of Neuroticism, Conscientiousness and Extroversion. In the Myers–Briggs Type Indicator, impulsivity is associated with a focus on the external world (extroversion), and staying open to new information and options (perceiving). Yet other questionnaires ask respondents to assess their behavioral predispositions, creating an operational definition of the impulsive personality. These include: (1) urgency or the tendency to behave quickly or without consideration of the consequences when experiencing strong positive or negative emotional states, (2) lack of planning, or behaving without forethought, (3) lack of perseverance, or an inability to remain on task, and (4) sensation seeking, the tendency to seek novelty or thrilling situations. These operational definitions provide an objective basis by which to study impulsivity and its underlying mechanisms.

Dimensions of Impulsivity

Impulsivity is a theoretical concept that can be deconstructed into several factors. Researchers, including those interested in the impact of psychoactive drugs, have

focused in particular on two factors: (1) an impairment of behavioral or response inhibition and (2) an inability to delay gratification or a pronounced devaluation of delayed outcomes (delay or intertemporal discounting). These two factors have been refered to variously as motor and cognitive impulsivity, motor and choice impulsivity, impulsive action and impulsive ▶ decision making. These terms have in common the distinction between preventing or terminating an ongoing behavior (inhibition), and preferring a more immediate to delayed reward outcome (delay aversion). Even though these factors are thought to represent basic behavioral tendencies, the factors are themselves the product of other, more basic, underlying neuropsychological processes. For example, the ability to inhibit behavior is influenced by the ability to learn and remember appropriate cues, and requires knowledge of the adverse consequences of failing to inhibit the behavior. Inhibition also requires attention to recognize "act" (go) versus "inhibit" (no-go) signals and discriminate appropriate signals from distractors, and it requires the ability to emit the appropriate motor response. Decision making about immediate versus delay outcomes requires an understanding of the duration of the delay, and either a memory for the delayed reward that spans the waiting period or an accurate concept of the value of the future reward.

Both inhibition and delay aversion have been measured using both self-report questionnaires and behavioral tasks. In general, questionnaires are more appropriate as measures of a stable trait because they typically refer to habitual behaviors occurring over a period in time, whereas behavioral measures may be more appropriate to assess momentary changes in the behaviors. Most of the commonly used impulsivity questionnaires, to a greater or lesser extent, incorporate both the inhibition and delay aversion aspects of impulsivity. The behavioral measures are typically more specific, and are used in both human and nonhuman models to assess responses to specific experimental interventions including the administration of psychoactive drugs.

Questionnaires are used to assess both clinically significant levels of impulsivity as well as variations in the normal range. One scale commonly used to assess clinically significant impulsive tendencies in children is the Conner's Behavioral Ratings, which is a parent and teacher rating scale used to diagnose attention-deficit/hyperactivity disorder. The items include behavioral descriptions such as difficulty sitting still in a classroom setting, inability to inhibit inappropriate behaviors such as running around the classroom. A self-report scale typically used to assess impulsivity in the normal population is the Barratt Impulsiveness Scale, which assesses variations in the tendency to engage in behaviors indicative of impulsivity. Factor analysis is commonly used to separate the responses on this questionnaire into the more fundamental neuropsychological processes underlying the behavior, such as attention, perseveration, motor, cognitive instability, self-control, and cognitive complexity. Other self-report questionnaires that include measures of impulsive behaviors are the Multiphasic Personality Inventory, Eysenck Impulsivity Questionnaire and the UPPS Impulsive Behavior Scale.

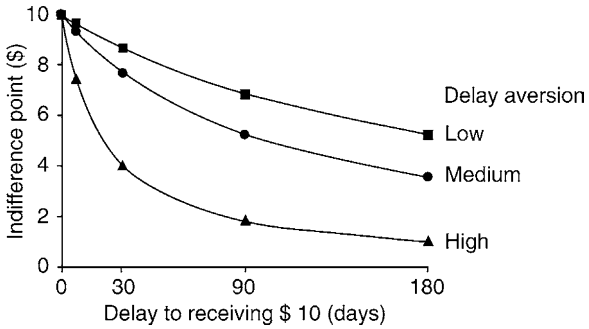
Both questionnaires and behavioral tasks have been used to measure delay aversion by quantifying relative preference for immediate rewards over delayed rewards. Typically, these tasks require individuals to choose between two alternatives, one of which is a smaller reward available sooner, e.g., $9 available now or $40 available now, and the other is a larger reward available later, e.g., $10 in 7 days or $100 in 5 years. The rewards may only be available hypothetically, or the rewards may actually be delivered though usually on a probabilistic basis. In these tasks, the ▶ subjective value of the delayed reward is assessed in terms of an equally valued reward available now (Table 1).

By providing a range of later options, e.g., $10 in 30 days, $10 in 90 days, it is possible to create a response-to-delay profile or a discount function (Fig. 1).

Individuals who exhibit a stronger tendency to accept small rewards rather than wait, and thus discount the value of the delayed reward more steeply, are considered more impulsive than individuals who prefer the larger, delayed reward. In Fig. 1, the delay profile is best described using a hyperbolic function: delayed amount/ 1+k * delay, where k represents the gradient of the

Impulsivity. Table 1. Participants choose between the alternatives in each row. The size of the immediate reward is varied in the left column. The subject's preference is indicated with stars. In this example, $9 now is the minimum value of immediate reward accepted instead of waiting a week for $10. The point of subjective equality or indifference point is defined as halfway between this minimum accepted amount and the largest rejected amount ($9.00 and $8.50), i.e., $8.75.

Which do you prefer?		
$10 now *	OR	$10 in 7 days
$9.50 now *	OR	$10 in 7 days
$9 now *	OR	$10 in 7 days
$8.50 now	OR	$10 in 7 days *
$8 now	OR	$10 in 7 days *



Impulsivity. Fig. 1. Indifference points for a series of delays in three hypothetical individuals, who show different levels of delay aversion.

discount function. However, there is some debate about whether discounting occurs exponentially or hyperbolically (Green and Myerson, 2004). The extent of discounting can be quantified using an index of the gradient, or by calculating the area under the discount curve.

Delay aversion, or delay discounting, has also been assessed in other species including pigeons, mice, rats and nonhuman primates. The studies with nonhumans use food, water, sucrose or drug rewards, and usually involve delays of up to 60 s. Notably, the animals experience the entire delay period, as well as receiving the delayed (larger) reward during the experimental session. This is in contrast to most studies with humans that involve prospective delays and rewards occurring in the future. There are two basic types of discounting tasks. One type is the "within session" procedure, in which the delay to large reward increases in a fixed, systematic way over trials within a session. Subjects choose between a small, sooner (often immediate) reward and a larger, later reward, e.g., three food pellets immediately and six pellets in 10 s, on a fixed number of consecutive trials. The delay to the large reward is 0 s on the first block of trials, but systematically increases over blocks within an experimental session. The within session procedure measures the percent of occasions on which the animals choose the small immediate reward or larger delayed reward at each delay. The other type of task is the "adjusting procedure," which requires multiple sessions to determine a discounting function. In adjusting procedure studies, the reward size or delay on each trial is adjusted, according to the animal's behavior on the previous trial, and different amount or delay conditions are determined on different sessions. There are two main variations of the adjusting procedure. In the adjusting amount procedure, the size of the smaller, sooner reward varies across trials, while the size of the large reward and its delay is fixed throughout the session. If the animal chooses the immediate reward then on subsequent trials the immediate reward is decreased, whereas if the animal chooses the delayed reward the size of the immediate reward is increased. Delay is varied between sessions. In the adjusting delay procedure, the delay to the large reward varies while the smaller reward has a fixed size and delay. Choices of the small reward cause the delay to the large reward to decrease, and choices of the large reward cause its delay to increase. In both adjusting procedures, subjects' choices cause the adjusting alternative to change systematically until subjects become indifferent between the smaller, sooner and larger later rewards, i.e., the ▶ indifference point is achieved. The dependent measure in the adjusting amount procedure is the size of the immediate reward at indifference, making this procedure similar to the questionnaire method shown in Table 1. As in the human assessment, the extent to which the animal accepts smaller immediate amounts is the measure of impulsivity. The dependent measure in the adjusting delay procedure is the length of the delay to the large reward at indifference. Less impulsive individuals will tolerate a longer delay to the larger reward. All of these tasks are used to assess the effects of experimental treatments, for example, the effects of drugs hypothesized to increase or decrease delay aversion.

Several tasks measure the ability to inhibit a prepotent response, i.e., a response that the organism is strongly inclined to make. Different tasks have been developed for humans and nonhumans. One response conflict task used in humans is the Stroop task, in which participants must suppress extraneous salient information. They are required to name the color of ink of a word that names a different color. Thus, there is a conflict between the response that is required (naming the ink color) and the response that occurs when reading the color word. In other tasks, the prepotent response is created by manipulating the relative frequencies of behaviors. The Conner's Continuous Performance Task is a ▶ Go/No-Go task, which requires a button press whenever a new letter of the alphabet is shown on a computer screen, except when the letter is a certain specific, designated letter. Errors of commission or false alarms refer to the tendency to emit the prepotent, but incorrect, response. More false alarms are indicative of greater impulsivity. In yet other tasks, the prepotent behavior has been signaled to be appropriate but the individual is required to terminate that behavior or switch to a different behavior (Logan et al., 1997). In these tasks, the dependent measure is the time needed to stop a response. For example, in the Stop task, an individual is signaled to press a button or make a saccadic

eye movement in a specific direction when a "Go" signal is presented. On a small percentage of trials, some milliseconds following the Go signal, a "Stop" signal is presented, signaling the individual to terminate the initiation of the button press or saccade. The amount of lead time needed to inhibit a Go response provides a measure of impulsivity, longer Stop Times indicate less ability to inhibit and thus more impulsivity.

The tasks used to assess conflict and response inhibition across species include some tasks that resemble the tasks used in humans and some are different. There are both human and nonhuman versions of Go/No-Go conflict procedures. In these procedures, typically the organism is rewarded for correct Go responses, and may either be rewarded for correct inhibitions or punished for not inhibiting appropriately (errors of commission). Higher numbers of false alarms, or failures to inhibit, indicate higher levels of impulsivity. One example of a widely used Go/No-Go procedure used with nonhumans to examine behavioral inhibition is the ► 5-Choice Serial Reaction Time Task (5CSRTT; Robbins, 2002). One of five response options is briefly illuminated, and the animal is required to respond at the correct location within a short time window to earn reward. This task measures the number of premature responses as the indicator of impulsivity, under conditions when premature responses are punished with a brief time out. Another example of a Go/No-Go procedure used with nonhumans but not humans is the differential reinforcement of low rates (DRL) schedule, in which the animals are required to refrain from pressing a lever until a certain minimum time (e.g., 72 s) has elapsed. In this case, the Go signal is internal, and ability to inhibit responding is viewed as largely reliant on timing processes.

Impulsivity and Substance Use Disorders

Impulsivity plays a significant role in substance use disorders. Individuals diagnosed with substance use disorders score higher on both behavioral and personality measures of impulsivity than comparison groups (Perry and Carroll, 2008). Thus, drug users score higher on personality measures of impulsivity, they exhibit a steeper devaluation of delayed rewards and they are also less able to inhibit prepotent responses. Impulsive behavior may be related to drug use in several ways. Impulsivity may affect the likelihood of initiating use, or it may affect the progression to problematic use or persistence of use in inappropriate situations. It may also affect the ability to abstain, or remain abstinent for extended periods. Drug use itself may in turn affect impulsive behavior, either through direct pharmacological effects or through mild toxicity related to chronic use. Finally, impulsivity and drug abuse may be related to a common etiological factor, such as genetic predisposition for both drug use and impulsive behavior. These various hypotheses are not mutually exclusive and indeed data support each point of view (see Perry and Carroll, 2008). It remains a challenge for behavioral scientists to identify the basic underlying constructs of impulsive behaviors and their role in substance abuse.

A substantial number of controlled studies have examined the effects of drugs of abuse on measures of impulsivity. Whereas in studies with humans, the measures of delay discounting have proven relatively insensitive to the acute effects of drugs, studies with nonhumans provide a rich body of data regarding the effects of drugs on delay aversion. Drugs such as ► alcohol, ► cocaine, and ► morphine reportedly increase discounting, whereas other drugs, such as ► amphetamine, may actually decrease discounting. Studies with laboratory animals have also investigated the neural basis of discounting by making selective lesions in brain regions associated with reward sensitivity and decision making. Studies with both humans and nonhumans demonstrate that certain drugs of abuse also impair behavioral inhibition, although again, there is evidence that certain drugs, especially stimulant drugs, may also improve inhibition at low doses. The effects of drugs on measures of impulsivity depend on many factors including the procedure, the animals, the drug doses, and the individuals' baseline levels of impulsivity. In general, however, drugs of abuse are associated with increased delay aversion as well as decreased behavioral inhibition.

Neural and Genetic Mechanisms of Impulsivity

Researchers are actively investigating the neural and genetic mechanisms underlying impulsivity, and several brain areas and neurotransmitter systems have been implicated (see Cardinal, 2006; Pattij and Vanderschuren, 2008). There is evidence that impulsive behavior is related to dysfunction in the ► nucleus accumbens and ► prefrontal cortex. Lesions of the nucleus accumbens and of the orbitofrontal cortex, a part of prefrontal cortex, lead to higher levels of delay aversion and impairments in behavioral inhibition. In humans, ► functional magnetic resonance imaging (fMRI) studies indicate that choosing between immediate and delayed rewards activates the caudate-putamen and prefrontal cortical areas, whereas tasks involving behavioral inhibition activate the rostromedial prefrontal cortex. Other brain areas implicated in impulsive behaviors include the mesial prefrontal cortex, the orbitofrontal cortex, the dorsolateral striatum, the insula, and the ► amygdala. Research has also implicated both dopamine and serotonin in the performance of impulsive

behaviors. For example, D2 receptor antagonists increase delay discounting while D1 receptor antagonists have little effect. Lesions of brain areas rich in ► dopamine result in increases in impulsive behaviors. Correlational studies assessing ► serotonin function, including the measurement of serotonin metabolites, have linked low levels of serotonin to higher impulsivity. Advances have also been made in identifying genetic determinants of impulsive behaviors (Verdejo-Garcia et al., 2008). For example, genes related to dopaminergic function such as DAT1, D2DR, COMT and MAO-A have been associated with impulse control disorders including ► substance use disorders, ► attention-deficit/hyperactivity disorder and other externalizing disorders.

In sum, impulsivity is a heterogenous construct, consisting of behaviors relating to poor inhibitory control, bias for immediate versus delayed rewards, and an insensitivity to negative consequences. Impulsivity is a characteristic of a number of psychiatric diagnoses such as externalizing disorder and drug use, and it also varies in the normal populations. The underlying constructs of impulsive behaviors are an active subject of research, as are efforts to identify the neural circuitry and genetic predispositions to the behavior.

In vivo

Definition

In vivo is when a treatment is given in real life rather than in imagination. The person therefore has to perform a certain task, for example, walk to the end of the road. It also refers to experiments carried out in whole, living organisms, as contrasted with studies of isolated cells or organs.

Inbred Strains

Definition

Inbred strains are the result of breeding between two animals that are closely related. This process of repeatedly breeding close relatives (usually for more than 20 generations) allows all animals within that strain to be genetically similar. Inbred strains allow investigators to assess genetic influences on behavioral traits. The use of inbred strains allows any behavioral differences seen within inbred strains to be attributed to factors other than genes.

Incoherent Thinking

Definition

Breakdown in the grammatical structure of what is expressed.

Independents

Synonyms

Autonomous; Separated; Unrelated

Definition

Independents have no relationship between the independent and the alternative – a change in price in either the alternative or the independent will not affect the demand for the other.

Cross-References

► Behavioral Economics

Indifference Point

Synonyms

Point of subjective equality

Definition

Subjective value of one alternative in a choice situation that equivalent to the other alternative. Used to quantify the value of a delay reward in the delay-discounting tasks. Mathematical description of the relationship between subjective value and delay to reward is a delay discount function.

Indirect-Acting Dopamine Agonists

Definition

Indirect-acting dopamine agonists are drugs that block and/or reverse the dopamine transporter, thereby producing elevated levels of dopamine in the synapse. Effects of these drugs, such as ► amphetamine and ► cocaine, are greatly diminished by prior brain amine depletion. Direct-acting dopamine agonists, such as ► apomorphine, interact directly with dopamine receptors and can produce ample behavioral effects in amine-depleted animals.

Informed Consent

Definition

In severe psychiatric cases, the capacity for giving an informed consent may be impaired and it depends on the level of the mental capacity of the patient. There are differences in the legislation in different countries concerning the requirement of consent on the part of psychiatric patients. The fact that a patient is legally admitted does not automatically allow involuntary treatment; therefore, an informed consent should be looked for; if this is not possible, the clinician has to follow the rules of good clinical practice and, above all, fulfill his duties as a clinician.

Inhalant and Solvent Abuse

Robert L. Balster
Institute for Drug and Alcohol Studies, Virginia Commonwealth University, Richmond, VA, USA

Synonyms

Solvent abuse; Volatile substance abuse

Definition

Abused inhalants contain volatile substances that are self-administered as gases or vapors to induce a psychoactive or mind-altering effect. These volatile substances are available in legal, relatively inexpensive, and common household products, which can be gases, liquids, aerosols, or, in some cases, solids (Balster et al. 2009). The use and abuse of these substances are referred to as inhalant use and abuse. ► DSM-IV defines Inhalant Abuse and Inhalant Dependence disorders using the same diagnostic symptom criterion sets employed for other Substance Use Disorders, with the exception that a characteristic withdrawal syndrome (or substance use for relief of withdrawal symptoms) is not included. Similarly the 2007 version of the International Classification of Diseases-10th edn (► ICD-10) provides Harmful Use and Dependence diagnoses for volatile solvent-related disorders. In some regions of the world, the terms "solvent abuse" or "volatile substance abuse" are preferred, but not all of the products contain solvents, so a broader term such as "inhalant abuse" or "volatile substance abuse" should generally be used.

Current Concepts and State of Knowledge

It is important to distinguish between abused inhalants and other drugs that are used by smoking or inhalation, such as opium or crack cocaine. "Sniffing," "snorting," "huffing" (soaking a rag with the abused product and inserting it into the mouth to breathe fumes), "bagging" (filling a plastic bag with the abused product and holding it over the nose and mouth), and "spraying" (directly spraying the abused product into oral cavities) describe various routes of administration for abused inhalants. Inhalant abusers can be identified by signs such as organic solvent odors on the breath or clothes, chemical stains on the clothes or around the mouth, and empty spray paint or solvent containers. They may exhibit neurological signs and symptoms and have other mental health or substance abuse problems.

Inhalant use is a very prevalent behavior, especially among youth aged 12–25 years. For example, in the US, lifetime prevalence in 18–25 year olds is about 15% and past year use is about 2% of the population (Wu and Ringwalt 2006), placing inhalant use as just below alcohol, tobacco, and cannabis use in this age group and making the use far more prevalent than the use of more widely studied drugs such as cocaine and heroin. Among 12–13 year olds, inhalant use is even more prevalent than cannabis use (http://www.oas.samhsa.gov/2k8/inhalants/inhalants.cfm). In addition, among all past year inhalant users, the prevalence of dependence was 8%. The association of early inhalant abuse with increased risk of many substance use disorders has also been described (Neumark et al. 1998), and there is also a very high rate of ► comorbidity of inhalant use and other psychiatric disorders. For example, Wu and Howard (2007) recently reported a very high rate of psychiatric disorders among inhalant abusers in the general US population. For example, 70% of inhalant users in this sample met criteria for at least one lifetime mood, ► anxiety, or personality disorder, and 38% of them experienced a mood or anxiety disorder in the past year. Females were more likely than males to have multiple comorbid psychiatric illness. Conduct disorder, mood

disorders, and suicidality are common among adolescent inhalant abusers (Sakai et al. 2004). Inhalant abuse is a worldwide problem, and there is some evidence that the public health impact of this behavior is a particular problem in some developing countries (http://international.drugabuse.gov/information/pubs_presentations.html; Kozel et al. 1995).

It is widely believed that inhalant abuse is associated with neurological problems and other organ toxicity, although the epidemiological evidence that these rates are significantly greater than the rates of neurological problems among other substance abusers is lacking. Nonetheless, inhalants clearly have the capability to produce central and peripheral nervous system toxicity as well as damage to other organs such as the liver and kidney (Balster 2003). Each abused chemical has its own profile of toxicity, and some are known to be more toxic than others. The fact that many products contain mixtures of solvents and other ingredients as well makes the problem of showing individual products or types of products as the sole cause of health problems among abusers a significant scientific challenge.

Background

There are several dozen abused inhalant chemicals available in thousands of commercial products, many of which are unique to a particular country or region. In addition, many of the products contain mixtures of chemicals. The products are available in several forms, including gases, vapors, aerosols, liquids, and solids. The complexity and diversity of abused inhalants have presented a problem in developing a useful, scientifically-based subclassification (Balster et al. 2009). It has been argued that, as with the classification of psychoactive drugs, abused inhalants would be best classified by different profiles of pharmacological and subjective effects. Using this approach, three different groups of inhalants have been proposed (Table 1).

Abuse of volatile ► nitrites has been decreasing. These chemicals apparently produce their abuse-related effects by peripheral vasodilatation resulting in blood pooling and brain anoxia. This results in dizziness and feelings of light-headedness. Engorgement of the penis may also be a factor in nitrite abuse. ► Nitrous oxide is a gas at room temperature and is primarily obtained by the diversion of tanks used in medicine as a source of nitrous oxide for anesthesia. Nitrous oxide was sometimes referred to as "laughing gas." The cellular mechanisms for the abuse of nitrous oxide are unknown although there is some evidence that opioid systems may be involved.

Many chemicals constitute the class of solvents, fuels, and anesthetics. The abuse of vapor anesthetics goes back to the use of ether, both by inhalation and orally. Of course, alcohol is a good solvent and a weak anesthetic, and the abuse of chemicals in this class is often compared to ► alcohol abuse and dependence and other ► sedative, hypnotic and anxiolytic drug dependence (Balster 1998; Bowen et al. 2006). An important difference is that the effects of abused inhalants are almost immediate and are very short acting, much like those of vapor anesthetics. Prototypal chemicals from this class include ► toluene and ► trichloroethane, and most of the animal and neurobiology research on abused solvents has utilized one or both of these compounds. Abuse of lighter fluid containing butane has emerged as a particular problem in some regions, and gasoline, which contains toluene and many aliphatic hydrocarbons, is also subject to abuse. As with ► alcohol and other depressant drugs, the enhancement of ► inhibitory amino acid neurotransmission and the ► antagonism of excitatory amino acid neurotransmission have been implicated as the neural basis for the abuse-related effects of compounds such as toluene and trichloroethane (Bowen et al. 2006).

There are no known pharmacotherapies for inhalant use disorders nor have there been any published controlled trials of potential medications for this condition. Because inhalant abusers are generally young, behavioral interventions used with adolescents are typically employed to assist users to reduce their use or to prevent future use episodes. It is widely believed that prevention is

Inhalant and Solvent Abuse. Table 1. Subclassification of abused inhalants, providing examples from each class and product sources

Class	Examples	Sources
Volatile nitrites	Amyl nitrite, butyl nitrite	Antianginal medication, room odorizers
Nitrous oxide	Nitrous oxide	Anesthetic
Solvents, fuels, and anesthetics	Toluene, trichloroethane, trichloroethylene, xylene, butane, isopropane, isoflurane	Adhesives, paint removers and thinners, inks, nail polish and remover, industrial solvents, cleaning fluids, compressed air dusters, correction fluids, lighter fluids, anesthetics

a key component of the control of inhalant abuse. Normal, regulatory strategies for drug abuse control have little use because so many of the abused products have widespread household use. Several broad strategies for inhalant abuse prevention have been proposed (http://www.inhalants.org/; http://www.doe.virginia.gov/VDOE/Instruction/Inhalantbook.pdf; http://www.health.gov.au/internet/main/publishing.nsf/Content/73AFC6ADE4DEED9CCA25746B00834DA8/$File/vol-sub-mis-rvw-int.pdf). In addition, a few specialized treatment programs for inhalant abusers, such as the network established by the Youth Solvent Addition Committee in Canada have been developed (http://www.members.shaw.ca/ysac/Who%20Are%20We/whoarewe.htm).

Inhibition of Memory

Celia J. A. Morgan, Valerie H. Curran
Clinical Psychopharmacology Unit, Department of Psychology, University College London, London, UK

Definition

The pharmacological inhibition of memory refers to the ability of certain compounds to impair the laying down of new memories, disrupt the consolidation of others, speed up the extinction of memory ("un-learning"), or lead to the forgetting of old memories.

Impact of Psychoactive Drugs

A startling number of both used and abused substances share the capacity to impair memory. Indeed, memory is often cited as a reason for ingesting psychoactive substances, for example, people will say they drink alcohol to "forget." But for many years, it was thought that pharmacological compounds only impaired the learning of new information (i.e., anterograde amnesia) but could not destroy the old memories (i.e., retrograde amnesia). More recently, however, it seems that several pharmacological compounds may be effective in erasing some – particularly recently acquired – memories.

Overview

Recent advances in psychopharmacology and neuroscience have allowed us to explore further the mechanism of memory-impairing compounds. Their final common pathway appears to be the blockade of the induction of ▶ long-term potentiation (LTP) and related processes most notably in the ▶ hippocampus. LTP is the process by which "neurons that fire together wire together," such that there is an increase in synaptic strength following activation of two neurons. A drug itself may impact on any one of a number of processes involved in memory

formation or destruction. Some key ways a drug may alter memory are

- By interfering with encoding or consolidation
- By changing the degree of interference from previous memories
- By affecting retrieval of a memory
- By capitalizing on the instability of memories on reactivation
- By enhancing "extinction" learning, i.e., learning a new memory that takes precedence over the old – this is particularly important in the case of conditioning, a nondeclarative form of memory

The use of amnestic agents in psychopharmacology and neuroscience has been valuable in learning not only about the effects of drugs that are used clinically or taken for recreational purposes, but also in teaching us about the memory itself.

Inhibiting the Formation of New Memories

The mechanism of most amnestic drugs is the inhibition of new learning. Some types of memories appear to be more vulnerable than others. Human memory has been subdivided – on the basis of findings from neuropsychological, neuroimaging, psychological, and psychopharmacological studies – into five different "memory systems": ▶ episodic memory, ▶ semantic memory, ▶ working memory, procedural learning, and the perceptual representation system. Different drugs have different profiles of memory-inhibiting effects on these types of memory. Episodic memory, our memory for events and occurrences encoded from a subjective perspective and accompanied by contextual details (what, where, when), appears to be the most susceptible to pharmacological inhibition. Drugs that principally act on varying neurotransmitter systems from GABA (e.g., ▶ benzodiazepines, ▶ alcohol) to glutamate (e.g., ▶ ketamine, PCP, alcohol) and acetycholine (e.g., ▶ scopolamine), all produce reliable, dose-dependent inhibition of the formation of new episodic memories. Working memory is also broadly inhibited by a variety of compounds, especially at higher doses, including some noradrenergic blocking drugs (e.g., ▶ propanalol, clonidine), dopamine antagonists (e.g., ▶ haloperidol), and ▶ NMDA-receptor antagonists such as ketamine.

The inhibition of other memory systems appears to be less widespread, with the caveat that those systems have, relative to episodic and working memory, been less thoroughly researched in psychopharmacology. Semantic memory is our memory for language and facts; it is not time locked and is thought to be formed via transfer of information from episodic memory. For example, when one first learns that the UK prime minister is Gordon Brown, it is an episodic memory; however, with time, he/she is no longer able to recall the occasion upon which he/she first learnt this information but just *knows* that Gordon Brown is the prime minister, this is termed as semantic memory. Psychopharmacological studies have assessed the impact of compounds on retrieval from semantic memory rather than their impact on the formation of new semantic memories. The glutamatergic NMDA-receptor antagonist, ketamine, has been shown to acutely inhibit semantic memory retrieval, whereas levodopa has been shown to increase retrieval from semantic memory on a semantic priming task. Other studies have suggested similar disinhibition of retrieval after a single dose of Δ9-tetrahydrocannabinol (THC) or when recreational users smoke cannabis (▶ Cannabinoids and endocannobinoids)

Interfering with Memory

Theories of forgetting in memory research initially suggested that interference from previously learnt material – proactive interference – was responsible for forgetting, where the prior existence of old memories makes it harder to recall newer memories. NMDA-receptor antagonists like ketamine have been found to increase proactive interference in rodents, impairing performance on a ▶ spatial memory task. However, nowadays research suggests that although proactive interference plays a part, a retroactive interference has more direct role in forgetting. Retroactive interference refers to the ability of more recently learnt information to inhibit previous memories. There is some suggestion that ketamine also increases retroactive interference in humans in a word-learning task. Administering amnestic agents such as scopolamine, prelearning of the second item in memory has been found to prevent retroactive interference in rodents.

One particularly interesting application of retroactive interference is retroactive facilitation. This happens when an amnestic compound, such as those described above, ingested after some information has been learnt, actually *facilitates* memory for this information. This phenomenon has been observed with a variety of compounds including ▶ alcohol, ▶ benzodiazepines, scopolamine, and NMDA-receptor antagonists. The mechanism of retroactive facilitation has begun to be identified: these amnestic agents cannot disrupt induction of LTP in the hippocampus for information learnt before they were ingested (what is known as retrograde amnesia), therefore their facilitatory effects are likely to occur by blocking the induction of new LTP without impairing the

maintenance of old information. This then protects new memory traces from interference when they are in a fragile state and are still being consolidated and reconsolidated. Preclinical studies confirm this assertion. The synthetic induction of LTP impairs recall of the prior learning of the ▶ Morris Water Maze; however, giving an NMDA-receptor antagonist post learning blocks this interference and performance is left intact.

Wiping Out Memories

The ability to forget information is important, for if we remembered every single event and stimulus encountered in our environment then the brain's workspace would be crowded with irrelevant information. The amnestic power of compounds such as alcohol and benzodiazepines as discussed above, can facilitate memory for information learnt before consuming or being administered drugs. Other compounds, however, appear to be able to destabilize the previously learnt information such that it becomes quickly "unlearnt," leading to the suggestion that it may be possible to "erase" certain unwanted memories.

It has long been known that smoked herbal cannabis, from the *Cannabis sativa* plant, in particular the active ingredient THC, impairs memory and like other drugs, it is known to prevent the induction of hippocampal LTP. However, recently the exact mechanism by which the drug exerts its effects on memory has begun to be studied. Mice lacking the cannabinoid 1 (CB1) receptor show enhanced memory and ▶ perseveration in their behavior, along with an impairment in both short- and long-term extinction of memories. It seems that in these animals memory is improved, but memories become almost impossible to erase. This has led to the suggestion that the ▶ endocannabinoid system may be involved in preventing the automatic ▶ consolidation of memories and destabilizing memories for forgetting. Hence, the drug cannabis may inhibit memory by modulating the brain's endogenous forgetting system.

Although interfering with the endocannabinoid system may destabilize memories, other compounds appear to be able to inhibit the consolidation of recently formed memories. ▶ Noradrenaline is thought to play a role in memory consolidation, via enhancement of LTP in the hippocampus and amygdala, such that memories become more quickly consolidated. Giving antagonists of the β-adrenergic receptor (beta-blockers) has been suggested as a potential means of inducing retrograde emotional amnesia in humans. Clinically, this has been suggested as a treatment for ▶ posttraumatic stress disorder (PTSD), as a means of weakening and erasing traumatic emotional memories. Emerging evidence, indeed, suggests that such drugs, when administered after a traumatic event, have the capacity to reduce the physiological responses associated with recalling a traumatic event. Further, these compounds appear to prevent full consolidation of emotional memories in the amygdala. One problem with using drugs like propanalol to treat PTSD is that the disorder itself cannot be diagnosed until at least a month after the traumatic event. However, animal studies have found that when memories are reactivated they become destabilized and vulnerable to destruction. Recent research has demonstrated that if propanolol is given following *reactivation* of a trauma memory, it also reduces physiological responsivity and intrusive images associated with the event.

Researchers have also capitalized on the vulnerability of reactivated memories to pharmacological modulation in treating other clinical disorders such as addiction. Infusing an NMDA-receptor antagonist into the ▶ amygdala prior to the reactivation of drug memories also has been found to disrupt drug-associated memory in rodents and their drug-seeking behavior. This impairment of memory for the drug was found to persist for 4 weeks following treatment. Highly experimental treatments of alcohol and heroin addiction in humans may also have inadvertently used a similar mechanism. Alcohol and heroin addicts given the NMDA-receptor antagonist, ketamine, prior to psychological therapy, also showed a reduction in drug-seeking behavior and relapse.

Inhibiting the Retrieval of Old Memories

Memory inhibition in retrieval is an important facet of any functioning memory system. A memory system would be rendered virtually useless if we were to recall all previously learnt information at once. An adaptive memory system selects only the relevant information from memory and inhibits the recall of huge swathes of irrelevant, but related, information. For example, if I wish to remember a friend's phone number, I need not recall all the phone numbers that I know, or even those that my friend ever had, so all of these must be inhibited in memory. As mentioned previously, there is indirect evidence that certain pharmacological compounds "inhibit the inhibition of memory" or *disinhibit* the retrieval from semantic memory, which can be as detrimental as impairing the encoding of new information. This disinhibition of retrieval has been inferred from increased semantic priming – a reduction in reaction time when a prime word is followed by a related word – with ▶ L-dopa and

cannabis. Following the ingestion of these compounds, it is suggested that activation spreads more quickly through semantic networks and retrieval is disinhibited. This is reflected in the quicker response time when two words are related than when they are unrelated. Similarly, increased priming has been observed in individuals with ▶ psychosis and ▶ mania, and it has been suggested that this is a cognitive basis of symptoms such as thought disorder and flight of ideas.

Memory retrieval can also be overinhibited; this too can be problematic. On the basis of the "encoding specificity principle" it was thought that information encoded while intoxicated with a drug would be most efficiently retrieved when again intoxicated with the same drug. In other words, retrieval would be best when in the same drug state as when information was initially acquired. Retrieval of information when not under the influence of a drug would thus be inhibited. The drug state was thought to act as a contextual cue around the memory, aiding retrieval. However, this effect is not reliably observed and even when it is, it is quantitatively very small.

Extinguishing the Past

Extinction learning itself is thought to involve active suppression of memories via processes different from normal forgetting. In humans, extinction learning has been powerful in the psychological treatment of ▶ anxiety disorders which involves "exposure therapy." Recent research has shown the strength of combining psychological treatments with pharmacotherapies in enhancing extinction learning. Preclinical studies have demonstrated the potential of augmenting extinction learning by boosting central glutamatergic neurotransmitter system functioning. In particular, the previously widely used antituberculosis drug, D-cycloserine (DCS) – which is a partial agonist at central glutamatergic NMDA-receptors – enhances the response to exposure therapy in patients with social phobia, fear of heights, and ▶ obsessive–compulsive disorder. In addition to these trials of DCS-related facilitation of exposure therapy, animal behavioral research also suggests that DCS may facilitate extinction of cocaine-induced ▶ conditioned place preference (CPP). This facilitative effect on extinction is also long-lasting and resistant to reinstatement (i.e., relapse). In humans, however, DCS has shown limited efficacy in enhancing fear extinction, but appears to enhance fear memory consolidation.

Cannabidiol (CBD) is a naturally occurring compound extracted from the *Cannabis sativa* plant. The pharmacology of CBD is not completely understood, but it is thought that it weakly binds to CB1 and CB2 receptors, functionally blocking the reuptake and hydrolysis of ▶ anandamide, an endogenous cannabinoid. As discussed above, the endocannabinoid system is thought to play a key role in the brain's natural forgetting mechanisms. There is now also an extensive preclinical literature examining the role of CB1 receptors in extinction learning. CB1-receptor knock-out mice exhibit impaired extinction learning and administration of exogenous CB1-receptor antagonists impairs the extinction of fear behaviors. Conversely, CB1 receptor agonists, eCB membrane transport inhibitors and CBD itself have been shown to facilitate fear extinction. CBD, like DCS, has also been found clinically to enhance the extinction of cocaine- and amphetamine-related CPP.

There is a clear parallel between fear extinction in animals and exposure therapy in humans. In the future, therefore, compounds which aid extinction of memories may have an important therapeutic role in treating clinical conditions such as addiction and anxiety.

Should Parts of the Past Be Extinguished?

Pathological memories – trauma, addiction, anxiety – may have a devastating impact on an individual's life. Therefore, there is an understandable excitement at the possibility of treating these conditions by manipulating the very memories that produce them. However, the notion of erasing memories carries with it a host of potential ethical problems. In the film "Eternal Sunshine of the Spotless Mind" individuals are able to choose "cosmetic" memory surgery to remove unwanted memories of painful life experiences or attachments. This raises the question: is it morally acceptable to remove parts of people's memories, given they are so fundamental to one's identity?

Bioethical committees have also considered the notion of the "erasing" of memories as a potentially hazardous endeavor. They have concluded that memories, however negative and distressing, are integral to one's continuity of experience. Ethically, this area is still largely controversial, and developments will depend on furthering our understanding of the effects of extinguishing memories. For example, how does inhibiting one type of memory impact on other forms of memory? It is possible that the removal of a memory itself may have psychological, and even neurobiological, consequences. However, thus far any induction of pharmacological retrograde amnesia seems limited to nondeclarative forms of memory, and as such the impact on *conscious* experience may be minimal. As science progresses and the sophisticated inhibition of

memory becomes a reality, there may be emerging, as yet unconsidered, ethical considerations. However, we should also bear in mind that reports of the use of compounds producing anterograde amnesia like alcohol and cannabis date back thousands of years. Indeed, this seems to be one of the appealing properties of drugs of abuse. When asked in surveys, drug and alcohol users often cite the memory-impairing capacities of drugs as a pleasurable effect. Given it seems accepted that individuals erase "memories" of the present by using drugs and alcohol, will it in future be acceptable for them to erase memories of the past?

Conclusions

Many psychoactive substances have a capacity to inhibit memory. Abused substances, for example, alcohol, cannabis, MDMA, and ketamine often acutely impair the laying down of new memories, and this can be perceived as a pleasurable effect which users often report as an experience of "living in the moment." Episodic memory is the type of memory most commonly inhibited by these amnestic psychoactive substances, chiefly via blockade of induction of hippocampal LTP. For a long time, it was thought that psychoactive substances could only cause anterograde amnesia and impair the laying down of new memories; indeed, for the majority of compounds, this is the case. Yet recently, research has demonstrated the capacity of some compounds to pharmacologically inhibit prior memories and produce a retrograde impairment. There is now evidence that when reactivated, memories can become destabilized and then "erased," and adrenergic receptor antagonists have emerged as potential treatments for PTSD. Creating stronger extinction memories, using compounds such as DCS, may compliment psychological treatments of anxiety and addiction. While the clinical potential of such treatments is clear, the ethical implications are not. The pharmacological inhibition of memory is an exciting field of research which has the potential to yield novel pharmacotherapies for psychiatric disorders as well as further insights into the very nature of memory itself.

Definition

Normal brain function is based on a delicate balance between inhibition and excitation of neuronal activity. Neuronal inhibition is primarily due to the neurotransmitter ▶ GABA (γ-aminobutyric acid) and also includes the neurotransmitter glycine. They exert inhibition via their respective receptors, i.e., ionotropic $GABA_A$ receptors, metabotropic $GABA_B$ receptors, and ionotropic glycine receptors. In this article, the role of GABA and glycine in brain function, their respective receptor pharmacology, and their therapeutic impact are briefly described.

Pharmacological Properties

GABA and the Inhibitory Interneuron "Clocking" Networks

Complex brains have developed specialized mechanisms for the grouping of principal cells into temporal coalitions of local or distant networks, the inhibitory interneuron "clocking" networks. They consist of ▶ GABAergic interneurons of rich diversity. In cortical circuits, these neurons control spike timing of the principal cells, sculpt neuronal rhythms, select cell assemblies, and implement brain states (Klausberger and Somogyi 2008). To achieve this regulatory control, distinct GABAergic interneurons innervate distinct subcellular domains of pyramidal cells and act in discrete time windows. Such a compartmentalized structure of pyramidal cells allows spatially segregated activities to occur at the same time. Also, the same domain of pyramidal cells can receive differentially timed GABAergic input from distinct sources. For instance, subcortical state-modulating input from brain stem nuclei is received by CCK expressing GABA neurons. Finally, cortical long-range GABA projections appear to prime and reset activity in multiple target areas in cognitive processes (Klausberger and Somogyi 2008).

Despite the daunting complexity of the inhibitory interneuron network, the search for a relevant pharmacological control target led to the discovery of the role of $GABA_A$ receptors in cognitive and emotional processing and in the regulation of behavior. This discovery arose

from the recognition that a major class of psychoactive drugs, the ► benzodiazepines, exerted their effects via an ► allosteric modulatory site of $GABA_A$ receptors, termed benzodiazepine receptors (Möhler and Okada 1977). Initially, this discovery was pertained to the regulation of ► anxiety, but was subsequently extended to the GABAergic regulation of vigilance, memory, ► schizophrenia, and pain. The clinical validity of this approach has been demonstrated by the emergence of a new pharmacology of $GABA_A$ receptor subtypes and first clinical proof of concept studies in patients with anxiety disorders and schizophrenia.

Functional Distinction of $GABA_A$ Receptor Subtypes

The diversity of GABAergic interneurons in network regulation is paralleled by a diversity of $GABA_A$ receptors. $GABA_A$ receptors are GABA-gated pentameric chloride channels, mediating largely tonic and phasic inhibition. They are generally composed of three types of subunits (α, β, γ) with multiple variants (α_{1-6}, β_{1-3}, γ_{1-3}). Receptors containing α_1, α_2, α_3, or α_5 in combination with β_2 or β_3 and γ_2 are benzodiazepine-sensitive, whereas those containing α_4 or α_6 or δ instead of γ_2 fail to be responsive to these drugs. Together with the structural diversity of receptor subtypes, the morphological distribution pattern suggested specific functional roles for specific receptor subtypes in distinct neuronal networks and associated cognitive processing. The $GABA_A$ receptor subtypes were taken as markers for behavior-relevant circuits (Möhler 2007a, b).

The behavioral relevance of the $GABA_A$ receptor subtype was identified using a point mutation strategy in mice. Each of the four benzodiazepine-sensitive $GABA_A$ receptor subtypes was rendered benzodiazepine-insensitive by a genomic point mutation in the α_1, α_2, α_3, or α_5 subunit gene, which converted a canonical serine residue in the drug-binding pocket to a histidine residue. The point-mutated receptors were diazepam-insensitive, but maintained their cellular and subcellular expression pattern. In these mice, the physiological response to GABA was unaltered. It was only when a benzodiazepine drug was administered that a particular drug response was absent in the mutant. The behavioral deficit could be ascribed to the particular mutated receptor subtype. In the wild type, this receptor subtype was expected to mediate the corresponding response. In addition, by means of their distinct expression patterns, the $GABA_A$ receptor subtype in question identified the neuronal network, which mediated the respective behavior (Möhler 2007a, b).

Three rho subunits, expressed mainly in retina, constitute $GABA_A$ receptors, which have also been termed $GABA_C$ receptors based on structural and pharmacological distinctions (potential homomeric subunit composition; insensitivity to bicuculline, picrotoxine, and benzodiazepines). However, these properties do not qualify for a terminology distinct from $GABA_A$ receptors (Barnard et al. 1998).

Regulation of Sedation and Sleep via $GABA_A$ Receptors

The sedative component of benzodiazepines, measured by the reduction of locomotor activity, is attributed to neuronal circuits expressing α_1GABA_A receptors, the most prevalent receptor subtype in the brain. Ligands with preferential affinity for α_1 receptors, such as ► zolpidem or ► zaleplon, are used as ► hypnotics (Table 1). However, the changes in sleep architecture (suppression of REM sleep) and EEG-frequency profiles (reduction of slow-wave sleep, increase in fast β-frequencies) induced by classical benzodiazepines are largely due to the effects mediated by receptors other than α_1. The most pronounced effect of diazepam on the sleep EEG in wild-type mice is derived from the enhancement of α_2GABA_A receptors. Thus, the hypnotic EEG fingerprint of ► diazepam can be dissociated from its sedative action. Future hypnotics might target changes in the EEG pattern, which are the characteristics of physiological sleep, and thereby aim at improving the sleep quality. For instance, the GABA-mimetic gaboxadol (4,5,6,7-tetrahydroisoxazolo [5, 4-c]pyridine-3-0l hydrochloride; synonym THIP), which interacts preferentially with $\alpha_4\beta_3\delta$ $GABA_A$ receptors in vitro, was found to enhance slow-wave sleep in vivo (Möhler 2008).

Anxiolysis via α_2 $GABA_A$ Receptors

The differentiation of $GABA_A$ receptors by knock-in point mutations showed that it was the α_2- but not the α_3- or α_5-$GABA_A$ receptor that mediated the ► anxiolytic activity of diazepam. In α_2(H101R) mice, but not α_3(H126R) or α_5(H105R) mice, diazepam failed to induce anxiolytic activity (light–dark paradigm, ► elevated plus maze). In keeping with this notion, the benzodiazepine site ligand L-838417, which showed efficacy at α_2, α_3, and α_5, but not at α_1GABA_A receptors, was proved to be anxiolytic in wild-type rats (Table 2). Similarly, the benzimidazo-derivative NS11394 acting as ► partial agonist at α_2, α_3, and α_5, but not at α_1 receptors, was found to show anxiolytic activity in rodents (Table 2). It remaines to be clarified to what extent the α_3GABA_A receptor component

I

Inhibitory Amino Acids and Their Receptor Ligands. Table1. $GABA_A$ receptor subtypes[a].

Subunits	Localization	Pharmacology
$\alpha_1\beta_2\gamma_2$	Major subtype (60%), Synaptic and extrasynaptic	Benzodiazepine-sensitive. Mediates sedative and anticonvulsant activity
$\alpha_2\beta_3\gamma_2$	Minor subtype (15–20%). Synaptic	Benzodiazepine-sensitive. Mediates anxiolytic and analgesic activity
$\alpha_3\beta_n\gamma_2$	Minor subtype (10–15%)	Benzodiazepine-sensitive. Mediates sensori-motor gating. Anxiolytic activity only at high receptor occupancy. Partly mediates analgesic activity
$\alpha_5\beta_{1,3}\gamma_2$	Less than 5% of receptors. Extrasynaptic (cerebral cortex, hippocampus, olfactory bulb)	Benzodiazepine-sensitive. Mediates modulation of temporal and spatial memory
$\alpha_4\beta_n\delta$	Less than 5% of receptors. Extrasynaptic	Insensitive to benzodiazepines. Sensitive to low concentration of ethanol
$\alpha_4\beta_n\gamma$	Less than 5% of receptors. Extrasynaptic	Insensitive to benzodiazepines
$\alpha_6\beta_n\delta$	Small population. Extrasynaptic (only in cerebellum)	Insensitive to benzodiazepines. Sensitive to low concentration of ethanol
$\alpha_6\beta_{2,3}\gamma_2$	Less than 5% of receptors. Synaptic (only in cerebellum)	Insensitive to benzodiazepines

[a]The term benzodiazepine refers to diazepam and structurally related agents in clinical use. The % values are estimates taking all brain $GABA_A$ receptors as 100%. For details see text and Möhler (2007a)

contributed to the anxiolytic activity of these ligands. In mice lacking α_3GABA_A receptors, the anxiolytic activity of diazepam was undiminished. However, TP003, a ligand with selective efficacy at α_3GABA_A receptor did show anxiolytics activity, an effect which was, however, apparent only at high receptor occupancy. Classical benzodiazepines exert anxiolysis at low receptor occupancy, suggesting that the α_2GABA_A receptors and not the α_3GABA_A receptors are the major mediators of this activity. Thus, the strategy to develop novel day-time anxiolytics, which are free of sedation, focuses on α_2GABA_A receptors, although α_3 receptors are not excluded. Such ligands are expected to display low or no dependence liability. The α_2 receptors take up strategic positions mainly on the soma and the axon initial segment of pyramidal cells in cerebral cortex and ► hippocampus and also occur in the ► amygdala. This selective inhibitory control seems to be sufficient to exert anxiolysis and defines a medically relevant anxiety circuit (Atack 2008; Löw et al. 2000; Möhler 2007a).

Regulation of Learning and Memory via α_5 $GABA_A$ Receptors

Spatial and temporal memory is linked to oscillatory neuronal activity in the hippocampus, where the NMDA-type glutamate receptors on principal neurons have attracted most attention in modulating memory performance. However, there is a balancing control by GABAergic tonic inhibition. α_5GABA_A receptors are located at the base of the dendritic spines, which receive the excitatory input. When α_5 receptors were partially reduced genetically, associative learning in the form of trace ► fear conditioning, a hippocampus-dependent memory task was enhanced, but not delay or contextual conditioning, which are hippocampus-independent. Similarly, spatial memory in water maze learning was reduced in mice lacking α_5 receptors. Thus, for the first time, a defined GABAergic control of temporal and spatial memory had been established. Indeed, a partial ► inverse agonist acting at α_5GABA_A receptors enhanced the performance of wild-type rats in the water maze test (Atack 2008; Möhler 2007a).

Schizophrenia: Alleviating the Cognitive Deficit and Regulating Sensorimotor Gating Through α_2 and α_3 $GABA_A$ Receptors

A large number of neurophysiological and neuroimaging studies of patients with schizophrenia have furnished in vivo evidence for dysconnectivity, i.e., abnormal functional integration of brain processes. This dysconnectivity could arise from aberrant wiring of connections during development or from aberrant synaptic plasticity. Among the various clinical symptoms of the disease, the cognitive deficits are associated with a deficit in EEG γ band

Inhibitory Amino Acids and Their Receptor Ligands. Table 2. $GABA_A$ receptor subtype ligands[a].

Drug	Main activity	Interaction with recombinant $GABA_A$ receptors[b,c]
A. Benzodiazepine site ligands		
Zolpidem	Hypnotic	Preferential affinity for α_1
Zaleplone	Hypnotic	Preferential affinity for α_1
Indiplon	Hypnotic	Preferential affinity for α_1
L-838 417	Anxiolytic Antihyperalgesic	Comparable affinity at α_1, α_2, α_3, α_5 subtype. Partial agonist at α_2, α_3, α_5 (not α_1) subtype
NS11394	Anxiolytic Antihyperalgesic	Partial agonist at α_2, α_3 (not α_1) subtype, nearly full agonist at α_5 subtype
Ocinaplon	Anxiolytic	Comparable affinity at α_1 α_2, α_3, α_5 subtype. Partial agonist at α_2, α_3, α_5 subtype nearly full agonist at α_1
SL 651 498	Anxiolytic	Agonist at α_2, α_3, partial agonist at α_1 and α_5 subtype
TPA 023	Anxiolytic	Partial agonist at α_2, α_3 subtypes, antagonist at α_1, α_5 subtypes
TPA 003	Anxiolytic	Partial agonist at α_3 subtype. Effective only at high receptor occupancy.
ELB 139	Anxiolytic	Selective receptor profile uncertain
α_3IA	Anxiogenic	Weak inverse agonist at α_3
L-655 708	Memory enhancer	Partial inverse agonist with preference for α_5 subtype
B. Modulatory site other than benzodiazepine site		
Ethanol	Anxiolytic Sedative	High sensitivity ($\geq$3 mM) at $\alpha_4(\alpha_6)\beta_3\delta$[d]; Medium sensitivity ($\geq$30 mM) at $\alpha_4(\alpha_6)\beta_2\delta$[d]; Low sensitivity ($\geq$100 mM) at $\alpha_4(\alpha_6)\beta_3\gamma_2$
Neurosteroids (e.g., 3α,5α-THDOC)	Anxiolytic Sedative Anesthetic	High sensitivity at δ-containing subtypes[d] and at α_1, α_3 receptors in combination with β_1
Intravenous anesthetics (Etomidate, Propofol)	Sedative Anesthetic	Act on receptor subtypes containing β_3, i.e., mainly α_2 and α_3 subtypes
C. GABA site		
Gaboxadol	Hypnotic	Partial agonist at α_1, α_3 subtypes, full agonist at α_5, and superagonist at $\alpha_4\beta_3\delta$ receptors[b]

[a]This table is a summary from Rudolph and Möhler (2006), Möhler (2007a, 2008), and Atack (2008)
[b]Classical partial agonists, which do not differentiate between $GABA_A$ receptor subtypes such as Bretazenil or Pagoclone, are not considered in this review
[c]Data should be treated with caution as properties of recombinant receptors that are expressed in foreign host cells might not give an accurate reflection of their neuronal counterparts
[d]GABA is a weak partial agonist on δ-containing receptors, which largely explains the strong modulatory response of ligands acting on δ-containing receptors. THDOC, 5α-pregnane3α,21-diol-20-one

activity, pointing to a potential deficit in GABAergic control. Indeed, in postmortem studies, GABAergic Chandelier neurons in frontal brain were found to be dysfunctional. These neurons are known to act via α_2GABA_A receptors. Furthermore, in mice, a deficit of α_3GABA_A receptors resulted in sensorimotor gating deficits and a hyperdopaminergic phenotype. These results pointed to a new GABAergic strategy in treating cognitive deficits, sensorimotor gating deficits, and possibly negative symptoms in schizophrenia. Restoration of GABA was expected to restore oscillatory synchronicity and cognitive function. MK0777, an α_2/α_3 $GABA_A$ receptor modulator, was therefore tested in the treatment of schizophrenia patients. In a proof of concept study, a 4-week treatment with MK0777, as add-on to the standard antipsychotic therapy, resulted not only in an increased level of ► attention and ► working memory, but also restored the oscillatory power of the γ band, when the patients performed a cognitive task. Thus, a GABA substitution therapy proved effective in reconstituting the phenotype and the biotype

of cognition. This example is expected to trigger further clinical trials to support an entirely new therapeutic concept of cognitive deficits based on α_2/α_3 $GABA_A$ receptors (Lewis et al. 2008).

Modulation of Chronic Pain: Spinal α_2 and α_3 $GABA_A$ Receptors

The canonical circuits of GABAergic control of principal cells also applies to circuits in the spinal cord with particular reference to sensory pain processing. Using the point-mutated mice described earlier, spinal α_2 (and α_3) $GABA_A$ receptors were identified as powerful gatekeepers of pain (Knabl et al. 2008). The experimental α_2/α_3 receptor ligand L-838 417 (Table 2) was highly effective in suppressing inflammatory and neuropathic pain, yet devoid of unwanted sedation and motor impairment. Most importantly, in contrast to ► morphine, L-838417 failed to show any ► tolerance in analgesic efficacy, as tested over nine days. The α_2/α_3 receptor ligand reduced not only the nociceptive input, but also reduced the activity in brain areas associated with the associative-emotional component of pain (fMRI) (Knabl et al. 2008). Similarly, NS11394, acting as ► partial agonist at α_2 and α_3 receptors and as almost full agonist at α_5 receptors, was effective in rat models of inflammatory and neuropathic pain (Table 2) (Mirza et al. 2008). These results provide a rational basis for a new class of drugs for the treatment of chronic inflammatory and neuropathic pain, based on a pain-related inhibitory interneuron network in brain and spinal cord.

$GABA_A$ Receptors for Consciousness

In the quest for neuronal correlates of consciousness, various avenues are being followed including the quest for the mechanism of action of anesthetic drugs by which consciousness is safely, painlessly, and reversibly switched off and on again for surgical interventions. Various molecular targets have been invoked in mediating the clinical effects of general anesthetics. Recent work focused on the role of $GABA_A$ receptors, based on the analysis of point-mutated knock-in mice, which carried point mutations in the β_3 and β_2 subunits of the $GABA_A$ receptor. These mutations rendered the $GABA_A$ receptors containing the respective subunits insensitive to modulation by the intravenous anesthetics propofol and etomidate and certain volatile anesthetics, e.g., enflurane. It was found that β_3-containing $GABA_A$ receptors mediated in full the immobilizing action of etomidate and propofol (Table 2), which correspond to the stage of surgical tolerance. Thus, β_3GABA_A receptors are a major control element for anesthesia.

$GABA_B$ Receptors and their Pharmacology

Besides ionotropic $GABA_A$ receptors, GABA acts on metabotropic $GABA_B$ receptors, which are heterodimers formed by the subunits B1 and B2, of which B1 occurs in two isoforms (B1a, B1b). The receptors are located both pre and postsynaptically, coupled to K^+ and Ca^{2+} channels. Therefore, when the receptor is activated, a variety of effects might be expected. The normal result is a long-lasting neuronal hyperpolarization, mediated by an increase in membrane conductance to K^+, and a reduction in the postsynaptic potential produced by a decrease in the release of excitatory transmitters, e.g., ► glutamate or ► substance P, via presynaptic $GABA_B$ receptors. $GABA_B$ receptors contribute to inhibitory events throughout the cerebral axis but are particularly preponderant in the spinal cord. In higher brain centers, $GABA_B$ receptors largely lack a direct innervation and are activated by "spill-over" from adjacent GABAergic synapses. In spinal cord, however, innervation of post and presynaptic $GABA_B$ sites does appear to occur (Bowery 2006).

There is a paucity of potent and selective $GABA_B$ receptor agonists. Through its muscle relaxant and antispastic activity, baclofen is the only $GABA_B$ receptor agonist in clinical use. Nevertheless, other uses of baclofen have been proposed in animal studies, such as the alleviation of pain, reduction of anxiety, and amelioration of drug addiction. Antagonists, acting at $GABA_B$ receptors, have yet to prove their therapeutic benefit. In animal models, antagonists, such as CGP36742, were shown to improve cognition, alleviate absence epilepsy, and improve depression-like behavior. At present, it remains to be seen how these apparent functional distinctions of $GABA_B$ receptor ligands can be equated with the lack of diversity in receptor structure (Bowery 2006).

Glycine Receptors and their Pharmacology

Besides GABA, glycine is the second major inhibitory neurotransmitter being highly concentrated in the ventral and dorsal horn of the spinal cord, but occurs also in higher brain regions. Glycine receptors (GlyR) are pentameric glycine-gated chloride channels and – like $GABA_A$ receptors, ► nicotinic acetylcholine receptors, and $5HT_3$ receptors – belong to the ligand gated ion channel family. GlyR are composed of α and β subunits in a ratio of 2α:3β. Four different genes encoding GlyRα subunits (α_1– α_4) and a single GlyRβ subunit gene have been identified in vertebrates (Betz and Laube 2006; Betz et al. 2001). Compared to $GABA_A$ receptors, the pharmacology of GlyR is much less developed. Among GlyR agonists, β-alanine and taurine, besides glycine, display inhibitory activity in vitro and may well do so also in vivo.

By inhibiting glycine binding, strychnine represents a unique tool to distinguish glycinergic from GABAergic inhibition. Consistent with a systemic disinhibition of motorneurons, strychnine poisoning leads to motor disturbances accompanied by unusual sensory impressions owing to the disinhibition of afferent pathways. Intoxicated persons report hyperactivity of vision and hearing and also acute pain. Indeed, the α_3 GlyR, which is primarily expressed in dorsal horn, is an essential target for pain regulation (Harvey et al. 2004). Agonists for α_3GlyR might qualify as future analgesics. The role of glycine as co-agonist of glutamate at NMDA receptors in excitatory synapses is described elsewhere in the Encyclopedia.

Summary

The roles of neuronal inhibition by GABA and glycine are increasingly incorporated into functional models of neuronal networks to understand complex brain functions. Based on the recognition of receptor subtypes, major advances were made in a new $GABA_A$ receptor pharmacology. Anxiolytics lacking sedation, novel nonopioid analgesics, and cognitive enhancers in schizophrenia are among the major achievements with clear potential of clinical benefit.

Insomnias

Malcolm Lader
Institute of Psychiatry, King's College London, London, UK

Synonyms

Inability to sleep; Sleeplessness; Unsatisfactory sleep.

Definition

► Primary insomnia is a complaint of difficulty in initializing or maintaining ► sleep or nonrestorative sleep that

lasts for at least 1 month and causes clinically significant distress or impairment in social, occupational, or other important areas of functioning. The disturbance in sleep does not occur exclusively during the course of another sleep disorder or mental disorder and is not due to the direct physiological effects of a substance or a general medical condition (► DSM1V).

Role of Pharmacotherapy

One third of our time is spent asleep. For years, sleep remained an enigma but modern scientific techniques such as the polysomnograph (► polysomnography) have given us useful insights (Lader et al. 2006). Recently, the discovery of several chemical agents involved in the regulation of sleep has emphasised the complexity of this state.

Polysomnographic recordings analysed by visual recognition of characteristic patterns have revealed two main types of sleep characterised by the presence of Rapid Eye Movements (REM sleep) or absence of these movements (non-REM sleep). The latter is divided into four stages – from light sleep through to two deeper stages, so-called slow wave sleep. The individual goes through a typical series of cycles of REM and non-REM sleep during the average 7–8 h of sleep. These patterns ("sleep architecture") change radically from the new-born, infants, adolescence, and adulthood to old age.

Sleep complaints are extremely common. Approximately, 10% of the population has a complaint of insomnia, which occurs every night for two weeks or more, whereas 3–4 times this number has the occasional sleep disturbance. However, despite this prevalence, only 5–10% approach a physician to discuss their sleep problems.

Diagnostic Categories

There are four main diagnostic categories of Sleep Disorders, according to presumed etiology (DSM-IV, APA 2000). These are:

(a) Sleep Disorder related to another mental disorder (usually ► depression or ► anxiety)
(b) Sleep Disorder due to a general medical condition,
(c) Substance-induced Sleep Disorder, and
(d) Primary Sleep Disorders, in which none of the above etiologies can be identified.

Primary sleep disorders are therefore presumed to arise from endogenous abnormalities in sleep−wake generating or timing mechanisms or conditioning factors.

The specific type of sleep complaint may vary over time with difficulty in falling asleep at one time and difficulty in staying asleep at other times. Maladaptive sleep habits may set in with erratic sleep schedules: these perpetuate the disorder patients to complain about decreased attention, energy, and concentration and increased feelings of fatigue and malaise. Many sufferers have previous history of increasing sleep difficulties culminating in complaints of insomnia: these may be delayed into late middle age. The polysomnograph (polysomnography) usually but not invariably shows impairment in sleep continuity such as increased sleep latency or frequent awakenings.

Other conditions that can give rise to sleep disorders are breathing-related sleep disorder (obstructive sleep apnoea) and circadian rhythm sleep disorder (delayed sleep phase, jet lag, and shift work) (American Sleep Disorders Association 1990). Mental disorders associated with insomnia include ► Major Depressive Disorder, ► Mania, Anxiety Disorders, ► schizophrenia, and organic disorders such as ► dementia. General medical disorders that are associated with insomnia are numerous and encompass all systems. Substances that impair sleep include ► caffeine, ► alcohol, ► nicotine, and medicines, such as ephedrine, and withdrawal of opioids, sedatives, anxiolytics, and hypnotics.

A range of drugs is available to treat primary insomnia on a symptomatic basis. Before doing so, it is a good practice to consider whether:

1. There is any cause that has not yet been identified such as depression, anxiety, breathing difficulties, pain, etc., even at a subclinical level? If so, treat the primary cause appropriately.
2. Is substance misuse, especially of alcohol, a problem? If so, treat the substance abuse and be very circumspect about prescribing psychotropic drugs, particularly benzodiazepines.
3. To rationalise any other medications, for example, do not give arousing drugs at night.
4. The patients' expectations of sleep is realistic and the patient napping during the day is thereby reducing night-time sleep requirements?
5. All relevant "sleep hygiene" stratagems have been mobilised? These include:
   (a) Increase daily exercise in the afternoon but not the evening
   (b) Reduce daytime napping
   (c) Reduce caffeine, alcohol, and nicotine intake, particularly in the evening
   (d) Reserve the bed for sleeping and not for watching TV

(e) Adhere rigidly to a regular time of retiring and rising at the same time each day, including weekends
(f) Learn and use anxiety management or relaxation techniques

Drugs Used as Hypnotics

The most widely prescribed drugs used as hypnotics are the ► benzodiazepines and chemically dissimilar but pharmacologically similar medications, the so-called "z-drugs" (see Table 1).

In treating insomnia, the expected duration of the disorder needs consideration. It is traditional to divide these into:

1. Transient insomnia, which occurs in those who are usually good sleepers. It may be due to extraneous factors such as jet-lag following time-zone crossings, temporary noise, and shift work. A clear end to the problem can be seen, and it is thought justifiable to prescribe a short-acting hypnotic for the duration of the expected disruption or until the sufferer adapts to it.
2. Short-term insomnia, which usually reflects disruption caused by emotional stress or serious medical illness. It is expected to last for a few days to a few weeks but may recur. It is often quite variable from night to night. A hypnotic may be helpful but should be used only for a few weeks. If the patient can reserve the medication for those nights when he or she feels that the insomnia is likely to be disturbing (i.e., intermittent use on an "as necessary" basis), the risk of inadvertent chronic use can be minimised. Again, a short-acting drug is usually preferred as it enables the insomniac to maintain a clear mind to deal with the day's problems.
3. Chronic insomnia, which is a much more contentious topic. It is the commonest form of primary insomnia and was long rather neglected. More recently, a consensus conference under the auspices of the US National Institutes for Health (2005) concluded that it was a common and major problem that caused a great deal of stress. Even more contentiously, there are wide differences of opinion as to whether this chronic disorder justifies long-term hypnotic use (Benca 2005). Again, identification of possible causes such as a chronic subclinical depression (dysthymia-like) should be undertaken and the primary cause such as pain, pruritus, or nocturnal respiratory distress should be treated.

A fairly large group of chronic insomniacs is left. Women are more likely to suffer from this condition than men; the elderly more likely than younger adults. The question as to whether prescribe a hypnotic focuses on three aspects – efficacy, tolerability, and risk of dependence.

1. *Efficacy*. Doubts have not been fully allayed about the long-term efficacy of hypnotics (Glass et al. 2005). Very few controlled studies have extended beyond a month. Some attenuation of effect has been noted and attributed to ► tolerance. However, some trials show that ► placebo effects persist and lessen drug-placebo

Insomnias. Table 1. Drugs used as hypnotics.

Drug	Usual therapeutic dose (mg/day)		Time until onset (min)	Duration of action
	Adult	Elderly		
Lormetazepam†	0.5–1.5	Quarter to half the adult dose 3	30–60	Short
Oxazepam†	15–30		20–50	Medium
Nitrazepam†	5–10		20–50	Long
Temazepam†	10–20		30–60	Short
Zaleplon	10		30	Very short
Zopiclone	3.75–7.5		15–30	Medium
Zolpidem	5–10		7–27	Short
Eszopiclone	6		15–30	Medium
Promethazine	25–50		Unclear but may be 1–2 h	Long
Ramelteon	8	8	15–30	Short
Melatonin -Extended Release (ages >55 only)	3	3	15–30	Short

†, benzodiazepines

differences. More recently, a few studies have shown convincing evidence of efficacy for at least six months, eszopiclone being a notable example.

2. *Tolerability.* This has been extensively evaluated for the benzodiazepines and the z-drugs, ► zopiclone, ► zolpidem, and ► zaleplon. Unwanted effects have been coruscatingly quantified with respect to residual ("hang-over") effects the next day. But even more important are cognitive and psychomotor impairment 2–4 h after ingestion, at the peak effects of the drug. The elderly are the main users of hypnotics and they are prone to nocturnal wakenings and trips to the bathroom. The problem of unsteadiness and falls has been studied both in a clinical and an epidemiological context. A recent warning from the FDA concerned bizarre nocturnal activity. Daytime functioning covers many topics of which driving behaviour has received most attention.
3. The third topic, ► *tolerance*, ► *dependence*, and *withdrawal problems*, is even more contentious (Lader 1998). First, long-term users may overestimate the benefits of continuous use. It is difficult for them, their carers, and doctors to distinguish between:
   (a) recurrence of the insomnia on discontinuation;
   (b) rebound when the symptoms of insomnia recur temporarily in exaggerated form;
   (c) Withdrawal when newly emergent symptoms supervene; they are usually transient but some patients complain of persistence of these symptoms, often muscle stiffness and perceptual heightened sensitivity.

Yet another problem is misuse, where doses escalate to higher than therapeutic levels; withdrawal is both difficult and protracted. Hypnotic drugs, particularly flunitrazepam and ► temazepam, can be abused either as primary agents or in conjunction with other drugs of addiction such as ► opioids, ► cocaine, and ► amphetamines. Personal health problems and social harm develop despite the "addict's" perception of the risks.

For all these reasons, the benefit/risk ratio of the benzodiazepines remains disputed. It has been known that they should not be prescribed indiscriminately; instead, shorter-acting compounds are to be preferred; they are not given to children or the elderly; their usage should be carefully monitored; attempts have been made to avoid their long-term use; and warnings have been given about drug interactions, particularly with ► alcohol, resulting in "paradoxical" overreactions. The patient should be warned that withdrawal may not be uneventful. The z-drugs are probably less likely than benzodiazepines of similar duration of action, such as triazolam, to cause adverse reactions. Nevertheless, one UK official body, the National Institute for Clinical Excellence, in a Technology Appraisal (2004), did not see z-drugs as a preference over the benzodiazepines.

Other Medications

Other medications, such as ► melatonin analogs, are also licensed for insomnia. An extended release form of melatonin has been licensed in Europe for primary insomnia aged 55 and over. A melatonin analog, ramelteon, which acts on M_1 and M_2 receptors, is available in the USA. It acts mainly to shorten the onset of sleep but slightly prolongs sleep as well. Both these compounds are largely devoid of adverse effects, such as sedation, and dependence and withdrawal problems.

Some antihistamines that penetrate to the brain are highly sedative; ► promethazine and diphenhydramine are examples. In some countries, they are available over the counter, but they can cause sedation the next day. Over-the-counter herbal remedies include valerian and hops.

With insomnia secondary to mental or medical causes, the presence of this comorbidity may influence the choice of medication for the primary disorder. For example, a depressive with distressing insomnia would prefer a sedative ► antidepressant rather than a neutral or stimulant one.

Conclusion

Insomnia in its many forms remains a therapeutic challenge. Careful elucidation and evaluation of the symptom pattern and possible etiological factors is essential to its successful management. Nondrug and drug treatments are both available, but use of the latter involves difficult judgments regarding the benefits and risks in each patient.

Instrumental Conditioning

Anthony Dickinson
Department of Experimental Psychology, University of Cambridge, Cambridge, UK

Synonyms

Operant conditioning

Definition

Instrumental conditioning occurs when a response is acquired and controlled by a contingency between the response and a reinforcer or outcome. In the case where there is a positive relationship between the response and the reinforcer, so that the response causes the reinforcer, two processes control responding: an S-R/reinforcement process mediating habitual behavior and an R-O process underlying goal-directed action. The conditions of training determine whether the habitual or goal-directed process predominates. Moreover, these two processes can be dissociated within the ► prefrontal cortex and striatum with the dopamine system being particularly implicated in habit learning. Stimuli serve multiple functions in instrumental conditioning. First, they act as ► discriminative stimuli in that they control when a response is performed. Although this control acts by the direct elicitation of the response in the case of habitual behavior, goal-directed action can be based on knowledge of the triadic relationships between stimulus, response, and outcome. Second, not only can a signal for an appetitive reinforcer motivate and prime an instrumental responding, but such a stimulus can also act as a ► conditioned reinforcer for instrumental behavior. Taken together, these processes and functions allow an agent to exert sophisticated and highly adaptive control over its environment in the service of needs and goals.

Principles and Role in Psychopharmacology

The capacity for instrumental conditioning is probably the most important form of behavioral learning. Although other forms of learning allow an animal to anticipate the occurrence of biologically significant events, it is only through instrumental learning that an animal can learn to control these events in the service of its needs and desires, whether it be learning how to exploit a new food resource, how to court a new mate, how to avoid a potential predator, or even how to procure and self-administer an addictive drug (see ► Self-administration of drugs). By definition, instrumental conditioning is a change in behavior controlled by a relationship between the target response and consequent event or outcome.

In practice, it is not always a straightforward matter to decide whether an acquired response is instrumental. Consider a simple case in which a hungry chick learns to approach a food bowl. Although the approach response is instrumental in gaining access to the food, it is far from clear that the approach behavior is actually controlled by this relationship. Consider an environment in which the usual response–outcome relationship is reversed so that the chick has to learn to move away from the bowl in order to gain access to the food. Under this reversed relationship, the bowl recedes at twice the speed the chick approaches it, and in order to feed, the chick has to learn to move away from the bowl because it will then

catch it up at twice the rate that the bird withdraws from it. If the chick's locomotion with respect to the food bowl is instrumental, then learning this reversed response–outcome relationship should not be a problem. In fact, chicks never learn to withdraw from the bowl to gain the food but rather persist in chasing it away. This maladaptive behavior suggests that the original approach response under the normal, nonreversed relationship may not be controlled of the instrumental approach-food relationship but rather reflect the natural propensity of chicks to approach a stimulus, in this case the food bowl, that has been rendered attractive by its association with food.

The reversed contingency procedure is an example of the bidirectional assay of the instrumental status of a response. To establish that a response is under instrumental control, it is necessary to demonstrate that both of the two opposing responses can be acquired under the appropriate response–outcome relationship. For example, not only should a rat be able to learn to push a lever to the left for food but also to reverse the direction of pushing when pushing to the right is required. The fact that it is often difficult to implement such a bidirectional assay with many nominally instrumental learning tasks, such a running in a runway or maze for a reward, has led contemporary researchers to favor operant tasks (see ► Operant behavior in animals), such as lever pressing for food, in which a discrete and relatively arbitrary response is used.

In the example of a hungry rat learning to press a lever for a food outcome, the outcome is referred to as the reinforcer because it is the event responsible for strengthening or reinforcing the response. Moreover, the acquisition of the lever pressing is an example of positive reinforcement because the food strengthens responding through a positive response-reinforcer contingency in that the response causes food delivery. Aversive events can also act as instrumental reinforcers, but in this case they reinforce the response through a negative response–reinforcer relationship so that performance of the response actively avoids or escapes the occurrence of the reinforcer, which would then be an example of ► negative reinforcement (see ► Active avoidance). If an aversive outcome is presented under a positive response–outcome relationship, it acts as a punisher and reduces responding, thereby allowing the animal to passively avoid the outcome (see ► Passive avoidance and ► punishment procedures). This essay will focus on the processes mediating positive reinforcement.

When Thorndike first characterized instrumental conditioning, he explained response acquisition by his "Law of Effect." According to this law, the presentation of a positive reinforcer strengthens an association between any stimuli present at the time of responding and the response itself so that subsequent presentation of the stimuli is more likely to elicit the response. We now know that this characterization of the instrumental learning in terms of stimulus–response (S-R) learning is insufficient in at least two respects. The Law of Effect assumes that the strength of the S-R association depends solely on the number of times and the probability that the response is followed by a reinforcer (paired reinforcement). However, if instrumental learning was solely dependent on paired reinforcement, performance could be insensitive to the causal relationship between the response and reinforcer. For example, if the probability of paired reinforcement is kept constant, the responding can be rendered causally ineffective by increasing the probability of the reinforcer in the absence of the response (unpaired reinforcement) until when the probability of paired and unpaired reinforcement are equal, when responding has no effect on the overall amount of reinforcement. The fact that such noncontingent schedules maintain a very low rate of responding shows that instrumental conditioning is in fact sensitive not only to response–reinforcer pairings but also to their contingency.

The second major limitation of the S-R/reinforcement theory is that it does not support goal-directed instrumental behavior. Specifically, an animal cannot select an appropriate response on the basis of the current incentive value of the associated outcome through an S-R mechanism and, therefore, responding is insensitive to changes of incentive value without undergoing reacquisition with the revalued outcome. Consider a case in which a rat initially learns to press a lever for a particular type of food before acquiring an aversion to the food (see ► Conditioned taste aversions). According to the S-R/reinforcement theory, the acquisition of this food aversion should have no impact on the animal's initial propensity to respond when once again given access to the lever. The only function of the food outcome during the initial training was to reinforce an association between the stimulus of the lever and the response of pressing it, so that the subsequent devaluation of the food should have no impact on the propensity to press the lever until the now-devalued food is once again presented contingent on the lever press. At variance with this prediction of S-R theory, there is now wealth of evidence that instrumental performance can be immediately sensitive to outcome revaluation. Sensitivity to outcome revaluation requires that the animal encodes the response–outcome (R-O) contingency during initial training so that a subsequent change in the

value of the outcome can immediately impact on responding through this R-O learning. In the absence of R-O learning, there is no mechanism by which a change in outcome value can directly modulate instrumental performance.

Instrumental performance mediated by R-O learning is characterized as goal-directed, whereas responding based on S-R learning is habitual (Dicknson 1994). In contrast to S-R learning, which is nondeclarative in form, R-O learning is declarative in that performance is mediated by a representation of the response–outcome relationship (see ▶ Declarative and nondeclarative memory). Clearly, goal-directed behavior, being immediately responsive to changes in outcome value, is much more flexible that habitual responding (see ▶ Behavioral flexibility). Instrumental contingencies engage both goal-directed and habitual learning with the relative contribution of these two forms of learning to the control of performance being determined by the conditions of training. Overtraining on a single response–outcome contingency produces insensitivity to outcome devaluation, thereby indicating habitual S-R control. However, responding remains sensitive to outcome devaluation, and therefore goal-directed action, even after overtraining on a more complex schedule in which different responses produced different outcomes. Another factor that determines whether performance is autonomous of the current incentive value of the outcome is the nature of the reinforcement schedule. On ratio schedules, there is constant probability of reinforcement and therefore a linear relationship between response and reinforcement rates, which should lead to good R-O learning. In contrast, under an interval schedule the reinforcement source depletes when a reinforcer is taken and time has to elapse before another reinforcer is available. This regeneration rate therefore sets an upper limit on the rate of reinforcement so that when responding is sufficient to procure a reinforcement rate near this upper limit, there is only a weak relationship between response and reinforce rates and consequently little R-O learning. Therefore, it is not surprising that responding more rapidly becomes habitual with training on an interval rather than on a ratio schedule. Variations in the type and parameters of reinforcement schedules allows the study of the economics of behavior (see ▶ Behavioral economics).

The behavioral distinction between goal-directed action and habitual responding has now been validated by neurobiological dissociations in the rodent by using the outcome devaluation and contingency manipulation assays (Balleine and Ostlund 2007; Cardinal et al. 2002). Lesions of the dorsomedial (prelimbic) prefrontal cortex prior to, but not following, training render performance insensitive to outcome devaluation and the degradation of the R-O contingency brought about by enhancing the probability of unpaired reinforcers. Therefore, dorsomedial prefrontal cortex functioning appears to be critical for the acquisition of goal-directed action but not for the retention and deployment of R-O learning. These latter functions depend on the integrity of the dorsomedial striatum in that both pre- and post-training lesions of this structure render responding insensitive to outcome devaluation and contingency degradation. In summary, goal-directed instrumental learning and performance depends on the interaction of the dorsomedial prefrontal cortex and striatum. A parallel cortico-striatal system is critical for the acquisition of S-R habits in the rat. The lesions of a more ventral area (infralimbic) of the rodent prefrontal cortex and of the dorsolateral striatum ensure that instrumental responding remains goal-directed in spite of a degree of overtraining that produces habitual responding by intact animals.

Ever since the discovery that dopamine antagonists produce extinction of instrumental responding, the importance of this neurotransmitter in instrumental conditioning has been well established. However, the exact functions of ▶ dopamine in instrumental performance remain unclear. It is known that the decrement in instrumental performance is observed under doses of neuroleptics that do not interfere with consumption of the food reinforcer nor with motor performance. Three lines of evidence suggest that dopamine may play a critical role in habit reinforcement. First, lesions of nigro-striatal dopamine system render performance sensitive to outcome devaluation under training conditions that produce S-R habits in control animals. Second, a regime of pre-treatment with dopamine agonists (see ▶ Psychomotor stimulants), which is thought to sensitize a dopamine-based reinforcement system, enhances the rate at which instrumental responding becomes habitual with training (see ▶ Reinforcement disorder). Finally, addictive drugs, which enhance dopamine function, are more effective reinforcers of habitual responding than are natural food rewards (see Self-administration of drugs). However, there is evidence that dopamine may also play a role in goal-directed performance in that dopamine infusions into the ▶ ventromedial prefrontal cortex restore sensitivity to outcome devaluation following a training regime that renders responding habitual in control animals.

Furthermore, dopamine also has a motivational function that is most clearly revealed by the so-called Pavlovian-instrumental transfer (PIT) paradigm. The rationale for

PIT lies in the fact that an instrumental contingency not only embodies the critical R-O relationship but also a predictive, or Pavlovian, stimulus–outcome (S-O) relationship. When a rat is trained to press a lever for food, not only does it experience the instrumental press-food contingency, but also pairings of the stimulus of the lever and, indeed, of the contextual cues of the operant chamber with the food. The PIT paradigm demonstrates the functions acquired by these stimuli by separately training the R-O and S-O relationships. When, on test, the stimulus that has been paired with the reinforcer is presented for the first time while the animal has the opportunity to perform the instrumental response (usually in extinction), the presence of the stimulus is found to enhance instrumental responding, a transfer effect that is reduced by the presence of dopamine antagonists either during training or during testing.

In part, PIT is thought to reflect a general motivating effect of reinforcer-associated stimuli on instrumental performance in that it is modulated by the motivational state of the animal at the time of testing and observed even if the stimuli and responses are associated with different appetitive reinforcers (Dickinson and Balleine 2002). For example, a stimulus associated with a starch solution potentiates lever pressing trained with food pellets more when the animal is hungry rather than sated. In contrast to this general form of PIT, a second, outcome-specific form of PIT is observed when the stimulus shows greater potentiation of a response with which it shares a common outcome. Unlike the general form, magnitude of outcome-specific PIT is relatively independent not only of the animal's current motivational state but also of the current incentive value of the stimulus-associated outcome. Whereas general PIT is evidence for the motivational influence of the conditioned stimuli, outcome-specific PIT suggests that such stimuli also has prime responses with which they share a common outcome. The behavioral distinction between these two forms of PIT is bolstered by their neurobiological dissociation within the amygdala. Whereas lesions of the central nucleus attenuate general PIT, it is dysfunction of the basolateral nucleus that abolishes outcome-specific PIT (Balleine and Ostlund 2007). A parallel dissociation is found following lesions of the ► nucleus accumbens with dysfunction of the core impacting on general PIT and that of the shell on outcome-specific PIT.

The ► amygdala also plays a role in mediating a second function of a reinforcer-associated stimulus, that of ► conditioned reinforcement (Cardinal et al. 2002). A stimulus that has been previously established as a predictor of an appetitive reinforcer will strengthen an instrumental response when delivered contingently on performance of that response. So, for example, rats will learn to press a lever for the presentation of light that has been paired with food delivery, an effect that depends on the integrity of the basolateral amygdala. Moreover, the effectiveness of the conditioned reinforcement is greatly enhanced by psychostimulants, a potentiation that is mediated by the nucleus accumbens. Conditioned reinforcement serves at least two important functions in the maintenance of complex behaviors. First, it enables animals to acquire a chain of responses that ultimately leads to primary reinforcement. The stimuli associated with each link in the chain act as conditioned reinforcers of responding in the prior link in the chain, thereby maintaining responding early in the chain. Second, conditioned reinforcers can act as tokens of primary reinforcement and so maintain behavior at times when access to the primary reinforcer is not available.

The final instrumental function of stimuli is as ► discriminative stimuli, signaling when a particular response–outcome relationship is operative. So, for example, an animal can learn that one of two responses, for example a left lever press, delivers the reinforcer in presence of one stimulus, a light, whereas the another stimulus, a tone, signals that the other response, a right lever press, is required for reinforcement. In the case of habitual responding, the discriminative function is a direct consequence of the S-R associations established by the reinforcement process. However, the discriminative control of goal directed behavior is more complex in that there is evidence that animals can learn about the three-term relationship between stimulus, response, and outcome (Rescorla 1991). Consider the following training contingencies between two stimuli, two responses and two outcomes:

S_A: $R_1 \Rightarrow O_X$ $R_2 \Rightarrow O_Y$ S_B: $R_1 \Rightarrow O_Y$ $R_2 \Rightarrow O_x$

The contingencies signaled by each stimulus are the same except for the fact that the relationship between the responses, R_1 and R_2, and the outcomes, O_Y and O_x, are reversed across the two stimuli, S_A and S_B. Evidence that rats learn about the specific R-O relationships signaled by each stimulus come from the effects of devaluing one of the outcomes. For example, if O_X is devalued, the animals should preferentially perform R_2 in S_A, but R_1 in S_B. The fact that rats show just such a pattern of test responding following the outcome devaluation demonstrates that goal-directed behavior can be controlled by knowledge of the three-term contingency.

In summary, instrumental conditioning occurs when a response is acquired and controlled by a contingency

between the response and a reinforcer or outcome. In case where there is a positive relationship between the response and reinforcer, so that the response causes the reinforcer, two processes control responding: an S-R/reinforcement process mediating habitual behavior and an R-O process underlying goal-directed action. The conditions of training determine whether the habitual or goal-directed process predominates. Stimuli serve multiple functions in instrumental conditioning. First, they act as ► discriminative stimuli in that they control when a response is performed. Although this control acts by the direct elicitation of the response in the case of habitual behavior, goal-directed action can be based on knowledge of the triadic relationships between stimulus, response, and outcome. Second, not only can a signal for an appetitive reinforcer motivate and prime an instrumental responding, but such a stimulus can also act as a conditioned reinforcer for instrumental behavior. Taken together, these processes and functions allow an agent to exert sophisticated and highly adaptive control over its environment in the service of needs and goals.

Instrumental Performance

► Operant Behavior in Animals

Insulin-Resistant Brain State

Synonyms

IRBS

Definition

Reduction or loss of insulin action; reduced binding to insulin receptors in regions of interest for AD, hippocampus, or cortical areas.

Integral Membrane Protein

Definition

A protein that is permanently incorporated in a cell membrane; such protein can only be separated from the cell membrane using detergents.

Intellectual Disability

► Autism Spectrum Disorders and Mental Retardation
► Mild Cognitive Impairment

Intensive Care Unit Psychosis

► Delirium

Intermittent Claudication

Definition

Intermittent claudication refers to muscle pain (ache, cramp, numbness, or sense of fatigue), which occurs during exercise, in individuals with peripheral vascular disease caused by the obstruction of large arteries in the arms and legs. It is often a symptom of severe atherosclerotic disease of the peripheral vascular system. The PDE3

inhibitor cilostazol has been approved for the treatment of intermittent claudication.

Cross-References
► PDE3 Inhibitors

Internalization

Definition
Translocation of receptors including GPCRs and ionotropic receptors from the surface membrane to intracellular compartments.

Interpersonal Psychotherapy

Synonyms
IPT

Definition
A brief form of psychotherapy that focuses on enhancing interpersonal skills in order to ameliorate interpersonal factors that may be contributing to psychological distress. IPT appears to be effective in the treatment of depressive disorders of mild to moderate severity.

Inter-Temporal Choice

► Delay Discounting Paradigms

Interval Timing

Definition
Interval timing refers to the perception, estimation, and discrimination of durations in the range of seconds-to-minutes-to-hours. It is crucial for fundamental cognitive processes related to obtaining reward, estimating the rate of event occurrence, decision making, and neuroeconomics (see behavioral economics).

Synonyms
Sharp microelectrode recording; Whole cell recording

Definition
► Intracellular recording denotes a group of electrophysiological techniques used to study the electrical properties of cells. These techniques permit the recording and manipulation of a cell's ► membrane potential, and the measurement of the ionic currents flowing across the plasma membrane. As such, these techniques allow for the study of a cell's membrane potential and its relationship to active and passive macroscopic ionic currents.

Principles and Role in Psychopharmacology
Living cells exhibit a membrane potential that is the result of the asymmetrical distribution of ions across the plasma membrane and the ion fluxes carried through the ion channels expressed by the cell. Excitable cells, and neurons in particular, express a rich complement of ion channels that produce not only a hyperpolarized membrane potential, but also endow the plasma membrane with a complex electrogenesis (Hille 2001; Kandel et al. 2000).

Foremost among the electrical phenomena of neurons is the ability to generate action potentials, which constitute the basic computational unit of neuronal networks. Action potentials reflect a brief increase in sodium permeability that causes a transient reversal of the membrane potential. Because action potentials represent a relatively large change in voltage across the membrane, they can be detected using extracellular recording techniques which allow for the assessment of neuronal activity under a variety of experimental conditions (see ► extracellular recording). However, most of the computational work of individual neurons involves changes in membrane potential at voltages below the threshold for the generation of action potentials. Direct investigation of this phenomenon requires recording of membrane voltage and ionic currents using intracellular recording techniques.

The simplest modality of intracellular recording monitors the membrane potential of a cell as a function of time. This is accomplished using a high input impedance "intracellular" amplifier that measures the voltage difference across the cell membrane using a fluid-filled

electrode whose lumen is continuous with the cell cytoplasm. The bath is generally considered to be at 0 mV (ground) and thus the cell's membrane potential is negative. This recording modality is known as ► current clamp, because the current flowing through the electrode, be it a sharp microelectrode or a patch electrode, is held "clamped" at a fixed level and the cell's membrane voltage is allowed to vary. This allows for recording of not only action potentials, but subthreshold excitatory and inhibitory synaptic potentials as well as the slow depolarizing and hyperpolarizing responses signaled by G protein-coupled receptors. The alternative to current clamp recording is ► voltage clamp recording, a less naturalistic recording modality where the amplifier actively controls the voltage across the membrane by current injection, and thus allows for the direct measurement of the ionic currents flowing across the membrane.

Current clamp and voltage clamp recordings can be implemented using either sharp microelectrode or patch clamp electrodes. In ► sharp microelectrode recordings, a glass capillary is heated and pulled at high velocity to produce a minute "sharp" tip. The electrode is then filled with a concentrated salt solution of high conductivity (e.g., 3 M KCl) and the cell is impaled with the electrode to obtain electrical continuity between the electrolyte filling the microelectrode and the cell cytoplasm. In ► patch clamp recording, a glass capillary is heated and pulled in multiple stages to produce a large tip electrode (generally 1–3 m diameter) that is filled with an intracellular solution, osmotically balanced to the cytoplasm. The electrode tip is then gently pressed against the plasma membrane with slight suction through the lumen of the electrode to obtain a "tight seal" between the smooth glass tip and the cell membrane. Further negative pressure is applied to the interior of the electrode to disrupt the membrane underneath the electrode tip and gain access to the cytoplasm, a recording configuration known as ► whole cell recording (Sakmann and Neher 2007).

Intracellular recording techniques constitute an important cluster of electrophysiological methods that allow for the mechanistic investigation of neuronal physiology and the study the cellular actions of neurotransmitters and their receptors. The use of these techniques on vertebrate and invertebrate experimental preparations over the last several decades has allowed us to gain important insight into multiple aspects of neuronal function including, for example, the microscopic physiology of ion channels and synapses, how ionotropic receptors excite and inhibit neurons and how G protein-coupled receptors regulate neuronal excitability (Hille 2001). Equally important, intracellular recording techniques combined with pharmacological (see ► Receptors: Functional Assays) and molecular biological interventions (see ► Genetically Modified Animals) have allowed us to explore cellular signaling *in situ*. This has permitted substantive advances in our understanding of the cellular and molecular mechanisms that underlie neuronal excitability and that are used by neurotransmitters receptors to signal their physiological responses.

All of the intracellular recording modalities outlined above can contribute to our understanding of neuronal physiology. However, each of them offers a unique set of advantages and disadvantages. ► Current clamp recordings offer a "naturalistic" approach to the study of neuronal physiology in that this methodology allows us to monitor the voltage across the cell membrane while it fluctuates while it would in a neuron *in situ*. A powerful experimental feature available during current clamp recordings is the ability to inject direct current into the cell to manipulate the cell's membrane potential. Of course, current injection through a high resistance electrode leads to the development of an additional voltage across the electrode in series with the membrane, but most modern current clamp amplifiers include a bridge circuit that allows for the cancelation of this voltage. The ability to inject direct current into the cell opens many experimental avenues for the study of neuronal physiology. In fact, current clamp recordings implemented using sharp microelectrodes form the experimental foundation upon which our current understanding of neuronal physiology and the actions of neurotransmitters was built. For example, they have allowed us to learn that synaptic potentials are composed of discrete quanta, that ► glutamate is the main fast excitatory neurotransmitter in central neurons and that ► G protein-coupled receptors exert their effects by regulating not only membrane potential but also by modulating a host of calcium- and voltage-activated currents. Sharp microelectrodes, however, tend to exhibit high resistances, which result in electrically noisy recordings and exhibiting limited current passing capacity. These factors limit the power of this technique to address subtler mechanistic issues.

Voltage clamp recordings offer a powerful alternative for the study of neuronal physiology. In this recording modality, the cell membrane potential is clamped at a set voltage controlled by the experimenter and the amplifier injects current as needed to maintain the set voltage. This injected current, of course, is the mirror image of the ionic current flowing through the membrane, thus allowing for its direct measurement. Voltage clamping is a powerful technique that allows for the direct study of the ion currents activated or modulated by

neurotransmitters. However, it is difficult to implement using sharp microelectrodes because of their limited and nonlinear current passing capacity. As such, voltage clamping with microelectrodes requires that the current injection be separated from the recording of voltage either through the use of two microelectrodes or of a discontinuous ("sample and hold") voltage recording protocol where current injection is temporarily dissociated from the recording of voltage. These technical difficulties delayed the widespread use of voltage clamp methodologies to the study of neuronal physiology until the maturing of patch clamp recordings techniques.

The development of patch clamp recording methodologies starting with the work of Sakmann and Neher in the 1980s revolutionized the study of neuronal electrophysiology (Hamill et al. 1981). One important aspect of this revolution was the development of whole cell recordings, which allowed for the use of low resistance patch electrodes to voltage clamp a variety of cell types. Because the resistance of a patch electrode (series resistance) is generally much lower than the resistance of the recorded cell, this allows for the easy implementation of whole cell voltage clamp recordings using a single electrode. This opened the ability to conduct sophisticated electrophysiological studies aimed at understanding the precise mechanisms by which neurotransmitters regulate ion currents and neuronal excitability. Additionally, the low electrical noise associated with whole cell recordings has made it possible to study synaptic transmission in central neurons at a level previously impossible due to the small amplitude of unitary synaptic potentials or synaptic currents. These developments led to profound insights into the mechanisms underlying the regulation of synaptic transmission and synaptic plasticity (see ► Synaptic Plasticity).

While whole cell recording offers a powerful avenue for the investigation of neuronal electrophysiology, it is not without limitations. Most importantly, the large tip of the patch electrode allows for the rapid exchange of the cell's cytoplasm with the electrode's filling solution, a process that is generally referred to as "dialysis" of the cell's interior. This results in the loss of diffusible components from the cytoplasm and can lead to the loss or "wash-out" of cellular responses. Similarly, responses that are dependent on complex enzymatic cascades for recovery may also be rendered artifactually irreversible upon prolonged whole cell recording. One alternative to the use of whole cell recording that does not suffer from this problem is "perforated patch" recording, where the membrane patch blocking access into the cell is permeabilized using an ionophore such as nystatin. Alternatively, sharp microelectrode recordings afford the ability to conduct long lasting intracellular recordings from neurons with little if any "wash-out" of cellular responses.

A second limitation results from the fact that neurons are complex cable structures (Bar-Yehuda and Korngreen 2008). Voltage clamp of such cells, even when conducted using whole cell recording techniques, allow for precise control of voltage only at one point of the cable structure, generally at the soma. This means that a large fraction of the dendritic arbor is, more likely than not, imperfectly voltage clamped. This severely restricts what can and cannot be inferred from voltage clamp recordings.

The usefulness of the electrophysiological approaches outlined above has been greatly magnified by the development of imaging techniques capable of visualizing neurons in living brain slices (Sakmann and Neher 2007). This allows for the routine targeting of visually identified neurons for whole cell recording. As such, it makes it possible to record from neurons that have been genetically-tagged or genetically-modified by the expression or co-expression of fluorescent proteins. It also allows for the targeting of specific cells' subpopulations defined by their axonal projections and identified through the use of fluorescent retrograde tracers. These developments provide electrophysiologists with the ability to conduct rigorous single cell work even within the highly heterogeneous cell populations that characterize most brain regions.

In summary, intracellular recording in its many implementations allows investigators to interrogate single neurons about the actions and mechanisms used by neurotransmitters to regulate their function. As such, this technique helps bridge the gap between native tissue physiology and the mechanistic insights originating from work in model systems. This in turn helps in the development of experimental assays capable of contributing to drug discovery and the characterization of novel therapeutic compounds. As such, intracellular recording constitutes a key technique in neuropsychopharmacology.

Brain stimulation reward

Definition

Intracranial self-stimulation (ICSS) is the performance of an instrumental act, such as lever pressing, to trigger delivery of electrical brain stimulation.

Impact of Psychoactive Drugs

Rats and other vertebrates will work avidly to trigger delivery of electrical stimulation to certain brain sites. The potent rewarding effect produced by the stimulation ("brain stimulation reward," BSR) can compete with, summate with, and substitute for the rewarding effects of natural goal objects, such as food and water. Thus, the stimulation appears to inject a signal into the central nervous system (CNS) that mimics those produced by natural rewards. Given that the electrically induced rewarding effect originates as a volley of observable action potentials in axons coursing past identifiable CNS sites, the phenomenon of BSR has long been regarded as a gateway to tracing the neural circuitry involved in the pursuit of natural rewards. It has also been proposed that dependence-inducing drugs gain their grip over behavior, at least in part due to their ability to alter neurotransmission in the circuitry underlying BSR. If so, working out the structure and operating principles of the circuitry responsible for BSR should shed light on issues central to modern psychopharmacological research.

Figure 1 summarizes the location of ICSS sites in the rat brain. This image drives home the spatial extent of reward-related circuitry, which is best conceived as a distributed network, rather than as a restricted set of "centers." Figure 2 complements Fig. 1 at a finer scale. This image shows that when a stimulation electrode is advanced through the brain in fine steps (at coronal planes near the level of #3 in Fig. 1), the strength of the simulation required to sustain a given level of responding varies sharply with depth. A simple interpretation of such data is that the neural circuitry underlying BSR is tightly concentrated within the broad areas depicted in Fig. 1.

Methods have been developed for inferring whether there are direct axonal links within the reward circuitry between pairs of BSR sites and, if so, which end of such links points toward the terminals that transmit the reward signal to efferent stages (Shizgal 1997). These methods demonstrate axonal continuity within segments of the medial forebrain bundle (MFB), as well as between the hindbrain/midbrain core and the MFB; the segment of the MFB between the lateral hypothalamus (LH) and the ventral tegmental area (VTA) includes neurons in which conduction in the descending (rostro-caudal) direction leads to efferent stages of the circuitry.

Figure 3 provides a minimal model of how the signals induced in the directly activated neurons that give rise to the rewarding effect (at the left of the figure) are translated into behavioral output, such as lever-pressing for BSR. In the directly stimulated neurons, the electrically induced

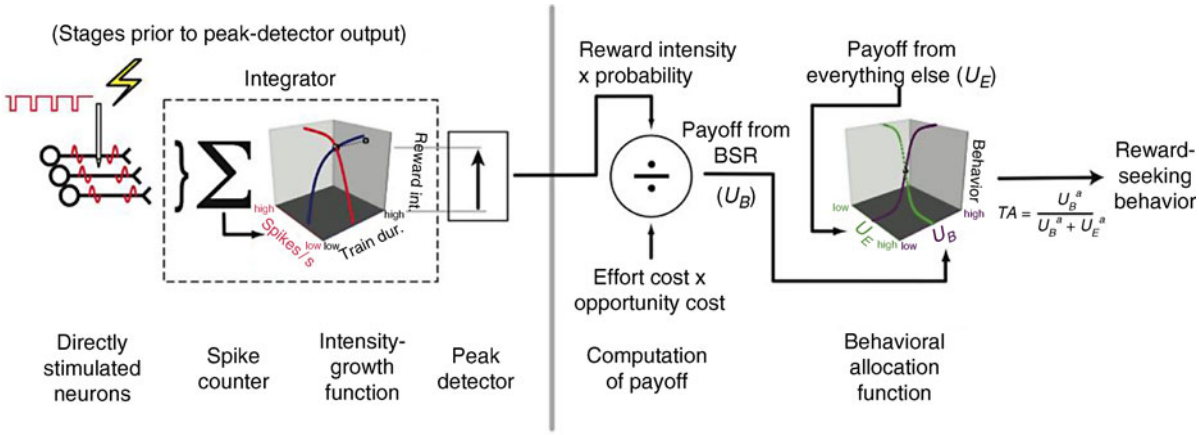
Intracranial Self-Stimulation. Fig. 2. Variation of self-stimulation threshold as a function of electrode depth. (Reproduced from Forgie ML, Shizgal P (1993) Behav Neurosci 107(3):506–524. Data on the left are from Rompre PP, Miliaressis E (1985) Brain Res 359:246–259.)

reward signal is represented by a rate code, which sums impulse flow across the population of activated neurons within a time window defined by the stimulation train. The resulting spike count is then transformed nonlinearly into a single time-varying quantity representing the intensity of the reward; growth of the reward signal decelerates over time and eventually levels off (darker curve). Within a time window of given duration, the reward signal grows as a function of the stimulation-induced spike count and eventually saturates (lighter curve). The peak reward intensity achieved during a stimulation train is recorded in memory (not shown) and translated ultimately into behavior.

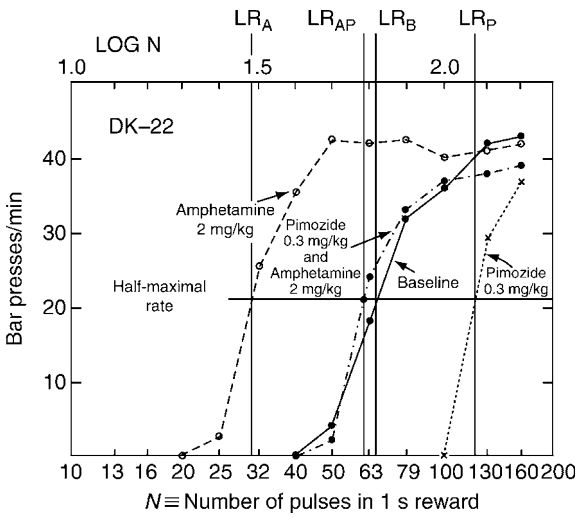
A vertical gray line in Fig. 3 demarcates the boundary between the BSR-specific and more general processes involved in the control of the reward-seeking behavior. The elements to the left of the gray line include the directly stimulated neurons and the circuitry that integrates their output over time and space, compressing the effects of the electrically triggered volley into a single quantity recorded in memory. To the right of the gray line, this stored reward-intensity signal is combined with information about a) the probability that a reward will be delivered once the response requirement (e.g., pressing the lever a given number of times) has been satisfied, b) the physical effort ("effort cost") and time



Intracranial Self-Stimulation. Fig. 3. Translation of the volley of action potentials triggered by the electrode into reward-seeking behavior. (Based on Fig. 1 in Arvanitogiannis and Shizgal (2008).)

("opportunity cost") required to do this, and c) the delay (not shown) between meeting the response requirement and delivery of the reward. In keeping with the generalized form of the ▶ matching law and behavioral decision theories in general, the subjective values of all these variables are combined in scalar fashion to yield an estimate of the payoff the subject can expect in return for satisfying the response requirement. Finally, in the spirit of the generalized single-operant matching law, the payoff from BSR (U_B, suitably transformed) is compared with the sum of all the (suitably transformed) payoffs available in the test environment, which include the payoffs (U_E, suitably transformed) from behaviors such as grooming, exploring, resting, etc. The result determines the proportion of time ("time allocation" (TA)) devoted to the pursuit of the electrically induced reward. Time allocation grows as the payoff from BSR is increased (darker curve) and as the payoff from competing activities falls (lighter curve).

Preliminaries: measuring the effects of drugs on BSR. The first psychopharmacological study of BSR was published within 3 years of the discovery of the phenomenon by Olds and Milner in 1953. The rate of lever pressing served as the behavioral measure of drug action. The deficiencies of that measurement method rapidly became clear. As can be seen at the right of Fig. 3 ("behavioral allocation function"), the payoff from BSR is translated into observable behavior by a saturating function. Thus, different levels of payoff can result in the same maximal level of time allocation, response rate, etc. For example, once the stimulation current or frequency are sufficiently high, response rates are not boosted by further



Intracranial Self-Stimulation. Fig. 4. Cancelation between the effects of amphetamine and pimozide on ICSS. (Reproduced from Gallistel CR, Karras D (1984) Pharmacol Biochem Behav 20(1):73–77.)

increments, but when offered a choice, rats will exhibit a preference for the stronger stimulation. A more general problem stemming from the use of response rates as the dependent variable can be seen in Fig. 4. As is typically the case, sigmoidal functions translate stimulation strength into behavioral output; a third variable, doses of two drugs that exert opposite influences on dopaminergic neurotransmission, displaces the sigmoidal psychometric functions laterally along the logarithmic axis representing stimulation strength. If only a single value of stimulation

strength (in this case, the pulse frequency) had been employed, the measured effects of the ► neuroleptic drug and the combination of the neuroleptic with a ► psychomotor stimulant would have depended on the arbitrary choice of pulse frequency. For example, had 160 pulses s^{-1} been selected, little influence of the drugs would have been apparent, but a profound influence would have been seen had 63 pulses s^{-1} been chosen instead. In contrast, if the curves are sectioned horizontally, rather than vertically, the measured effects of the drugs are essentially independent of the chosen criterion; similar shifts are apparent at behavioral criteria of 25%, 50%, and 75% of the maximal response rate. Thus, by measuring responding for the stimulation over a broad range of pulse frequencies, the countervailing influences of the two drugs can be discerned.

Quantifying the influence of drug treatments on ICSS by measuring lateral displacements of psychometric functions is called the "curve-shift" method (Miliaressis et al. 1986). In addition to the benefits described above, it is also argued that this method can distinguish changes in performance caused by disruptive effects of drugs, such as sedation or stereotypy, from *bona fide* influences on BSR. Performance disruption is said to alter the maximal rate of responding and the slope of the psychometric functions, whereas, changes in reward effectiveness are said to produce lateral shifts. If correct, this statement would confer a most convenient property on the curve-shift method. Unfortunately, there is contradictory evidence demonstrating that performance variables, such as alterations in the force required to depress the lever, produce systematic lateral curve shifts. Figure 3 argues that such effects should be expected: increases in effort cost decrease payoff but can be offset by increases in reward intensity.

Arvanitogiannis and Shizgal (2008) have delineated a related problem with the curve-shift method. They show that a given curve shift can arise from changes in different variables controlling reward pursuit. In effect, the same shift produced by an action of a drug to the left of the vertical gray line in Fig. 3, such as potentiation of spatio-temporal integration, can be mimicked by an action to the right of the vertical gray line, such as a reduction in subjective effort cost.

The curve-shift method has become the dominant means of assessing the influence of drugs on BSR, and it was employed in most of the work summarized in this essay. However, a new method is required to distinguish actions of drugs on the two sides of the vertical gray line in Fig. 3. Arvanitogiannis and Shizgal (2008) have proposed that by varying both the strength and cost of reward, the influence of drugs on components of the reward circuitry prior to the output of the spatiotemporal integrator in Fig. 3 can be distinguished unambiguously from influences brought to bear on downstream components. Successful application of their method would bring the field into the third turn of a spiral course of progress.

Experiments performed using the rate measurement proved useful in identifying drugs that are effective in altering performance for BSR. The curve-shift method provided a clear methodological advance by eliminating the dependence of drug-induced changes on arbitrarily selected stimulation parameters. The three-dimensional method developed by Arvanitogiannis and Shizgal (2008) promises to better distinguish the influence of drugs on different components of the circuitry underlying pursuit of the rewarding stimulation and to better distinguish effects of drugs on performance capacity from effects on reward integration. However, Fig. 3 points to a limitation of this new method: numerous interacting variables (depicted to the right of the vertical gray line) influence performance in ways that will be indistinguishable unless the mapping of the objective to the subjective values of these variables is nonlinear and these nonlinearities can be exploited experimentally. Thus, there will be a need for continued methodological advances in order to fully account for the effects of drugs on BSR and to maximize the contribution of such experiments in determining the neurochemical basis of reward.

The neurochemical basis of BSR. In the following sections, we summarize the contributions of the most extensively studied neurotransmitter systems to ICSS.

► *Dopamine* is the neurotransmitter most closely associated with BSR (Wise and Rompré 1989). Reductions in dopaminergic neurotransmission lower the effectiveness of the electrical stimulation in supporting ICSS, leading to rightward displacements of psychometric functions measured by the curve-shift method; as can be seen in Fig. 4, a higher stimulation strength is required to produce a given rate of lever pressing following administration of a dopamine receptor blocker ("► Pimozide 0.3 mg/kg"). Conversely, drugs that enhance dopaminergic neurotransmission increase the effectiveness of the electrical stimulation in supporting ICSS and thus, produce leftward shifts ("► Amphetamine 2 mg/kg"); such drugs reduce the simulation strength required to produce a given level of behavioral output. When two drugs that exert opposing influences on dopaminergic neurotransmission were coadministered, their effects on performance for BSR canceled ("Pimozide 0.3 mg/kg and Amphetamine 2 mg/kg"). Similar cancelation has been achieved by pitting the selective ► dopamine transporter blocker, GBR-12909 against the D-1 receptor blocker, SCH-23390. Drugs that

block D-2 receptors have also been shown to produce rightward curve shifts, and there is evidence that D-1 and D-2 receptors exert synergistic influences in this regard.

Dopamine neurons manifest multiple activity states. Under resting conditions, roughly 50% of the midbrain population is quiescent. Two active states have been described: sustained low-frequency (tonic) firing and intermittent high-frequency (phasic) bursting. Self-stimulation of the MFB is accompanied by a prolonged increase in tonic output, which is manifested in an increased extracellular concentration of dopamine, as observed by means of in vivo microdialyis probes in dopamine terminal fields. Phasic release, as measured by means of fast-scan cyclic voltammetry, is also observed in self-stimulating rats. In an early report, these brief increases in the local extracellular concentration of dopamine were described as transient, falling below the detection limit within a minute or so of the onset of self-stimulation. However, in more recent experiments that incorporate a 10-s post-reward time-out, a dopamine transient was recorded in the nucleus accumbens following each and every pulse train delivered via electrodes at the ventral tegmental level of the MFB.

As the evidence reviewed above suggests, there is wide agreement that dopaminergic neurotransmission is deeply implicated in ICSS. Nonetheless, a lively debate continues over exactly what role(s) dopaminergic neurons and their different activity states play. For example, many authors assume that the rewarding effect of stimulating the MFB is due to direct activation of dopaminergic fibers. However, the properties of these fibers are largely incompatible with this idea. The axons of dopamine neurons are unmyelinated and of fine caliber; their thresholds for activation by extracellular currents are high. Thus,relatively few such fibers should be excited directly under the typical conditions of BSR experiments, which entail the use of stimulation electrodes with large exposed tips and currents that are low with respect to the thresholds of dopaminergic fibers at the short-pulse durations commonly employed. The refractory periods of dopaminergic fibers are long and their conduction velocities low in comparison with the estimated values for the directly stimulated axons mediating self-stimulation of the MFB. Given the limited overlap between the excitability properties of dopaminergic fibers and those of the directly stimulated fibers mediating BSR, it would appear that activation of midbrain dopaminergic neurons during ICSS is achieved largely via a trans-synaptic route (Shizgal 1997). As predicted by this proposal, blockade of ► glutamate receptors in the VTA decreases the magnitude of ventral striatal dopamine transients elicited by rewarding VTA stimulation.

Moisan and Rompre (1998) have proposed a way to reconcile the influence of dopaminergic manipulations on ICSS with the mismatch between the properties of dopaminergic neurons and those of the directly activated neurons underlying BSR. They first varied the current and pulse frequency of rewarding MFB stimulation so as to determine two sets of stimulation parameters that produced the same level of behavioral responding: one that activated many directly stimulated neurons at low frequency and a second that activated fewer directly stimulated neurons at higher frequency. They then showed that putative midbrain dopamine neurons trans-synaptically activated by the rewarding stimulation fired at similar rates in response to the two different sets of stimulation parameters. Thus, the firing of the dopamine neurons reflects the "counter property" of spatiotemporal integration previously described in behavioral studies of BSR (depicted by the Σ symbol in Fig. 3). On this basis, Moisan and Rompré proposed that midbrain dopamine neurons may compose an integral part of the spatiotemporal integrator or relay its output to efferent stages of the circuit.

Salomone has developed an alternative perspective (Salamone 2002). In his view, dopaminergic neurons influence the proclivity to invest effort in the pursuit of reward; changes in the activity of these neurons do not alter reward intensity. Thus, Salomone's view is compatible with an influence of dopamine on subjective effort costs (Fig. 3) or the motivation to pay such costs to obtain reward.

Hypotheses concerning the contribution of dopamine to reward intensity or investment of effort in meeting work requirements are based directly or implicitly on curve-shift data, obtained using either stimulation strength or the work requirement as the independent variable. Arvanitogiannis and Shizgal (2008) have argued that such data cannot link the influence of dopamine unambiguously to processes operating at either side of the vertical gray line in Fig. 3; data obtained by varying both the strength and cost of reward are required to do so. The results of such an experiment have yet to be published as of this writing.

The following sections summarize the contributions of various other neurotransmitters to ICSS. The centrality of midbrain dopamine neurons to the phenomenon remains evident, as several other neurotransmitters appear to exert their influence on ICSS by means of their interactions with dopaminergic neurons.

► *Noradrenaline* figured heavily in early psychopharmacological research on BSR. The early interest waned after the reductions in response rate produced by agents that decrease noradrenergic neurotransmission were attributed to sedation, and early claims that

self-stimulation of sites in the vicinity of the locus coeruleus were due to activation of noradrenergic neurons were disputed. Nonetheless, neurons in the locus coeruleus and lateral tegmental A7 cluster do show increased double labeling for the rate-limiting enzyme in noradrenalin synthesis, tyrosine hydroxylase, and the immediate early-gene product, Fos, following self-stimulation of the MFB. Injection of the α_1 receptor antagonist, terazosin, into the locus coeruleus has been shown recently to produce rightward shifts in rate-frequency curves obtained from rats working for electrical stimulation of the MFB. Given the evidence that activation of α_1 receptors excites noradrenergic neurons in the locus coeruleus, this finding suggests that the firing of these neurons contributes in some way to the pursuit of rewarding MFB stimulation.

► *Acetylcholine* has been implicated in self-stimulation by experiments entailing manipulation of projections to midbrain dopamine neurons from cholinergic cell bodies in the pedunculopontine and lateral dorsal tegmental nuclei (Yeomans et al. 1993). Activation of these excitatory projections potentiates MFB self-stimulation and drives dopamine release in the ► nucleus accumbens. Neurotransmission in the cholinergic projections to the VTA is suppressed by the action of cholinergic agonists at autoreceptors on or near the cholinergic somata or by the action of cholinergic antagonists in the VTA terminal field. These manipulations reduce self-stimulation of the MFB (i.e., they cause rightward curve shifts). Disinhibition of the cholinergic projections by administration of cholinergic antagonists in the vicinity of the cholinergic cell bodies potentiates MFB self-stimulation, as evinced by leftward curve shifts. Enhanced release of acetylcholine is observed during self-stimulation of the MFB, both in the vicinity of the cholinergic cell bodies and in the VTA terminal field. Although modest effects on MFB self-stimulation have been reported following nicotinic manipulations of the cholinergic projections to the VTA, muscarinic receptors, the M_5 sub-type in particular, appear to mediate most of the effect of the cholinergic drive on MFB self-stimulation and on dopamine release in the nucleus accumbens. Administration into the VTA of ► antisense oligonucleotides for the M_5 receptor suppresses MFB self-stimulation. The potent modulation of MFB self-stimulation by cholinergic agents suggests that the effects of activating MFB fibers are relayed to VTA dopamine neurons, at least in part, by constitutively active cholinergic afferents.

► *Serotonin.* An important role in emotional and behavioral control has been attributed to serotonergic neurons. However, the multiplicity of serotonergic receptors, the widespread distribution of the serotonergic projections, and the action of serotonin both at the cell bodies and in the terminal fields of dopamine neurons make it challenging to build a comprehensive account of the action of serotonin on brain reward circuitry. Nonetheless, there is good agreement on the overall pattern of the results obtained to date in studies of the role of serotonin in ICSS: Release of this neurotransmitter generally exerts a suppressive influence on ICSS and opposes the influence of dopamine release (Harrison and Markou 2001). For example, stimulation of inhibitory cell-body autoreceptors decreases the activity of serotonergic neurons in the rostral raphé nuclei and potentiates self-stimulation of sites along the LH-VTA segment of the MFB. The effects of systemically administered agonists vary as a function of dose, stimulation site, and affinity for different subtypes of serotonin receptors. That said, rightward curve shifts or related increases in ICSS thresholds have been observed following administration of agonists for the 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2C} receptors. Systemic administration of antagonists for these receptors and the 5-HT_3 receptor usually leaves ICSS unaltered but can reverse changes produced by concurrent administration of serotonergic or dopaminergic agonists.

Histamine. A reward-inhibiting role has been proposed for histamine-containing neurons in the tuberomammillary regions of the posterior hypothalamus (Wagner et al. 1993). These neurons project to the nucleus accumbens, where blockade of H_1 receptors increases the extracellular concentration of dopamine. Ipsilateral damage to the tuberomamillary histamine neurons or blockade of H_1 receptors in the nucleus accumbens increases the rate of LH self-stimulation. It remains to be determined whether leftward curve shifts can be produced by such manipulations.

Glutamate and GABA. Given the ubiquity of these amino-acid neurotransmitters in the brain, it would be surprising indeed if they did not play important roles in the rewarding effects of electrical brain stimulation.

► Glutamate is released in the VTA during MFB self-stimulation. Numerous nuclei provide glutamatergic input to the VTA, and it is not yet known which subset of glutamatergic neurons are responsible for the release of this neurotransmitter during ICSS. Identifying these neurons is of substantial potential interest because they may well contribute to the directly activated stage of the circuit responsible for BSR. The notion that directly activated MFB fibers provide excitatory input to dopamine cells is compatible with the abovementioned hypothesis of Moisan and Rompré.

Experience with ICSS of the MFB has been shown to downregulate the expression of the GluR1 subunit of

AMPA receptors, a phenomenon that has been proposed as an explanation of the lack of sensitization observed over the course of long periods of ICSS testing. Viral-induced increases in the expression of GluR1 in the shell region of the nucleus accumbens produce rightward curve shifts, whereas, increased expression of the GluR2 subunit in the above region shifts the psychometric curves leftward (Todtenkopf et al. 2006).

Microinjection of GABAergic agonists or antagonists into the VTA or into basal forebrain regions such as the sublenticular extended amygdala can produce systematic shifts in rate-frequency curves obtained from rats working for MFB stimulation (Waraczynski 2006). In the case of VTA injections, the level of activity of the local dopaminergic cell bodies appears to determine the sign of the effect. For example, the $GABA_A$ agonist, muscimol, produces rightward curve shifts when injected alone, but can reinstate self-stimulation after it has been abolished by intra-VTA injection of a large dose of ► morphine in rats pretreated with the dopaminergic receptor blocker, pimozide. This effect has been interpreted to reflect the restoration of firing in dopamine cell bodies that had been driven into depolarization block by the combination of autoreceptor blockade and strong opioidergic excitatory drive; the ► $GABA_A$ stimulation is posited to have hyperpolarized the dopamine cells sufficiently to restore their ability to generate action potentials (Wise and Rompré 1989).

Endorphins. The role of ► endogenous opioids in reward has been investigated extensively, and studies of ICSS have played an important role in this endeavor. Peripherally administered opiates and ► opioids to drug-naïve rats exert a biphasic influence on performance for BSR: an initial decrease in the vigor of responding is followed by an increase above baseline levels. The initial depression tolerates with repeated administration of the drug whereas the enhancement of performance does not, and thus the potentiation of ICSS by systemically administered opiates and opioids emerges as the principal effect of these drugs as a regimen of repeated administration proceeds.

Injection of opioid receptor agonists into either the VTA or the nucleus accumbens terminal field of VTA dopamine neurons can produce leftward shifts in psychometric curves obtained from rats working for rewarding MFB stimulation. In the case of the nucleus accumbens injections, such effects are observed following administration of agonists for either μ- or δ-opioid receptors. In contrast, systemic administration of the ► κ opioid agonist, U-69,593 produced rightward curve shifts and counteracted the left-shifting influence of cocaine.

The modulation of ICSS by opiates and opioids is linked strongly, but not exclusively, to the effects of these drugs on dopaminergic signaling. For example, GABAergic interneurons in the VTA are hyperpolarized by ► μ-opioid agonists, thus disinhibiting dopaminergic cell bodies. Opioid agonists have also been shown to increase release of dopamine in the nucleus accumbens. That said, opposite effects on dopamine tone in the core and shell subregions of the nucleus accumbens were observed following local administration of μ- and δ agonists. Given that opioid receptors are found both pre- and postsynaptically in the nucleus accumbens and have been identified on dopaminergic, cholinergic, glutamatergic, and GABAergic neurons, there are multiple ways that opiates and opioids could influence the processing of reward-related signals in the ventral striatum.

► *Cannabinoids.* An abundant literature links the endogenous cannabinoid system to the pursuit and evaluation of rewards, and there is evidence that cannabinoid agonists activate both dopaminergic and opioidergic neurons. Within this literature, the data on ICSS are anomalous: in the hands of different investigators, drugs that alter ► cannabinoid signaling have been observed to enhance, suppress, or fail to alter pursuit of BSR. Methodological issues could be at the root of these conflicting reports, and application of the 3D model described in Fig. 3 may help shed light on these issues. Given the steep slope of the "intensity-growth function" (lighter curve in the left-hand graph), substantial changes in the values of variables on the right-hand side of the figure can produce only modest shifts in 2D projections of the 3D surface, such as rate-frequency curves, which can prove hard to discern through the measurement noise, individual differences in drug sensitivity, etc. However, such changes should be readily detectable when the 3D-measurement method is used.

Concluding remarks. Together with the conditioned place-preference and drug self-administration paradigms, ICSS has been, and continues to be, a mainstay of research on the psychopharmacology of reward. As this essay suggests, rather a lot has been learned from ICSS experiments about the roles of different neurotransmitter systems in brain reward circuitry. Nonetheless, much additional work will be required to fully account for the powerful influence of drugs on ICSS. Advances in behavioral measurement methods promise to tie the effects of pharmacological manipulations to specific psychological processes that contribute to the pursuit of BSR, and new methods, such as techniques for optical stimulation and inhibition of neurons expressing particular neurotransmitter-related genes, promise to refine our understanding of reward processing at the cellular and circuit levels.

Intradimensional

Synonyms

ID

Definition

In the context of a ID/ED task, the intradimensional (ID) stage involves discriminating between two (generally novel) stimuli that differ from each other in at least two dimensions (e.g., color and shape), but for which the relevant discriminative dimension (e.g., color) has been primed by prior experience.

Intrathecal

Definition

An injection into the space surrounding the spinal cord, avoiding the blood–brain barrier.

Intrinsic Sympathomimetic Activity

Definition

The term used with β-blocking drugs that show both agonism and antagonism at a given β-receptor, so that, for example, there is improved cardiac function without cardiac rate being reduced significantly. Drugs that have intrinsic sympathomimetic activity are also known as ▶ partial agonists.

Inverse Agonists

Gregory D. Stewart, Patrick M. Sexton, Arthur Christopoulos
Drug Discovery Biology Laboratory, Monash Institute of Pharmaceutical Sciences and Department of Pharmacology, Monash University, Melbourne, VIC, Australia

Synonyms

Negative antagonists

Definition

Inverse agonists are ligands that inhibit spontaneous (ligand-independent) receptor activation.

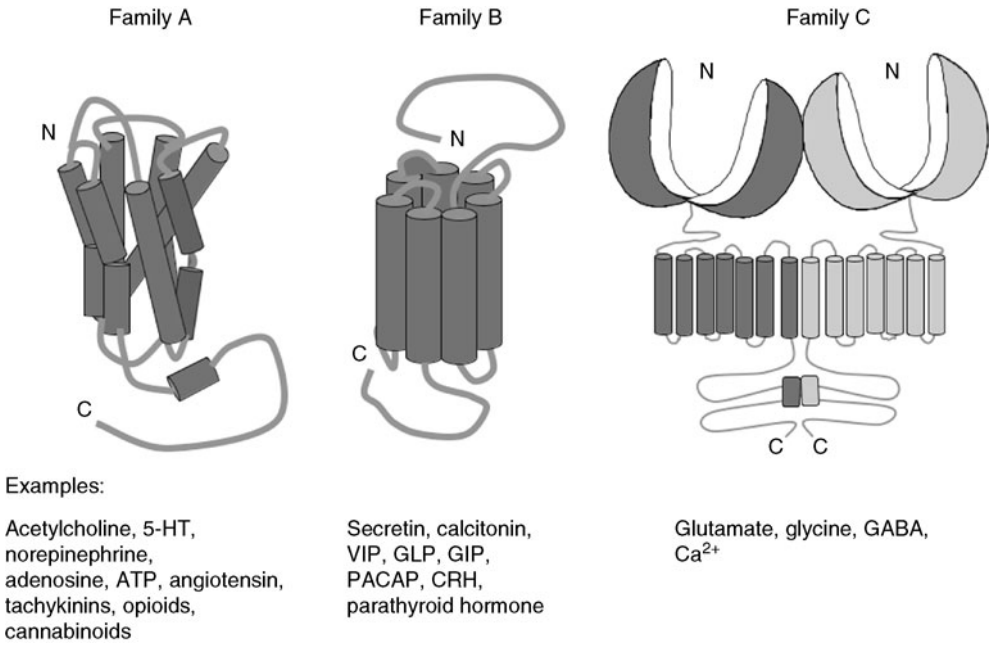
Pharmacological Properties

Introduction

► G-protein-coupled receptors (GPCRs) are the largest family of receptors in the human genome, are ubiquitously expressed on the surface of all cells, and constitute the predominant signaling system in living organisms. Given that hormone and neurotransmitter activity at GPCRs is such a prevalent phenomenon in virtually every physiological process, it is not surprising that aberrations in GPCR-mediated signal transduction have been associated with many disease states, including CNS disorders, metabolic disorders, cardiovascular disease, and many cancers. Approximately 30% of all medicines currently on the market target GPCRs, but this figure only relates to a small fraction of the total number of GPCRs that could be effectively exploited therapeutically. Thus, these receptors remain one of the most tractable and widely pursued groups of drug targets.

Structurally, GPCRs are defined by a common architecture composed of an extracellular N-terminal domain, an intracellular C-terminal domain, and seven transmembrane domains linked by three extracellular and three intracellular loops (Fig. 1). Despite this common architecture, GPCRs exhibit a remarkable diversity in the range of ligands that they recognize and the intracellular signal transduction cascades that they couple to, which is indicative of a very flexible and dynamic nature. Mammalian GPCRs are further subdivided into three groups: Family A or Class I GPCRs ("rhodopsin-like"), the largest family comprising receptors for prototypical neurotransmitters and hormones such as biogenic amines (epinephrine, norepinephrine, ► serotonin, ► dopamine, histamine, acetylcholine), adenosine, ► cannabinoids and angiotensin; Family B or Class II GPCRs, incorporating peptide hormone receptors such as calcitonin, parathyroid hormone, glucagon, and secretin receptors; and Family C or Class III GPCRs, including receptors for small molecules such as ► glutamate, ► GABA, and calcium (Fig. 1).

For many years, the traditional view of signaling via GPCRs posited that these receptors were quiescent in the absence of ligand, and that activation was mediated by a ligand-induced conformational change that subsequently promoted coupling to a variety of members of the heterotrimeric G-protein family to initiate intracellular signal transduction. This simplistic view was considered consistent with the (even older) phenomenological classification of drugs as either ► agonist or ► antagonist, i.e., compounds that activated the system were agonists, whereas compounds that had no apparent effect on the system but could block the actions of agonists were classed as antagonists. However, it is now known that GPCR-mediated signaling is a more complex process than originally envisaged, and a number of important developments in the field have led to a reclassification of the molecular nature of drugs and a change in the approaches used to screen for them. One of these developments was the discovery that GPCRs, like many other proteins, can spontaneously adopt one or more active states in the absence of ligand. This ligand-independent activity is termed ► constitutive activity and is now acknowledged as a naturally occurring phenomenon for nearly all GPCRs to varying extents. A second, more recent, development is the recognition that different active states of a GPCR can be coupled to markedly different signal transduction processes, some of them in a G-protein-independent manner, and that not all states are promoted by all ligands that recognize the GPCR. This dynamic, "multi-conformational," view of GPCR activity has led to a re-evaluation of the molecular nature of drug efficacy and highlighted the inadequacy of the simple agonist/antagonist paradigm for describing the effects of drugs. In particular, it is now evident that the role of a ligand is to stabilize one or more GPCR states for which it has the highest affinity and, by doing so, bias the possible conformations of the receptor toward those states. In this new paradigm, agonists are ligands that promote GPCR active states over and above those states that occur spontaneously, whereas ligands that promote inactive states, i.e., reduce the constitutive (basal) activity of a signaling pathway, are termed inverse agonists (Fig. 2). Compounds that bind to the GPCR but do not bias the distribution of active to inactive states are termed ► neutral antagonists.



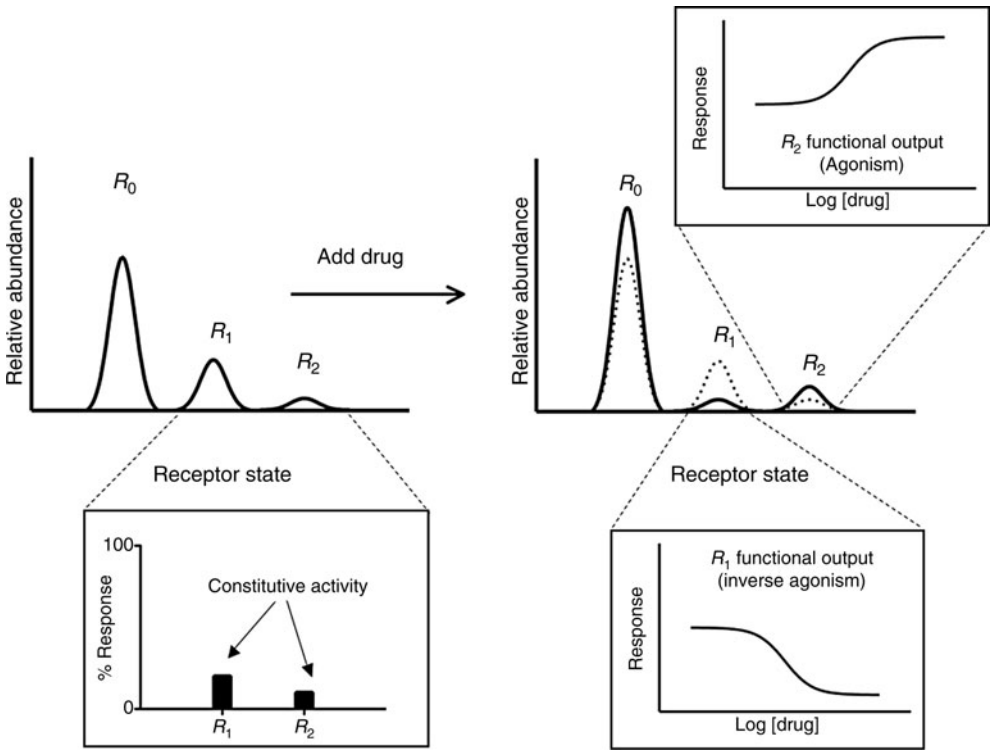
Inverse Agonists. Fig. 1. The three major families of mammalian G-protein-coupled receptors (GPCRs) with some representative examples of their endogenous agonists.

This chapter briefly considers the implications of these ligand behaviors for drug action and therapeutics.

Cellular and Molecular Basis of Constitutive Activity and Inverse Agonism

The term "inverse agonist" was first used to describe the actions of certain compounds, such as the β-carbolines, at the ionotropic $GABA_A$ receptors, where it was observed that the compounds not only antagonized the actions of ► benzodiazepines at the receptor, but also appeared to evoke an effect opposite to that of the benzodiazepine in the absence of the latter (Costa and Cotecchia 2005). However, given that the mechanism of action of benzodiazepines is to act as positive ► allosteric modulator of the endogenous agonist, ► GABA, rather than as true agonists in their own right, compounds such the β-carbolines are more appropriately classed as "negative allosteric modulators" rather than true inverse agonists; the reversal of "basal" activity in this instance reflects allosteric antagonism of the endogenous agonist. This is an important pharmacological consideration that extends beyond the specific $GABA_A$ example. Namely, the in vivo effects of drugs that reduce basal activity may reflect the true inverse agonism of a constitutively active receptor, or they may reflect the antagonism of an endogenously released agonist of that receptor.

Given that the unambiguous demonstration of inverse agonism requires the experimental observation that the effect is not due to antagonism of an endogenous agonist, most observations and assays of inverse agonist behavior are routinely made using a variety of cell-based in vitro bioassays. It was in this context that the earliest report of true inverse agonism occurring at a GPCR was presented by Costa and Herz, who demonstrated the constitutive activation of guanosine triphosphatase (GTPase) activity by the δ-► opioids receptor expressed natively in NG108-15 cell membranes and its reversal by compounds that were previously classed as simple opioid receptor antagonists (Bond et al. 2000). Moreover, that same study was the first to differentiate antagonists on the basis of the ability to inhibit constitutive activity (inverse agonists) from the ability of not perturbing constitutive activity but still antagonizing the actions of both agonists and inverse agonists (i.e., act as neutral antagonists). Since the initial report of constitutive GPCR activity and inverse agonism, there has been an explosion in the number of ligands identified to express this type of pharmacology (Bond et al. 2000), including compounds acting at prototypical Family A neurotransmitter receptors, such as the adrenoceptors (α_1, α_2, and β_2), ► muscarinic receptor (M_1, M_2, M_3, and M_5), histamine H_2 receptors, serotonin receptors ($5\text{-}HT_{1A}$, $5\text{-}HT_{2A}$, $5\text{-}HT_{2C}$, $5\text{-}HT_4$, $5\text{-}HT_6$, and



Inverse Agonists. Fig. 2. Agonism and inverse agonism arising due to ligand-induced redistribution of multiple receptor conformational states. The figure shows the distribution of three theoretical receptor states: R_0 inactive; R_1 active conformation that induces functional output 1; R_2 active conformation that induces functional output 2. In the absence of ligand (left side), most of the receptors exist in an inactive state, but some constitutive activity may be detected. In the presence of ligand (right side), the conformations of the receptor change such that the behavior of the system is altered; in this example, the abundance of receptors in the R_1 is reduced, and thus the ligand would be classified as an inverse agonist in an assay measuring functional output 1. However, the R_2 state is increased by ligand, and so an assay of functional output 2 would classify the ligand as an agonist.

5-HT_7), and dopamine receptors (D_2, D_3, and D_5), as well as Family B and C GPCRs, such as the vasoactive intestinal peptide (Kenakin 2004) and metabotropic glutamate (Bond and Ijzerman 2006) receptors. Importantly, a number of established or potential ▶ antipsychotics, ▶ antidepressants, and other psychopharmacological drugs have inverse agonist activity at such targets, e.g., serotonin, dopamine, histamine, opioid, cannabinoid, and muscarinic receptor subtypes (Bond and Ijzerman 2006). As mentioned earlier, GPCRs are highly dynamic proteins, and their ability to fluctuate between various conformational states is a natural property common to most proteins governed at the molecular level by random thermal fluctuations in the energy of the protein in its microenvironment. Physiologically, however, organisms have evolved to keep most constitutive receptor activation at relatively low levels; it would be metabolically wasteful to maintain a permanent state of cellular activation, in addition to reducing the dynamic response range available for signal transduction. For GPCRs, this is generally governed by key microdomains of the receptors that have evolved to minimize the spontaneous isomerization of the proteins into active conformations (Pontier et al. 2008). Thus, at any point in time, only a small fraction of a given population of GPCRs will be in a ligand-independent active state (Fig. 2). An important question, thus, is under what conditions is constitutive activation of a GPCR appreciable such that inverse agonist activity of various ligands is readily detected? Perhaps, a more important consideration is under what circumstances does the phenomenon become therapeutically relevant?

Overexpression of GPCRs Can Result in Detectable Constitutive Activity

If only a small fraction of the total population of a GPCR is constitutively active in a given cellular background, then a common mechanism by which such activity can be regulated is by the control of the total amount of the receptor. Indeed, the overexpression of various wild-type GPCRs in ►recombinant cell line represents one of the most common strategies for amplifying low levels of constitutive receptor activation to a degree that is readily detected in many cell-signaling assays. Overexpression of GPCRs has thus been instrumental in the detection of constitutive activity in both native tissues and recombinant cell lines (Milligan 2003). Furthermore, the use of receptor overexpression systems permits the study of constitutive activity of most GPCRs, and it is largely for this reason that the surge of inverse agonist reports in the literature coincides with the rise of the molecular biology era of the 1980s onwards; as is often the case, it is not the biological phenomenon that is new but, rather, it is the new technologies that facilitate the detection of the phenomenon. This can also explain why, in the past, compounds were more simply classified as either agonists or antagonists – in the presence of low levels of constitutive activity, or in a bioassay that did not have the sensitivity to detect such activity, an inverse agonist would appear indistinguishable from a neutral antagonist.

Constitutively Active Receptor Mutants in (Patho) Physiology

Another common means of engendering constitutive activity in a GPCR is through the introduction of mutations that reduce the energy barrier for transition of the protein between inactive and active states. There are a number of key regions of GPCRs, such as the bottom of transmembrane domains 3 and 6 as well as parts of the intracellular loops, that are well known to govern receptor isomerization into an active state. Hence, in addition to overexpression, mutational strategies that target these key activation regions to engender constitutive GPCR activity are another mainstay of studies that have identified inverse agonist actions of ligands previously classified as simple antagonists. A common criticism of such studies is that, in many instances, the mutations that are introduced to make a receptor constitutively active are not naturally occurring and it is thus possible that the pharmacology described for various ligands at these mutant receptors in artificial systems will not be predictive of their behavior in a more physiological environment. However, even overexpression studies of wild-type receptors in recombinant cell lines can be criticized as not necessarily being physiologically predictive.

In addition to the intracellular domains of GPCRs as key activation regions, more recent studies have identified hitherto unappreciated roles of the extracellular loops of some GPCRs in controlling receptor activation, both in the absence and presence of ligand. For instance, the receptors for sphingolipids, melanocortin, and cannabinoids lack a pair of key disulfide bond-forming cysteine residues in the extracellular loops, which are conserved across many other Family A GPCRs; it has been hypothesized that the lack of these cysteines leads to a reduction in ground-state receptor stability and, therefore, may explain the notably high constitutive activity of these receptors (Milligan 2003). This latter situation is an example of a naturally occurring structural feature of some GPCRs that may predispose them to high levels of constitutive activation in a physiological setting.

Another means by which GPCRs can display robust constitutive activity in the absence of overexpression is as a result of ►polymorphism or ►splice variant (Bond and Ijzerman 2006). Three interesting examples of the latter include the serotonin 5-HT_{2C} receptor, the histamine H_3 receptor, and the β_1-adrenoceptor. The serotonin 5-HT_{2C} receptor achieves this as a consequence of RNA editing. This is a process of posttranscriptional modification of the receptor's mRNA transcript, which results in changes in the second intracellular loop at amino acid positions 156, 158, and 160. In the nonedited 5-HT_{2C} receptor, these positions correspond to isoleucine, asparagine, and isoleucine, respectively, and predispose the receptor to exhibiting very high constitutive activity. Depending on the degree of RNA editing, the amount of constitutive activity observed is markedly decreased, with the fully edited 5-HT_{2C} receptor isoform containing valine, glycine, and valine in the same intracellular loop 2 positions and displaying virtually no constitutive activity (Bond and Ijzerman 2006). The histamine H_3 receptor undergoes alternative splicing to generate many isoforms, two of which have a propensity to display high levels of constitutive activity. The β_1-adrenoceptor is associated with a number of single nucleotide polymorphisms, one of which (S49G) has been identified in patients with cardiac failure and is characterized by high constitutive activation (Bond and Ijzerman 2006). Collectively, these observations suggest that the inherently labile nature of some GPCRs that allows them to readily adopt a ligand-independent active state may have either physiological and/or pathophysiological relevance.

There are also naturally occurring mutations in some GPCRs that yield constitutive receptor activation and

have been linked to congenital diseases. These include constitutively active mutants of the thyrotropin receptor, which was found to be the cause of hyperfunctioning thyroid adenoma, the luteinizing-hormone receptor, which leads to inappropriate testosterone release and early onset male precocious puberty, the parathyroid hormone receptor, leading to Jansen-type metaphyseal chondrodysplasia, and the rhodopsin receptor, which leads to the development of retinitis pigmentosa (Bond et al. 2000).

Endogenous Inverse Agonists

Some GPCRs utilize endogenous inverse agonists as important regulators of their function. A primary example is the endogenous ligand for rhodopsin, 11-*cis*-retinal, which in the resting state exists covalently bound to the receptor to ensure that it stays in an inactive state; it is only when exposed to light that the ligand isomerizes to all-*trans*-retinal and allows signal transduction (and hence the perception of vision) to proceed. Without this tight inverse agonist-mediated mode of regulation, even slight constitutive activation of rhodopsin would be calamitous for the fidelity of signaling required to ensure appropriate vision. Another example is the peptides, agouti and ► agouti-related peptide (AgRP), both endogenous inverse agonists of the melanocortin MC1 (agouti) and MC4 (AgRP) GPCRs (Bond et al. 2000; Costa and Cotecchia 2005). The MC1 receptor plays an important role in melanin production and the control of pigmentation (Milligan 2003), whereas the MC4 receptor is a key mediator of feeding behaviors and body weight regulation. Although it is not clear why these particular systems require tonic input from both endogenous agonists and inverse agonists, their existence implies a need for very tight regulation.

In a pathophysiological setting, the Kaposi's sarcoma-associated herpes virus encodes a constitutively active chemokine GPCR, ORF-74, as part of its viral replication mechanism. The very high constitutive activity of this virally encoded GPCR promotes cell proliferation to achieve increased viral replication. Interestingly, the endogenous chemokine *agonist* of the interleukin-8 receptor (the mammalian homolog of ORF-74), stromal cell-derived factor-1, acts as an *inverse agonist* at ORF-74 (Bond et al. 2000). In addition to its therapeutic implications, the finding that the same ligand can act as an agonist of one GPCR and an inverse agonist at another GPCR highlights the multidimensional nature of ligand efficacy, and the fact that the cellular assay system can have a profound effect on the classification of ligand pharmacology.

Inverse Agonists or Neutral Antagonists: Clinically, Which Is Better?

The majority of current therapeutic agents on the market are clinically utilized as antagonists. With respect to GPCRs, it has been estimated that approximately 85% of ligands classified as antagonists are actually inverse agonists (Kenakin 2004), assuming the endogenous receptor is constitutively active (which may well depend on tissue expression and/or disease). This finding has both theoretical and practical implications. On theoretical grounds, it is to be expected that most ligands will possess some degree of efficacy, either in a positive direction (agonists) or negative direction (inverse agonists). According to current models of ligand–receptor interaction, the act of binding to a GPCR will bias its conformations such that its properties in the presence of ligand are unlikely to be coincident with its properties in the absence of ligand. Thus, neutral antagonists, which in theory should display similar affinities for all GPCR states such that they do not perturb the conformational equilibrium on binding, should not represent a substantial proportion of the chemical space encompassing GPCR-recognizing compounds. Table 1 shows a representative sample of inverse agonists currently on the market, most of which were believed to be neutral antagonists at the time of their release.

At a practical level, the abundance of inverse agonists relative to neutral antagonists raises the question as to which type of ligand is preferred as a therapeutic agent for disorders where receptor antagonism is a desired endpoint. At this point in time, the question remains to be adequately addressed. Certainly, for diseases where the cause is directly attributable to a constitutively active GPCR, such as some of the congenital disorders described above, it can be reasoned that an inverse agonist would be preferable to a neutral antagonist. However, these disorders are relatively rare, and both types of agents (inverse or neutral) would still effectively antagonize the endogenous agonist for the target receptors. Nonetheless, recent studies in heart failure and asthma models (see below) suggest that the balance may indeed be in favor of inverse agonists (neutral antagonists are apparently devoid of effect). With respect to neuropsychiatric disorders, it is of particular note that the 5-HT_{2C} receptor has various levels of constitutive activity depending on the degree of RNA editing (as outlined above). Consequently, it is conceivable that in certain disease states, such as ► depression, the level of constitutive activity of the receptor may increase significantly, suggesting that inverse agonism may be a treatment of choice rather than neutral antagonism. This is currently largely speculative, as it remains to

Inverse Agonists. Table 1. Examples of therapeutics with inverse agonist activity and their receptor targets. (Adapted from Bond and Ijzerman 2006.)

Receptor target	Example drug(s)	Disorder
α_1-Adrenoceptor	Prazosin, terazosin	Hypertension
β_1-Adrenoceptor	Metoprolol, carvedilol, bisoprolol	Heart failure
Muscarininc M_1	Pirenzipine	Gastric ulcers
Muscarinic M_3	Darifenacin, tolterodine	Bladder dysfunction
Histamine H_1	Cetirizine, loratadine	Allergy
Histamine H_2	Cimetidine, ranitidine, famotidine	Duodenal and gastric ulcers
Angiotensin AT_1	Candesartan, irbesartan	Hypertension, heart failure
Oxytocin OT	Atosiban	Preterm labor
Cysteinyl leukotriene $CysLT_1$	Montelukast, zafirlukast	Asthma
Cannabinoid CB_1	Rimonabant	Obesity, smoking cessation
Histamine H_3/Serotonin 5-HT_2	Mianserin	Depression
Serotonin 5-HT_2/Dopamine D_2	Risperidone	Psychosis
Dopamine/Serotonin	Chlorpromazine	Psychosis
μ-Opioid	Naloxone	Drug overdose
α_2-Adrenergic/Serotonin 5-HT_2	Mirtazapine	Depression
Dopamine D_2	Haloperidol, clozapine	Schizophrenia

be established that 5-HT_{2C} receptor modulation is clinically relevant, although animal data may suggest so.

It is possible that further insight into clinical differences between inverse agonists and neutral antagonists may currently be gleaned not from the acute effects of these compounds, but rather from their long-term effects; this is particularly pertinent given that most drug therapies require chronic administration. Specifically, GPCRs are subject to dynamic, postsignaling regulatory mechanisms, such as desensitization, phosphorylation, internalization, and downregulation, and drugs can differentially modulate these processes. As occurs with most receptors on long-term exposure to agonists, constitutively active receptors are nearly always downregulated. It may thus be anticipated that prolonged exposure to inverse agonists will have the opposite effect, i.e., an upregulation in GPCR number or function over time. This has indeed been shown to be the case for many (but not all) GPCRs (Bond et al. 2000). Consequently, the upregulation of the receptor mediated by an inverse agonist may produce unwanted side-effects during treatment or postwithdrawal. For example, inverse agonist-mediated upregulation of the histamine H_2 receptor has been proposed as a mechanism for patients developing tolerance to antiulcer drugs such as cimetidine and ranitidine, as well as rebound effects on cessation of their therapy (Bond and Ijzerman 2006). A similar mechanism has been proposed for adverse events associated with withdrawal from antipsychotic medications, including ► clozapine (Moncrieff 2006). Unfortunately, this mechanism may also cross over to produce off-target or -tissue side-effects. At least two cases have been reported of patients who were treated with the dopamine receptor inverse agonist, metoclopramide, for abdominal discomfort, vomiting, and nausea, but who subsequently experienced psychotic episodes on cessation of treatment.

On a positive note, long-term adaptive changes in system responsiveness that are promoted by inverse agonists may also be linked to improved therapeutic outcomes. Recent large-scale placebo-controlled clinical trials of patients being chronically treated with ► β-adrenoceptor blockers for heart failure have demonstrated significant decreases in morbidity and mortality for the inverse agonists, carvedilol, metoprolol, and bisoprolol, but not the neutral antagonist, bucindolol (Parra and Bond 2007). A similar hypothesis has now been proposed as a putative chronic treatment for asthma (Parra and Bond 2007). In each instance, the acute effects of the inverse agonist would be anticipated to initially worsen the symptoms of the disorder, but chronic compensatory mechanisms may eventually lead to improved and potentially sustained clinical outcomes. This is currently a controversial area of

research, but one that definitely warrants further study given that many other types of established therapeutic agents have inverse agonist properties; it is remarkable, for instance, that a number of clinically used antipsychotics acting at either dopamine D_2 and/or serotonin 5-$HT_{2A/2C}$ receptors have inverse agonist effects.

Extending the Paradigm: The "Pluridimensional" Nature of Drug Efficacy

The discovery and acceptance of inverse agonism as a widespread phenomenon in the mode of action of many drugs has led to additional studies on the molecular nature of drug efficacy and its manifestations. There are now numerous examples where the same ligand, acting at the same receptor, can display totally different degrees of efficacy, ranging from positive to inverse, depending on the cellular background and/or the signal pathway being measured. For example, ► propranolol is an inverse agonist for the cAMP accumulation pathway linked to the β_2-adrenoceptor, but an agonist for the phosphorylation of extracellular signal-regulated kinases 1/2 (ERK1/2) mediated by the same receptor; proxyfan, a histamine H_3 receptor ligand, is a partial agonist for both ERK1/2 and cAMP signaling, but an inverse agonist for arachidonic acid release (Galandrin et al. 2007). These types of observations are becoming increasingly prevalent and indicate that the classification of a ligand's efficacy depends on one's signaling vantage point (Fig. 2). Furthermore, they also indicate that ligand efficacy is not "linear" in the sense that receptor occupancy and stimulus generation by a given ligand does not necessarily trigger all possible receptor behaviors in a sequential (linked) fashion. This nonlinear view of drug efficacy has been associated with a variety of terms, including "protean agonism," "biased agonism," "collateral efficacy," "stimulus-trafficking," and "functional selectivity" (Urban et al. 2007). The potential for terminological confusion notwithstanding, these recent discoveries highlight the fact that ligands can have a plethora of effects at the cellular level but that, in many instances, there is no proven relationship between the magnitude and direction of ligand efficacy at a given cellular pathway and clinical outcome. This means that when screening for new drugs, multiple assay formats are required to capture as many potential ligand behaviors as possible. In addition, more studies are clearly warranted to correlate clinical efficacy with cellular efficacy(ies).

Concluding Comments

Within the last two decades, the concepts of constitutive receptor activity and inverse agonism have gone from being pharmacological curiosities to accepted paradigms in drug and receptor behavior. Constitutively active receptors are now used routinely in drug discovery research in order to classify potential hits in terms of their possible spectrum of efficacies. Moreover, most compounds that have previously been classed as (neutral) antagonists are very likely to be inverse agonists. However, the clinical relevance of inverse agonists remains largely unknown. The challenge now is to be able to better correlate improved mechanistic understanding of the pluridimensional nature of drug efficacy with improved clinical outcomes.

Inverse Problem

Definition

The inverse problem refers to an underdetermined problem that researchers encounter when trying to identify the locus or loci of neural activity that give rise to a particular ERP scalp distribution. The problem is that there is, in principle, an infinite number of possible source configurations that can produce any given scalp distribution. Therefore, additional assumptions and information about the brain are needed to arrive at a unique solution.

Irreversible Trapping

Definition

A pharmacokinetic model used in PET imaging in which a radiotracer partially follows the metabolic pathway of an endogenous compound but stops or undergoes much slower metabolism than the endogenous compound at a certain point in the process. The radiolabel (it is no longer attached to the original tracer at this point, but rather, to one of its metabolic byproducts) is considered trapped at this stage, and the model is used to estimate the rate of the metabolism of the endogenous compound up to this point.

Isocarboxazid

Synonyms

Marplan

Definition

Isocarboxazid is a nonselective and irreversible monoamine oxidase inhibitor (MAOI) with a hydrazine chemical structure. It acts by inactivating the enzyme monoamine oxidase, which is involved in the catabolism of several key neurotransmitters, including norepinephrine, serotonin, and dopamine. Its primary use is in the treatment of ► depression, but it is also used for treating ► panic disorder. Because of the potential for serious toxicity common to all nonselective, irreversible MAOIs, isocarboxazid is reserved for treating patients who have proven refractory to other antidepressants. Isocarboxazid may cause mild dry mouth and sexual dysfunction; more troublesome side effects may result from orthostatic hypotension, including dizziness and syncope. Like other MAOIs, isocarboxazid may interact with foods containing tyramine and with certain catecholaminergic drugs to result in a hypertensive crisis. Similarly, isocarboxazid and other nonselective, irreversible MAOIs can interact with serotonergic drugs and compounds to result in ► serotonin syndrome, characterized by hyperpyrexia, hyperreflexia, and myoclonus. Hypertensive crisis and serotonin syndrome, when severe, can be fatal without proper treatment.

ISOFORM

Synonyms

Splice variant

Definition

The term isoform, when discussing ► corticotrophin-releasing factor (CRF) receptors, refers to the alternative splicing of the CRF receptor mRNA, shortening the final amino acid sequence. The CRF_1 receptor has no known isoforms, while the CRF_2 receptor has three: CRF_{2A}, CRF_{2B}, and CRF_{2C}. These receptor isoforms have identical primary structure until the N-terminus, where they differ in their N-terminal domains. It is likely that they have identical secondary and tertiary structure in their transmembrane domain.

Ketamine is a ► dissociative anesthetic used in human and veterinary medicine. Its primary mechanism of

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

action is as a noncompetitive ► NMDA receptor antagonist. In humans, ketamine is mainly used as a general anesthetic, usually in combination with other compounds. However, it can also be used at sub-anesthetic doses as a sedative, analgesic, and bronchodilator although its dysphoric psychoactive side effects limit such use to emergency clinical situations only. These side effects include detachment, depersonalization, altered perception and thought processes, loss of normal time sense, ► hallucinations, and amnesia. Some of these side effects underlie ketamine's high-abuse potential and its recreational use of this drug (mainly intranasally but occasionally intravenously). In small doses, the experience is often pleasurable and many users report feelings of euphoria, whereas at larger doses unpleasant and uncontrollable effects emerge, including hallucinations and out-of-body experience labeled "passing through the K-hole." One of the main short-term problems associated with ketamine abuse is a potentially fatal interaction with depressant drugs such as alcohol, heroin, and barbiturates which, at higher doses, results in complete suppression of vital functions. It impairs cognition and its long-term abuse can lead to addiction as well as urinary tract problems.

Definition

Khat, derived from the plant *Catha edulis* Forsk, is a social stimulant drug whose effects are mainly due to cathinone, a psychoactive alkaloid also referred to as a "natural amphetamine" for its pharmacological profile.

Pharmacological Properties

Introduction

Khat is the transliteration of an Arabic word that indicates the leaves and shoots of *Catha edulis* Forsk, a small tree of the ► Celastraceae family endemic of the highlands of the Horn of Africa and Arabic peninsula. In these regions, recreational khat chewing for experiencing its psychostimulant effects is deeply rooted in the everyday life and recent efforts to control this use are facing strong resistance. Moreover, in the last three decades the khat habit has followed the stream of migration moving away from the countries where the plant is cultivated. Among the many alkaloids that have been isolated from khat, alpha-aminopropiophenone (cathinone) and (+)-norpseudoephedrine (cathine) are considered responsible for the psychostimulant effects of khat. Cathinone appears to be between seven and ten times more potent than cathine and accordingly, the commercial value of khat at markets has been found to relate to its actual cathinone content. Experienced chewers are aware that the fresher the leaves and shoots, the stronger the subjective effects to be expected. Indeed, cathinone is an unstable molecule, and apart from being converted to cathine during plant maturation, it also degrades during harvesting and drying processes. For this reason, khat leaves are usually wrapped up in banana leaves in order to preserve the freshness and buyers do not allow more than 2 or 3 days before consumption.

Mechanism of Action, Pharmacokinetics and Effects

Cathinone structure and mechanism of action resemble quite closely that of ► amphetamine. Indeed, cathinone increases ► dopamine, ► noradrenaline, and ► serotonin release from the postsynaptic terminals (Kalix and Braenden 1985). Additionally, it prevents neurotransmitters reuptake by inhibiting the relative transporters, as observed in the striatum of drug-treated rats (Fleckenstein et al. 1999). In vivo ► microdialysis studies showing an increase in striatal dopamine metabolites are coherent with these actions.

The ► pharmacokinetic profile of khat emerged in detail when typical "khat sessions" were arranged in an experimental setting, where subjects chewed the leaves enabling active principles to be gradually released and absorbed by the buccal and gastrointestinal mucosa. Results showed that cathinone plasma concentration, which reaches its peak at about 1.5–3.5 h from the start of the sessions, declines over nearly 7 h from ingestion, being metabolized to norephedrine and cathine (Widler et al. 1994). Cathine shows a slower clearance,

contributing to the extension of the overall effects of khat ingestion and to the prolonging of analytical evidence of this ingestion.

The effects induced by chewing khat are typically amphetamine-like. Euphoria, elation, logorrhea (excessive and often incoherent talking), and increased feelings of alertness are experienced, usually in a milder form with respect to amphetamines. This is intrinsic to the modality of consumption, which usually requires hours to allow subjective effects to gradually build up and be perceived by the chewer. Khat-induced "arousal" facilitates interpersonal relations in a convivial setting, as subjects, enhanced in mood and loquacity, feel confident to engage in animated discussions, although their attentional abilities may be negatively affected. Reduced fatigue, insomnia, anorexia, and increased libido are also often reported. Sympathetic stimulation determines an increase in body temperature, mean arterial pressure, and heart and respiratory rates (Nencini et al. 1984), though a certain degree of ▶ tolerance typically develops in habitual consumers.

Stimulation of the central nervous system may also lead to mood disturbances and irritability, especially at the end of a khat session, but dysphoric responses during consumption are not infrequent, and may be due to an inappropriate setting interfering with the experience of mood elevation.

Dependence

As an amphetamine-like stimulant, the addiction potential of khat has been a matter of debate among the expert committees questioned by national authorities on the effective risk for public health and social functioning caused by khat chewing. Indeed, similar to amphetamine, khat users may experience craving, as shown by the buyers' behavior at markets, and a certain degree of tolerance to the neurovegetative and endocrine effects seems to develop (Nencini et al. 1984). Drowsiness and ▶ dysphoria experienced the morning after the session may be considered the expression either of hangover or of mild ▶ withdrawal syndrome. Nevertheless, a proper withdrawal syndrome has not been described yet, although interrupting prolonged use may result in mild depression, anergia, and sleep disturbances. Animal studies have been of great help in elucidating khat's behavioral pharmacology inherent to addiction in comparison with other stimulant substances. Animal models of ▶ self-administration of psychoactive drugs have been proved to be highly reliable in predicting human abuse when exposed to the same drug. As expected, cathinone, similar to amphetamine but two to four times weaker, maintains self-administration in a variety of species (Johanson and Schuster 1981), thus demonstrating considerable reinforcing properties. Moreover, its properties in ▶ drug discrimination experiments, which determine the emission of specific behavioral responses only in the presence of the drug, generalize to amphetamine and ▶ cocaine. Pharmacological studies with dopamine antagonists have pointed out the major role of dopaminergic neurotransmission in mediating these effects, a common thread among psychostimulants that exert positive reinforcing effects. Given the tight qualitative similarity between khat's most active alkaloid and amphetamines, it may seem odd that only a few cases of ▶ dependence have been reported. This, however, should not come as a surprise, since the addictive potential of a drug is usually related to the rapidity of onset of action and ultimately to the route of administration. Hence, since khat intake by chewing is intrinsically limited by the bulkiness of the plant material and 2–3 h are required to reach maximal plasma levels, in the natural setting the reinforcing properties of the drug are weaker compared to amphetamine or cocaine; thus, it is improbable that dependence develops to the same extent and severity. This is perhaps the reason why habitual users usually do not show serious problems when stopping use.

Psychiatric Adverse Effects

Repeated exposure of rodents to khat extract or to cathinone causes a variety of behavioral effects that model psychotic disturbances. It is important to note that experimental results may differ when using khat extracts instead of cathinone, since standardized bioavailability of the extract cannot be easily obtained. With this caveat in mind, parenteral administration of cathinone in rats and mice determines an increase in locomotor activity and stereotyped movements, which are considered indexes of a psychomotor stimulant effect, although not as potent than that of amphetamine (Kalix and Braenden 1985). A dose-related increase in locomotor activity in rats was also seen after bilateral microinjections of cathinone directly into the brain's ▶ *nucleus accumbens*, again consistent with the hypothesis of a dopaminergic mediated phenomenon. Other paradigms have pointed out khat's potential for inducing strong and long-lasting behavioral ▶ sensitization (Banjaw and Schmidt 2005), since its repeated administration caused an augmented number of rearings and upward and downward sniffing, which persisted after discontinuation of treatment. Behavioral sensitization to psychostimulants models many aspects of the development of toxic psychosis in human addicts. Recently, khat extract and cathinone have been found to cause a deficit in ▶ prepulse inhibition (PPI), which is also disrupted in schizophrenic patients and thus serves as a model of sensorimotor gating for the study of psychotic disorders. The deficit develops

gradually after repeated administration and is attenuated by the atypical antipsychotic ► clozapine. Another experimental behavior elicited by cathinone that is strongly linked to human psychosis is the excessive water consumption observed in rats after repeated administration (Graziani et al. 2008). In fact, it may model psychotic polydipsia, a potentially fatal complication of ► schizophrenia. The hyperdipsic effect in conditions of free access is common to other dopaminergic drugs, such as amphetamine and quinpirole. Interestingly, cathine does not induce per se excessive water consumption in rats, but can reinstate the polydipsic response to amphetamine.

The psychotic potential of khat is partially confirmed by several reports of onset of paranoid psychosis in khat users. Manic-like psychosis and persistent ► hypnagogic hallucinations have also been described in human literature. These adverse psychiatric sequelae, however, are thought to be mainly correlated with both traumatic experiences, such as combat, and severity of khat use, in terms of daily intake and early onset of heavy use (Odenwald et al. 2005). A large survey among Yemeni adults has excluded any correlation between khat chewing and psychopathological alterations (Numan 2004). Although the causality between the two variables remains difficult to ascertain and would benefit from further and better-designed investigations, there have been growing reports of khat-induced psychosis in immigrants residing in Europe and USA. The estrangement of the immigrant condition and the lack of social support once the use is dislocated from their native culture might create a setting that favors the risk of experiencing the negative effects of the drug in vulnerable subjects.

Experimental and Clinical Toxicology

Studies on acute and chronic toxicity of khat on organs and functions have often led to contrasting or even misleading results. Potential toxic effects on organs have been experimentally reported, but modalities and doses of administration reflect an unrealistically heavy daily consumption. A negative impact on reproduction has been documented, both in mice (fertility reduction and postimplantation loss) and humans (higher incidence of low birth weight in regular female khat chewers). Cathinone, as well as cathine-induced vasoconstriction in the placenta may account for these detrimental effects. In males, data on the effects of khat on testosterone plasmatic levels and ► capacitation function of spermatozoa are far from being clear and vary with the species in exam.

A mutagenic and ► teratogenic effect of khat was evidenced in rats and cellular lines, suggesting that the drug may induce chromosomal aberrations and a selective type of cell death similar to ► apoptosis. However, teratogenic effects in pregnant women have never been reported.

Along with mood and psychotic disorders, oral lesions and adverse cardiovascular events are thought to represent the major concerns in terms of public health. In the buccal cavity, irritant and proinflammatory action of terpenoids and tannins released from khat leaves may be responsible for the onset of chronic inflammatory processes and ► keratotic lesions. Although evidence are once again contradictory, khat consumption, especially when associated with ► alcohol and tobacco use, might be a potential cause of oral leukoplakia and malignant lesions, as suggested by the micronucleus test for genetic damage in buccal mucosa cells of consumers. The already mentioned sympathetic activation caused by chewing khat is unequivocally involved in the genesis of cardiovascular accidents. Cathinone acts as a competitive antagonist of the noradrenaline transporter, increasing monoamine action on the cardiac ventricles of rats. Several case reports and an epidemiological study showing a 39-fold increase of risk of acute myocardial infarction in heavy khat chewers seem to remove all doubts on this topic (Al-Motarreb et al. 2005).

Socioeconomic Considerations

The spreading of the habit of chewing khat has roused a political debate in those countries where the plant is cultivated and deeply rooted in the everyday life. The number of habitual consumers is growing rapidly, mostly in Yemen: children under the age of 12 and especially women, who refrained from using in the past mostly because it was considered a male habit, are additional to the 90% of the adult male population already consuming daily. Apart from the detrimental health consequences, khat is pointed out by its detractors as one of the leading causes of family disintegration and increasing the economic burden in home countries. When commenting adversely, one should nevertheless consider the profound negative impact on the local culture of a hypothetical ban. In fact, immigrants have kept alive the tradition of chewing in Europe and USA, confirming khat as tightly bonded to their former social culture and thus an expression of identity.

Although the active alkaloids of the plant, cathinone and cathine, have been labeled Schedule I and Schedule III substances respectively by WHO since 1988, the legal status of khat in western countries is not uniform. At the moment, it is prohibited in Finland, France, Ireland, Italy, Norway, Sweden, Switzerland, and also in the USA if it contains cathinone or cathine, but legal in the Netherlands and in the UK. In several countries of Africa khat is

considered legal. Recently, the WHO committee, revising the international literature, has judged the potential for abuse and the threat to public health of khat as not significant and not requiring any scheduling (WHO 2006).

K-Hole

Definition

The term "K-hole" is a slang term for a state of dissociation occurring when large doses of ► ketamine are ingested. These effects, which mimic the schizophenic symptoms, result in the user feeling trapped in a state in which they may feel detached from their bodies and unable to move. Other symptoms include distortion of the senses, particularly vision, result in disorientation, and can cause nausea and vomiting. Distortions in bodily awareness, perceptions of falling and flying, and intense hallucinations may also be experienced. The combination of these effects leave the user feeling trapped in a frozen state, as if stuck in a hole peering out.

Protein kinase inhibitors

Definition

Protein kinases, one of the largest human gene families, play a key regulatory role in cell functioning. The common feature of all protein kinases is to function as a catalyst in the transfer of the terminal phosphoryl group of ATP, covalently attaching it to a free hydroxyl group of their protein substrates' amino acids – tyrosine (tyrosine kinases), or serine or threonine (serine/threonine kinases). A number of kinases can also act on all three amino acids (dual-specificity kinases). Based on sequential and structural similarities, approximately 518 protein kinases encoded in the human genome could be classified into seven major groups (further divided into families and subfamilies): tyrosine kinase (TK); tyrosine kinase-like (TKL); cyclin-dependent kinases (CDK), mitogen-activated protein kinases (MAPK), glycogen synthase kinase 3 (GSK-3), and CLK (CMGC); homologs of Sterile 7, Sterile 11, and Sterile 20 kinases (STE); casein kinase 1 (CK1); protein kinase A (PKA), protein kinase G (PKG), and protein kinase C (PKC (AGC)); calcium/calmodulin-dependent protein kinase (CAMK); and a group of unclassified and atypical protein kinases (Manning et al. 2002).

Protein phosphorylation is involved in a myriad of complex biological and physiological cellular processes, including receptor tyrosine kinases, second-messenger generators, ► signaling cascades participation, and kinases regulating cell life cycle. Thus, deregulation of kinase function has been associated with an equally diverse number of pathophysiological processes. These include immunological disorders (inflammatory and infectious disease), metabolic disorders, cancer, and central nervous system (CNS) diseases (including neurodegeneration-related disorders). Thus, protein kinase regulation (through activation or inhibition) presents as a logical molecular target for the treatment of these conditions.

Different types of inhibitors, as discussed below in more detail, can be classified based on their kinetic characteristics, including substrate-competitive inhibitors (inhibitors that directly compete with protein substrate binding), ATP-competitive inhibitors (inhibitors that directly interact with the ATP-binding site), activation inhibitors/allosteric modulators (allosteric inhibitors that primarily alter protein kinase conformation to block ATP binding), and irreversible inhibitors. However, despite the large body of knowledge currently available, protein kinase inhibition persists as a challenge for targeted drug development due to the structural similarity among kinases (and the inherent difficulties of selectively inhibiting them without affecting normal physiology), their functional redundancy for specific signaling, and the still unclear connections between these pathways and specific disease processes.

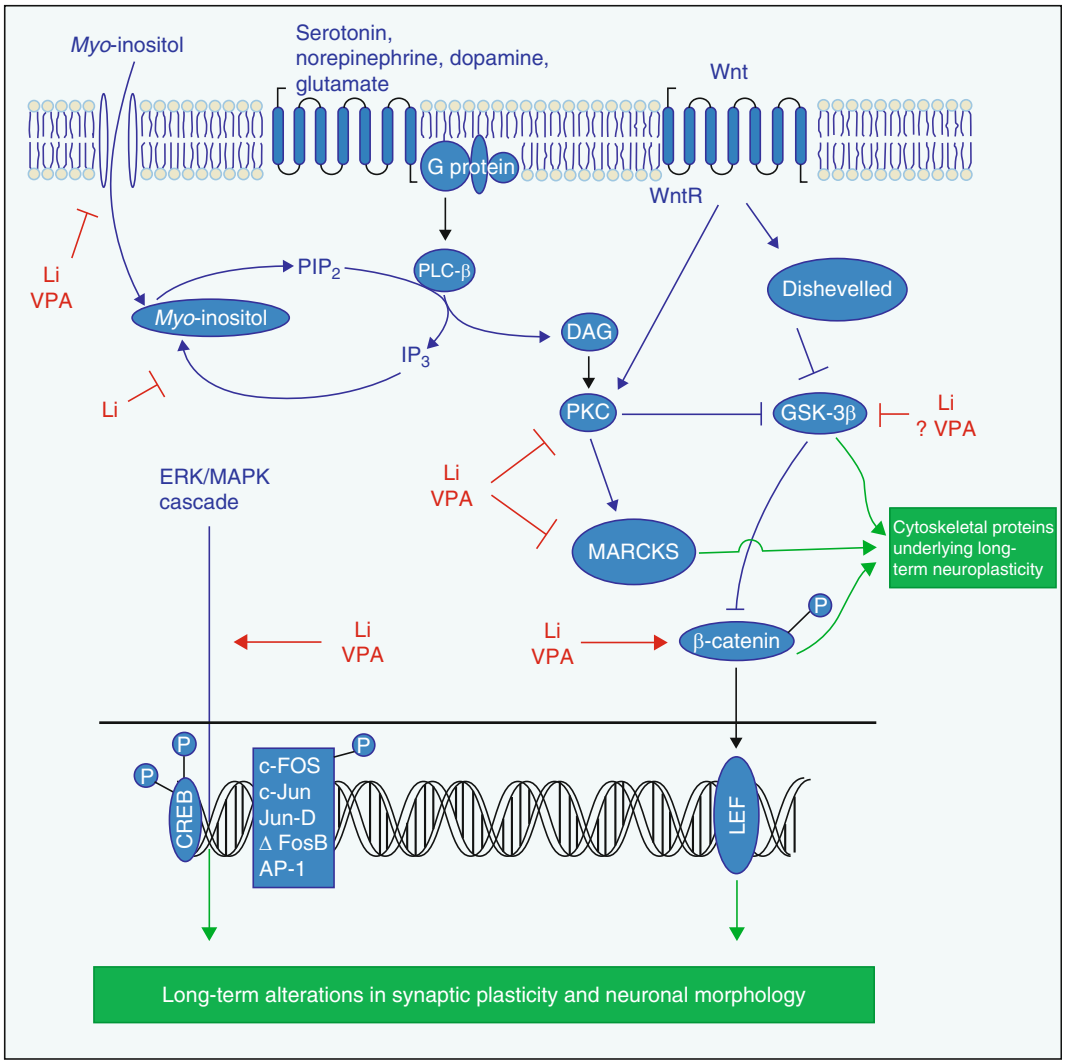
Pharmacological Properties

While discussing the potential strategies and particular issues regarding the targeting of kinases in the treatment of CNS disorders, we focus here on the protein kinase inhibition of two signaling molecules that represent targets for novel therapies for ► bipolar disorder: glycogen synthase-3 (GSK-3) and protein kinase C (PKC). Both have been identified as therapeutically relevant biochemical targets of currently available and effective medications, holding the possibility of mediating more refined and sophisticated treatment for this devastating illness.

Although many drugs that target kinase inhibition are in clinical development for various medical illnesses and even more are being investigated at the preclinical level, the use of modulators of ubiquitous kinases in the CNS still raises concerns of specificity, tolerability, and safety. However, the success of a number of kinase-targeted drugs in cancer treatment, including Gleevec (Imatinib, an inhibitor of tyrosine kinase BCR-Abl), Iressa (Gefitinib, an inhibitor of tyrosine kinase EGFR), and Herceptin (Trastuzumab, an antibody against tyrosine kinase receptor HER2), has initially proved the feasibility of such strategy. Modulators that target the brain are, for the most part, still in the preclinical stages of development. However, ► lithium, a mood stabilizer that targets signaling cascade molecules, including the inhibition of protein kinases as GSK-3, has been a mainstay of treatment for bipolar disorder for almost 60 years, provides a key example of a safe and effective modulator of signaling systems in the CNS. Tamoxifen, mainly an antiestrogen agent, is another regulator of CNS signaling molecules including PKC inhibition with an acceptable efficacy and safety profile. Both drugs modulate signaling pathways that are involved in diverse brain functions, and possibly other CNS disorders, demonstrating relatively circumscribed clinical effects. Thus, developing other CNS kinase-targeted drugs with adequate specificity and tolerability is possible, albeit challenging.

PKC Inhibition

PKC is a family of serine/threonine kinases that are involved in the transduction of signals for cell proliferation, differentiation, ► apoptosis, senescence, and angiogenesis. The family is comprised of at least 12 isoforms, which are subdivided into three classes (classical/conventional, novel, and atypical) on the basis of calcium- and diacylglycerol (DAG) dependence. PKC isoforms differ in structure, subcellular localization, tissue specificity, mode of activation, and substrate specificity. Activation of PKC results in its translocation, and subcellular localization is thought to regulate accessibility to activators and substrates. PKC is activated by such varied upstream signals as ► G protein-coupled receptors (GPCRs), receptor tyrosine kinases (RTKs), and nonRTKs via DAG activation (Fig. 1). Several PKC isoforms are independently activated by the phospholipase C (PLC) and phosphoinositide-3 kinase (PI3K) pathways. Of PKC's numerous substrates, a major target is the MEK–ERK pathway, also thought to be involved in the activation of Raf1 (Serova et al. 2006) (The Raf–MEK–ERK pathway is a signaling cascade – the first entirely mapped from the cell membrane with many substrates both in the cytosol and the nucleus). PKC has been identified as a potential target for the treatment of a number of medical diseases, including diabetes, cancer, and ► bipolar disorder. With respect to its potential role in bipolar disorder, it is significant that lithium and valproate bring about strikingly similar effects on the PKC signaling cascade (Manji and Lenox 1999), as discussed below.



Kinase Inhibitors. Fig. 1. Intracellular signaling cascades involved in the long-term stabilization of mood by lithium (Li) and valproic acid (VPA). Activation of receptors coupled to PI hydrolysis results in the breakdown of phosphoinositide 4,5-biphosphate (PIP_2) into two second messengers: IP_3 and diacylglycerol (DAG), which is an endogenous activator of PKC. Lithium is an uncompetitive inhibitor of inositol monophosphatases, whereas both lithium and VPA, upon chronic administration, decrease *myo*-inositol uptake. These perturbations by mood stabilizers likely contribute to the reduction in PKC activity and the reduced levels of PKC-α, PKC-ε, and myristoylated alanine-rich C kinase substrate (MARCKS), a major PKC substrate in the CNS (MARCKS proteins play important roles in multiple cell functions, including cell architecture, cell cycle, and exocytosis, and are regulated by Ca^{2+}/calmodulin and PKC.) In the Wnt signaling pathway, binding of the Wnt signal to the Wnt receptor (WntR) activates an intermediary protein, Disheveled, which regulates GSK-3β. GSK-3β regulates cytoskeletal proteins, and also has an important role in determining cell survival and cell death. Lithium (and possibly VPA) directly inhibits GSK-3β, which may underlie, at least in part, the increases in β-catenin that occur after chronic treatment with these agents. The ERK MAP kinase cascade regulates several important transcription factors, most notably CREB and activator protein-1 (AP-1) (AP-1 is a transcription factor that regulates gene expression in response to diverse stimuli.) Recent studies have demonstrated that both lithium and VPA activate the ERK MAP kinase cascade, which may contribute to the long-term changes in synaptic plasticity and morphology that follow chronic treatment. Together, regulation of these signaling pathways through selective kinase inhibition might bring about an enhancement of synaptic connectivity, potentially necessary for long-term stabilization of mood. Preclinical and Clinical Evidence of the Role of PKC Inhibition in the Pathophysiology and Treatment of Bipolar Disorder

Evidence from numerous studies using widely varying methodologies implicates PKC in the pathophysiology and treatment of ► bipolar disorder. These include peripheral blood cell studies that have showed altered PKC isozyme levels and activity in bipolar subjects, and postmortem studies similarly demonstrate altered PKC levels and activity in subjects with bipolar disorder. Importantly, lithium and ► valproate – two efficacious medications with mood-stabilizer properties, widely utilized in the treatment of bipolar disorder – decrease PKC levels in an isozyme-specific manner and decrease PKC activity. Lithium interacts with the PI/PKC pathway via the inhibition of inositol mono-phosphatase (IMPase), resulting in decreased free myo-inositol and the subsequent production of DAG, with the downstream effect of decreasing PKC levels and activity. Valproate – structurally dissimilar from lithium – also appears to inhibit PKC, suggesting that this inhibition is important to the common therapeutic effects of both medications.

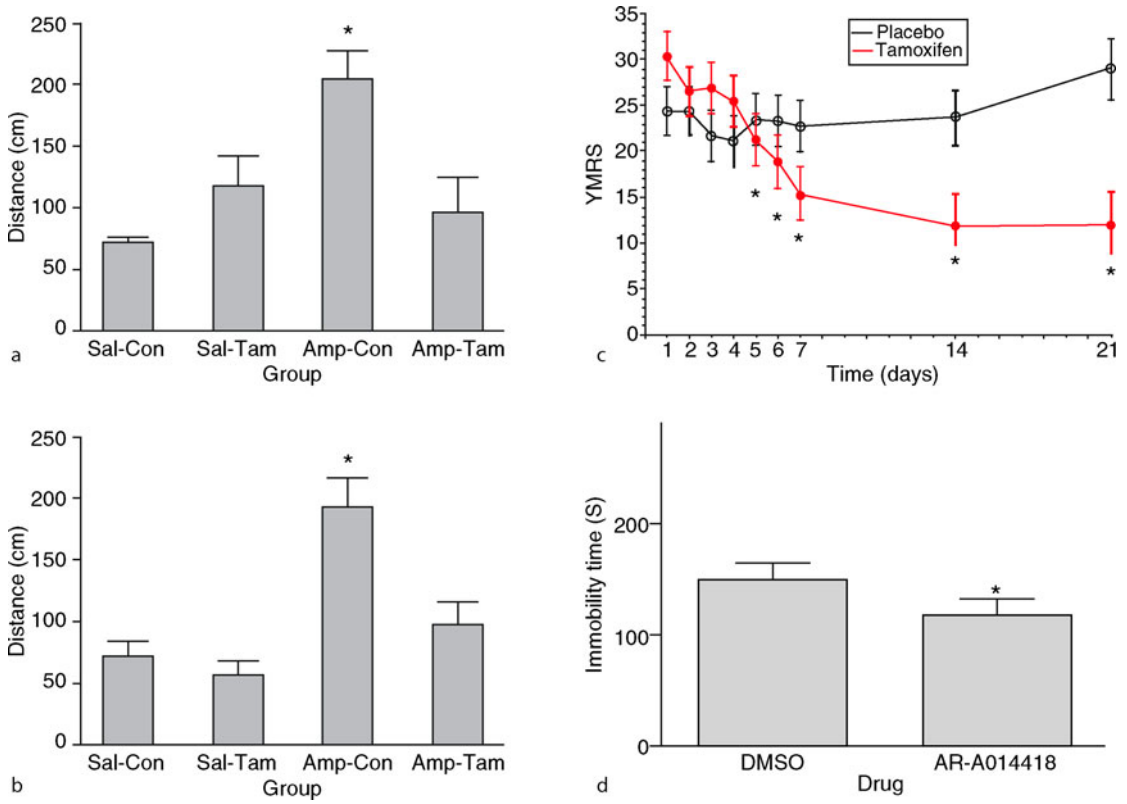
Based on the clinical observation that ► psychostimulants (amphetamine and cocaine) worsen manic symptoms in hypomanic patients and induce manic relapses in subjects with a personal or family history of bipolar disorder, stimulant-induced behavioral alterations in rodents are utilized as experimental models of mania. Lithium treatment prevents these forms of psychostimulant-induced behaviors, which provides additional validation to these models. Notably, the behavioral alterations induced by psychostimulants in rodent are associated with changes in PKC, and furthermore, pharmacological inhibitors of this kinase-attenuate amphetamine-induced hyperlocomotion (Fig. 2a, b). In fact, excessive activation of PKC dramatically impairs cognitive functions of the prefrontal cortex, while PKC inhibition protects it, suggesting that PKC might play a role in some of the cognitive features of mania.

The first study in humans with a fairly selective PKC inhibitor was a small, open-label trial, in which treatment with tamoxifen produced a greater than 50% decrease in manic symptoms in five of seven subjects. Noticeably, this effect was recently confirmed in a ► double-blind, placebo-controlled, 3-week study of 16 manic patients (Zarate et al. 2007), effects found as early as day 5 of treatment with the PKC inhibitor (Fig. 2c). The potential role of the PKC signaling pathway in the pathophysiology of bipolar disorder has been further strengthened by the identification of a bipolar susceptibility gene, which is an upstream regulator of this kinase. Diacylglycerol kinase eta (DGKH), a major regulator of DAG that activates all known classical and novel isoforms of PKC, was identified as a risk gene for bipolar disorder in two recent independent genome-wide association studies (Baum et al. 2008; Wellcome Trust Case Control Consortium 2007).

Development of PKC Inhibitors

A large number of structurally distinct PKC inhibitors have been identified or developed, mostly for use in cancer treatment, and Tamoxifen has been investigated and found efficacious in three independent clinical trials for bipolar disorder. PKC inhibitors that are used in treatment or have undergone clinical trials for cancer include the already-mentioned tamoxifen (treatment for estrogen receptor-positive breast cancer); the lipid analogs safingol (Phase-I trial with doxorubicin for solid tumors) and miltefosine (Phase-II trial of topical treatment for cutaneous breast cancer metastases); the indolocarbazoles UCN-01 (Phase-II trials for several cancers) and PKC412 (Phase-II trials for solid tumors); the bisindolylmalemide enzastaurin (Phase-II trials for glioblastoma and B-cell lymphoma); and the PKCα-specific antisense oligonucleotide ISIS3521 (several Phase-II and Phase-III trials) (Serova et al. 2006). The PKC inhibitors that have been investigated thus far are relatively nonspecific, with the exception of the ► antisense oligonucleotides, that unmodified, however, very rarely cross the brain–blood barrier and will probably require forms of central delivery or adaptations to increase its lipophilicity. The potential of isoform-, cell type-, and substrate-selective PKC inhibitors has therefore not been fully explored.

The development of highly selective PKC inhibitors is critical for the possibility of novel therapies with good efficacy, tolerability, and safety profiles. As mentioned, strategies such as the use of non-ATP-competitive inhibitors, or inhibitors that target binding proteins or substrates that are less promiscuous than the target kinase, may prove useful in the development of anti-PKC agents. A substrate-competitive inhibitor has been designed for PKCα, and peptides corresponding to PKC-anchoring proteins like RACK (receptors for activated C kinases) selectively inhibit specific PKC isozyme activity. A related strategy is to target PKC in specific subcellular locations. Because PKC isoforms are translocated upon activation, targeting location-specific anchoring proteins may produce isoform- and/or substrate-specific inhibition. Finally, combination strategies may prove beneficial for increasing specificity and sustained therapeutic effectiveness and reducing resistance. Examples of target combinations might include kinase-targeted agents with (a) binding or scaffolding proteins that are location- and/or



Kinase Inhibitors. Fig. 2. Preclinical and clinical behavioral evidence of the effect of protein kinase inhibition: (**a**) Effects of two injections of tamoxifen, a PKC inhibitor, (1 mg/kg) on amphetamine-induced hyperactivity in rats, measured in a large open field after acute or (**b**) chronic (7 daily injections) amphetamine treatment. The y-axis represents total distance traveled during the 45-min test session. Both acute and chronic amphetamine increased total distance traveled, and this increase was attenuated by tamoxifen pretreatment without affecting nonamphetamine-treated rats. Sal = Saline; Con = vehicle; Amp = amphetamine; Tam = tamoxifen; Sens = sensitized. * $p<0.05$. (**c**) Clinical study: change in scores on the Young Mania Rating Scale (YMRS) over three weeks ($n=16$). Subjects on tamoxifen showed significant improvement in mania when compared with placebo as early as 5 days, an effect that remained significant throughout the 3-week trial. * $p<0.05$. (**d**) Immobility time in the forced swim test (in seconds) in Rats; $n=14$ per group; bar graphs represent mean $\pm$ SE. Animals treated with AR-A014418 (a selective GSK-3 inhibitor) demonstrated significantly reduced immobility time (suggesting an antidepressant-like action) when compared with vehicle-treated animals. * $p<0.05$. DMSO = Vehicle. With permission.)

isoform-specific (such as RACK); (b) up/downstream molecules within the same signaling pathway to accomplish a synergistic effect with increased specificity; or (c) functionally related molecules with narrower expression profiles. Bisubstrate inhibitors might combine, for example, ATP and a particular kinase substrate for a higher degree of specificity. Ideally, combinations of therapies are designed such that they accomplish increased effectiveness to a greater degree than increased side effects. Disadvantages of this strategy include the increased likelihood of drug–drug interactions and the potential of decreased compliance. Therapies combining PKC modulators with other anticancer agents have been investigated at the preclinical level and in clinical trials (Serova et al. 2006).

GSK-3 Inhibition

GSK-3 is a ubiquitous, multisubstrate, serine/threonine kinase that is a key component of many intracellular signaling pathways including the insulin, neurotrophin,

and Wnt pathways (Fig. 1). (The Wnt signaling pathway, which involves a large number of proteins, is initiated when Wnt proteins bind to transmembrane receptors of the Frizzled family, activating Disheveled proteins that will ultimately change the amount of β-catenin that reaches the nucleus.) GSK-3 is encoded by two genes, GSK-3α and GSK-3β, whose protein kinase domains are 98% identical. GSK-3 is regulated by many of the key players in mood-disorder pathophysiology and treatment, including serotonin, dopamine, glutamate, psychostimulants, ► antidepressants, and ► mood stabilizers (Gould and Manji 2005). GSK-3 plays a critical role in multiple cellular processes, such as metabolism, proliferation, differentiation, axonogenesis, and synaptogenesis. Its role in the regulation of apoptosis and cellular plasticity/resilience is thought to be the target of the mood-stabilizing agents, lithium and valproate.

Preclinical and Clinical Evidence of GSK-3 Inhibition in the Pathophysiology and Treatment of Bipolar Disorder

As in the case of PKC inhibition, GSK activity is also inhibited by lithium and valproate, agents with mood-stabilizing properties in humans. Lithium inhibits GSK-3 through a combination of direct binding to this kinase and increased phosphorylation of its inhibitory N-terminal serine (Martinez et al. 2006). Direct inhibition of GSK-3 at therapeutically relevant concentrations of lithium occurs in vitro and in vivo, and in diverse cell types, including cultured neurons and rodent brain, subsequently activating glycogen synthesis and Wnt/ß-catenin-dependent transcription. In mice, GSK-3 has also been shown to be inhibited by valproate (although whether this is via direct or indirect action remains controversial) and by electroconvulsive seizure, a nonpharmacological therapy utilized in the treatment of mood disorders.

At the cellular level, lithium and valproate have also been shown to promote neural viability and exert neuroprotective effects ► neuroporotection in a variety of preclinical cell-toxicity ► neurotoxicity and injury paradigms in vitro and in vivo. It is then relevant to note that GSK-3 is a major regulator of apoptosis, cellular plasticity, and resilience. In general, the increased activity of GSK-3 is proapoptotic phenomena compatible with evidence showing that treatment of cultured neurons with GSK-3 inhibitors or transfection with GSK-3 small interfering RNAs (siRNA) induce neuroprotective effects that mimic those observed under lithium exposure. In addition, additional evidence has been generated that supports the role of GSK-3 in mediating lithium's own axonogenesis effects. While N-terminal phosphorylated GSK-3ß localizes to growth cones, agents that collapse growth cone also induce dephosphorylation of GSK-3.

Pharmacological and genetic data from animal behavioral models have shown that manipulation of GSK-3 produces both antidepressant and antimanic effects. Of note, mice lacking one copy of GSK-3β exhibit antidepressant-like behavior in the forced swim test (Fig. 2d), ► Depression: animal models, and reduced amphetamine-induced locomotor activation. Very importantly, this is the only manipulation, other than that of lithium, that we are aware results in both antimanic-like and antidepressant-like effects. In addition, when the downstream effects of GSK-3 inhibition are investigated, data have shown a decrease in phosphorylation and degradation of its target β-catenin, evident that parallel lithium's increases of β-catenin and Wnt-mediated gene expression at therapeutically relevant concentrations in rodent brain. At last and of importance to clarify the functional effect of GSK-3 inhibition on decreasing β-catenin degradation, it has been observed that β-catenin overexpressed in transgenic mice have mood-stabilizing-like actions in prototypical animal models of mania (D-amphetamine hyperlocomotion) and depression (forced swim test).

Although genetic studies have not reproducibly found GSK-3 polymorphisms to be associated with bipolar disorder, a recent whole genome association study did identify ► polymorphisms in molecules in the overall GSK-3 signaling cascade to be associated with the disease. Finally, experimental data that have shown the role of GSK-3 in the modulation of ► neurogenesis, neuronal survival, and mood-related behaviors, in addition to the mediation of ► AMPA-receptor trafficking and ► circadian rhythms (in drosophila and mice), provides further support to the potential role of GSK-3 inhibition in the pathophysiology and treatment of mood disorders.

Development of GSK-3 Inhibitors

GSK-3 has emerged as a key target in the development of novel treatments for ► Alzheimer's disease, based on evidence that it is involved in formation of both amyloid plaques and neurofibrillary tangles, two pathological hallmarks of the disease. GSK-3 interacts with presenilin, which mediates the gamma-secretase cleavage step in the formation of ► amyloid-beta peptide (Phiel et al. 2003). GSK-3 also regulates the phosphorylation of the microtubule-associated ► protein tau, which, in its hyperphosphorylated form, is a main component of neurofibrillary tangles (Hernandez and Avila 2006). Preclinical studies in animal models of Alzheimer's disease have shown that

GSK-3 inhibition by lithium reduces beta-amyloid production (Phiel et al. 2003). These and other studies have raised considerable interest in the potential of GSK-3 inhibitors in the treatment of Alzheimer's and other neurodegenerative diseases and tauopathies.

More than 30 inhibitors of GSK-3 have been identified to date, represented by such diverse classes of molecules as pyridyl-oxadiazoles, malemides, thiadiazolidindiones, and pyrazolopyrimidines (Martinez et al. 2006). As with protein kinase inhibitors in general, there are many considerations regarding selectivity and safety in the development and potential use of GSK-3 inhibitors. The need for substrate-selective modulators is a critical issue, given that GSK-3 is known to phosphorylate at least 40 substrates. In fact, the selectivity of most available GSK-3 inhibitors is poorly characterized, and many demonstrate overlapping interaction with the closely related kinases, CDK2 and CDK5. In order to phosphorylate its target, GSK-3 requires a "priming phosphorylation," carried out by another kinase that is substrate-dependent. Inhibitors that target the "priming phosphate" have the potential for superior specificity. Cell-permeant phosphopeptides have been studied that bind to these sites and inhibit GSK-3 activity. A further specificity challenge is the high-sequence similarity mentioned between the catalytic domains of the two GSK-3 isoforms, making it difficult to develop isoform-selective inhibitors (Martinez et al. 2006). AR-A014418, a thiazole, and SB-216763 and SB-415286, structurally distinct malemides, are ATP-competitive inhibitors that have been shown to be highly specific for GSK-3. AR-A014418 and SB-415286 demonstrate neuroprotective properties in vitro (Faci and Skaper 2006) and AR-A014418 demonstrates antidepressant properties in animal models. In general, ATP-noncompetitive kinase inhibitors have the potential for greater target specificity than those that compete reversibly with ATP, which is the strategy of the majority of currently available inhibitors. 2,4-disubstituted Thiadiazolidiones (TDZDs) were the first class of ATP-noncompetitive inhibitors for GSK-3, demonstrating high potency and selectivity (Martinez et al. 2006), and neuroprotective properties in in vitro studies. Thienylhalomethyl ketones represent a second class of ATP-noncompetitive GSK-3 inhibitors that has yet to be fully investigated. A substrate competitive inhibitor, L803-mts, has been developed demonstrating antidepressant properties in the forced swim test.

Several strategies for reducing toxicity may be combined with the above methodologies in the development of signaling molecule-targeted drugs for psychiatric disorders. The use of partial inhibitors can be a preferred strategy in cases in which the targeted kinases are essential for life, as is the case for GSK-3. The GSK-3β knockout mouse is embryonic lethal, indicating that its function is essential and nonredundant, at least during development. Partial inhibition may not only be necessary to reduce toxicity, but may also be optimal for therapeutic effect, based on the fact that only 25% inhibition of GSK-3 is sufficient to account for lithium's behavioral effects in animal models. In addition, this partial inhibition of GSK-3 may account (at least in part) for the lack of the oncogenic effect of increasing β-catenin. Finally, CNS-selective delivery, e.g., delivery of inactive prodrug with conversion to the active drug only in the CNS, may bypass non-CNS toxicity and prove to be an effective strategy for GSK-3 inhibition.

Summary

Recent data suggest that regulation of signaling molecules is probably involved in mechanisms of action of mood stabilizers and antidepressants, and the possibility of targeting signaling molecules for treatment, particularly protein kinases such as GSK-3 and PKC, holds promising therapeutic opportunities. The debate regarding whether protein kinases can be safely targeted for directed medical therapies has focused primarily on concerns of specificity and safety. The success of several kinase inhibitors in cancer treatment, as well as the use of lithium for almost six decades, demonstrates the realistic potential of using kinase inhibitors safely and efficaciously. We have discussed a number of strategies that may be employed to increase specificity and limit toxicity with the goal of developing novel treatments with improved efficacy, tolerability, and safety.

L-Alpha-Acetyl-Methadol

Synonyms

LAAM

Definition

LAAM is an opioid drug with limited usage in opioid agonist maintenance therapy. It is a derivative of and has a similar mode of action as ► methadone but has a longer half-life (two active metabolites) of up to 72 h. Because of a number of adverse events under LAAM, it has been withdrawn currently from the European and the American market.

Lamotrigine

Definition

Lamotrigine acts on ► GABA receptors to produce an anticonvulsant action. There are also some positive findings in the treatment of ► bipolar depression. The half-life is around 30 h and it is metabolized primarily by glucuronic acid conjugation. Serious, potentially life-threatening dermatological adverse events have been reported, albeit very rarely.

Lanreotide

Synonyms

BIM-23014; Somatuline

Definition

Lanreotide is a peptide analogue of SRIF, used to treat acromegaly and tumors in the gastroenteropancreatic tract. Lanreotide has high affinity for sst2 and sst5 receptors.

Laser Desorption Ionization

Latent Inhibition

Ina Weiner
Department of Psychology, Tel-Aviv University, Tel-Aviv, Israel

Synonyms

Stimulus pre-exposure effect

Definition

Latent inhibition (LI) is the reduced efficacy of a previously exposed, inconsequential stimulus to generate a conditioned response when paired with reinforcement, compared with a novel stimulus. LI is extremely robust, appearing across many different learning paradigms and mammalian species, including humans.

While a variety of behavioral tasks are used to demonstrate LI in rodents, all of them share a basic procedure. In the first stage, pre-exposure, animals from each of two groups are placed in an environment that will later serve as the conditioning-test apparatus. Subjects in the "stimulus pre-exposed" (PE) group are repeatedly exposed to a stimulus (e.g., tone), which is not followed by a significant consequence. Subjects in the "nonpre-exposed" (NPE) group spend an equivalent amount of time in the apparatus without receiving the stimulus. Either immediately or a certain time after the pre-exposure time is completed, all subjects enter the conditioning stage of the procedure, in which the PE stimulus is paired with a reinforcer over a number of trials. Performance is assessed by examining some behavioral index of conditioned responding, either during the conditioning stage or in a third, test stage. LI is manifested in poorer performance of the PE when compared with the NPE group.

In terms of psychological processes underlying LI, it is believed that the pairing of stimulus–no event in the pre-exposure stage results in reduced attention to, or salience of, the stimulus, which subsequently interferes with the generation of the conditioned response resulting from the stimulus–reinforcement association in conditioning (Fig. 1).

LI is a phenomenon of ► selective attention in the sense that it reflects a modulating effect of past experience on the current performance. Specifically, it reflects the ability of organisms to ignore stimuli that had been irrelevant in the past, in spite of their current relationship with a reinforcer. Since selective attention deficit is a hallmark cognitive deficit of ► schizophrenia and a central target for treatment, research that examined the effects of psychoactive drugs on LI in rodents has focused primarily on the use of LI to develop animal models of deficient attention in schizophrenia and the identification of ► anti-psychotic activity. The link between LI and schizophrenia is supported by the presence of LI abnormalities in schizophrenia patients.

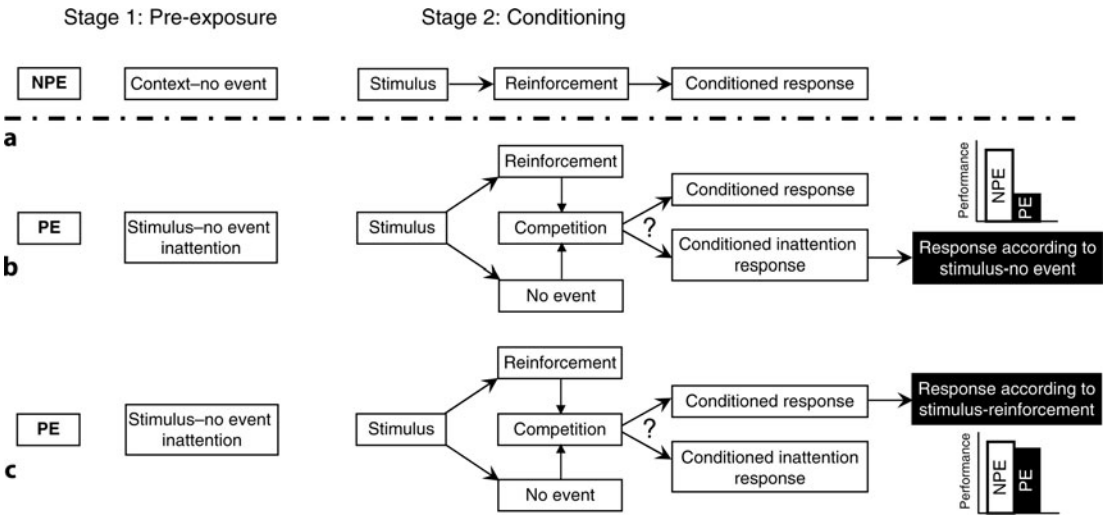
Impact of Psychoactive Drugs

Disrupted and Persistent LI

While drug effects are typically measured as a reduction or an abolition of the target behavior in comparison with its presence in drug nontreated controls, pharmacology of LI has taken a different path from its very inception, focusing on both the disruption and the *induction* of the phenomenon. The latter effect, termed interchangeably LI potentiation, enhancement, or persistence, is indexed by comparison with the *absence* of LI in drug nontreated controls. Thus, psychoactive drugs can produce two poles of LI abnormality, namely, disrupted LI under conditions that lead to LI in normal rats and abnormally persistent LI under conditions that disrupt LI in normal rats (Fig. 2). Both disruption and persistence of LI can stem from drug action in the pre-exposure stage or in the conditioning stage. In addition to unraveling the psychological mechanism by which a given drug affects LI (alterations in the acquisition or the expression of inattentional response), stage-specific action allows for a refined discrimination between the effects of different drugs on LI.

Models of LI Disruption and Persistence

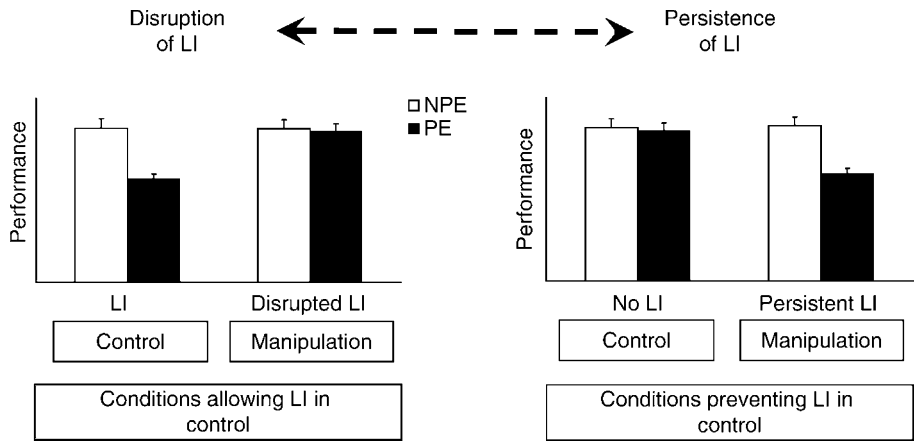
DA agonists. The notion of a hyperactive ► dopamine system in schizophrenia is supported by the capacity of the DA releaser, ► amphetamine, to induce psychosis in healthy humans and exacerbate symptoms, as well as enhance striatal dopamine release in schizophrenia patients. Because amphetamine produces only positive (psychotic) symptoms, amphetamine-induced behavioral abnormalities in animals are considered to model positive symptoms. Consistent with the expectation that the capacity to ignore irrelevant stimuli would be lost in a psychotic-like state, amphetamine disrupts LI in both rodents and humans. Amphetamine-induced LI disruption is due to the drug's action in conditioning stage rather than in pre-exposure stage, indicating that increased dopamine transmission does not produce a psychotic-like state by increasing stimulus salience but rather by weakening the inhibiting effect of reduced stimulus salience on behavior. LI is disrupted also after, as well as during withdrawal from, repeated amphetamine administration. Results with direct DA agonists are inconsistent.



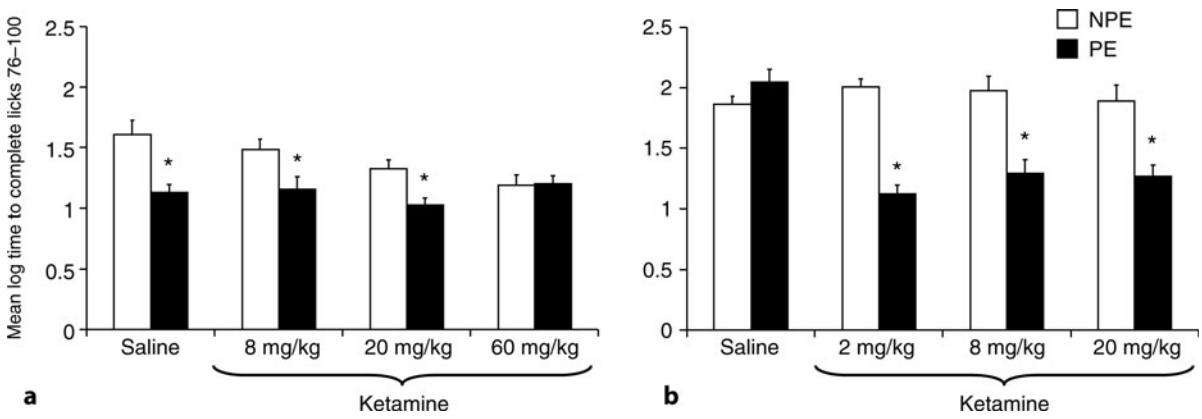
Latent Inhibition. Fig. 1. Latent inhibition as a response competition phenomenon. In the pre-exposure stage, stimulus pre-exposed (PE) animals acquire a stimulus–no event association, which results in a conditioned response of inattention to the PE stimulus. Following conditioned attention theory (Lubow et al. 1981), inattention is treated as a classically conditioned response, acquired when stimuli are consistently followed by the lack of a consequence and governed by the same rules that govern association formation during classical conditioning. In the conditioning stage, the stimulus signals conflicting outcomes, no-event vs. reinforcement, that compete for behavioral expression (conditioned inattention response vs. the conditioned response acquired in conditioning). Which of the two associations gains behavioral control depends on factors that determine their relative behavioral impact during conditioning. The three most conspicuous factors are strength of pre-exposure (usually manipulated by changing number of stimulus pre-exposures but can involve any manipulation known to affect classical conditioning such as stimulus intensity, ISI, etc.), strength of conditioning (usually manipulated by changing the number of conditioning trials or intensity of reinforcement), and context (manipulated by changing the context between pre-exposure and conditioning), but there are other factors as well, such as the time interval between pre-exposure and conditioning or the motivational state of the animal in the two stages. Pharmacological LI experiments typically manipulate number of pre-exposures and/or conditioning trials.

NMDA antagonists. The hypo-glutamatergic hypothesis of schizophrenia is derived from findings that noncompetitive NMDA antagonists such as ▶ phencyclidine (PCP) and ▶ ketamine provoke symptoms in human volunteers and exacerbate symptoms in schizophrenia patients, as well as abnormalities of glutamate neurotransmission in schizophrenia. Since NMDA antagonists also induce negative symptoms and ▶ cognitive impairments characteristic of endogenous schizophrenia, NMDA antagonist-induced behavioral effects in animals are considered to model negative/cognitive symptoms. Unlike amphetamine, low doses of noncompetitive NMDA antagonists, including PCP, ketamine, and MK-801, spare LI. While these results have led to the suggestion that NMDA antagonist-induced effects in LI cannot provide a valid model of the disorder, later studies have shown that NMDA antagonists affect LI in an opposite manner to that of amphetamine, namely, they induce persistent LI under conditions that prevent LI expression in controls (Fig. 3). Importantly, persistent LI is induced by doses of NMDA antagonists that do not produce the well-known deleterious effects of these drugs on associative learning. Higher doses that impair conditioning disrupt LI. NMDA antagonists produce LI persistence via effects in conditioning, indicating that ▶ NMDA blockade impairs rats' capacity to switch response based on changed relationships between stimuli and outcomes. The latter is consistent with numerous demonstrations of inflexible behavior following NMDA blockade in rats and humans and supports the relevance of NMDA antagonist-induced persistent LI to cognitive/negative symptoms of schizophrenia, which are characterized by inflexible and perseverative behaviors.

▶ Muscarinic antagonists. Muscarinic antagonists such as ▶ scopolamine and atropine induce a schizophrenia-like syndrome in humans, which includes positive



Latent Inhibition. Fig. 2. Two poles of LI abnormality. Based on the view of LI as a window phenomenon, namely, present under very specific and restricted conditions, two abnormalities can be produced in LI depending on the status of the phenomenon in control animals: disrupted LI under conditions producing LI in controls, and persistent LI under conditions preventing the expression of LI in controls. In psychological terms, the former reflects loss of normal ability to ignore irrelevant stimuli, whereas the latter reflects a failure to switch to respond to such stimuli when they become relevant.



Latent Inhibition. Fig. 3. Effects of ketamine on LI with weak and strong conditioning. LI was measured in a conditioned emotional response procedure in which rats were either PE to 40 tone presentations or not pre-exposed (NPE) prior to conditioning with 2 tone-shock trials (weak conditioning; Fig. 3**a**) or 5 tone-shock trials (strong conditioning; Fig. 3**b**). Time to complete 25 licks in the presence of the tone was used as a measure of fear conditioning to the tone. LI is manifested in faster times of the PE when compared with the NPE animals. The figures present mean times (logarithmically transformed) to complete 25 licks in the presence of the tone of PE and NPE rats treated with vehicle or ketamine. (**a**) Under conditions yielding LI in vehicle controls, ketamine spared LI at 8 or 20 mg/kg and disrupted LI at 60 mg/kg. (**b**) Under conditions preventing LI in vehicle controls, ketamine at doses of 2, 8, and 20 mg/kg led to persistent LI.

symptoms and cognitive impairments. Recent focus on cognitive impairments in schizophrenia has promoted attention to the cholinergic system because of its well-known role in cognition. Scopolamine can produce both LI disruption and persistence as a function of dose. Low doses of ► scopolamine disrupt LI, supporting the pro-psychotic quality of this agent. The mechanisms underlying this psychotic-like state differ however from those of amphetamine because scopolamine disrupts LI via effects at the pre-exposure stage. High doses of scopolamine spare LI under conditions yielding LI in controls, and induce persistent LI under conditions that prevent LI expression. The latter action is exerted in conditioning. Thus, scopolamine mimics both positive and negative/cognitive symptoms by

disrupting normal attentional processing, low doses preventing the development of inattention and high doses producing attentional perseveration.

Antipsychotics. In rodents, ▶ antipsychotics (APDs) are typically investigated for their ability to antagonize the effects of other drugs, but in research concerned with APD effects on LI, their direct influences on LI are also of central importance. Specifically, LI in nontreated rodents is used for indexing antipsychotic activity as well as for discriminating between typical and atypical APDs. The former is achieved under conditions of weak or absent LI in controls. Under these conditions, both typical and atypical APDs produce persistent LI. This effect, produced by a wide range of APDs differing in their in vivo and in vitro pharmacology, is also obtained in humans, and is the most widely used index of antipsychotic action in LI. The LI potentiating action of APDs is exerted at the conditioning stage, and is mediated by D2 blockade. Although APD-induced LI potentiation is very robust, it does not discriminate between typical and atypical APDs. Such discrimination is manifested under conditions that *produce* LI in controls. Whereas typical APDs do not affect LI, atypical APDs can, depending on dose and stage of administration, *disrupt* LI. The LI disruptive action of atypical APDs is exerted in the pre-exposure stage and is due to their $5HT_{2A}$ receptor antagonism. The pre-exposure-based $5HT_2$ antagonistic action competes with the conditioning-based D2 antagonistic action of these drugs. Since $5HT_2$ antagonism predominates at lower doses and D2 antagonism occurs at higher doses, depending on the dose, atypical APDs can potentiate, spare, or disrupt LI. The competition between the D2 and $5HT_2$ antagonism of atypical APDs has critical implications for interpreting the effects of these drugs on LI in animals and humans, as well as the clinical efficacy of these drugs.

In addition, since DA blockade is therapeutic against positive symptoms associated with abnormally increased DA function, but is ineffective for and may worsen negative symptoms associated with reduced DA function, recently it has been suggested that dopaminergic blockade-induced persistent LI, as exemplified by haloperidol-induced LI persistence, can model not only alleviation of positive symptoms but also induction of negative symptoms.

Reversal of Disrupted and Persistent LI

The four schizophrenia-relevant aberrations of LI, i.e., those induced by amphetamine, NMDA antagonists, and low and high-dose scopolamine, have been tested with typical and atypical antipsychotics to assess the predictive validity of these models for the identification of clinical treatments for schizophrenia. In recent years, new therapeutic strategies for schizophrenia, considered/hoped to improve negative symptoms and cognitive dysfunction, have emerged. These strategies include enhancement of NMDA transmission via the glycineB modulatory site on the NMDAR, either directly by agonists such as ▶ glycine transporter and D-serine, or indirectly by inhibiting the ▶ glycine transporter (GlyT1), and enhancement of cholinergic transmission using ▶ acetylcholinesterase inhibitors such as physostigmine, ▶ muscarinic agonists such as xanomeline, and alpha-7 nicotinic receptor agonists. Table 1 summarizes the distinct responses of five LI models (including haloperidol-induced persistence) to typical and atypical APDs, NMDA function enhancers, and cholinergic function enhancers.

Amphetamine- and low scopolamine-induced disrupted LI, although reflecting distinct psychological processes, are reversed by both typical and atypical APDs as well as by glycinergic enhancers. Scopolamine- but not

Latent Inhibition. Table 1. Summary of representative antipsychotic and other putative treatments tested against models of disrupted and persistent LI.

Drug \ Model	Disrupted LI		Persistent LI		
	Low amph	Low scop	Low MK801	High scop	Haloperidol
Haloperidol	+	+	–	–	
Clozapine	+	+	+	–	+
Glycine	+[a]	+	+	+	–
Physostigmine	–	+	+	+	–
α7 nicotinic agonist	+	?	+	?	?

+ effective; – ineffective; ? unknown; [COND] acts via conditioning stage; [PREEX] acts via pre-exposure stage

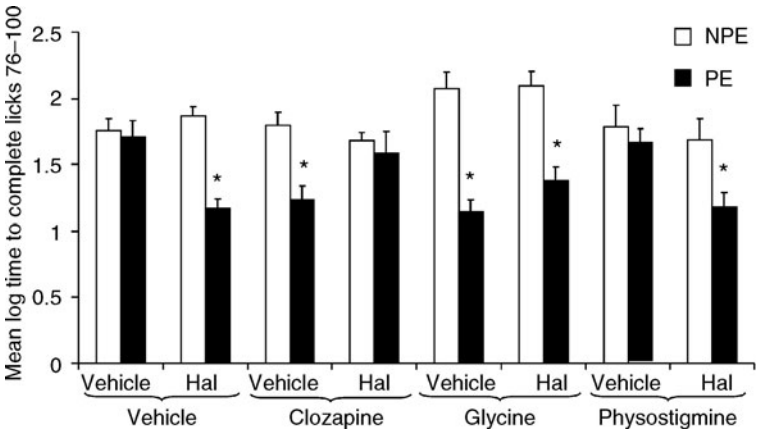
[a]The active compound is Glyt1 inhibitor SSR103800

amphetamine-induced LI disruption is reversed by ► physostigmine. *MK801-induced persistent LI* is reversed by atypical APDs (e.g., ► clozapine and ► risperidone) but not by typical APDs, as found with other NMDA antagonist-induced behavioral deficits, and in line with the differential efficacy of typical and atypical APDs in the clinic. MK801-induced persistent LI is also reversed by a wide range of compounds that potentiate NMDA transmission including glycine, D-serine, D-cycloserine (DCS), and GlyT1 inhibitors GDA, ALX5407, and the novel GlyT1 inhibitors SSR103800 and SSR504734. Importantly, MK801 is the only model that discriminates between atypical APDs and glycinergic compounds as the former reverse this abnormality via effects at pre-exposure and the latter via effects in conditioning. Finally, the novel alpha7-nAChR ► partial agonist SSR 180711 (4-bromophenyl-1,4-diazabicyclo(3.2.2)nonane-4-carboxylate-hydrochloride) is also effective in this model. *Scopolamine-induced persistent LI* is reversed by physostigmine and xanomeline, as well as glycinergic enhancers, but is resistant to both ► haloperidol and clozapine. While the inefficacy of haloperidol is expected based on its ineffectiveness in models of negative/cognitive symptoms including MK801-induced persistent LI, the inefficacy of clozapine is unexpected and sets this abnormality apart from MK801-induced as well as all other known instances of drug-induced LI persistence. *Haloperidol-induced persistent LI* is reversed by atypical APDs clozapine and risperidone but is resistant to glycine and physostigmine (Fig. 4). In addition, haloperidol-induced persistent LI is the only persistent LI that is alleviated by amphetamine, like negative symptoms in the clinic.

Using Pharmacology of Disrupted and Persistent LI to Model Domains of Pathology in Schizophrenia

Disrupted and persistent LI can be seen as two poles of dysfunctional attentional control, namely, a failure to inhibit attention to irrelevant stimuli and a failure to re-deploy attention when previously irrelevant stimuli become relevant. The former would likely give rise to the aberrantly increased salience perception and distractibility that are associated with psychotic symptoms, whereas the latter would result in the cognitive inflexibility and impaired attentional shifting that are associated with negative/cognitive symptoms. Indeed, both disrupted and excessively strong LI are found in schizophrenia patients, the former associated with acute psychosis and the latter associated with predominance of negative symptoms.

Based on their distinct pharmacological profiles, LI abnormalities produced by amphetamine, haloperidol, NMDA antagonists, and scopolamine have been suggested to represent four domains of pathology in schizophrenia (Table 2). *Amphetamine- and scopolamine-induced disrupted LI* represents the domain of positive symptoms, the only domain responsive to both typical and atypical APDs. Notably, disrupted LI is responsive to APDs irrespective of the mechanisms underlying the disruption. *NMDA antagonist-induced persistent LI* represents a (hypoglutamatergia-driven) domain of negative/cognitive



Latent Inhibition. Fig. 4. Effects of clozapine, glycine, or physostigmine on haloperidol-induced persistent LI. Mean times (logarithmically transformed) to complete 25 licks in the presence of the tone of PE and NPE rats treated with vehicle or haloperidol (hal) and pre-treated with clozapine (5 mg/kg), glycine (800 mg/kg), or physostigmine (0.15 mg/kg). No LI was evident in the vehicle control but there was LI in rats treated with haloperidol. Haloperidol-induced persistent LI was antagonized only by clozapine. Clozapine and glycine but not physostigmine led to LI persistence in vehicle-treated rats.

Latent Inhibition. Table 2. Five pharmacological LI models proposed to model five domains of pathology of schizophrenia.

Model / Pharmacological response	Disrupted LI		Persistent LI		
	Amphetamine	Scopolamine	Scopolamine	MK801	Haloperidol
Reversed by	Typical and atypical APDs and some cognitive enhancers	Typical and atypical APDs; cognitive enhancers	Cognitive enhancers	Atypical APDs; cognitive enhancers	Atypical APDs
Resistant to	Some cognitive enhancers		Typical and atypical APDs	Typical APDs	Cognitive enhancers
Symptom domain	**Positive**		**Cognitive**	**Negative/ Cognitive**	**Negative**

symptoms that respond to atypical APDs and cognitive enhancers but not to typical APDs. *Scopolamine-induced persistent LI* represents a domain of cognitive impairments that are resistant to APDs. This model may have utility in identifying effective treatments for APD-resistant cognitive impairments in schizophrenia. However, given its insensitivity to APDs, the model is likely to represent a class of behavioral inflexibility that is common to a variety of neuropsychiatric disorders, including Parkinson's disease (PD), and obsessive compulsive disorder (OCD). Indeed, both PD and OCD patients display abnormally enhanced LI. Finally, *haloperidol-induced persistent LI* represents a domain of (hypodopaminergia-driven) negative symptoms that are treatable by atypical antipsychotics but are resistant to cognitive enhancers. This abnormality may represent a class of cognitive/behavioral inflexibility that is selective to schizophrenia. The domain-specific LI model fits the future directions of drug development for treatment of schizophrenia, which will use polypharmacy strategies, with independent therapeutic agents for each domain of pathology.

Leaden Paralysis

Definition

A feature of atypical depression, leaden paralysis refers to severe fatigue creating a sensation of extreme heaviness of the arms or legs.

Learned Helplessness

Definition

First described by Seligman and colleagues in the 1970s, learned helplessness describes the impairment of learning that follows exposure to uncontrollable stress. The term "learned helplessness" implies that animals learn that they are helpless to control their environment. A variety of simpler explanations have also been proposed, and most "learned helplessness" experiments are not conducted in a manner that allows a clear interpretation.

Learning

Definition

In its broadest sense: the fact or process of change that occurs in the relationship between a stimulus and a response as a result of experience. Also referred to as acquisition. The "black box" that relates the stimulus to the response usually refers to a whole organism but may also refer to part thereof or to an isolated biological system. Learning concerns cognitive, but also sensory, motor, emotional, and mood-related life events or items.

Learning & Memory: Molecular Mechanisms

Eric J. Nestler
Fishberg Department of Neuroscience, Mount Sinai School of Medicine, New York, NY, USA

Definition

Alterations in gene expression have been proposed to underlie key aspects of learning and memory in diverse systems. The mechanisms by which behavioral experience, via alterations in synaptic transmission, induce changes in gene expression in specific brain regions are reviewed. Such mechanisms include alterations at the level of chromatin structure, which might be expected to mediate particularly long-lasting adaptations. There are many examples of psychotropic drugs that regulate learning and memory via their effects on gene expression.

Impact of Psychoactive Drugs

The ability of an organism to learn and remember, sometimes for extended periods of time, indicates that environmental experience can induce long-lasting changes in the brain. The nature of these changes, at the molecular and cellular levels, has accordingly been intensively studied for several decades. This work has provided an impressive appreciation of the types of adaptations that

occur in the brain in association with many types of learning and memory. It also has been possible to directly demonstrate the importance of a given molecular or cellular mechanism in mediating a particular aspect of learning and memory. However, despite these important gains, we still know relatively little about how these molecular and cellular adaptations actually summate to create a behavioral memory or enable its long-term storage and retrieval. This latter level of understanding, which represents perhaps the greatest remaining challenge in the neurosciences, requires a neural circuit level of analysis that is not yet available.

This chapter provides a brief overview of the types of molecular and cellular adaptations in the brain that have been implicated in learning and memory, and focuses on changes achieved at the level of ▶ gene expression, or gene transcription, which have been thought for over a decade to provide the long-lasting mechanisms underlying stable behavioral change.

From Synapse to Nucleus

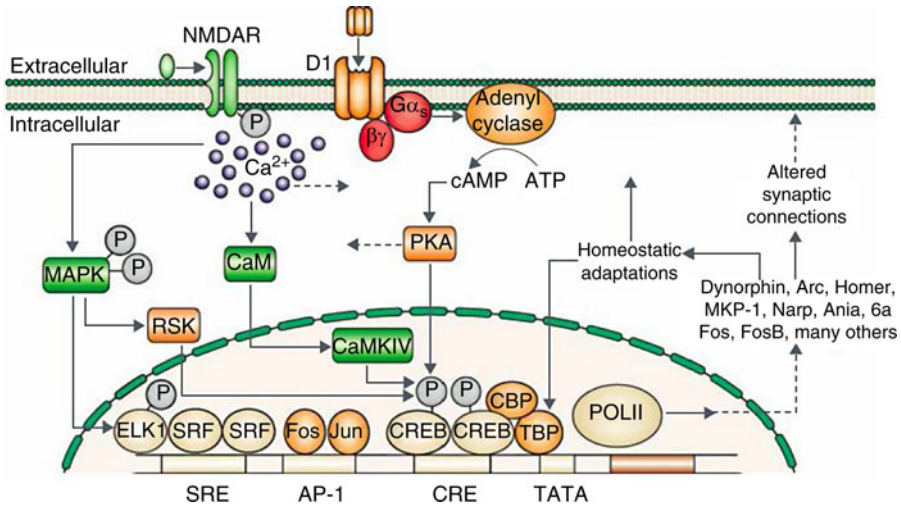
Synaptic transmission is best understood as the effects that a neurotransmitter, released by one nerve cell, exerts on a second nerve cell by virtue of its binding to a specific receptor. The activation of a receptor by its neurotransmitter triggers chemical changes inside the second nerve cell that alter its electrical activity. This occurs on the time scale of milliseconds to seconds. Operating on a much slower time scale, on the order of minutes to hours, are more complex chemical changes triggered by that very same neurotransmitter–receptor interaction. Thus, in addition to regulating ion channels, such interactions initiate cascades of chemical changes that eventually signal to the nerve cell's nucleus, where changes in gene expression – alterations in the amounts and types of proteins expressed by that cell – are induced. For example, synaptic transmission can alter the levels of ion channels or receptors expressed by a nerve cell. Consequently, at some later time point, when the first nerve cell again releases neurotransmitter onto that second nerve cell, the second nerve cell shows an altered response due to these changes in gene expression. This represents a unit of "molecular memory." Somehow, by summating these changes across the trillions of synapses in the brain, and integrating them over time, an organism learns and remembers and thereby adapts and responds to its environment.

We now know a great deal about the mechanisms by which synaptic transmission alters gene expression. The most important mechanism involves the activation of a class of proteins termed transcription factors (TFs), which bind to regulatory regions (called promoters) of specific genes and thereby increase or decrease the rate by which those genes are expressed. Hundreds of TFs are known, which exhibit three general mechanisms for their activation by synaptic transmission. Some TFs, expressed in nerve cells under basal conditions, are activated by cascades of ▶ second messenger and protein phosphorylation pathways that are stimulated (or inhibited) when neurotransmitters bind to their receptors. A prototypical example is CREB (cAMP response element binding protein), which can be phosphorylated and activated by a wide range of second messenger cascades illustrated in Fig. 1. For example, in striatum, ▶ dopamine (via activation of the cAMP pathway) and ▶ glutamate (via activation of Ca^{2+} pathways) activate several different protein kinases, each of which phosphorylates CREB on the same serine residue, resulting in the activation of its transcriptional properties. The TFs Elk1 and SRF (serum response factor) are regulated via similar mechanisms (Fig. 1). A related mechanism exists for another TF, termed NFκB (nuclear factor κB). At baseline, NFκB is bound to an inhibitor protein, IκB (inhibitor of κB), which sequesters NFκB in the cytoplasm. Upon activation of certain second messenger cascades, IκB is phosphorylated, leading to its degradation and the freeing up of NFκB to enter the nucleus where it exerts its transcriptional effects.

Other TFs are expressed at very low levels under normal conditions but are induced in nerve cells in response to neurotransmitter–receptor interactions. Examples include Fos (e.g., c-Fos, FosB) and Egr (early growth response) families of TFs. These TFs are induced because their promoter regions contain target sites for preexisting TFs such as CREB and SRF (see Fig. 1).

The third paradigm of TF activation operates for the steroid hormone receptor family of proteins, which are activated upon binding their respective hormone (e.g., glucocorticoids, gonadal steroids, etc.) and can therefore be viewed as ligand-activated TFs. Under basal conditions, steroid hormone receptors are bound by chaperone proteins which keep them in the cytoplasm. Steroid hormones, which readily permeate cell membranes, bind to the receptors and trigger their release from the chaperones and their movement to the nucleus. Once in the nucleus, the steroid receptors bind directly to responsive genes or bind to and inhibit other TFs (e.g., CREB, c-Fos).

An important principle of TF action is that most bind to DNA as dimers. Some bind as homodimers (e.g., CREB), whereas others must complex with distinct families of TFs: Elk1 dimerizes with SRF, Fos family proteins dimerize with Jun family proteins (to form an



Learning & Memory: Molecular Mechanisms. Fig. 1. Regulation of CREB activity in striatum. Stimulation of D1 dopamine receptors and glutamate receptors on striatal neurons activates several second messenger cascades. Not shown is the ability of several growth factor-associated receptors to stimulate some of the same cascades, for example, MAPK. Depicted in the cell nucleus is a model of binding sites from the *cFos* promoter including a serum response element (SRE), activator protein-1 element (AP-1), and a cyclic AMP (cAMP) response element (CRE). CBP, CREB binding protein; CREB, cAMP response element binding protein; MAPK, MAP kinase; NMDAR, NMDA receptor; PKA, protein kinase A; TBP, TATA binding protein. (From McClung CA, Nestler EJ (2008) Neuroplasticity mediated by altered gene expression. Neuropsychopharmacology 33:3–17.)

AP1 (activator protein 1) complex), and so on. Together, this results in an incredibly complex array of transcriptional regulation during the normal process of synaptic transmission.

Implicating TFs in Learning and Memory

An important role for all of the aforementioned TFs, and many others, in diverse types of learning and memory has been established over the past decade. Investigators have demonstrated the activation of specific TFs in a given brain region in response to an environmental challenge in tight temporal correlation with a form of behavioral plasticity. Examples include the phosphorylation and activation of CREB, and the induction of c-Fos and Egr, in hippocampus and amygdala in parallel to aversive learning, in some cases in parallel to a specific facet of aversive learning such as acquisition, consolidation, or extinction, among others. Likewise, exposure to a drug of abuse activates each of these TFs in drug-responsive regions (e.g., striatum, ► amygdala, ► prefrontal cortex) and such activation has been correlated with different aspects of drug-induced plasticity, such as locomotor sensitization, reward tolerance, or sensitization, etc. An interesting variation in this theme is the induction of ΔFosB, a truncated splice variant of the *fosB* gene, uniquely by chronic drug exposure. ΔFosB, normally present at very low levels in nerve cells, is induced to a small extent via CREB and SRF, but unlike all other Fos family members (which are highly unstable and therefore degrade to low basal levels shortly after the stimulus), ΔFosB is highly stable which enables it to accumulate to high levels in response to chronic stimuli. In this way, ΔFosB could mediate some of the longer-lasting effects of drug exposure on behavior.

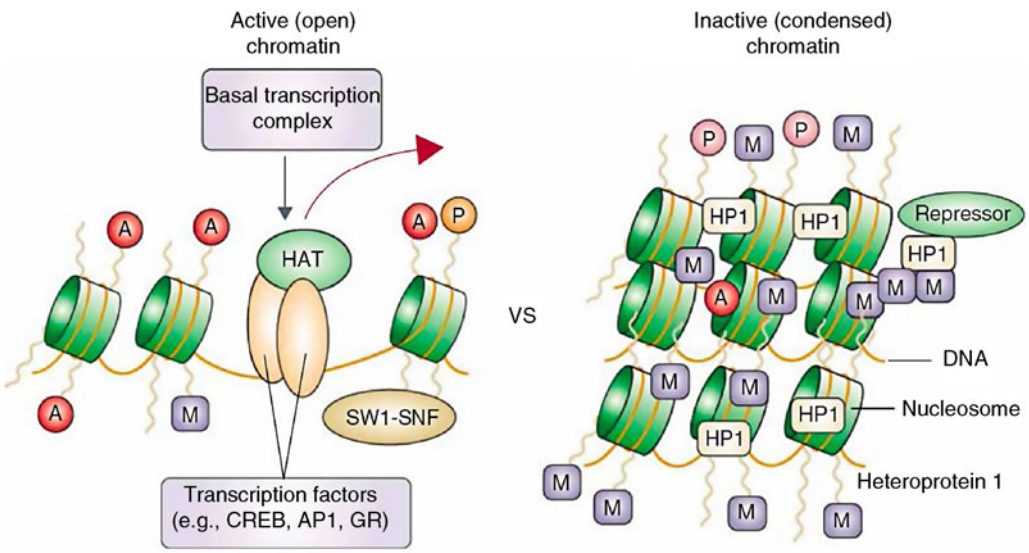
The second key step in implicating a TF in learning and memory is to manipulate that TF and demonstrate an effect on behavior. This causal information came initially from gene knockout studies, where deletion of CREB or another TF of interest was shown to obliterate an aspect of learning and memory. However, the interpretability of these early experiments was limited by the fact that the TF was knocked out from all brain regions (indeed all tissues) from the earliest stages of development, making it difficult to conclude that the TF was required in a given brain region of an adult. Such limitations have been overcome in recent years with the advent of an awesome array of powerful genetic tools, where a TF of interest – or an inhibitor (sometimes referred to as a dominant negative antagonist) – can be overexpressed in a given brain region of an adult animal or can be knocked out

selectively from that region of an adult animal. Such methods have greatly strengthened the level of proof for a TF's role in learning in memory. Overexpression of CREB specifically in ▶ hippocampus or amygdala promotes aversive learning, while overexpression of a CREB antagonist has the opposite effects. Likewise, CREB overexpression in striatum dampens an animal's sensitivity to the rewarding effects of a ▶ drug of abuse, with a CREB antagonist having the opposite effect. These latter data support the hypothesis that CREB induction by drugs of abuse represents a homeostatic mechanism mediating ▶ tolerance and ▶ dependence. Conversely, ΔFosB overexpression in striatum increases the rewarding effects of a drug of abuse, while its antagonist reduces drug reward, supporting the notion that ΔFosB induction represents a mechanism of sensitization.

From TF to Chromatin

In recent years, our level of analyzing transcriptional mechanisms in the brain has been extended to ▶ chromatin structure, where the covalent modification (e.g., acetylation or methylation) of ▶ histone proteins, around which DNA is wound in the cell nucleus, and methylation of the DNA itself, have profound effects on the ability of genes to be expressed. ▶ Chromatin exists in a continuum from a permanently inhibited (closed) state to a constitutively active (open) state (Fig. 2). Genes in closed chromatin are not expressed because they are not accessible to the cell's transcriptional machinery, whereas other genes exist in permissive chromatin where the genes are accessible to transcriptional machinery. This explains, for example, why CREB cannot induce neural gene targets in peripheral tissues where the genes exist in silenced chromatin, but can in nerve cells where the genes exist in permissive chromatin. TFs induce genes in permissive chromatin by recruiting to those genes many types of co-activator proteins. TFs recruit ▶ histone acetyltransferases, enzymes that acetylate histones; such acetylation further opens the chromatin. TFs also recruit so-called SWI-SNF factors, proteins that provide the molecular motor for histones to move across a strand of DNA as it is being actively transcribed.

This knowledge of chromatin biology has now begun to inform our understanding of gene expression regulation in the brain and, in particular, its role in learning and memory. First, changes in histone acetylation and DNA



Learning & Memory: Molecular Mechanisms. Fig. 2. Differential states of chromatin. Chromatin exists in a continuum of states from being open (i.e., active, allowing gene expression) to condensed (i.e., inactive, repressing gene expression). Changes across this continuum are mediated in part by modifications to core histone proteins. Histone acetylation (A) is associated with chromatin relaxation and the binding of TFs and coactivators, such as HATs (histone acetyl transferases) and SWI-SNF proteins that mediate the movement of histone complexes along a strand of DNA. Histone methylation (M) results in condensed chromatin and transcriptional repression (REP). Methylation of the DNA itself also results in condensed, repressed chromatin. (From McClung CA, Nestler EJ (2008) Neuroplasticity mediated by altered gene expression. Neuropsychopharmacology 33:3–17.)

methylation have been shown to occur in hippocampus in parallel to aversive learning. These findings are striking because they emphasize the degree to which fundamental mechanisms of gene regulation are affected during the course of normal synaptic transmission – on a time scale of hours. Similar changes in chromatin have been demonstrated in striatum in response to drugs of abuse. Second, it has been possible to directly implicate mechanisms of chromatin regulation in aversive learning and drug addiction by demonstrating that direct manipulations of histone or DNA modifications has profound effects on behavior. Inhibitors of ► histone deacetylases (enzymes that remove acetyl groups from histones and thereby inhibit gene expression) or of DNA methyltransferases (enzymes that add methyl groups to DNA and thereby inhibit gene expression) promote hippocampal-dependent memory as well as the rewarding effects of drugs of abuse. In contrast, overexpression of these inhibitory enzymes in specific brain regions exerts the opposite effects.

The Future

One of the major challenges of current research is to identify the target genes through which a given TF exerts its particular effects on behavioral plasticity. Small numbers of target genes have been identified for all of the TFs mentioned above; however, some TFs may regulate hundreds of targets. This has been demonstrated by use of gene expression arrays (which measure levels of all mRNAs in a tissue) and ChIP (chromatin immunprecipitation)-chip or ChIP-Seq (sequence) methods (which measure levels of chromatin modifications across the entire genome). Understanding how the coordinated regulation of such large numbers of genes summate to produce the net functional effects of a TF, and how the effects of multiple TFs are summated, remains a great technical challenge.

Ultimately, it is essential to define the many ways in which brain function is altered by transcriptional and chromatin regulation to mediate the behavioral plasticity associated with learning and memory. In addition to altering levels of ion channels and neurotransmitter receptors, and many related second messenger proteins, as stated at the outset, there is increasing evidence that environmental experience produces more profound changes in nerve cells, including alterations in their overall size and shape, and the extent of their dendritic arborizations and synaptic inputs. Work is beginning to define the changes in gene expression, and the specific TFs and chromatin modifying enzymes that underlie this long-lasting reordering of nerve cells. As we build this increasingly complete view of molecular and cellular changes that occur in concert with behavioral plasticity, it is essential to then understand at a circuit level how such changes mediate behavioral memory.

Learning Set

Definition

Learning set (and the closely related concept, task set), is when a learned rule is generalized so that there is facilitation of learning a new discrimination or task when a previously learned rule or principle applies to the new situation (see Harlow, 1949). There is a corresponding impairment of new learning when a previously learned rule or principal does not apply, as exemplified by the "Einstellung effect" (Luchins, 1942).

Legal Aspects of Psychopharmacology

Malcolm Lader
Institute of Psychiatry, King's College London, London, UK

Synonyms

Allowable; Constitutional; Lawful; Legitimate (aspects of psychopharmacology)

Definition

"Legal" as a topic means falling within the province of the law and its study. It also has the more specific connotation of such as is required by the law and not falling outside what is permitted.

Current Concepts and State of Knowledge

Introduction

Human societies are governed by social rules that moderate our basic biological instincts. Moreover, such social rules reflect moral and ethical principles (Harris 2002). These social institutions and conventions are governed by the rules of law. These can be complex with codes of law extending to numerous densely written tomes. In a complex society, it is almost impossible to find any human activity that is not touched on in some way by the law. Psychopharmacology, a branch of science that involves the activities of the most complex human organ – the brain – is particularly affected by rules, regulations, and the panoply of the law. Both criminal and civil laws contain swathes of material directly relevant to psychopharmacology. Rules of law may forbid certain activities or specify certain conditions that must be carried out. Rules are normative – what ought to happen, rather than factual – what actually does happen. They lay down rules of behaviour to which we are expected to conform. If we do not, the law can apply sanctions, from a fine, or restriction of liberty, right through to the death penalty, still imposed in a minority of countries.

Durkheim (1964) regarded society as ranging from a relatively simple, technologically undeveloped society to an advanced, mobile, sophisticated social structure. The purpose of laws was to maintain social cohesion by striving for balance between competing ideas and interests. If a group perceives a law as failing to recognize a strongly held belief, they may adopt extralegal measures, for example, some animal rights activists.

Legislation of Morality

This raises the question of the relationship between the law and morality. A society's code of morality is the set of beliefs, values, principles, and standards of behaviour adhered to by most members of the society. In a homogeneous society, the set of morals tends to be fairly consensual. In a multicultural society, moral values may differ greatly. To accommodate these disparate views, the law which formalizes such moral principles may have to introduce special cases, exemptions, and exceptions. Even so, some members of the society may feel unable to abide by the law, for example, human embryo research may clash with imperatives from established religions.

One cardinal example in psychopharmacology concerns the complex laws relating to the use of the oldest of psychotropic substances, ▶ alcohol. Laws outlawing alcohol in the USA ("Prohibition") were in response to pressures from those in society who took the moral high ground. These groups were organised into religious and temperance organisations that emphasised both the moral shortcomings of heavy drinking and its medical and social toll. The moral disadvantages and legal injustice of penalising moderate and occasional social drinkers were submerged under the waves of moral temperance rectitude. The Prohibition Laws failed because they were too draconian and large numbers of US citizens flouted them. But, in many countries, achieving a just balance in the licensing of alcohol still remains a distant objective, viz. ▶ binge drinking in the United Kingdom.

Legal Instruments

It is an impossible task to even outline different forms of jurisdiction. Most European countries rely on systems of law based on the Roman model and codified by Napoleon. The United States and England (but not Scotland) use a common law system, in which judges interpret and modify legislation. Some countries maintain tight central control; others devolve to the periphery. Some have both, such as Federal and State laws in the United States, the relationship between which is being constantly adjusted. In some countries, religious law such as sharia is paramount; in others it exists in parallel and may be resorted to by the religious groups. In the European community, national laws have yielded precedence to EC laws, regulations, and directives. International courts such as those in The Hague have become increasingly recognised.

Research

Legal systems, under pressure from animal rights activists, have long introduced measures to regulate the treatment of animals. As these activists vary in their attitudes from

country to country, so do the regulations. Many countries have a set of rules rather than guidelines. In some, registration of laboratories, projects, and individual experimenters is required. Particular stringency is often applied to studies on primates. Research on Great Apes may be prohibited altogether, as may that on species deemed at risk of extinction even if they are not primates (► ethical issues in animal psychopharmacology).

In the human sphere, a series of declarations followed the abhorrent practices of the Nazis. The Declaration of Helsinki (1964) states that, "It is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject." Ethical committees were set up, first in the USA, and then in other countries, to regulate human research, first voluntarily but increasingly under statute (► ethical issues in human psychopharmacology). On basis of a detailed protocol, a properly constituted ethical committee containing both professional and lay members should consider the proposal, modify it if necessary, and ensure that it is adhered to. Such committees have a special (fiduciary) duty to act properly and responsibly. Any researcher failing to submit an appropriate protocol would, depending on the jurisdiction, find himself subject to the criminal code for inflicting bodily harm, or to redress under the civil code for causing a personal injury ("tort"), or expulsion from the relevant professional body. With psychotropic drugs, psychological harm could be the basis for a court action (Carson and Bull 2003).

► Informed consent is typically a sine qua non for the recruitment of experimental subjects. This entails that each potential participant be adequately informed of the purpose of the study, its methods, sources of funding, any possible conflicts of interest, institutional affiliations of the researcher, the expected risks and potential benefits of the study, and the anticipated discomfort. The presence of a neutral witness is a useful safeguard. The volunteer should be informed of the right to withdraw from the study at any time without explanation. The investigator must be sure that the potential subject has understood the information and has been encouraged to ask questions. Consent should be in writing wherever possible. Special rules generally pertain to subjects who suffer from a severe psychiatric disorder, or lack mental capacity to give informed consent, and to children. Recently, the question of genetic privacy has been raising concern.

Two European Directives, Clinical Trials Directive (2001) and Good Clinical Practice (2005) initiated change in medical research procedures across Europe to varying extents (Brazier and Cave 2007). A Directive sets out the broad goals of the legislation but allows each EU country to determine the form and precise content of that legislation (► randomized clinical trials).

Therapeutics

It is a truism that every administration of a therapeutic substance is essentially an experiment. If that usage in a patient is grossly negligent, criminal proceedings may follow. If it falls short of that, then the injured party generally has to show that the drug administration was below acceptable clinical standards, that it caused an injury that can be quantified, at least in financial terms. Standard rates are applied to gross physical injuries such as an amputation, but psychological or psychiatric damage is difficult to quantify. Often the functional impairments are evaluated, as well as symptomatic complaints.

Psychotropic drugs have some special aspects. First, on occasion a treatment may be administered compulsorily and stringent safeguards are essential. Second, some medications have a low therapeutic index and must be monitored according to the specified protocols (e.g., ► lithium salts, ► clozapine).

No consensus exists between various jurisdictions with respect to topics such as ► withdrawal syndromes, ► neuroleptic malignant syndrome, and ► tardive dyskinesia. Currently, much concern is being expressed with regard to suicidal phenomena with ► SSRIs, especially in adolescents where evidence for efficacy is often exiguous.

In most jurisdictions, the development of an ► adverse effect, ipso facto, does not constitute grounds for action as long as the drug was administered in accord with accepted clinical standards. These can change over time, and regulatory bodies may suggest different practices. Prescribers must be aware of the latest developments and even trends.

Regulatory Affairs

How medicines are developed and licensed is dealt with elsewhere ("► Licensing and Regulation of Drugs"). Randomised Clinical Trials raise particular concerns.

Consumer Protection

Various jurisdictions (including the EU) have brought in legislation to protect consumers from defective products – those that are unfit for purpose, or those that are not of a quality that a reasonable consumer has a right to expect. Medicinal products are usually subject to such control. A group of consumers who believe that a product is defective and that they have suffered from using the product may bring an action and may subsequently recover damages. The manufacturer's usual defence is to try and prove that

the produce is not defective or that scientific knowledge at the relevant time was not sufficient for a reasonable manufacturer to detect the defect.

Misuse of Drugs

One area where psychopharmacology is closely involved with the law is in the area of drug misuse. This can relate to drugs which have no recognised therapeutic properties, such as ▶ LSD, and therefore whose use can only be a misuse, or to products that have a licit indication, such as ▶ morphine, but can be misused (Glaser and Warren 1999). A controversy attends the use of ▶ cannabis products, where some products have been licensed in some countries to establish a legitimate therapeutic usage in pain and nausea.

Jurisdictions differ widely in both the form and content of the illicit drug "scheduling" legislation. The classification of drugs of dependence is usually into several categories, and maximum penalties for use, possession, and supply vary according to the category. For example, sanctions, often swingeing, are imposed with respect to heroin and ▶ cocaine; at the other end of the spectrum, penalties are minimal with ▶ benzodiazepines, which may not even be scheduled in some countries. Cannabis is controversial and debates continue as to where it should be classified. Chemical precursors and intermediates can be scheduled.

The penalties cover a range of unlawful activities – producing a Controlled/Scheduled Drug, supplying or offering to supply one to another person, possessing a Controlled/Scheduled Drug, and in some countries, cultivating any plant of the opium or cannabis type. Exemption is available for legitimate purposes, for example, the manufacturers of morphine, the pharmacists who store and supply it, and the medical, dental, and veterinary practitioners who prescribe and administer it. Special dispensations for research purposes can be applied for but are often notoriously difficult to facilitate. Most jurisdictions lay down strict rules for safe custody.

The misuse of Controlled Drugs is further regulated in various ways. In professional circles, the prescription of a Controlled Drug usually has to follow a strictly applied proforma, and careful records are mandatory. Addicts may have to be reported to a government department or agency. Some Controlled Drugs such as heroin can only be prescribed by specially recognised doctors. Irresponsible prescribing is penalised.

Various crimes are established under legislation and involve the criminal law system, police, judges, the prison system, and customs and excise departments. Much of this is governed by the Single Convention on Narcotic Drugs signed in New York on March 30, 1961 and by the 1971 convention covering drugs more widely. Searches of individuals, possessions, and premises can usually be authorised.

Sales Outlets

Jurisdictions generally reorganise various ways in which medicinal products can be provided (Appelbe and Wingfield 2005). The most restricted is a Prescription-Only Medicine, prescribed by a recognised medical, dental, or veterinary practitioner. The least restricted is a General Sale Medicine which can be sold in shops and supermarkets. Some countries have an intermediate category of drugs which are available without prescription under the supervision of a pharmacist.

Many remedies are "alternative"; the most widely used being herbal and homeopathic "medicines." Countries vary enormously with respect to whether or how these are regulated. Finally, concoctions that are used as folk remedies are rarely encountered in legal systems unless poisonous effects are produced. Alternative medicines may also raise problems with toxic constituents (▶ herbal remedies).

Alcohol is also subject to regulation. The Scandinavian countries are typically the most stringent. Some states in the United States are also quite restrictive. The minimum age for purchasing and drinking alcoholic beverages may be 21, and the bottles containing the same cannot be openly displayed.

Definition

A hormone produced in and secreted primarily by adipose tissue that regulates appetite, body weight, and neuroendocrine functions.

Pharmacological Properties

History

The hormone leptin was discovered in 1994; its name is derived from the Greek word for thin, *leptos*. Like other hormones, leptin is secreted in a pulsatile manner and shows a diurnal variation with a peak during the night. Lack of leptin signaling due to a mutation of *leptin* (e.g., ► ob/ob mouse) or the leptin receptor (*lepr*) (e.g., ► db/db mouse) in rodents and humans results in increased food intake, reduced energy expenditure, and severe obesity. Leptin replacement reverses many of the phenotypes of leptin-deficient mice. However, it was quickly apparent that an absolute leptin deficiency is an extremely rare cause of human obesity. Plasma leptin levels are elevated, rather than reduced, in the majority of obese subjects and plasma leptin levels are highly correlated with total fat mass. Thus, resistance to leptin action appears to be a more likely cause of human obesity.

Leptin also plays a role in the regulation of neuroendocrine function. Mutations in the leptin gene are associated with not only obesity but also neuroendocrine impairments, including impaired reproduction and low ► sex hormones, low thyroid hormone, low growth hormone, and elevated glucocorticoids. In 1996, it was first proposed that the physiological role of leptin is the regulation of the neuroendocrine system during starvation. Fasting reduces leptin gene expression and plasma leptin levels. Leptin treatment to prevent fasting-induced fall in endogenous leptin, blunts the fasting-induced changes in the neuroendocrine system. Thus, circulating leptin serves to communicate the state of body energy stores to the central nervous system (CNS) in order to maintain normal metabolic and neuroendocrine functions. A tremendous amount of research has since then focused on the role of leptin in the regulation of metabolism and neuroendocrine function as well as CNS signaling pathways that mediate leptin action.

Mechanisms of Action

Substantial evidence shows that the leptin pathway plays a significant role in body weight regulation by communicating the status of the energy stores to the brain. Leptin has been implicated in activating a variety of intracellular signaling cascade primarily through the long-form leptin receptor, LepRb.

Leptin Receptors (LepR or ObR)

The LepR contains a single transmembrane domain and is structurally similar to the class 1 ► cytokine receptor family. There are multiple LepR isoforms, all of which are products of a single *lepr* gene containing 17 common exons and several alternatively spliced 3′-exons. In mice, the six distinct LepR isoforms that have been identified are designated LepRa–LepRf. LepR isoforms can be divided into three classes: secreted, short, and long forms. The secreted form (LepRe) contains only extracellular domains that bind circulating leptin, perhaps regulating the concentration of free leptin. Short forms (LepRa, LepRc, LepRd, and LepRf) and the long form LepR (LepRb in mice) have identical extracellular and transmembrane domains as well as the same first 29 intracellular amino acids, but diverge in sequence thereafter due to the alternative splicing of exons. Unlike the other LepR isoforms, the long form LepRb contains a 302-amino acid cytoplasmic domain that includes motifs for binding of intracellular signaling molecules, and therefore LepRb is crucial for leptin action. The *db/db* mice are deficient in LepRb, but not other LepR isoforms, as a consequence of a mutation that causes mis-splicing of the LepRb mRNA. These mice display a ► phenotype that is indistinguishable from that of mice, which are deficient in all LepR isoforms (db^{3J}/db^{3J} mice) and of leptin-deficient *ob/ob* mice. The function of short form

LepRs is less clear, although proposed roles include the transport of leptin across the ► blood-brain barrier (BBB).

CNS Leptin Action

It is currently accepted that a leptin receptor-bearing neurons within the ► hypothalamus are responsible for mediating a concerted response to fluctuations of body energy stores. Before leptin reacts with its target cells in the hypothalamus, leptin must first cross the BBB. This step is facilitated by a transporter that is an alternatively spliced product (LepRe) of the leptin receptor gene present in brain endothelial cells. Long form leptin receptors, LepRb, are expressed in the CNS and leptin injection induces neuronal activation as evidenced by c-Fos induction. Substantial evidence suggests that the brain mediates the majority of leptin's action on energy homeostasis. Intracerebroventricular injection of leptin decreases food intake and body weight. Mice with a specific deletion of LepRb in the brain are obese, but the deletion of peripheral leptin receptors does not change the normal phenotype of the animal. Expression of LepRb in neurons of LepRb-deficient mice leads to an amelioration of their obesity.

Among the various brain areas that express LepRb, the basomedial hypothalamus is implicated as playing an especially important role. There are two primary populations of neurons that express LepRb and exert potent, opposing effects on food intake and body weight in the arcuate nucleus (ARC) of the ► hypothalamus. Leptin stimulates the production of proopiomelanocortin (POMC) and its derived products including ► α-melanocyte stimulating hormone (α-MSH), which act on melanocortin 4 receptor (MC4R). Leptin also stimulates the production of cocaine amphetamine-regulated transcript (CART). Both α-MSH and CART inhibit feeding as ► appetite suppressants. In another type of ARC neuron, leptin inhibits the production of ► agouti-related peptide (AGRP), an endogenous antagonist that acts on MC4R, and ► neuropeptide Y (NPY). AGRP and NPY are potent stimulators of feeding as ► appetite stimulants. Thus, leptin decreases food intake and increases energy expenditure by simultaneously stimulating the production of α-MSH and CART and inhibiting the production of NPY and AGRP in the ARC. These ► neuropeptides are transmitted to and interact with receptors in neurons of the paraventricular nucleus (PVN) of the ► hypothalamus. These PVN neurons, in turn, generate outputs that coordinate feeding behavior and energy expenditure and send these outputs to the hindbrain. Expression of LepRb is sufficient to reduce food intake and body weight gain when directed to the ARC, but not other hypothalamic regions of leptin receptor-deficient animals. Consistently, deletion of LepR only in POMC neurons leads to a mild obesity and restoration of ARC LepRb signaling attenuates obesity and ► hyperphagia in LepRb-deficient mice. These findings constitute direct evidence that LepRb signaling in the ARC is required for normal energy homeostasis.

Leptin Signaling

The hypothalamus is a major CNS site of leptin's action. It has been proposed that several signaling pathways are involved in mediating the diverse functions ascribed to leptin.

Jak-STAT3

Leptin has been postulated to signal through the Jak kinase family (JAK)-signal transducer and activator of transcription (STAT) signal transduction pathway (Villanueva and Myers 2008). Like other cytokine receptors, LepRb does not contain intrinsic enzymatic activity, but instead signals via a noncovalently associated tyrosine kinase of the JAK family, specifically Jak2. LepRb exists as a preformed homodimer before leptin binding. Leptin binding alters the conformation of the LepRb dimer, enabling transphosphorylation and activation of the intracellular LepRb-associated Jak2 molecules. The activated Jak2 molecule then phosphorylates other tyrosine residues within the LepRb/Jak2 complex to mediate downstream signaling.

Several lines of evidence strongly support a major role of STAT3 in mediating leptin signaling in the hypothalamus. Upon leptin binding, activated Jak2 phosphorylates itself and residues Tyr985, Tyr1077, and Tyr1138 within the intracellular tail of LepRb. Tyr1138 recruits and phosphorylates STAT3 proteins, which then dimerize and translocate to the nucleus and activate a specific program of gene transcription. Leptin activates STAT3 in the hypothalamus, and neuron-specific STAT3 knockout mice develop obesity recapitulating phenotypes of leptin-deficient *ob/ob* and leptin-resistant *db/db* mice. A knockout mouse that leaves the leptin receptor intact but specifically disrupt the LepRb-STAT3 signal are hyperphagic and obese. In these animals, the cytoplasmic tyrosine residue (Tyr1138) in LepRb was replaced with a serine residue, causing a disruption of the LepRb-STAT3 signaling. These findings indicate that the cytoplasmic tyrosine residue (Tyr1138) is necessary for proper LepRb-STAT3 signaling in the hypothalamus after leptin stimulation.

STAT3 mediates the transcription of the suppressor of cytokine signaling 3 (SOCS3) which then binds to Tyr985 of LepRb to inhibit LepRb-STAT3 signaling. Deletion of SOCS3 in the brain results in prolonged leptin-induced STAT3 activation in the hypothalamus and increased leptin sensitivity. More specifically, mice with a mutation

of Tyr985 show reduced food intake and body weight. Hypothalamic STAT3 phosphorylation and anorectic and weight-reducing effect of leptin are also increased in these mice. Thus, Tyr985-dependent attenuation of LepRb signaling represents a leptin-stimulated autoinhibitory signal and SOCS3 functions as a negative regulator of leptin signaling in the hypothalamus.

The mechanisms controlling and terminating the leptin signal transduction also include the dephosphorylation and inactivation of signaling proteins, mediated by protein-tyrosine phosphatase (PTP). PTP1B dephosphorylates activated Jak2 and STAT3. Ablation of PTP1B in *ob/ob* mice attenuates obese phenotype caused by leptin deficiency. PTP1B-deficient mice show an enhanced response toward leptin-mediated weight loss and suppression of feeding. Hypothalami from these mice also display markedly increased leptin-induced STAT3 phosphorylation. Consistent with the inhibition of Jak-STAT signaling, PTP1B overexpression attenuates leptin-induced, STAT-dependent gene activation. Thus, PTP1B is another negative regulator of leptin signaling.

Shp2

Src homology-containing tyrosine phosphatase 2 (Shp2) is a widely expressed cytoplasmic tyrosine phosphatase with two Src homology 2 domains. Phosphorylation of Tyr985 recruits Shp2, which then downregulates Jak2/STAT3 activation by leptin. Thus, it is assumed that the deletion of Shp2 in the CNS enhances leptin-induced Jak2/STAT3 activation and thereby shifts to negative energy balance. However, neuron-specific Shp2 knockout mice develop obesity in the presence of enhanced leptin-induced tyrosine phosphorylation levels of Jak2 and STAT3. Leptin also induces phosphorylation of extracellular signal-regulated kinase (ERK) in the hypothalamus and leptin-induced ERK activation is attenuated in neuron-specific Shp2 knockout mice compared to wild-type mice. However, mice with a mutation of Tyr985 show increased leptin sensitivity, possibly by inhibiting Tyr985-SOCS3-mediated inhibition of LepRb signaling (Villanueva and Myers 2008). Thus, although Shp2 enhances leptin signaling by enhancing ERK signaling, the physiologic role for Shp2 in leptin action remains unclear.

MAPK

ERK, a member of the mitogen-activated protein kinase (MAPK) family, is a key enzyme for many intracellular signaling processes. Leptin induces phosphorylation of ERK1/2 in a receptor-mediated manner that involves Jak2. Leptin-induced ERK1/2 activation was restricted to the ARC POMC neurons. Activation of ERK by leptin is mediated by both Shp2 and direct interaction with Jak2. Pharmacological blockade of hypothalamic ERK1/2 reverses the anorectic and weight-reducing effects of leptin (Rahmouni et al. 2009). Thus, hypothalamic ERK plays a key role in the control of food intake and body weight by leptin.

IRS-PI3K

The phosphatidylinositol-3-kinase (PI3K)/Akt pathway in hypothalamic neurons has been implicated in the regulation of food intake and energy homeostasis. Insulin receptor substrates (IRS) proteins are members of a class of intracellular signaling molecules termed docking proteins that are phosphorylated on multiple tyrosine residues to mediate SH2-protein recruitment and downstream signaling. Although IRS proteins contain tyrosine phosphorylation sites, most of them lie in motifs that bind and activate PI3K.

LepRb signaling is also coupled to the intracellular IRS-PI3K pathway (Villanueva and Myers 2008). IRS-2-deficient mice display increased adiposity and food intake and decreased metabolic rate. Plasma leptin levels are elevated in IRS-2-deficient mice, suggesting that these mice are resistant to the metabolic effect of leptin. Deletion of any of other three IRS proteins does not cause such obese phenotype. Thus, IRS-2 plays a specific role in mediating the effect of leptin on energy homeostasis. Leptin stimulates IRS-2-associated PI3K activity in the hypothalamus, and the pharmacological blockade of hypothalamic PI3K activity blocks the anorectic effect of leptin. Although the cellular mechanisms by which LepRb couples to the regulation of PI3K remain unclear, these findings indicate that PI3K is downstream of leptin signaling. Leptin and insulin act in parallel to stimulate PI3K in POMC neurons, suggesting that the effects of leptin and insulin are integrated by these anorexigenic neurons in the hypothalamus. Thus, IRS-2-PI3K is likely to lie downstream of leptin signaling and participates in mediating the metabolic action of leptin.

AMPK

AMP-activated protein kinase (AMPK) is a heterotrimer consisting of catalytic α-subunits and regulatory β- and γ-subunits. AMPK is regulated by the cellular AMP/ATP ratio and by upstream kinase. AMPK is activated by stress and regulates cellular metabolism by inhibiting energy-consuming pathways and inducing pathways that generate ATP. Once activated, AMPK phosphorylates acetyl-CoA carboxylase (ACC) and switches on energy-producing pathways at the expense of energy depleting processes. Leptin decreases α2AMPK activity in the hypothalamus and decreases food intake by reducing the expression of ► orexigenic AGRP and NPY in the ARC. In contrast to

leptin-induced STAT3 phosphorylation in many hypothalamic regions, leptin-induced decrease in α2AMPK activity is restricted in the PVN and ARC of the hypothalamus (Minokoshi et al. 2004). Thus, AMPK signaling specifically in the PVN and ARC plays a role in mediating anorectic effect of leptin. Insulin-induced inhibition of hypothalamic AMPK activity is blocked by the PI3K inhibitor. Because the effects of leptin and insulin are integrated by hypothalamic neurons via the PI3K/Akt signaling pathway, the leptin-induced inhibition of hypothalamic AMPK activity may be mediated through the PI3K/Akt pathway.

mTORC1

The mammalian target of ▶ rapamycin complex 1 (mTORC1) protein is a serine–threonine kinase that regulates cell-cycle progression and growth by sensing changes in energy status. A number of hormones and cytokines mediate their cellular effects through the mTORC1 signaling pathway. Leptin treatment increases the phosphorylation of both S6 kinase 1 (S6K1) and S6 ribosomal protein (S6), downstream targets of mTORC1 action, in the hypothalamus. Rapamycin, an mTOR inhibitor, attenuates the anorectic and weight-reducing effects of leptin, indicating that increased mTORC1 activity is required for the leptin-induced anorexia (Villanueva and Myers 2008). Mutation of Tyr985 in *leprb* blocks S6 phosphorylation, suggesting a potential role for the Shp2-ERK signaling cascade in leptin-induced mTORC1 activation. While mTORC1 was presumed to serve as the direct cellular sensor for ATP levels, mounting evidence has implicated AMPK in the regulation of mTORC1 activity. Most neurons expressing AMPK in the ARC and PVN possess mTORC1, and leptin-induced anorexia and the AMPK activator blocks hypothalamic mTORC1 activation. Thus, AMPK and mTORC1 interact in the hypothalamus to mediate the metabolic effect of leptin.

FoxO1

The forkhead transcriptional factor subfamily forkhead box O1 (FoxO1 or Fkhr) is a downstream target of Akt. Activation of Akt phosphorylates FoxO1, leading to its nuclear exclusion and proteosomal degradation, and thereby inhibiting its action. The anorectic effect of leptin is inhibited when hypothalamic FoxO1 is activated. Moreover, rats receiving constitutively nuclear mutant FoxO1 in the ARC showed impaired satiety in response to leptin treatment. The anorectic effect of leptin was almost doubled in FoxO1 heterozygous knockout mice compared to wild-type littermate controls, indicating that the loss of FoxO1 function is associated with increased sensitivity to the anorectic effect of leptin. Conversely, the anorectic effect of leptin was greatly reduced in mice expressing FoxO1-3A, indicating that hypothalamic FoxO1 activation can attenuate the effects of leptin on food intake. Furthermore, leptin decreases the hypothalamic expression of FoxO1, a downstream target of Akt and the i.c.v. administration of the PI3K inhibitor attenuates the effect of leptin on hypothalamic FoxO1 expression, suggesting that leptin decreases hypothalamic FoxO1 expression through PI3K activation and that FoxO1 is downstream of the PI3K/Akt signaling pathway in hypothalamic neurons. FoxO1 binds to *Agrp* and *Pomc* promoters and leptin inhibits FoxO1 binding to these promoters through STAT3-mediated competition (Kitamura et al. 2006). Thus, the hypothalamic PI3K-Akt-FoxO1 signaling pathway mediates the effect of leptin on the transcriptional regulation of *Agrp* and *Pomc* and thereby mediates the effect of leptin on energy homeostasis.

Leptin Resistance and Obesity

Leptin resistance, rather than leptin deficiency, appears to be a major cause of human obesity. Although the identity of the crucial mediator(s) of leptin resistance remains unclear, there are some possibilities including the failure of circulating leptin to reach its targets in the brain and inhibition of the intracellular LepRb signaling cascade.

One possible mechanism for leptin resistance is a defective leptin transport across the BBB. The transportation of leptin into the brain is mediated via a specific transport mechanism across the BBB and/or via the ▶ circumventricular organs. Leptin is transported across the BBB by a saturable transport system that may be in part mediated by the short form of leptin receptor, LepRe. In rats, lacking all leptin receptor isoforms, there is a marked decrease in leptin transport rate from the circulation into the brain. Normal transport rate of leptin is maintained in *db/db* mice in which only LepRb is missing, but other isoforms are intact. Leptin transport rate is also reduced in high-fat diet-induced obese (DIO) rats, an animal model of leptin resistance, and DIO mice do not respond to peripherally administered leptin (Levin et al. 2004). Similar impairments are also observed in aged animals, another model of leptin resistance (Scarpace et al. 2001). Systemic administration of leptin inhibited glucose-stimulated insulin secretion in young rats, but this effect was abolished in aged rats. These findings indicate that impairments in leptin transport rates across the BBB cause leptin resistance in the CNS.

Another possible mechanism for leptin resistance is impairments in intracellular LepRb signaling system.

Leptin-resistant DIO mice and aged rats do not respond to peripherally administered leptin, but they partially respond to central injection of leptin, suggesting that the downstream signaling pathways are partially capable of mediating leptin action. This also indicates that the ability of leptin to activate hypothalamic signaling is impaired in leptin-resistant animals. For example, leptin-induced phosphorylation of STAT3 is reduced in the hypothalamus of DIO animals and aged rats. Leptin-induced activation of PI3K and mTORC1 and the inhibition of AMPK are reduced in DIO animals (Cota et al. 2008; Martin et al. 2006; Metlakunta et al. 2008). These data indicate that impairments in these LepRb signaling contribute to the development of leptin resistance. SOCS3 and PTP1B are known to be negative regulators of leptin signaling in the hypothalamus. Overexpression of each of these proteins attenuates signaling through LepRb. Thus, PTP1B and SOCS3 are important physiologic determinants of leptin signaling strength, and PTP1B or SOCS3 contribute to the development of leptin resistance and obesity by inhibiting signaling through LepRb. The LepRb-STAT3 pathway stimulates SOCS3 expression and SOCS3 expression levels correlate with the attenuation of LepRb signaling. Thus, high levels of leptin may induce SOCS3 expression and thereby attenuates leptin signaling in obesity. Theoretically, this increase in SOCS3 should inhibit LepRb signaling, which in turn reduces SOCS3 expression. However, SOCS3 levels are elevated in obese animals with elevated leptin levels. It is possible that chronically elevated leptin levels induce its own feedback inhibition through the induction of SOCS3, effectively limiting the efficacy of chronic exposure of high levels of leptin.

Conclusion

Leptin serves to communicate the state of body energy stores to the CNS in order to maintain normal metabolic and neuroendocrine functions. These actions of leptin require its transportation to the CNS across the BBB via the short form LepRe and its binding to the long form LepRb, followed by the activation of diverse intracellular signaling pathways. Resistance to the metabolic effect of leptin is a major cause of human obesity. Interventions that can enhance the rate of leptin transport across the BBB and intracellular signaling through LepRb are expected to be therapeutically effective in the treatment of obesity.

Leucoplakia

Definition

A white-coloured thickened patch in the mucosa of the oral cavity. This lesion is primarily caused by chronic

irritative stimuli such as tobacco use or friction and may potentially evolve in cancer.

Levodopa

Synonyms
l-DOPA; l-3,4-dihydroxyphenylalanine; 3-hydroxy-l-tyrosine

Definition
Levodopa is used in the treatment of Parkinson's disease, since it is a precursor of dopamine. l-DOPA can cross the ▶ blood–brain barrier, but tends to be metabolized peripherally by both aromatic l-amino acid decarboxylase or DOPA decarboxylase (DDC) and catechol-O-methyl transferase (COMT). Therefore, l-DOPA is often associated with a DDC inhibitor (e.g., ▶ carbidopa) or a ▶ COMT inhibitor (▶ entacapone) as double combinations, or even with both a DDC inhibitor (e.g., carbidopa) and a COMT inhibitor (entacapone), as a triple combination. The combinations are used to prolong the plasma half-life of l-DOPA, but also to avoid its conversion into ▶ dopamine in the periphery, thus avoiding peripheral dopaminergic side effects. Once in the brain, l-DOPA is converted to dopamine, since the DDC inhibitors do not cross the brain barrier, and dopamine will then activate dopamine receptors; this is the basis for the treatment of ▶ Parkinson's disease or dopamine responsive dystonias. Unfortunately, l-DOPA treatment response diminishes over the years, at which point various combination therapies must be started. Also, long-term treatment with l-DOPA may be accompanied by the "on-off" phenomenon, patients oscillating between symptom improvement and abrupt onsets of ▶ akinesia.

Licensing and Regulation of Medicines in the UK

Angus Mackay[1], Sarah Morgan[2]
[1]Agency Board, Medicines and Healthcare Products Regulatory Agency, London, UK
[2]Pharmacovigilance Risk Management, Vigilance and Risk Management of Medicines, Medicines and Healthcare Products Regulatory Agency, London, UK

Synonyms
Drug licensing; Medicines control; Medicines regulation

Definition
The licensing and regulation of ► medicines in the United Kingdom is the statutory responsibility of their Medicines and Healthcare Products Regulatory Agency (MHRA), based in London. Before any medicine can be prescribed or sold in the UK it must have a marketing authorization (previously known as a product license). The marketing authorization specifies precisely the ► summary of product characteristics (SPC), along with the labeling and package leaflet for the product. The regulation of medicines, and the overall responsibilities of the MHRA, involves considerably more than a "once only" marketing authorization. Regulation also entails post-licensing surveillance of safety and scrutiny of any proposed variation to the clinical indications for the medicine, any changes in availability, the on-going quality of the production process, and the enforcement of regulations when required, all in respect of the Agency's principal aim, which is to safeguard the public health. Marketing authorization is given or refused on the grounds of safety, quality, and efficacy. Financial cost plays no part in regulatory decisions.

Current Concepts and State of Knowledge

Status and Function of the MHRA
The legal context within which MHRA operates is described in the Medicines Act of 1968, which became operational in 1971. The Act designated the Secretary of State for Health in England (and equivalents in Scotland, Wales, and Northern Ireland), the Licensing Authority for Human Medicines in the UK. This is a retained authority within the UK. In 2003, the then Medicines Control Agency was re-established as the MHRA, which became responsible not only for the regulation of medicines, but also medical devices and, more recently, blood and blood products. Many of the provisions of the 1968 Act have now been superseded by regulations implementing European legislation on medicines. A diminishing number of medicines are licensed on a national basis by MHRA, solely for use in the UK. Most medicines are now authorized through European procedures to ensure that they are available to, and used in the same way across, all the member states of the European Union (EU). This is either through agreement of identical national authorizations in all member states, based on the assessment of a lead member state (a mutual recognition or decentralized authorization) or through a single EU authorization issued by the European Medicines Evaluation Agency (EMEA) (centralized authorization). Under the "mutual recognition or decentralized" procedures, all EU countries in which marketing permission is sought receive the full marketing authorization application and any objections are considered and resolved through the EMEA's scientific advisory committee, the Committee for Medicinal Products for Human use (CHMP). The centralized approval system is compulsory for biotechnology products and has expanded in scope to cover drugs for AIDS, cancer, neurodegenerative diseases, and diabetes. Often the MHRA will be asked to take the

lead on the licensing process in Europe, particularly for biological and biotechnology treatments, such as a gene therapy.

The Marketing Authorization Process

Authorization to market a medicine is based on detailed requirements and elaborate processes, the scope of which is constantly changing. However, the core elements of medicines control remain essentially unchanged, the primary focus being on the evaluation of pre-licensing data (from nonclinical tests and phases 1 to 3 clinical trials) on safety, quality, and efficacy generated or commissioned by companies and submitted for approval in a Marketing Authorization Application. A medicine progresses "from bench to bedside" over a period of many years, and innovation usually involves the discovery, development, and bringing to market of a new molecular entity (NME). Often the NME is original, such as the first SSRI or atypical antipsychotic, but it may also be a relatively minor molecular modification of an existing drug. The preclinical and nonclinical assessment involves necessary animal and bench testing before administration to humans. ► Phase 1 clinical trials are also known as "first time in man" studies and are conducted usually with healthy volunteers. ► Phase 2 clinical trials are for "proof of concept"; evidence of efficacy, and safety in patients with the target condition. ► Phase 3 clinical trials represent the main clinical reference point upon which marketing authorization may be granted. These are usually large trials (involving many thousands of patients suffering from the target condition), they usually involve comparison of clinical benefits and risk between randomized samples of the target population given either the active drug or a ► placebo and/or active comparator and the results inform the labeling and patient information for the medicine when it is marketed. The benefits recorded in phase 3 clinical trials represent the main database on "► efficacy." Phase 4 trials are conducted post-marketing, the principal aim being to provide ongoing, structured safety information. Benefits recorded in Phase 4 trials are usually more appropriately termed the medicine's "► effectiveness" and more faithfully reflect every day clinical practice in that they derive from patients who have not been so strictly selected or supervised as those involved in Phase 3 studies.

Clinical Trial Authorization

Clinical trials are conducted according to Guidelines on Good Clinical Practice (GCP) as described in EU Directive 2001/20/EC, Article 1, Clause 2, which deal with ethical and scientific issues relating to the design, conduct, recording, and reporting of clinical trials that involve human subjects. The principles of GCP are outlined in Articles 2–5 in the EU Directive 2005/28/EC. The serious side effects experienced by volunteers taking part in a trial of TGN1412 in March 2006 at Northwick Park Hospital are extremely rare but indicate the importance of thoroughly testing a treatment before widespread use. Another regulatory responsibility of MHRA is to authorize any clinical trial of a medicinal product in the UK. Information on the quality of the product and its nonclinical safety will have been obtained before Clinical Trial Authorization can be obtained and any clinical trial programme commencing.

Judging the Balance of Risks and Benefits

Evidence in pursuit of authorization is submitted by the applicant (normally a pharmaceutical company) either in paper form or electronically. Thorough assessment of all of the clinical and preclinical data is conducted in-house by MHRA assessors and a recommendation is then made to one or more elements of the Agency's expert advisory structure. The main independent, expert, group advising the Agency is the Commission on Human Medicines (CHM), which came into being in October 2005. The Commission has three statutory, standing, Expert Advisory Groups – in (1) pharmacovigilance, (2) chemistry, pharmacy, and standards, and (3) biologicals and vaccines. The Chairs of the Expert Advisory Groups are members of the Commission. In addition, there are a number of established Expert Advisory Groups covering a range of specific therapeutic areas such as Psychiatry and Old Age Psychiatry. The Commission is charged with the responsibility to advise Ministers, through the MHRA, on matters relating to human medicinal products.

The Life Cycle of a Medicine

Marketing Authorizations are granted for periods of up to 5 years, when they then have to be renewed. On renewal each marketing authorization must reflect all current knowledge about the product, including any necessary action from the most recent periodic safety update report (PSUR) submitted by the applicant. Once renewed, the marketing authorization will be valid for an unlimited period unless there are justified grounds relating to pharmacovigilance, when it may become necessary to proceed with one additional 5-year renewal. Variations to marketing authorizations must be approved before introducing any changes. They take account of technical and scientific progress, introduce additional safeguards, or reflect

evolving therapeutic indications. It is common practice for new products to be varied many times, particularly in the first 2 years after marketing. Once licensed, a medicine is normally under patent protection for 10 years. Once that period has expired, the originating pharmaceutical company is deemed to have been rewarded for the costs and risks of innovation, and generic versions of the medicine may then enter the market. Such generic medicines contain the same active ingredients as the original product, and the regulatory standards for safety, quality, and efficacy, are the same as for branded products, and marketing authorization must be obtained before the generic medicine is allowed on to the market.

Safety Monitoring

No medicine is completely free of risk but sound evidence underpins all of the MHRA's decisions to ensure that an acceptable balance exists between risks and benefits. Companies applying for a marketing authorization are required to submit a risk management plan which states what is known about the medicine, identifies any gaps in knowledge about safety, and outlines plans to collect data in the post-marketing period to fill those gaps. The MHRA monitors safety and quality standards by a number of means. It conducts regular inspections of good and safe practice including medicines manufacture and supply, carries out routine sampling of marketed medicines at manufacturers' premises, considers on-going reports from health professionals, patients, and manufacturers (such as the Yellow Card scheme, see below), reviews important new evidence on products (such as the SSRIs), and assesses misleading or incorrect information contained in advertisements, product labeling, or product information leaflets (PILs).

Pharmacovigilance is the process of detection, assessment, understanding, and prevention of adverse effects of medicines, against which benefits must be weighed in coming to any decision about the need to modify, restrict, or withdraw marketing authorization. By law, manufacturers must report to the MHRA any important defects in the quality (chemical identity and purity) or clinical safety of a medicine. Any action taken by MHRA is determined by the scale of the threat posed to the public health. If a new side effect is identified, MHRA can seek advice from its external experts and/or commission further research to illuminate the issues. A number of options are available to the Agency short of requiring withdrawal of the product, and any modifications to clinical usage are reflected in the SPC. Health professionals are informed of important new information and advice in relation to medicines via a letter sent by the manufacturer, or via a direct communication from the MHRA through the Department of Health Central Alerting System. The MHRA also issues a monthly bulletin "Drug Safety Update" which includes the latest advice for users of medicines and is available on the Agency's website; www.mhra.gov.uk/mhra/drugsafetyupdate The MHRA operates a "Black Triangle Scheme" under which all new medicines, and established medicines newly authorized for a different patient population, are intensively monitored for the first few years of marketing. Products monitored under this scheme are denoted by an inverted black triangle which appears on any advertising material and in the British National Formulary (BNF). For medicines denoted by a black triangle, it is advised that *all* suspected reactions (including any considered not to be serious) should be reported. The "Yellow Card" scheme is run by the MHRA and the CHM and is used to collect information submitted spontaneously from health professionals and the general public on suspected side effects or adverse drug reactions (ADRs). For established drugs and herbal remedies, all serious adverse reactions in adults and all serious and minor adverse reactions in children under the age of 18 should be reported. Prescribers and users need not be certain about causality, and the golden rule is "if in doubt, report." Reports can be made through the MHRA website; www.yellowcard.gov.uk and paper copies of yellow cards are attached at the end of the BNF. A rich source of data on marketed medicines comes from the general practice research database (GPRD), the management of which is entrusted to the MHRA. The GPRD is the World's largest computerized database of longitudinal medical records from Primary Care. Currently, data are collected on over 3.6 million active patients from around 450 Primary Care practices throughout the UK. It is used worldwide for research by the pharmaceutical industry, clinical research organizations, regulators, Government departments, and leading academic institutions, and is an internationally recognized source of information on the safety and effectiveness of licensed medicines.

The potential for ► selective serotonin reuptake inhibitors (SSRIs) to cause withdrawal reactions, dependence, and suicidal thoughts and behavior has been the subject of controversy and public concern since the late 1980s. The safety of SSRIs was closely monitored leading to updates to the SPC and patient information as evidence accumulated. An Expert Working Group of the Committee on Safety of Medicines (predecessor of CHM) established in 2003 conducted a detailed investigation of clinical trial data, data from the Yellow Card Scheme, and from GPRD.

Their recommendations were published in 2004 and fed into the NICE clinical guideline on depression. In 2005 analyses of 17 placebo-controlled studies found that ▶ atypical antipsychotics were associated with an increased risk of death in elderly people with ▶ dementia. The product information for these medicines was updated to include warnings about this risk. There is increasing awareness of psychiatric adverse effects of non-psychiatric medicines. ▶ Rimonanbant (Acomplia) was withdrawn from the market in the EU in 2008 because the risk of psychiatric disorders, particularly depressive reactions, was considered to outweigh its benefits in the management of obesity.

Herbal Medicines

The regulation of ▶ herbal medicinal products also falls within the remit of MHRA. There are three possible regulatory routes by which a herbal remedy can reach a consumer as an unlicensed, registered, or licensed herbal medicine. By April 2011 all manufactured herbal medicines will be required to have either a traditional herbal registration or a product license. The simplified registration scheme (the Traditional Herbal Medicines Registration Scheme) began in October 2005. Registered products are required to meet specific standards of safety and quality and to be accompanied by agreed indications based on traditional usage. To be licensed a herbal medicine requires to demonstrate safety, quality, and efficacy (or effectiveness) and to be accompanied by the necessary information for safe usage. As with conventional medicines, herbal remedies may be the subject of Yellow Card reports.

Counterfeit Medicines

The detection and confiscation of counterfeit medicines represents a growing activity for MHRA. The World Health Organisation (WHO) estimates that up to 1% of medicines available in the developed world are likely to be counterfeit, and this figure rises to 10% globally. Therapeutic psychoactive drugs are no exception – counterfeit Zyprexa (▶ olanzapine) was detected and recalled in the UK by the MHRA in 2007. Counterfeit medicine is commonly available to consumers via internet online pharmacies, WHO estimating that 50% of medicines available from such sites which conceal their physical address are counterfeit. Counterfeits discovered in the UK typically contain a reduced amount of the active pharmaceutical ingredient, although the wrong ingredient or no ingredient at all have been found less frequently; therefore all counterfeit medicines are potentially dangerous.

Medicines Availability

Marketing authorization of a medicine may specify whether it can be made available either on prescription (prescription only medicines (POM)), available in a pharmacy without prescription under the supervision of Pharmacist (P), or on general sale (GSL). Prescriptions can be issued by doctors, dentists, nurse independent prescribers, pharmacist independent prescribers and supplementary prescribers. Before restrictions on the supply of a medicine can be downgraded from POM, Ministers, advised by MHRA, must be satisfied that it would be safe to allow it to be supplied without prescription. Similarly, switching from P to GSL requires demonstration of acceptable safety if sold or supplied otherwise than by or under the supervision of a pharmacist.

Orphan Drugs

The pharmaceutical industry has little interest, under normal market conditions, in developing and marketing medicines intended for small numbers of patients ("orphan drugs"), and the EU offers a range of incentives to encourage the development of these medicines, including reduced licensing fees. In that case the company applies to the EMEA requesting "orphan designation" for their product.

Powers

When regulations have been breached, the MHRA has the power to prosecute. Courts can impose fines or prison sentences when the law has been broken and the Agency has the power to require unlicensed/illegal products to be withdrawn from the market.

Ligand Binding

▶ Receptor Binding

Ligand-Directed Trafficking

▶ Functional Selectivity

Ligands

Definition

Substances that bind to receptors and alter the three-dimensional shape of selected receptor proteins. The shape of a receptor protein determines the functional state of a receptor. Ligands include substrates, inhibitors, activators, and neurotransmitters.

Liking and Wanting

Definition

Liking is the hedonic quality of food and the pleasing experience of consumption, while wanting is the desire to consume food and its motivational salience. The two are distinct as we can like a food without wanting it and vice versa; however, both are probably intrinsic components of palatability. In terms of animal behavior, the strength of initial feeding response is held to indicate liking, while later feeding behavior, including returning to food source, indicates the desire to consume.

Liquid Diet for Administering Alcohol

Tayfun Uzbay[1], Lisiane Bizarro[2]
[1]Gulhane Military Medical Academy, Department of Medical Pharmacology Psychopharmacology Research Unit, Etlik, Ankara, Turkey
[2]Universidade Federal Do Rio Grande do Sul, Instituto de Psicologia, Porto Alegre, RS, Brazil

Definition

This is a technique of feeding ► alcohol (ethanol) as part of a liquid diet. The technique helps to mimic in experimental animals the effects of chronic alcohol intake in man and is used in research on alcohol effects in experimental animals, especially rodents. It has been used for more than forty years in many experimental studies that investigate and evaluate the effects of ► alcohol abuse and dependence in animals.

Proper controls and dietary adequacy pose significant challenges in studies on chronic exposure to ► alcohol in rodents. Thus, a suitable ► animal model that mimics the effects of chronic alcohol intake in man has long been sought. The technique of feeding ethanol as part of a totally liquid diet was first reported in 1963 (Lieber et al. 1963). Then the liquid diet technique became the most preferred and practical method to induce alcohol physical dependence experimentally since aversions to alcohol can be overcome and the intake is sufficient to sustain high daily alcohol consumption.

The route of drug delivery is an important consideration when evaluating the long-term biobehavioral adaptations occurring in response to chronic drug administration. Before the development of liquid diet technique of alcohol feeding, alcohol was commonly given to rats as part of their drinking water. Alcohol administration in water is associated with insufficient consumption and heavy weight loss. Insufficient intake of alcohol results in low levels in blood; on the other hand, if the intake of alcohol is sufficient, there is significant liver damage due to an inadequate intake of dietary nutrients rather than to effects of alcohol (Lieber and DeCarli 1989). Esophageal and gastric ulceration may also frequently appear. Administering alcohol to experimental animals as part of a liquid diet provides an efficient model allowing investigation of chronic effects of alcohol without irrelevant harmful effects. It is also closer to chronic intake of alcohol in man. In addition to achieving a significant alcohol intake, this technique has also the advantage of following minimization of alcohol-induced liver injury.

There are several liquid diet formulae available containing a mixture of mainly carbohydrates, oils, proteins, vitamins, and mineral (Lieber and DeCarli 1989). Milk is known to be an essential nutrient for growth of mammals. Cow's milk contains the major ingredients of an ideal liquid diet. It has also been reported that cow's milk may be used as a liquid diet in rats after addition of 1% (w/v) sugar (Parale and Kulkarni 1986) or a synthetic sweetener and vitamin A (Uzbay et al. 1995). A modified liquid diet of chronic alcohol administration to rats has also been defined and used (Uzbay and Kayaalp 1995).

Principles and Role in Psychopharmacology

Some Critical Points in Liquid Diet Practice

Liquid diet mixtures with or without alcohol provide 1,000 kcal/L. The liquid diet method for administration of alcohol involves pair-feeding of control and treated animals with identical amounts of the same diet to control exposure to putative nutritional deficits. Control rats are pair-fed with an isocaloric liquid diet containing a carbohydrate such as sucrose or dextrin maltose as a caloric substitute for ethanol. It is highly recommend to have a second control group with continuous access to standard laboratory diet and water. If the alcohol-treated group differs from both control groups and the control groups do not differ from each other, effects seen will not be due to limitations in dietary intake or the liquid diet but rather to alcohol *per se* (Driscoll et al. 1990).

To prevent decrease in diet intake and weight loss, ethanol (96.5%, v/v) should be gradually presented in progressively increasing concentrations during a habituation phase. After almost a week's feeding with liquid diet without ethanol, ethanol (about 2.5% v/v) can be added to the liquid diet for 3–4 days. Then the ethanol concentration can be increased to approximately 5% for 3 days and finally to 7.0–7.5%. When ethanol concentration is increased, a carbohydrate ingredient such as sucrose or dextrin maltose is reduced to maintain isocaloricity of the diet. Then, exposure to ethanol contained in liquid diet (approximately 7%, v/v) is carried on (Uzbay and Kayaalp 1995). A simple formula is shown in Table 1.

Although the liquid diet is meant to be the sole source of fluid and food, decreases in diet consumption can be avoided by giving access to water. Animals which receive water *ad libitum* lose less weight than groups that do not receive water *ad libitum* and keep consuming the same amount of liquid diet (Piano et al. 2001).

Daily alcohol consumption and blood ethanol levels are the most critical parameters for testing the validity of a liquid diet as a vehicle for alcohol administration. Above 10 g/kg/day alcohol consumption for a couple of week and more than 150 mg/dl blood ethanol concentrations may be adequate for development of ► physical dependence on alcohol in rats (Uzbay and Kayaalp 1995). It has been recommended that in an acceptable liquid diet 36–50% of total energy should be acquired by ethanol (Lieber and DeCarli 1989; Uzbay and Kayaalp 1995). Lieber and DeCarli (1989) found that the alcohol obtained from a liquid diet containing 35% ethanol provided about 36% of the daily energy intake, with average ethanol intakes in the range of 10–14 g/kg/day. The associated blood-alcohol levels were over 100 mg/dl when pregnant rats consume the majority of their daily intake. These 100 mg/kg levels were similar to those estimated after human consumption of three drinks in 1 h, and produced most major neurobehavioral effects of ► prenatal exposure to alcohol in their offspring (Driscoll et al. 1990).

Liquid Diet for Administering Alcohol. Table 1. A simple liquid diet formula for studies on alcohol dependence.[a]

Ingredients	Liter
Cow milk	925 ml
Ethanol (%96.5)	75 ml
Vitamin A	5000 IU
Sucrose	17 g

[a]Uzbay and Kayaalp 1995; 1000.7 kcal/L

Utilization of Liquid Diet Technique in Experimental Practice

► Alcohol abuse and dependence remain among the greatest substance abuse problems worldwide. The mechanisms underlying physical dependence to alcohol are poorly understood. Generally accepted criteria for animal models of alcoholism include physical dependence upon and ► tolerance to alcohol. Tolerance is often inferred when large doses of alcohol have minimal effects on behavioral performance after chronic alcohol exposure. Physical dependence is defined by the appearance of withdrawal signs upon removal of alcohol after a period of intoxication.

The technique for the administration of ethanol as part of a liquid diet is preferable in the animal models for the development of alcohol tolerance and dependence. Alcohol ► withdrawal syndrome induced by discontinuing chronic ethanol intake is the most important evidence indicating the presence of physical dependence on alcohol (O'Brien 1996). A severe alcohol withdrawal syndrome is produced by the liquid diet technique in rats. Also, this

method can be used to assess the pharmacological profile of drugs on the alcohol withdrawal syndrome in rodents (Uzbay and Kayaalp 1995).

The liquid diet technique has been adapted to a number of animal species other than rodents. One of the most successful applications has been the baboon liquid diet. The composition of the liquid diet is adjusted to meet the primate's needs. Thus, the ethanol content of the baboon liquid diet is significantly higher than that in the rat because of a lesser aversion to ethanol in the former species (Lieber and DeCarli 1989).

Advantages of Liquid Diet Techniques

The liquid diet technique is a relevant model for alcohol consumption in humans. It provides high daily alcohol intake and sufficient blood alcohol concentrations. It does not cause severe body weight loss. Even body weight increases have been reported in rats consuming ethanol-containing liquid diet (Lieber and DeCarli 1989; Uzbay and Erden 2003).

One of the major advantages of this technique is facilitation of the pair-feeding process. Usually the alcohol-fed animals are allowed dietary consumption *ad libitum,* with amounts consumed being self-limited. Their dietary intake is monitored by determining the amount of liquid consumed (Lieber and DeCarli 1989).

The liquid diet technique has also the advantage of allowing for an accurate recording of the nutrients consumed and for an easy change of the nutritional components according to specific experimental needs. This technique has been useful in characterizing the metabolism of alcohol, in assessing the interactions between ethanol and nutrition, other drugs that are also hepatotoxic agents and carcinogens, as well as in elucidating the mechanisms of alcoholic liver injury, endocrine abnormalities, withdrawal states, developmental problems and other central nervous system changes, including some degenerative and harmful complications (Lieber and DeCarli 1989).

Another use for the liquid diet technique is investigation of prenatal exposure to alcohol in animals. When prenatal exposure to alcohol is required, pregnant rats should receive a liquid diet as their sole source of nutrition and thus a proportion of their caloric intake will consist of ethanol or an isocaloric carbohydrate such as sucrose. A commercially available liquid diet with high protein content meets the requirements during pregnancy and lactation. This technique facilitates comparisons with controls by simplifying pair-feeding procedures (Lieber and DeCarli 1989); this method also avoids effects due to inadequate maternal diets that can exacerbate the effects of ethanol (Lieber 1991).

In contrast to administering ethanol by gastric intubation, not allowing the development of physical dependence to alcohol in rats within a short time may be the main disadvantage of the liquid diet technique. More exposure time is necessary for a satisfactory model of physical dependence in animals.

Lisdexamfetamine

Definition

Lisdexamfetamine (L-lysine-D-amphetamine) belongs to the phenethylamine and ▶ amphetamine chemical classes, and is a drug specifically developed as an alternative to

D-amphetamine for the treatment of ADHD. Lisdexamfetamine has been tailored to have a more prolonged effect than D-amphetamine, yet with a reduced abuse potential. Despite these advantages, the use of lisdexamfetamine has been associated with several side effects including dry mouth, decreased appetite, insomnia, and heart attack or stroke in individuals with preexisting cardiovascular disorders.

Listening Span Test

Definition

In this test, subjects listen to sets of two to seven sentences and complete a written factual verification question for the content of each sentence. After the last sentence of each set, subjects recall the final word of each sentence in the order in which they were presented. The span (working memory capacity) represents the maximum number of sentences performed correctly on at least two out of three trials.

Lithium

Dietrich van Calker[1], Anne Berghöfer[2]

Synonyms

Lithium salts

Definition

Lithium is an alkali metal. Its salts, lithium salts, are used as a psychopharmacological drug for recurrence prevention of manic-depressive illness, in the treatment of acute mania, in augmenting the effects of antidepressants, and in cluster headache. The pharmacologically active compound is the lithium ion (Li^+).

Pharmacological Properties

History

Lithium was first used in psychiatric patients in 1871, based on a wrong pathophysiological hypothesis but abandoned shortly afterwards. In 1949, the Australian psychiatrist John Cade showed first antimanic effects of lithium in psychotic patients. Starting an intensive research in the 1950s, his Danish colleagues Mogens Schou and Poul Christian Baastrup proved the efficacy of lithium in the treatment of acute ► mania and in the prevention of affective episodes in controlled studies.

Mechanism of Action

The initial direct target of Li^+ is the competition with Mg^{2+} at circumscribed metal ion-binding sites of proteins that need the binding of this ion as a cofactor in order to function. The enzymes thus inhibited by Li^+ comprise quite a heterogeneous group of enzymes such as inositolmonophosphatase (IMPase), phosphoglucomutase (FGM), biphosphate-3′-nucleotidase (BNP1), adenylylcyclase (AC), and glycogen synthase kinase 3 (GSK-3). AC, IMPase, and GSK-3 play a critical role in cellular signal transduction mechanisms, which are believed to be the main targets in the mechanism of action of Li^+ ions. Signal transduction mechanisms transmit the information impinging at receptors on the surface of the cell into the interior of the cell. Particularly important components are the "G-proteins," a family of heterotrimeric proteins located at the inner plasma membrane consisting of an α-subunit and the tightly associated βγ-subunits. The α-subunit binds guanyl nucleotides. Interaction with an activated receptor induces exchange of the bound GDP with GTP and dissociation into free α- and βγ-subunits which can activate various effector proteins. Activation is terminated by hydrolysis of GTP to GDP by the intrinsic GTPase activity of the α-subunit and reassociation of the heterotrimeric αβγ-complex. Effector proteins encompass enzymes like AC and phospholipases (C, D, A_2), which synthesize ► second messenger-molecules such as cyclic AMP, inositoltrisphosphate (IP_3), or diacylglycerol (DAG). "Second messengers" often act via activation of protein kinases, which phosphorylate various target proteins such as ion channels or transcription factors. Given the crucial role of signal transduction in cellular regulation, it is not surprising that these systems in the brain are also critically

involved in ► neural plasticity and resilience, and are therefore candidates as potential targets in the mechanism of action of ► mood stabilizers such as lithium. Effects of lithium ions on signal transduction mechanisms have therefore been a major focus of research during the last two decades (for review, see van Calker 2006).

Effects of Lithium on the Adenylylcyclase System

The inhibition by Li^+ ions of AC is known for 30 years. It appears to be due to a competition with Mg^{2+} ions at the catalytic unit of AC. In contrast, the chronic inhibitory effects of lithium on AC are not influenced by Mg^{2+} ions, but reversed by GTP, and therefore believed to be due to actions of lithium on G-proteins (discussed below). More recent research has also confirmed an inhibitory effect of lithium on the inhibitory interaction of receptors with AC and revealed its mediation by an action of lithium on the G_i-protein. In summary, lithium ions appear to balance signal transduction via the AC system. This could dampen the excessive pathological fluctuations of signaling that might be causative related to the mood swings in bipolar disorder.

Effects of Lithium on Phosphatidylinositol (PI) Signaling

Phosphatidylinositolphosphates (PIP), minor components of the lipids in the cell membrane, play an important role in the process of receptor-activated signal transduction. Hormones and neurotransmitters stimulate via activation of particular receptor subtypes the hydrolysis of PIP_3 to two second-messenger molecules, DAG and IP_3, which activate, respectively, protein kinase C (PKC) and the intracellular release of Ca^{2+}-ions. IP_3 is metabolized to myo-inositol, which is used together with DAG for the resynthesis of PIs. The last step in the metabolism of IP_3, the hydrolysis of inositolmonophosphate to myo-inositol by IMPase, is inhibited by lithium ions in the therapeutic concentration range (K_i = 0.8 mM). The "inositol depletion hypothesis" postulates that the lithium-induced inhibition of IMPase leads to a depletion of the brain of myo-inositol and, subsequently, due to a compromised synthesis of PIs to a reduction of receptor-stimulated formation of PI-dependent second-messenger molecules. It is, however, now clear that even a 90% reduction of myo-inositol content in the brain as observed in mice with targeted deletion of the Na^+/myo-inositol-cotransporter (SMIT, discussed in detail below) does not result in functionally relevant reduction of PI synthesis (Buccafusca et al. 2008) although these mice show behavioral abnormalities reminiscent of mice treated with lithium salts (Bersudsky et al. 2008). Thus, while myo-inositol appears to play a role in the behavioral effects of lithium, effects beyond PI-formation seem to be responsible.

Measurements of the effects of lithium treatment on myo-inositol levels in the human brain are partly consistent with the inositol depletion hypothesis. Proton magnetic resonance spectroscopy (MRS) scans of bipolar patients show a significant reduction of myo-inositol content in the frontal cortex already after 5 days of lithium administration, at a time when the patient's clinical state was completely unchanged. Thus, while lithium indeed lowers the myo-inositol in the brain this action alone cannot explain the therapeutic effect but may be the initial trigger for a cascade of subsequent alterations that ultimately account for the therapeutic effect.

In addition to hydrolysis of PIs, brain cells also acquire myo-inositol from the extracellular space by virtue of the sodium/myo-inositol cotransporter (SMIT), a high-affinity myo-inositol transport system that transports myo-inositol into the cells against a steep concentration gradient. Both the activity of SMIT and the expression of its mRNA in astrocytes are downregulated after chronic treatment with therapeutical concentrations of lithium salts. Two other mood stabilizers, ► valproate and ► carbamazepine, elicit the same effect, indicating that it might represent a common mechanism of action of ► mood stabilizers.

Similar to rat astrocytes, downregulation of SMIT mRNA expression also occurs in vivo in bipolar patients chronically treated with lithium or valproate as measured in neutrophils (Willmroth et al. 2007). SMIT expression in neutrophils was increased in bipolar-1 patients. On the one hand, IP_3 and Ca^{2+} signaling were found to be compromised in peripheral blood cells of patients chronically treated with lithium salts. On the other hand, peripheral blood cells of depressive or manic patients showed an increased sensitivity of the PI-system when compared with controls. These results provide evidence for an increased sensitivity of the PI system in peripheral cells of manic-depressive patients that is compensated or even overcompensated by treatment with lithium and, perhaps, other mood stabilizers (see van Calker 2006 for review).

Effects of Lithium on the Arachidonic Acid Cascade in the Brain

Membrane phospholipids can serve as a substrate for phospholipase A_2 (PLA_2), which is also activated by receptor/G-protein coupling. The released arachidonic acid (AA) and its bioactive eicosanoid metabolites can influence many physiological processes, including membrane excitability, gene transcription, ► apoptosis, sleep, and behavior. All three mood stabilizers, lithium, carbamazepine, and valproate downregulate the ► gene expression,

protein level, and activity of the AA-specific PLA_2, and also reduce the protein level and activity of cyclooxygenase 2 (COX-2) and prostaglandin E_2. Thus, AA metabolism might be another common target of mood stabilizers (see Rao et al. 2008 for review).

Effects of Lithium on Glycogensynthase-Kinase-3 (GSK-3)

GSK-3 is recognized as an important regulator of many vital cellular functions such as apoptosis, ► synaptic plasticity, cytoskeletal rearrangement, and ► circadian rhythm. Lithium inhibits GSK-3 directly by virtue of competition with Mg^{2+}-ions and indirectly by virtue of Akt-mediated phosphorylation on the n-terminal serine (for review see Beaulieu et al. 2009). The inhibition by lithium of GSK-3 likely contributes to its antiapoptotic and neuroprotective effects.

Effects of Lithium on Protein Kinase Activities and Protein Phosphorylation

As discussed above, lithium ions modulate the basal and agonist-stimulated concentrations of the second-messenger molecules cyclic AMP, IP_3, Ca^{2+}, and DAG, and should therefore also influence the activity of the protein kinases A, C, and others that are regulated by these second messengers. Several studies have reported that lithium can modulate protein kinase A-mediated protein phosphorylation. Alterations of PKC activity by lithium have been conjectured earlier after the formulation of the inositol depletion hypothesis, since a depletion of inositol should result in a decreased consumption for PI-resynthesis and, thus increased accumulation of DAG, the activator of PKC. PKC regulates many pre- and postsynaptic aspects of neurotransmission including long-term alterations in gene expression and neuronal plasticity. Persistent activation of PKC is often followed by its rapid proteolytic degradation and downregulation of enzyme activity. This could explain why lithium after acute or subchronic treatment induces an increase, while chronic treatment results in a decrease of PKC or PKC-mediated processes. The alterations in gene expression observed after chronic lithium treatment (see below) could at least in part be mediated by effects on PKC.

Effects of Lithium on G-Proteins

As discussed above, the effects of lithium on AC and its actions on PI signaling suggest the involvement of mechanisms beyond alterations of the catalytic subunit of AC or depletion of myo-inositol, respectively. One additional mechanism by which lithium could modify the activity of these signal transduction systems is the alteration of activity of G-proteins. An influence of lithium on G-protein function can be assessed by cholera toxin and pertussis toxin, which via ADP-ribosylation directly activate or inhibit, respectively, the G_s-protein, which stimulates and the G_i-protein, which inhibits adenylylcyclase. Using this approach, it was shown by in-vivo experiments with microdialysis technique that chronic lithium treatment inhibits the function of G_i thereby increasing the basal level of cyclic AMP in the brain of rats. On the other hand, chronic lithium treatment apparently also inhibits the function of G_s, since the inhibition by chronic lithium of the receptor-mediated activation of adenylylcyclase is counteracted by GTP. The inhibition of G_i may be due to a lithium-induced stabilization of the undissociated, inactive heterotrimeric $\alpha\beta\gamma$ state of the G_i-protein. Only this form is subject to ADP-ribosylation (for review, see Manji and Lenox 2000).

Effects of Lithium on Gene Expression

As already mentioned the activation by second messengers of protein kinases can lead to phosphorylation of nuclear transcription factors that regulate gene expression. Accordingly, treatment with Li^+ ions affects the expression of a number of genes, most likely at least in part secondary to modulation of PKC and/or GSK-3 (for review, see Wang and Young 2006). Of particular interest are the actions of lithium on so-called "immediate early genes," members of the c-fos and c-jun families, which encode proteins that form the constituents of a family of transcription factors called AP-1 (activator protein 1). These genes are of pivotal importance for long-term changes in neuronal function. Genes regulated by AP-1 include neurotrophins, ► neuropeptides, neurotransmitter synthesizing enzymes, and other transcription factors. It is now well established that lithium regulates AP-1-binding activity and function. The regulation by lithium of transcription factors is obviously not restricted to AP-1, since it also modulates two other such factors, cyclic AMP-responsive element-binding protein (CREB) and nuclear factor κB (NF-κB).

Effects of Lithium on Cellular Resilience

The neuroprotective effects of lithium were only recently fully appreciated. They are at least partly explained by the finding that lithium upregulates the neuroprotective and antiapoptotic protein Bcl-2. Very recently, it has been shown that mood stabilizer also increases BAG-1, an antiapoptotic, glucocorticoid receptor co-chaperone protein. Many of these effects may be in part mediated via inhibition of GSK-3β. That neuroprotection could also be an important mechanism in vivo is suggested by the

findings that lithium induces ▶ neurogenesis in adult rodent brain and increases the total gray matter in human brain. These results are particularly important in view of the recent evidence from brain imaging and post-mortem studies that mood disorders are associated with morphometric changes suggestive of cell loss and/or atrophy.

Pharmacokinetics

After oral application lithium salts are almost completely resorbed from the intestine. Maximal plasma concentrations are reached after 1–3 h. Elimination occurs exclusively through the kidneys. Steady-state concentrations are achieved after 4–5 days of treatment.

Dosage

The dosage of lithium should be slowly escalated if possible to minimize initially more pronounced adverse effects. At steady state, i.e., 5 days after the last dose escalation, plasma levels should be determined (12 h after last intake). When determining the dose of lithium, it is important to consider that different lithium salts have quite different molecular weights. Lithium tablets must therefore be dosed according to their content of Li^+ given in mmol. When switching from one lithium salt to another, this must be accounted for to avoid, for example, severe intoxication. Thus, for example, while lithium aspartate tablets of 500 mg contain 3,2 mmol Li^+, lithium carbonate tablets of 450 mg contain 12,2 mmol Li^+. When changing 1:1 from lithium aspartate to lithium carbonate this would slightly reduce the dose measured in milligram, but, in fact, increase the dose of the active compound (Li^+) by a factor of almost 4, given the narrow therapeutic range of Li^+ – perhaps, already a toxic dose! While ordinary daily doses amount to 20–30 mmol, older patients with reduced lithium clearance often need much smaller doses.

Efficacy

Lithium salts have been proven efficacious as a monotherapy of acute mania of the euphoric type. Lithium is only a second-line treatment in mixed or dysphoric mania where valproate, ▶ atypical antipsychotics, and carbamazepine are considered first-line choices.

The second indication for lithium is the treatment of acute ▶ bipolar disorder. Lithium can be used as monotherapy as well as in combination with an ▶ antidepressant agent. The latter strategy of primarily combining lithium with an AD should not be mistaken as lithium augmentation (see below). The combination of lithium and the antidepressant should prevent the patient from switching into mania.

There is convincing evidence that lithium is the drug of first choice in the long-term treatment and prophylaxis of bipolar disorder. However, with the expansion of the bipolar spectrum, data on the effectiveness of lithium in routine care have been controversial.

Current guidelines specify that long-term lithium treatment is indicated in patients

(a) who experienced at least one single-manic episode of disruptive severity and have a positive family history;
(b) who experienced two episodes, one of them manic, and have a positive family history;
(c) who experienced three episodes.

In addition, lithium has the greatest evidence supporting an antisuicidal and mortality-reducing effect in bipolar disorder. Clinicians should thus strongly consider initiating lithium treatment in patients with mood disorders accompanied by a high risk of suicide.

Lithium augmentation of an antidepressant has been recommended as the strategy of first choice in patients with therapy-resistant unipolar depression in many of the current guidelines. The addition of lithium to a preceding antidepressant serves as a net-enhancing effect on serotonin function.

Lithium may as well be used for the long-term treatment of recurrent unipolar depression, first of all as the antisuicidal effect has been proven for this diagnostic group too, but in addition due to lithium's episode-preventing effect. However, evidence is not as solid as for bipolar illness.

Other indications for lithium treatment are

- conduct disorder including severe aggression and explosive affect in children and mentally retarded patients, based on lithium's serotonin-enhancing effects;
- cluster headache, with a minor role of lithium behind various first-choice drugs;
- prophylaxis of herpes virus infections, based on lithium's antiviral activity.

Recent research covers the immunoregulatory effects of lithium, possibly relevant in AIDS and cancer as well as neuroprotective effects that are potentially useful in the prevention of dementia and neurological diseases.

Safety/Tolerability

Long-term side effects of lithium are infrequent and serious side effects are rare, if the patients and the dosage are properly selected and monitored. Because lithium ions influence a large number of important biochemical

processes (see above), lithium has a potential to induce a relatively wide spectrum of adverse reactions in a variety of organ systems. With regard to safety and tolerability, acute and prophylactic lithium therapies follow similar basic principles. When considering side effects, it is important to distinguish between acute and long-term changes, the relatively common symptoms that can appear during the normal course of lithium prophylaxis, and the rare, intense symptoms indicative of lithium intoxication.

Table 1 shows the relative and absolute contraindications of lithium therapy.

Table 2 shows adverse effects of lithium therapy and comments on frequency and therapeutic options.

The most important laboratory tests before starting long-term lithium treatment are

- serum creatinine and creatinine clearance (estimate using the Cockcroft equation);
- T3, T4, TSH levels;
- complete blood count;
- ECG;
- fasting glucose levels.

The serum lithium level should be measured 12 ± 1 h after the last dose has been taken. The dose requirement can then be estimated proportionally. Following the initiation of lithium prophylaxis, serum lithium levels must be checked on a weekly basis. Later, monitoring should be performed approximately once per month during the first year of treatment and, subsequently, every 6–12 weeks.

In general, for most patients, a serum lithium level in the range of 0.6–0.8 mmol/l is recommended for lithium prophylaxis. In older patients, in most women, and in patients who are particularly sensitive to side effects, it may be advisable to reduce lithium levels to 0.6 mmol/l.

Serum creatinine should be monitored at least every 6–12 months. Serum calcium should be monitored every 6–12 months due to the risk of hyperparathyroidism during lithium treatment. The patient's thyroid hormone status should be checked by measuring serum T3, T4, and basal TSH once a year. Regular ultrasound examination of the thyroid is also recommended.

A complete blood count (or at least a leukocyte count) should be performed every 6–12 months.

Medical diseases occurring during lithium treatment should be carefully monitored. Serum lithium should be assessed more frequently and the dosage adjusted so that serum lithium levels remain as low as possible.

In patients with arterial hypertension, low salt diets should not be used, and diuretics should only be

Lithium. Table 1. (Absolute and relative) Contraindications to lithium.

	Absolute	Relative	Special caution with
Renal	Acute renal failure	Disorders with decreased glomerular filtration rate, tubular disorders	
Cardiovascular	Acute myocardial infarction	Cardiac rhythm disorders ("sick sinus" syndrome)	Arterial hypertension
Neurological		Cerebellar disorders Myasthenia gravis	Cerebral sclerosis Dementia; epilepsy Parkinson's disease
Dermatological		Psoriasis	
Endocrine		Hypothyroidism Addison's disease	
Gynecological		Pregnancy, 1st trimester	Pregnancy, 2nd and 3rd trimesters; childbirth; breastfeeding
Hematological		Myeloid leukemia	
General		Low sodium diet Anesthesia/surgery	Diarrhea, vomiting, fever
Medication		Diuretics	Antiphlogistics Muscle relaxants; anesthesia Anticonvulsants Tetracyclines; spectinomycin ACE inhibitors Methyldopa; neuroleptics

Lithium. Table 2. Adverse effects of lithium salts.

Organ system	Symptoms	Remarks/Therapy
Neurological/Psychiatric	Fine tremor of the fingers	Frequent side effect. Therapeutic options: dose reduction, change of dose regimen, beta-receptor blockers
	Muscle weakness	More likely at start of therapy
	Memory impairment	
Gastrointestinal	Nausea	Often at start of therapy
	Vomiting	Diarrhea and vomiting can be signs of lithium intoxication!
	Abdominal pain	
	Diarrhea	
Cardiovascular	Changes in ECG; flattening/ inversion of T wave	Reversible. Nonspecific changes are not dangerous
	Arrhythmias	Very rare. Result from initiation or conduction defects
	First-degree atrioventricular block	Regular ECG monitoring
	Sick-sinus syndrome, ventricular extrasystoles	Discontinuation of lithium
	Second- and third-degree AV block, bundle-branch block	
Renal	Polyuria, polydipsia, reduced concentration capacity	Reversible on discontinuation. Management options: dose reduction, amiloride
	Reduced glomerular filtration rate	Rare, prevent or avoid transient lithium subintoxications
	Nephrotic syndrome	Rare, reversible on discontinuation
Metabolism, electrolytes, and water balance	Weight gain	Frequent. Consider low caloric diet with normal sodium intake
	Edema	Rare. Caution when administering diuretics
Endocrine	Euthyroid goiter	Common. Suppressive therapy with L-thyroxin
	Rise of TSH, hypothyroidism	Common in long-term treatment, substitution necessary
	Hyperparathyroidism with hypocalcemia	Infrequent. Check serum calcium
Hematological	Moderate leukocytosis	Common. Reversible
Dermatological	Acne	Treat as usual
	Hair loss	Rare (check for hypothyroidism)
	Psoriasis	Can be exacerbated; maybe a relative contraindication

administered cautiously. Furthermore, in renal hypertension and diabetes mellitus, the late renal sequelae of each disease must be taken into account.

In cases of cerebral sclerosis, dementia, and other psychoorganic disorders, lithium – even at therapeutic levels – can lead to disorientation and other neurotoxic symptoms.

Pregnancy, breastfeeding

The risk of abnormal fetal development under lithium therapy has been overestimated for a long time. Based on case-control studies, the risk can be estimated as only slightly higher than normal during lithium therapy in pregnant women (at standard serum lithium concentrations). If the course of affective illness does not allow for interrupting long-term treatment, a continuation of lithium treatment during the first 3 months of pregnancy may be considered (Cohen et al. 1994). The side effects of lithium therapy apply both to the pregnant mother and the fetus. However, the toxicity threshold for the fetus is lower. A mother may nurse her child when on lithium therapy. However, the child's development must be properly monitored and the advantages of breastfeeding over formula-feeding need to be weighed against the risks.

Local Field Potentials

Synonyms

Field potentials

Definition

The electrophysiological recorded local field potential (LFP) is thought to represent the synchronized input (sum of somato-dendritic potentials) into a neuronal ensemble, as opposed to output neuronal spiking activity. This signal is typically recorded using a low impedance extracellular microelectrode that is subsequently band-pass filtered to remove slower (<10 Hz) and faster signal fluctuations (>300 Hz) indicative of sleep-related slow oscillations and neuronal spiking (action potential) activity, respectively.

Long-Delay Learning

Definition
Long-delay learning refers to the phenomenon whereby an association of two temporally related stimuli can be made when there is an extended period of time between their presentations. Traditional learning theory suggests that as the temporal delay between the presentations of two stimuli increases, there is a graded reduction in the strength of the association between the two. When long-delay learning occurs, the association of the two stimuli occurs over longer intervals than seen under traditional learning conditions. Such learning is usually suggested to be evolutionarily important.

Definition

Memory
► Memory describes the storage of information acquired during learning in a form that can be accessed and retrieved. It encompasses the conscious memory of factual information as well as the unconscious use of procedural information.

The acquisition, storage, and retrieval of information are arguably the most complex and fascinating functions of the nervous system, and undoubtedly involve many brain regions. Following pioneering studies in the twentieth century, a convenient working model of learning and memory emerged whereby different brain regions are deemed responsible for storing different types of learned information (Table 1). The famous case of patient H.M. who suffered specific memory deficits following bilateral removal of the medial temporal lobe (reviewed by Squire and Zola-Morgan 1988) was pivotal in highlighting the separation of brain systems concerned with ► declarative memory (conscious recollection of episodic or semantic information) vs. nondeclarative memory (unconscious use of learned information). Whether or not the different forms of memory stored in different brain regions involve common mechanisms, such as alterations in synaptic strength (e.g., long-term depression), remains controversial.

Long-Term Depression
Long-term depression (LTD) is the weakening of neuronal synaptic connections, typically following a specific pattern of neuronal activity. The reduction in synaptic strength (a form of ► synaptic plasticity) lasts from hours to days. It can be ► homosynaptic (specific to the synapses

Long-Term Depression and Memory. Table 1. Classification of memory. (Reviewed by Squire and Zola-Morgan 1988.)

	Declarative	Nondeclarative
Synonyms	Explicit	Implicit
Definition	Conscious recollection of specific information	Unconscious use of learned information
Brain regions	Hippocampus	Basal ganglia
	Perirhinal cortex	Amygdala
	Prefrontal cortex	Cerebellum
Examples	Episodic memory – the features of an event, e.g., *what, where, who*	Procedural learning of skills and habits

	Recognition memory	Classical Pavlovian conditioning, e.g., emotional conditioning; motor conditioning (e.g., eye-blink)
	Working (short-term) memory	

that are subject to the inducing pattern of activity) or ► heterosynaptic (spreading to nonstimulated synapses).

LTD is widely expressed throughout the central nervous system (CNS) and is elicited at excitatory and inhibitory synapses via a diverse number of mechanisms (Table 2). Evidence suggests that mechanisms of LTD contribute to experience-dependent development and forms of learning and memory, as well as being implicated in neurological disorders, including mental retardation, ► Alzheimer's disease, and drug addiction. For the purpose of simplicity, we have chosen to focus on LTD at excitatory synapses in two brain regions: the hippocampal CA1 area, where the classical form of LTD is expressed, best understood mechanistically, and a potential target site for cognition-enhancing drugs (► cognitive enhancers), and the ► ventral tegmental area (VTA) of the midbrain, where LTD is targeted by ► drugs of abuse and is therefore of particular psychopharmacological interest.

LTD and Memory in the Hippocampal CA1 Region

The ► hippocampus forms part of the temporal lobe learning and memory system concerned with declarative memory of episodic and semantic information (Table 1). Three forms of ► glutamate receptor-dependent LTD have been described in the hippocampal CA1 region (reviewed by Malenka and Bear 2004); each form is summarized in Table 3. The first description of LTD in the hippocampus was Homosynaptic NMDAR-Dependent LTD at Schaffer collateral synapses onto pyramidal cell dendrites in the CA1 region of hippocampal slices (Fig. 1). Postsynaptic NMDA glutamate receptors permit Ca^{2+} entry into the neuron and it is generally well accepted that this Ca^{2+} influx triggers activation of ► postsynaptic proteins including the protein phosphatases, calcineurin, and protein phosphatase 1 (PP1). Expression of NMDA receptor-dependent LTD depends on modification of AMPA glutamate receptor phosphorylation states in addition to physical loss of ► AMPA receptors from the synapse (► receptor trafficking). ► Protein synthesis and degradation of postsynaptic density 95 (PSD-95) are required for the expression of this form of LTD.

Hippocampal mGluR-dependent LTD was first described in the CA1 region of hippocampal slices (reviewed by Malenka and Bear 2004) and requires mGluR5 receptor activation for its induction. This form of LTD can be induced chemically, via application of the selective group I mGluR agonists, or electrically via synaptic stimulation (Table 3). mGluR-dependent LTD, like NMDA receptor-dependent LTD, is expressed via mechanisms involving protein synthesis and the loss of postsynaptic AMPARs.

A distinct form of mGluR-dependent LTD exists in young rats that is induced by the group 1 mGluR agonist, DHPG, and synaptic stimulation but is expressed presynaptically. A retrograde messenger released from the postsynaptic cell is required, and likely candidates include ► endocannabinoids and 12-lipoxygenase metabolites of arachidonic acid, including 12-(S)-HPETE, recently shown to be the endogenous mediator of mGluR-dependent LTD at excitatory synapses onto CA1 stratum radiatum interneurons (Gibson et al. 2008). This heterosynaptic form of LTD (*TRPV1-dependent LTD*) occurs in response to high-frequency stimulation and release of

Long-Term Depression and Memory. Table 2. Examples of LTD in different brain regions.

Brain region	LTD expressing synapses	Drugs affecting LTD	Implications in memory
Hippocampus	*SC–CA1* pyramidal neurons	*NMDAR* and Ca^{2+} channel antagonists	Declarative learning and memory
	SC and *AC* input to *CA1* and *CA3* pyramidal neurons	mGluR antagonists	e.g., semantic and spatial memory, novelty and learned recognition of environment, stress-induced memory recall
	PP to dentate gyrus interneurons	mGluR antagonists	
	SC–CA1 interneurons	Rimonabant (SR141716A), *CB*1 and TRPV1 receptor antagonists, mGluR antagonists	Clinical relevance: amnesia and cognitive impairment
	Interneuron to *CA1* pyramidal neurons	Δ^9-THC	
Ventral tegmental area	*EPSC*s onto dopamine neurons *IPSC*s onto dopamine neurons	Amphetamine, D2 receptor agonists, Opioids	Nondeclarative forms of learning and memory
Caudate/ putamen	Cortical inputs to medium spiny neurons	NOS and soluble guanylyl cyclase inhibitors, mGluR, D2 and *CB1* receptor antagonists	Adaptive learning of motivated actions in response to salient stimuli; development of habits
Nucleus accumbens	Cortical inputs to medium spiny neurons	Δ^9-THC, *CB1* and TRPV1 receptor antagonists, mGluR antagonists	Clinical relevance: development of "unhealthy" habits, e.g., drug addiction
Perirhinal cortex	Cortical inputs from entorhinal cortex to layer II/III pyramidal neurons	Quinpirole, NMDA, and kainate receptor antagonists	Recognition memory
Prefrontal cortex	Layer II/III fibers to layer V/VI pyramidal neurons	5-HT2A/C antagonists, Group I mGluR antagonists, *CB1*R antagonists, MAPK inhibitors	Executive memory functions e.g., working memory, organization of voluntary movements, emotion
Visual cortex	Thalamocortical input to layer V pyramidal neurons	Group II mGluR antagonists, *NMDAR* antagonists, cocaine	Development of visual circuitry
	White matter to layer II–IV neurons	mGluR antagonists	
Cerebellum	Parallel fiber input to Purkinje neurons	NOS and soluble guanylyl cyclase inhibitors, mGluR, D2 and *CB1* receptor antagonists	Procedural (motor) learning

CB1 cannabinoid type 1 receptor; *EPSC* excitatory postsynaptic currents; 5-HT, serotonin; *IPSC* inhibitory postsynaptic currents; *MAPK* mitogen-activated protein kinase; *mGluR* metabotropic glutamate receptor; *NMDAR* ▶ *N*-methyl-D-aspartate glutamate receptor; *NOS* nitric oxide synthase; Δ^9-THC, delta 9-tetrahydrocannabinol; *TRPV1* transient receptor potential vanilloid 1; *SC* Schaffer collateral; *AC* associational commissural; *PP* perforant path.

endocannabinoid-like molecules known as endovanilloids that act on presynaptic TRPV1 (transient receptor potential vanilloid 1) receptors.

The question of whether or not experimental models and mechanisms of LTD in the hippocampus underlie memory (reviewed by Massey and Bashir 2007) remains controversial. In principle, one would determine whether or not LTD is induced in the hippocampus coincidentally with learning and memory and then block LTD, producing correlating impairments in memory acquisition and storage. In practice, the difficulties of "measuring" learning and memory make definitive, conclusive experiments of this kind challenging. CA1-restricted *NMDAR1* gene knockout mice lack NMDA receptor-dependent LTD at CA1 synapses and exhibit impaired spatial memory during a hippocampal-dependent task, while learned

Long-Term Depression and Memory. Table 3. Different forms of LTD in the hippocampal CA1 region.

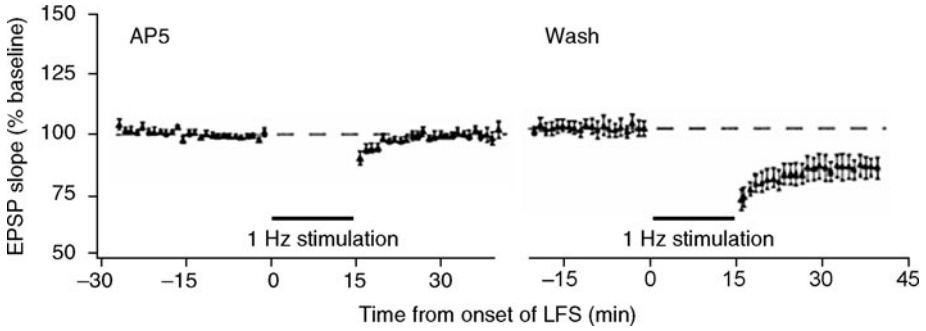
Synapses expressing	*SC–CA1* pyramidal neuron	*SC–CA1* pyramidal neuron, *SC–CA1* s. radiatum interneuron	*SC–CA1* pyramidal neuron, *SC–CA1* s.radiatum interneuron
Induction protocol	Low-frequency stimulation (*LFS*), 0.5–3.0 Hz, typically 1 Hz for 15 mins	Paired-pulse low-frequency stimulation (*PP–LFS*), typically 1 Hz for 15 min; Application of *DHPG*	*PP–LFS*, typically 1 Hz for 15 mins; application of *DHPG;* high-frequency stimulation (*HFS*); e.g., 100 Hz (× 2, 20 s inter-train interval)
Mechanism of induction	*Postsynaptic:* NMDAR activation; Ca^{2+} influx and release from intracellular stores	*Postsynaptic*: Group 1 mGluR activation; Ca^{2+} influx	*Postsynaptic:* Group 1 mGluR activation; Ca^{2+} influx; phosphoinositide hydrolysis; release of retrograde messengers
Mechanism of expression	*Postsynaptic*: Activation of protein phosphatase, calcineurin, *PP1*; *PSD-95* degradation; modification and internalization of *AMPARs*; protein synthesis	*Postsynaptic*: Activation of protein tyrosine phosphatase, p38 mitogen activated protein kinase cascade, *PI3K* and Ras-activated *ERK*; *AMPAR* internalization; protein synthesis	*Presynaptic*: Activation of presynaptic receptors e.g., *CB1* and *TRPV1* by retrograde messengers; decreased presynaptic neurotransmitter release

AMPAR α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate acid glutamate receptor; *CB1* cannabinoid type 1 receptor; *DHPG* Dihydroxyphenylglycine; *HFS* high-frequency stimulation; *hertz* (Hz); *mGluR* metabotropic glutamate receptor; *NMDAR* N-methyl-D-aspartate glutamate receptor; *PI3K* phosphoinositide-3 kinase; *PP1* protein phosphatase; *PP-LFS* paired-pulse low-frequency stimulation *PSD-95* postsynaptic density-95;*TRPV1* transient receptor potential vanilloid 1;*SC* Schaffer collateral



Long-Term Depression and Memory. Fig. 1. Original experimental data of Dudek and Bear (1992) showing NMDA receptor-dependent LTD in the hippocampus. In the presence of the NMDA receptor antagonist AP5, low-frequency synaptic stimulation (1 Hz for 15 min) produces no change in the synaptic response. When AP5 is washed off, the same low-frequency synaptic stimulation now produces a decrease in synaptic responses: LTD. (Reproduced from Dudek S, Bear M (1992) Homosynaptic long-term depression in area CA1 of hippocampus and effects of *N*-methyl-D-aspartate receptor blockade. Proc Natl Acad Sci USA 89: 4363–4367 with permission.)

recognition of a novel environment in rats correlates well with the facilitation of homosynaptic NMDAR-dependent CA1 LTD. Hippocampal LTD is also enhanced by stress, which may be significant in stress-induced cognitive impairment. Overall, evidence suggests that LTD in the hippocampus is associated with at least certain forms of learning and memory (Massey and Bashir 2007).

LTD in the Ventral Tegmental Area (VTA)

The VTA is a midbrain nucleus containing dopaminergic neurons that project to the ventral striatum and the prefrontal cortex, along with nondopaminergic projection and local circuit neurons, some of which are GABAergic. Ascending mesocorticolimbic dopaminergic pathways along with nigrostriatal pathways play a role in internally

generated movements, motivation and reward processing, learning, and cognitive functions, including nondeclarative forms of learning and memory. From a psychopharmacological perspective, these pathways are interesting because they are targets for drugs of abuse and are likely target sites for ▶ anti-psychotic drugs.

A substantial body of literature suggests that glutamatergic synaptic plasticity in dopaminergic pathways may contribute to reward-related learning and the neuronal plasticity mechanisms underlying drug ▶ addiction (reviewed by Kauer and Malenka 2007; Wolf et al. 2004). Persistent forms of synaptic plasticity have been described in dopaminergic pathways (reviewed by Kauer 2004; Kauer and Malenka 2007; Wolf et al. 2004). A form of LTD at glutamatergic synapses was first described in VTA dopaminergic neurons in 2000. This form of VTA LTD was not dependent on either NMDARs or mGluRs, but did require an increase in intracellular Ca^{2+}, most likely via influx through voltage-gated Ca^{2+} channels, subsequent activation of a novel signaling mechanism utilizing protein kinase A, and downregulation of AMPARs. A second form of mGluR-dependent LTD is also expressed in VTA (Bellone and Lüscher 2006).

VTA LTD has been proposed as a potential "brake" on dopaminergic neuron excitability (Kauer 2004), as weakening excitatory synaptic strength would limit the tonic and phasic excitatory drive to these neurons from cortical and brainstem regions, potentially minimizing opportunities for synaptic strengthening such as ▶ long-term potentiation. Removal of this "braking" mechanism is a plausible route for psychoactive drugs to manipulate synaptic plasticity in dopaminergic pathways and drive forms of learning that may be dysfunctional, such as habit learning in drug addiction.

Impact of Psychoactive Drugs

Hippocampal LTD, Cognitive Dysfunction, and Cognition-Enhancing Drugs

Evidence supports the idea that LTD may contribute to cognitive dysfunction. For example, soluble ▶ amyloid-beta protein (Aβ) extracted from the brains of ▶ Alzheimer's disease patients enhances hippocampal mGluR-dependent LTD and disrupts the memory of learned behavior in rats (Shankar et al. 2008). Mouse models of ▶ Huntington's disease, a neurological disorder involving cognitive dysfunction, exhibit impairments in CA1 hippocampal LTD as well as behavioral deficits in hippocampal ▶ spatial learning tasks (e.g., Murphy et al. 2000). NMDAR-dependent hippocampal LTD is both necessary and sufficient to cause an acute ▶ stress-induced impairment of ▶ spatial memory retrieval and may be involved in mediating some of the cognitive deficits that occur in disorders whose symptoms are aggravated by stress (reviewed by Massey and Bashir 2007). Taken together, these data suggest an underlying role for the mechanisms of hippocampal LTD in some aspects of cognitive dysfunction associated with specific neurological disorders.

Mechanisms underlying hippocampal LTD serve as possible drug targets for the treatment of cognitive dysfunction. For example, 17beta-estradiol ameliorates cognitive and memory dysfunction in postmenopausal women in addition to minimally suppressing hippocampal LTD in adult rats, suggesting that estrogen may act to improve memory by suppressing forgetfulness via a synaptic mechanism such as LTD (Vouimba et al. 2000). The NMDAR co-agonist D-serine enhances ▶ NR2B-dependent hippocampal LTD and reversal learning in the ▶ Morris water maze, supporting a role for NMDAR-dependent LTD in spatial learning, and highlighting molecular components of the LTD mechanism as targets for cognition-enhancing drugs.

VTA LTD and Psychoactive Drugs

VTA LTD is blocked by dopamine D2 (but not D1) receptor agonists (reviewed by Wolf et al. 2004), and therefore may be targeted by drugs of abuse that cause an increase in extracellular dopamine levels in the VTA. This has been shown for ▶ amphetamine, which blocks and reverses the somatodendritic ▶ dopamine transporter, thus causing release of dopamine within the VTA. One might expect that D2 receptor antagonists, such as many of the anti-psychotic drugs used to treat ▶ schizophrenia, could potentially enhance VTA LTD. However, comprehensive testing of the antipsychotic drugs used in clinical practice against VTA LTD has not been carried out.

If VTA LTD acts as a "brake" on the excitability of dopaminergic neurons (Kauer 2004), inhibiting LTD may provide a window of opportunity for synaptic strengthening. This ▶ synaptic plasticity would be associated with the salient event that caused elevated levels of extracellular dopamine in the VTA – for example, acquisition of novel reward information, or the presence of a drug of abuse. Such associations may contribute to the learning of procedural information with respect to drug-seeking and drug-taking behaviors that are, one might argue, maladaptive forms of memory. Conversely, induction of VTA mGluR-LTD reverses the ▶ cocaine-induced

strengthening of glutamatergic synapses in dopaminergic neurons, and is a putative mechanism for reversing the neuronal plasticity induced by cocaine (Bellone and Lüscher 2006).

Long-Term Memory

Definition

A protein synthesis-dependent type of memory in charge of maintaining acquired information in a long-lasting manner.

Cross-References

- ► Protein Synthesis as a Mechanism of Memory

Long-Term Potentiation

Synonyms

LTP

Definition

The process by which simultaneous stimulation of two or more neurons induces a long-lasting improvement in the efficacy of the communication between them. A brief and rapid series of stimulation of axons can lead to a long-lasting potentiation of the response of the postsynaptic neurons to a new input. The duration of the potentiation varies from minutes or hours in brain slices and (more rarely) up to weeks in intact animals. It is especially associated with glutamatergic synapses that lasts many hours.

Long-Term Potentiation and Memory

Elizabeth C. Warburton
MRC Centre for Synaptic Plasticity, Department of Anatomy, University of Bristol, Bristol, UK

Definition

Memory is central to our understanding about ourselves with a personal history, and consequently memory loss has a devastating impact on both the individual concerned and their carers. Thus, one of the major goals in neuroscience is to understand the neural mechanisms that underlie the formation of memory within different brain

regions. ►Long-term potentiation (LTP), which is the long-lasting increase in synaptic strength produced by trains of stimuli, has been proposed to provide a suitable cellular model of information storage in the brain. This argument is based on the defining characteristics of LTP (i.e., specificity, associativity, and persistence) and the demonstration that psychoactive drugs that block LTP have been shown to impair memory. This chapter presents the evidence that the mechanisms that underlie LTP may be the same as those that are responsible for the formation of memory, with a focus on the impact of specific pharmacological manipulations. Memory formation clearly relies on fast, long-lasting changes in the connections between neurons; however, whether LTP, as per current studies, underlies learning and memory is still unproven and consequently a matter for ongoing debate.

Impact of Psychoactive Drugs

Any neural mechanism underlying learning and memory must involve processes that enable rapid but lasting changes in the efficacy of synaptic connections in the brain. Hebb (1949) famously proposed that memories may be stored in the brain through changes in the strength of communication between neurons. He postulated that "When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased." In 1973, Bliss and Lømo showed that the repeated application of high-frequency stimulation (a tetanus) to the perforant pathway in the ►hippocampus produced a long-lasting increase in the synaptic response to a subsequent single-pulse stimulus. This long-lasting increase in synaptic strength is termed long-term potentiation (LTP).

The Induction of LTP

LTP has been most extensively studied in the CA1 region of the hippocampus, a region significant because damage here results in severe memory impairments in both humans (specifically, impairments in episodic memory) and in animals (spatial and associative memory). At excitatory synapses in this region, there are two subtypes of ionotropic ►glutamate receptor, the ►AMPA and ►NMDA receptor. LTP is known to depend on the activation of ►NMDA receptors, which are not involved in normal synaptic transmission owing to the presence of magnesium in the ion channel pore of the receptor. However, sustained release of glutamate, which occurs during high-frequency stimulation, causes the post-synaptic cell to depolarize, which removes the magnesium ions from the pore of the NMDA receptor, thus enabling the NMDA receptor to become activated. The NMDA receptor is therefore in a position to detect the co-activation of the presynaptic and postsynaptic cells and can act as what has been described as a "coincidence detector" (Collingridge 2004). Following activation of the NMDA receptor, there is an influx of calcium into the postsynaptic cell, which triggers a range of intracellular second messenger systems, the effect of which is to produce an increase in synaptic strength (LTP). Thus, in most synapses that show LTP, the increase in calcium and thus the induction of LTP depend on the activation of NMDA receptors, but note that there are other forms of LTP, for example in the mossy-fiber-CA3 synapses, that do not depend on NMDA receptors (described as NMDA receptor-independent LTP).

LTP, A Cellular Basis for Memory

It has been argued that LTP displays properties that are consistent with the premise that it is a cellular mechanism underlying memory storage (see Collingridge 2004). These properties include the demonstration that LTP is (1) input-specific, (2) associative or cooperative, and (3) persistent. Input specificity refers to the demonstration that only the afferents that have received stimulation show potentiation. Associativity or cooperative refers to the demonstration that if stimulation of one pathway is insufficient for the induction of LTP, simultaneous strong stimulation of another pathway will induce LTP at both pathways. If LTP is to be considered as a model mechanism for the storage of information, it needs to fulfil other criteria; for example, it must be relatively long lasting, although how long it is required to last is still unclear. Further, LTP must be demonstrated in regions of the brain other than the hippocampus, and indeed there is now accumulated evidence that LTP may be induced in brain areas associated with memory including cortex, striatum, thalamus, cerebellum, and amygdala (see Lynch 2004).

One strategy to investigate the link between memory and LTP has been to investigate whether learning produces LTP-like changes. A number of studies have reported that exposure to stimulus-enriched environment or training on learning tasks such as eye-blink conditioning or radial arm maze can result in increases in synaptic strength within the hippocampal formation (see Martin and Morris 2002). In addition, there is increasing interest in the relationship between LTP in the amygdala and a specific form of learning and memory process known as ►fear conditioning. Fear conditioning is a simple Pavlovian conditioning paradigm, which involves pairing a neutral stimulus, for example a tone (the conditioned stimulus, CS) with an aversive stimulus, for example a mild footshock (the

unconditioned stimulus, US). This form of memory is rapidly acquired, the memory is long-lasting, and the paradigm presents an attractive model for investigation of the neural basis of memory as it is relatively simple when compared with the memory paradigms associated with the hippocampus.

There are several lines of evidence to suggest that LTP in the amygdala underlies the formation of fear conditioning memory. For example, first, LTP may be induced in the same sensory afferents to the amygdala, which show enhanced synaptic transmission during fear conditioning, and second, pharmacological and molecular manipulations that block LTP have also been shown to block the acquisition of fear conditioning (see below). It has also been demonstrated that both LTP and fear conditioning are dependent on the reliability of the CS to predict the US (known as CS–US contingency). Thus, in fear conditioning paradigms, it is well reported that if the CS does not accurately predict the US, or if there is a better predictor, for example other environmental cues, then the memory will be weaker. Similarly, in electrophysiological experiments, it has been shown that when a train of high-frequency stimuli applied to the afferents of the amygdala, were paired with a series of depolarizing current pulses to the postsynaptic cell in the lateral amygdala, robust LTP was produced. However, if a further, unpaired, depolarization was added 10 s after the pairing, no LTP occurred (see Martin and Morris 2002).

Different Forms of LTP may Subserve Different Memory Processes

Further evidence to support the link between LTP and memory is provided by the demonstration that neither LTP nor indeed the formation of a memory is a single process. Different forms of LTP have been described, depending on how long the increase in synaptic efficacy lasts and the degree to which each form of LTP is sensitive to receptor antagonism, dependent on protein synthesis and/or ▶ gene transcription. Broadly, LTP has been divided into two sub-categories: early LTP (E-LTP) and late LTP (L-LTP), where L-LTP lasts for hours in vitro and weeks in vivo. E-LTP (also described as LTP1) decays rapidly, is insensitive to protein synthesis inhibitors, and therefore does not depend on the formation of new proteins in the cell. L-LTP has been further subdivided into LTP2 and LTP3. LTP2 last for an intermediate length of time and depends on new protein synthesis, but not on gene transcription, LTP3 is the long-lasting and most stable component of LTP, which depends on both new protein synthesis and gene transcription (Raymond 2007).

In light of this dissociation between different forms of LTP, mediated by distinct cellular processes, it has been suggested that each may subserve different mnemonic processes. Thus, LTP1 may underlie short-term memory, LTP2 intermediate memory, i.e., memory that lasts up to 3 h, and LTP3 may underlie long-term memory, i.e. memory retained for longer than 3 h (see Blockland and Boess 2008).

The Effects of Pharmacological Agents on LTP and Memory

There is now a vast body of experimental evidence, which has identified pharmacological agents that block both LTP and memory or indeed enhance LTP and memory; hence, a comprehensive review of all such treatments is beyond the scope of this chapter and the reader is referred to the references provided.

Glutamate

NMDA Receptors

One of the first pieces of evidence to suggest that LTP might be required for memory formation in vivo was provided by the demonstration that blockade of ▶ NMDA receptors, by the NMDA receptor antagonist AP5, in the hippocampus, blocks both the induction of LTP and produces an impairment in ▶ spatial learning but not in visual discrimination learning in the rat (see Martin and Morris 2002). Since that initial demonstration, NMDA receptor blockade has been shown to impair a range of hippocampal-dependent memory tasks including T-maze alternation, ▶ contextual fear conditioning, and non-hippocampal-dependent tasks such as fear conditioning. Interestingly, while blockade of NMDAR have been shown to impair both the ▶ encoding and early ▶ consolidation of memory information, and the induction of LTP, blockade of these receptors, has been shown to have no effect on memory ▶ retrieval or on pre-established LTP (Collingridge 2004; Martin and Morris 2002).

▶ Metabotropic Glutamate Receptors

There has been disagreement over the role that metabotropic glutamate receptors (mGluRs) play in LTP. LY341495, an mGluR antagonist, which at certain concentrations antagonizes all known mGlu receptors, has been shown to have no effect on LTP at hippocampal CA1 synapses. In contrast, antagonism of group 1 MGlu receptors has been shown in some studies to block the induction of LTP and blockade of group 1 mGLURs has also been shown to impair a range of behaviors including spatial learning, contextual fear conditioning, and inhibitory avoidance learning (see Lynch 2004).

AMPA Receptors

► Ampakines are a class of compounds, which bind to AMPA receptors but do not show either agonist or antagonist effects. These compounds act to keep the channel open once glutamate has bound, thus prolonging current flow through the receptor. Ampakines have been shown to lower the threshold for the induction of LTP and increase the magnitude of LTP. Behavioral studies have revealed that these compounds improve retention in the ► radial arm maze and improve ► short-term memory (Lynch and Gall 2006).

► Acetylcholine

► Muscarinic Receptors

Acetylcholine muscarinic receptors (mAChRs) are ► G-protein coupled receptors of which there are five subtypes (M_1–M_5). mAChRs have long been implicated in a variety of memory functions, for example ► scopolamine a non-selective mAChR antagonist has been shown to produce significant behavioral impairments in tasks including the water maze, fear conditioning, and ► object recognition. Consequently, the roles of the mAChRs in LTP at many areas of the central nervous system have been extensively studied. Activation of mAChRs has been shown to facilitate the induction of LTP and application of the muscarinic agonist carbacol has been shown to enhance LTP and to improve memory performance (see Blockland and Boess 2008; Shinoe et al. 2005). However, in contrast to such reports, administration of the nonselective mAChR antagonist atropine was found to have no effect on the induction of LTP, although it did significantly reduce the magnitude of the LTP, and scopolamine has been shown to have no effect on the induction of LTP in the perirhinal cortex.

► Nicotinic Receptors

Neuronal acetylcholine nicotinic receptors (nAChRs) are ligand-gated ion channels comprising either α subunits or a combination of α and β subunits, with α7 and α4 β2 being the two main subtypes in the central nervous system. Studies have shown that application of ► nicotine can both induce LTP and enhance LTP produced by sub-threshold levels of stimulation, an effect dependent on both α7 and non- α7 nAChRs. In memory tasks, acute intrahippocampal administration of nicotine after training has been shown to enhance hippocampal-dependent memory, and chronic administration of nicotine has been shown to improve spatial working memory in the radial arm maze however other studies using different doses, dosing methods, and regimes have found conflicting results (see Kenney and Gould 2008).

► Dopamine and Noradrenaline

The neuromodulators dopamine and noradrenaline have been implicated in both LTP and memory. Thus, pharmacological blockade of dopamine D1/D5 receptors has been shown to impair L-LTP in the CA1 region of the hippocampus and to impair long-term but not short-term spatial memory in the water maze while blockade of beta-adrenergic receptors modulates E-LTP (see Martin and Clark 2007). LTP has been produced in the mesolimbic dopamine system, which comprises the ► ventral tegmental area and ► nucleus accumbens and in view of the key role this neural system plays in the behavioral effects of drugs of abuse, there is increasing research into the role of LTP, and other forms of ► synaptic plasticity in the development of addiction (see Saal and Malenka 2005).

Conclusions

There is now a huge body of research attempting to evaluate the hypothesis that LTP is a cellular substrate for learning and memory, and clearly much of this evidence has been obtained from pharmacological studies like those described above. However, such evidence is correlative, and although both LTP and memory may be disrupted by the same interventions, this does not prove that both processes are mediated by the same underlying mechanisms. For example, it has been argued by some investigators that the observed impairments in the water maze following NMDA or muscarinic receptor blockade might be accounted for by impairments in sensorimotor processes, or that LTP might play a role in cognitive processes other than memory, for example attention, that contribute to performance in behavioral tasks (see Martin and Morris 2002). Further, LTP is often studied in vitro, using highly artificial stimulation protocols; so, while the processes that produce LTP in the laboratory may provide valuable insights into synaptic physiology, it must be remembered that they do not represent the actual mechanism for the storage of information in vivo.

Thus, while the acquisition and consolidation of memory must require quick and long-lasting changes in neural circuitry, a definitive link between LTP and the engram has not yet been provided.

Long-Term Treatments for Bipolar Disorder

► Mood Stabilizers

Loprazolam

Definition

Loprazolam is a high-potency medium-acting benzodiazepine medication used in the treatment of sleep disorders. It has some antispasmodic and anticonvulsant effects. It is not antidepressant. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Long-term use may induce dependence with withdrawal reactions. Recreational use and abuse can occur: loprazolam is a scheduled substance.

► Benzodiazepines
► Insomnias
► Minor Tranquilizers

Lorazepam

Definition

Lorazepam is a ► benzodiazepine that has anxiolytic, sedative, and anticonvulsant properties. Its duration of action is of intermediate length relative to other benzodiazepines (i.e., its ► elimination half-life is 10–18 h) and it does not have active (i.e., benzodiazepine) metabolites. Lorazepam is used primarily to treat anxiety, including panic. Like most similar compounds, it is subject to tolerance, dependence, and abuse.

Definition

Lormetazepam is a benzodiazepine medication that has anxiolytic, sedative, and anticonvulsant properties. Its duration of action is of intermediate length relative to other benzodiazepines (i.e., ► elimination half-life 10–12 h) and it does not have active (i.e., benzodiazepine) metabolites. It has been used clinically as a hypnotic. Like most similar compounds, lormetazepam is subject to tolerance, dependence, and abuse.

μ-Receptor

Definition

The term μ-opioid (μ from *m*orphine) peptide receptor represents the ▶ G-protein-coupled receptor that responds selectively to the majority of clinically useful ▶ opioid drugs. It is usually named the μ-receptor or MOR. It is expressed in areas of the nervous system that mediate therapeutic and adverse effects of most opioid drugs. The MOR receptor protein is produced by a single gene. Several mRNA splice variants are known to exist and produce receptor proteins that display different properties when expressed in cells. When activated, the MOR receptor predominantly transduces actions via inhibitory G-proteins. The direct electrophysiological consequences of MOR receptor activation are usually inhibitory.

μPET

Definition

A μPET machine is a relatively high-resolution positron emission tomography imaging device for the noninvasive assessment of small animals, for example, to study receptor occupancy (with specific radioligands) or functional activity (with radiolabeled deoxyglucose) of the brain, to evaluate animal models of psychiatric or neurological disorders, or to develop novel radiotracers for use in man.

Definition

Functional magnetic resonance imaging (fMRI) is a specialized form of MRI and a modern ▶ neuroimaging technique that is typically used for investigating brain activity in animals and humans. Most fMRI experiments measure blood-oxygenation-level dependent (▶ BOLD) contrast – an endogenous hemodynamic signal that reflects blood oxygenation changes linked to neuronal activity. BOLD fMRI is thus an *indirect* or surrogate measure of neuronal function. Because intracranial recordings of ▶ local field potentials better predict changes in BOLD signal amplitude than ▶ multiunit activity, it is generally considered to reflect synaptic input and local processing in neuronal ensembles as opposed to neuronal spiking activity per se. In conventional applications, BOLD fMRI has a temporal resolution in the order of seconds (1–3 s) and a spatial resolution in the order of millimeters (cubes of tissue 3–5 mm on each side) when covering the whole

brain. Largely due to its noninvasive nature and good spatiotemporal resolution, but also through growing understanding of the biophysical basis of the BOLD signal, as well as advances in the acquisition, design, and statistical analysis of brain mapping experiments, BOLD fMRI has become a principal research tool in human ▶ cognitive neuroscience since the mid-1990s.

Principles and Role in Psychopharmacology

Blood circulation and energy metabolism are closely linked to neuronal synaptic activity in the brain – an observation first suggested by nineteenth century researchers. fMRI, and specifically BOLD contrast fMRI (BOLD fMRI), is a modern neuroimaging technique that exploits the fact that such processes, particularly blood flow and blood oxygenation, are regionally coupled to changes in neuronal activity levels.

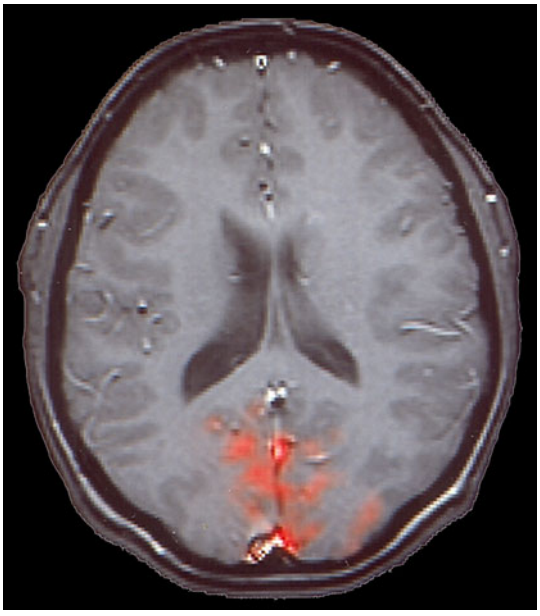
Background Principles

Active neurons consume oxygen that is carried by hemoglobin in capillary red blood cells. Under periods of increased neuronal demand for oxygen (⇑ oxygen utilization), there is an accompanying increase in cerebral blood flow (CBF) to active brain areas, or functional hyperemia. Central to understanding BOLD fMRI is that, during this period of increased blood flow, blood oxygenation increases more than what is required to satisfy the increased neuronal demand for oxygen, leading to local changes in the relative concentration of oxygenated and deoxygenated blood, as well as local cerebral blood volume.

Magnetic resonance imaging (MRI), extending the principle of ▶ nuclear magnetic resonance (NMR), has the capacity to measure physiological changes associated with increased (or decreased) neuronal activity, such as measurements of tissue perfusion, blood volume, and blood oxygenation. To understand these measurements, it is necessary to have basic knowledge of the physical, biophysical, and engineering principles of MRI and its functional variants such as BOLD fMRI. For this, several comprehensive introductory texts are available (inc. Buxton 2002; Huettel et al. 2004; Jezzard et al. 2003).

Two early discoveries of special relevance to BOLD fMRI are (1) that deoxygenated hemoglobin is ▶ paramagnetic and (2) that there is an oxygenation dependence of the transverse relaxation time of water protons in whole blood at high magnetic field strengths (1.5 or greater). This led Ogawa et al. (1990) to investigate whether altering blood oxygenation levels would influence the visibility of blood vessels on T_2^*-weighted MR images. When increasing the relative concentration of deoxygenated hemoglobin in blood, they observed reduced T_2^*-weighted signal intensity in local vasculature on ▶ gradient-echo images (GE). Ogawa and colleagues went on to suggest that their observation of "BOLD contrast" could potentially be used to investigate neuronal activity, albeit indirectly, through changes in blood flow and tissue oxygenation.

The first BOLD fMRI studies of the brain in humans were reported in 1992 and involved sensory related activation of the visual and motor cortices (Fig. 1). This work confirmed that MRI could be used to investigate regional changes in brain activity, similar to functional brain mapping studies undertaken at the time with ▶ PET imaging. Since these initial studies, the growth of BOLD fMRI in neuroscience applications has been extraordinary. While BOLD fMRI initially provided a noninvasive and improved brain mapping alternative to PET imaging, it has since taken on its own unique role in cognitive neuroscience research, as well as having a variety of



Magnetic Resonance Imaging (Functional). Fig. 1. An early blood-oxygenation-level dependent (BOLD) fMRI study of visual cortex activation in a single human subject. This study was performed in October 1992 at the Magnetic Resonance Centre of Pedralbes in Barcelona, Spain (gradient-echo sequence at 1.5 T, GE Signa), single-slice acquisition, 96 × 64 pixel matrix; round surface coil; TR=7 s. The subject was stimulated with an 8 Hz visual flicker in a blocked-design experiment that compared four blocks of visual stimulation alternating with four blocks of darkness. Eight images were acquired per block. (Image courtesy of J. Pujol.)

clinical and commercial applications. According to a recent estimate, over 19,000 peer-reviewed articles are returned from an ISI/Web of Science search with the keyword terms "fMRI" or "functional MRI" or "functional magnetic resonance imaging," and where the rate of fMRI-related publications has risen from a total of four papers in 1992 to eight papers per day by 2007 (Logothetis 2008). Of the total number of reports, approximately 43% investigated functional localization and/or anatomy associated with specific stimuli or tasks (sensory, cognitive, and emotional); 22% were "region of interest" (ROI) studies examining the physiological properties of distinct brain regions; 8% were related to neuropsychology; 5% were on the properties of the fMRI signal; and the remaining work was related to various topics including plasticity, drug action, experimental design, and analysis methods. For a specific overview of fMRI applications in clinical neuroscience, including ▶ pharmacological fMRI (ph-fMRI), see Matthews et al. (2006).

Spatial and Temporal Resolution

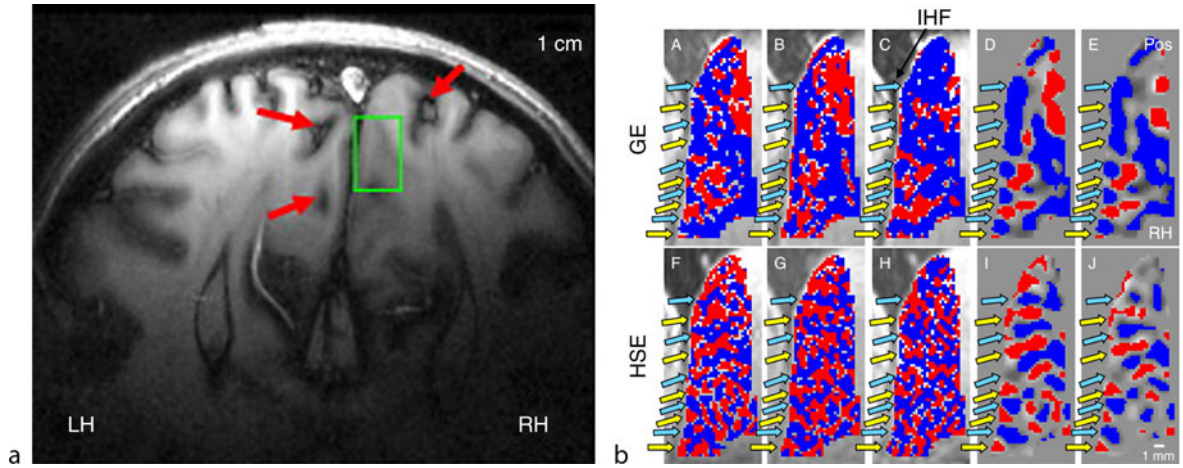
Spatial resolution in fMRI experiments is defined by voxel size – 3D rectangular prisms (volume elements) that form the basic unit of measurement in MR images. In whole brain fMRI studies, voxels will typically have a resolution of 3–5 mm (on a side), which is determined by the field of view, matrix size, and slice thickness of the imaged volume. Reducing the size of voxels generally comes at the risk of decreasing signal-to-noise (given the various noise sources in BOLD fMRI; see below) and increasing acquisition times, especially in whole brain studies. Larger voxels, on the other hand, may contain to a larger extent signal contributions from distinct tissue types or regions, known as "partial volume effects." Determining appropriate voxel size is therefore a trade-off with respect to spatial coverage, resolution, and acquisition time in fMRI studies.

Ultimately, the spatial resolution of BOLD fMRI is constrained by the specificity of the brain's vascular system, which can be said to define the technique's *functional resolution*. This refers to the anatomical coincidence between hemodynamic and neuronal activities, which varies in the brain depending on characteristics of the local microvasculature (e.g., density and architecture). BOLD fMRI is sensitive to signal changes in the capillary bed ($<$10 μm in diameter) and the venous side of the circulation, including venules and larger draining veins (100 μm to mm in diameter), since arteries and arterioles are close to full saturation and contain no deoxygenated blood. In the case of large vessels, signal changes can be displaced up to several millimeters from the activated site and may obscure the localization of smaller magnitude changes, such as those in the capillary bed supplying active neurons. Higher spatial specificity is therefore advantageous in BOLD fMRI experiments. To this end, advanced acquisition sequences have been developed to emphasize or de-emphasize vascular components of the BOLD signal that are distant from neuronal activity, while fMRI experiments can also be designed to better localize hemodynamic responses to specific regions of interest (see example in Fig. 2). The experiments that have compared BOLD fMRI and intracranial microelectrode recordings has shown that the BOLD signal is a robust (linear) predictor of neuronal activity only when considered at the supra-millimeter scale (3–6 mm^2).

Temporal resolution in BOLD fMRI experiments is usually defined by repetition time (TR), or the time taken to acquire one image of the brain or specified volume (number of slices) of interest. In conventional experiments, TR may range from 1 to 3 s, giving such measurements an intermediate level of temporal resolution in-between electrophysiological (ms) and positron emission tomography (PET) imaging (tens of seconds) techniques. Like its spatial resolution, temporal resolution in BOLD fMRI is constrained by technical and physiological factors. In the former case, a major contribution to its current success has been the development of novel acquisition schemes, notably ▶ echo-planar imaging (EPI), that permit rapid functional imaging of T_2^*-weighted images of the whole-brain. Currently, BOLD fMRI with segmented GE-EPI can acquire single slices at a sampling rate of less than 100 ms. Depending on the experimental design, reducing TR (⇑ temporal resolution), will improve the statistical estimation of the BOLD hemodynamic response to a certain extent, although this presents a trade-off between image quality and spatial coverage. Ultimately, temporal resolution in BOLD fMRI is constrained by the slower nature of the hemodynamic response to neuronal activity, whose onset lags behind the timing of actual neuronal events by 4–6 s (see below). Despite these absolute timing differences, well-designed experiments have been able to discriminate the *relative timing* of BOLD signals between different stimuli or brain regions within a few hundred milliseconds (reviewed in Chapter 8, Huettel et al. 2004).

Characteristics and Generation of the BOLD Response

As introduced above, BOLD signal is inversely proportional to the concentration of deoxygenated hemoglobin, which is influenced by local changes in three physiological parameters: cerebral blood volume (CBV), CBF,



Magnetic Resonance Imaging (Functional). Fig. 2. BOLD fMRI of ocular dominance (OD) columns in the human visual cortex: vertical neuronal columns that respond preferentially to visual stimuli presented to one eye rather than to stimuli presented to the other eye. fMRI studies of OD are often presented to showcase the level of spatial specificity that can be achieved with advanced fMRI techniques. In humans, OD columns are separated by approximately 1 mm. *Left panel* **a**: The imaging slice from a single subject selected in a study by Yacoub et al. (2007) that permitted a resolution of 0.25×0.25 mm^2 in-plane for a slice thickness of 3 mm. *Right panel* **b**: Differential functional OD maps depicting increased activity for left eye stimulation (blue) and right eye stimulation (red) for this subject across distinct sessions (A, B, C & F, G, H) and different filtered averages (D, E and I, J). The upper and lower rows show maps obtained using gradient-echo (GE) and hahn spin-echo (HSE) fMRI, respectively. Both approaches reproduced the expected OD columns, although with increased specificity seen with the HSE method due to its enhanced ability to suppress the influence of large vessels. *Pos* posterior; *RH* right hemisphere; *IHF* inter-hemispheric fissure. and the cerebral metabolic rate of oxygen consumption (CMRO2). Signal increases reported in BOLD fMRI experiments are related to the fact that neuronal activity increases regional CBF and glucose utilization (CMRglu) to a larger extent than CMRO2. The net effect of neuronal excitation is therefore to decrease the concentration of deoxygenated hemoglobin ("deoxyhemoglobin washout"; Brown et al 2007), which in turn increases BOLD signal strength. It is now understood that the characteristic BOLD signal changes observed in fMRI studies reflects the summation of these competing events (CBF, CMRO2, and CBV), resulting in a complex response function that is controlled by several parameters (Buxton 2002). In other words, the BOLD signal does not reflect a single physiological process, but rather represents the combined effects of CBF, CBV, and CMRO2 (Fig. 3).

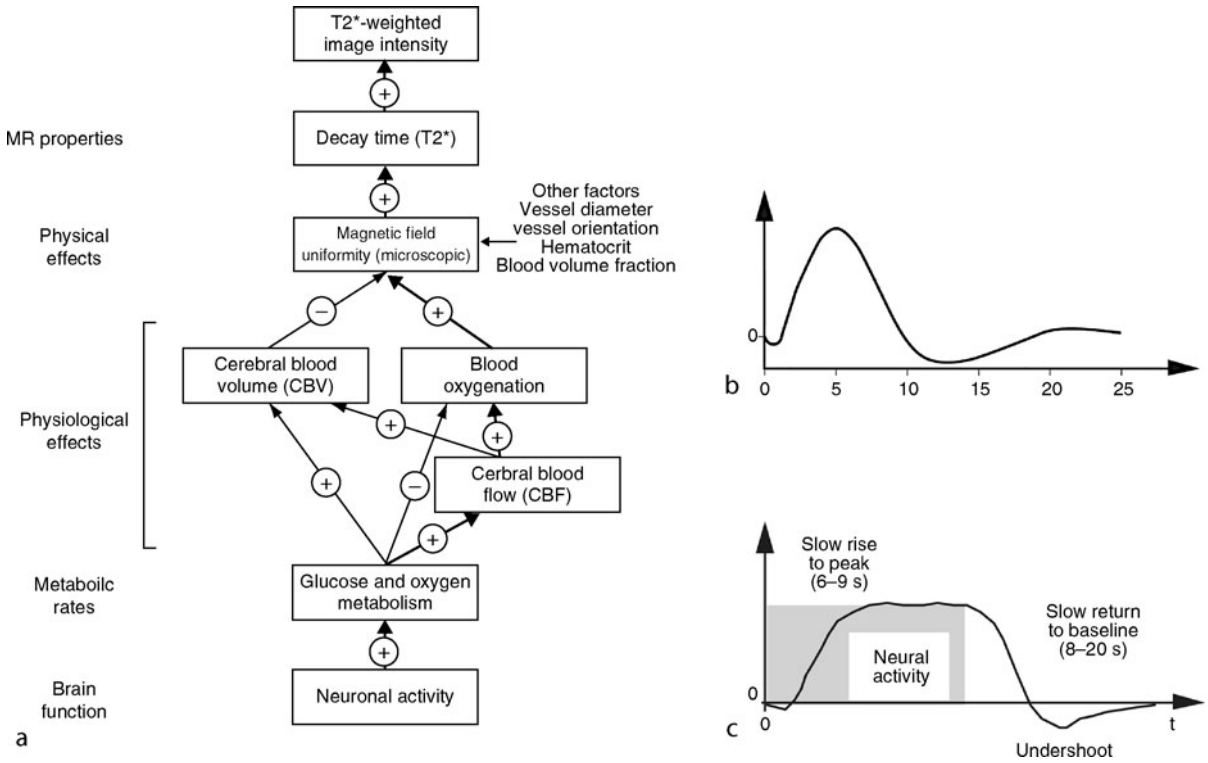
The BOLD response to a short duration event or single stimulus has a canonical hemodynamic waveform shape, which is often described as consisting of (1) a fast response lasting 1–2 s ("initial dip") in which there is a small decrease in BOLD signal amplitude, (2) a larger amplitude hyperemia associated with the inflow of oxygenated blood, which peaks at approximately 4–6 s after stimulus presentation, and (3) a refractory period lasting 6–12 s where the signal undershoots the baseline due to the combination of reduced regional CBF and increased CBV ("post-stimulus undershoot"). The second phase of hyperemia (or hyperoxic phase) is the common focus for detecting increases in brain activity measured by BOLD fMRI. The so-called "initial dip" is suspected to result from early oxygenation changes (oxygen extraction) localized to capillaries, and has been argued as more closely related to neuronal activity than the ensuing hyperemia. However, this observation remains controversial and is not reliably detected in BOLD fMRI studies. Like the BOLD response to a single event, multiple repetitions of the same stimuli in blocks (see below), will see the BOLD response rise to a steady plateau and decline once the block ends, although there are variations to this rule, such as an initial overshoot, slow increasing and decreasing ramps, or an undershoot at the end of the stimulus.

Neurovascular Coupling and Neuronal Correlates of BOLD

The process by which neural activity influences the hemodynamic properties of the surrounding vasculature (principally arterioles) is referred to as neurovascular coupling,



Magnetic Resonance Imaging (Functional). Fig. 3. *Left panel* **a**: Measuring signal changes in fMRI experiments depicted as a complex multistage process, beginning with neuronal activity and ending with BOLD signal measurement as a property of the MRI scanner and pulse sequence. This figure presents a schematic illustration of interactions in the formation of the BOLD signal. Positive/negative arrows indicate positive/negative correlations between the parameters. The right pathway (bold arrows) is the most significant effect in most BOLD fMRI. *Right panels* **b** *and* **c**: Simplified schematic representation of the BOLD hemodynamic response waveform to a short duration stimulus (**b**), and to a block of multiple consecutive stimuli (**c**). (Parts of this figure reproduced with permission from http://www.eecs.umich.edu/~dnoll.)

although the mechanism(s) responsible for this is not fully understood. One hypothesis regarding a principal signaling route is that a feedforward pathway involving neuronal-glial interactions after neurotransmitter release stimulates regional CBF. Astrocytes play a crucial role in neurotransmitter recycling, using energy reliant on glycolysis (nonoxidative glucose metabolism) to clear extracellular glutamate and convert it to glutamine after neuronal firing. Increased glycolysis in astrocytes is suspected to trigger intracellular events that couple glutamate cycling rate to the production of vasoactive agents, including nitric oxide and eicosanoids. Therefore, according to this view, neurovascular coupling is mediated by neuronal signaling mechanisms via glial pathways, as opposed to signaling mechanisms of an energy deficit in neurons per se. This view supports, in part, the notion that glycolysis is relevant to the detection of BOLD activity changes and in explaining the apparent mismatch between CBF, CMRglu, and CMRO2 during evoked brain activity (Raichle and Mintun 2006).

Detailed biophysical models have also been proposed to explain the complex shape of the hemodynamic response observed in BOLD fMRI studies, accounting for the changes in CBF, CBV, and CMRO2 that accompany increased neuronal activity. Most prominent is the "balloon model" of Buxton and colleagues. According to this work, the apparent discrepancy between CBF and CMRO2 results from how oxygen is supplied to neurons related to its poor diffusion in brain tissue. That is, blood flow must increase more than oxygen consumption to maintain tissue–oxygen gradients supporting oxygen delivery to tissue because its extraction (by passive diffusion) from blood is less efficient at higher flow rates (Buxton 2002). Evidence favoring this model versus the former hypothesis (and vice versa) can be found in expanded form in Buxton et al. (2004) and Raichle and Mintun (2006), respectively.

Regardless of the precise cause(s) of the physiological changes that give rise to the BOLD signal, evidence has been marshaled in support of a close relationship between evoked hemodynamic and neuronal activity changes. Notably, in the work of Logothetis et al. (2001), which compared BOLD fMRI and intracranial electrophysiological measurements recorded simultaneously in monkeys, BOLD signal was found to be spatially well localized and scaled with neuronal activity. Specifically, these authors reported that the amplitude of the BOLD signal was better correlated with recordings of local field potentials rather than multiunit activity (Logothetis et al. 2001). That is, BOLD signal better reflects the weighted average of synchronized activity of the input signals into a neuronal ensemble than their spiking (action potential) activities. This suggests that BOLD signal changes, primarily reflect input and integrative processes rather than output (communicative) activity. However, there remains some debate about the contributions of different types of neuronal activity to the BOLD signal (local field potentials vs. spiking activity), as the former will be correlated with the latter in many instances (Raichle and Mintun 2006).

Experimental Design

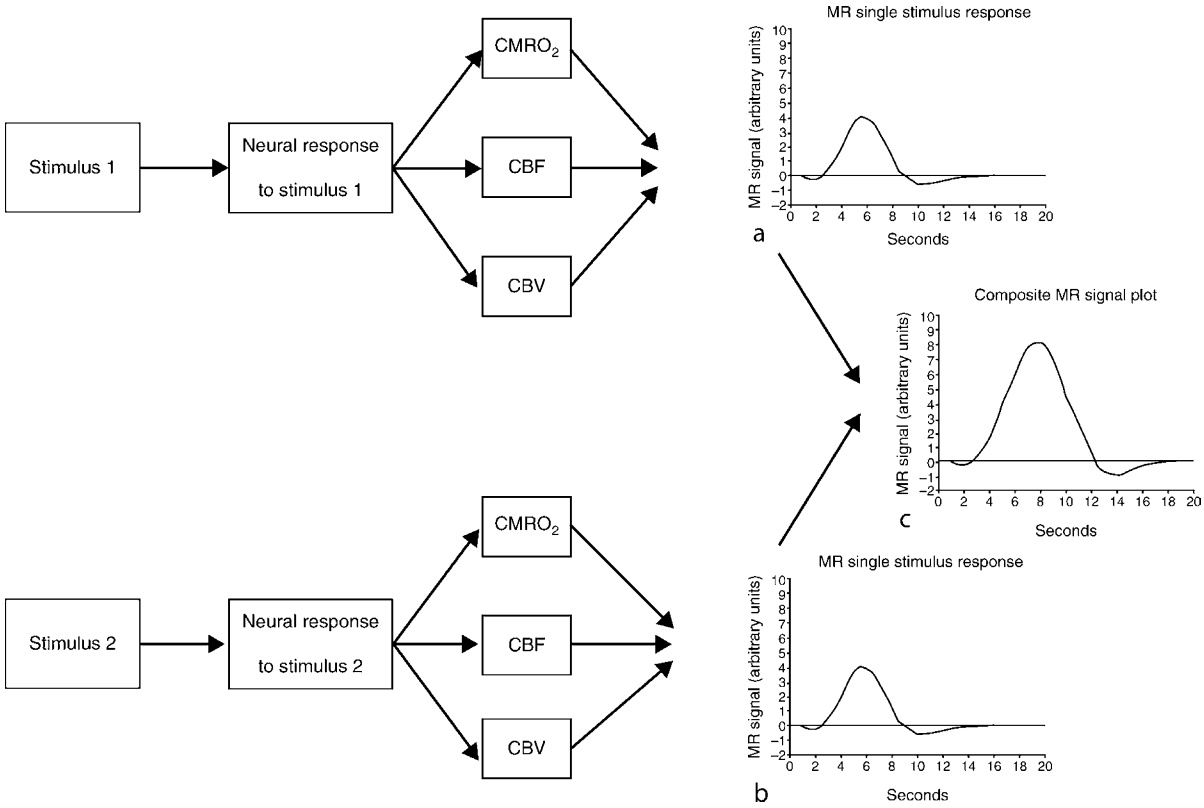
In a conventional fMRI experiment, ▶ time-series of T_2*-weighted images are acquired while subjects are exposed to a specific stimulus or set of stimuli ("task-on") that is systematically varied with respect to a "control-off" condition, typically in the context of a serial or ▶ cognitive subtraction or factorial design. The goal of this approach is to evoke significant changes in blood flow and oxygenation within a given region or network associated with the "task-on" state that will modulate BOLD signal intensity about its mean value. The duration of these stimulus presentations or epochs must be tailored to the dynamics of the hemodynamic response, and will be repeated multiple times to establish sufficient contrast and functional signal to noise ratios for the mapping of "activation" responses. In practice, the magnitude of task-related changes in fMRI studies is small (up to $\pm$5% but usually less) in comparison to the total image intensity and variability across time due to various sources of physical (MR system) and physiological noise. Careful experimental design and the use of post-processing methods for maximizing the detection of activation in the BOLD time series is therefore a critical feature of fMRI studies (Chapter 8–13, Huettel et al. 2004).

One common approach is to take advantage of the summed signal as a way of minimizing the influence of noise in fMRI experiments (Fig. 4). The idea here is that the BOLD response summed over several trials will reduce the influence of random noise sources as a result of averaging (Brown et al 2007). Blocked designs that present the same class of stimuli on multiple occasions seek to capitalize on this strategy. In turn, this involves selecting the correct number and timing of stimuli to occur within a block, the duration of the block itself and its number of repetitions, as well as the number of different block types to be included in a single acquisition for later comparison. Overall, block designs are powerful in terms of detecting significant sustained (steady-state) activation in fMRI studies but are generally poor estimators of the time course of the regional hemodynamic response to neuronal events because of their reliance on linear summation of individual responses.

Event-related designs are a second common approach in fMRI experiments and involve the presentation of specific stimuli as short duration events in order to detect transient associated changes in neuronal activity. With this approach, each event is separated temporally by an interval ranging from a few to tens of seconds and typically in a random order of predefined range. Investigators typically assume a canonical shape to the hemodynamic response to each stimulus presented and model it as a weighted sum to consecutive stimuli – although this linearity assumption may not hold, especially for the early phase of the hemodynamic response. Compared to blocked designs, event-related designs are superior in investigating the shape of regional hemodynamic responses and to compare features such as amplitude or relative timing differences between events. Event-related designs also allow for the investigation of BOLD responses sorted by response types, for instance comparing correct versus incorrect or fast versus slow responses. By comparison, their detection power is relatively poor with respect to blocked designs due to the fewer number of events that can be presented and averaged in a single experimental run.

Analysis of BOLD fMRI

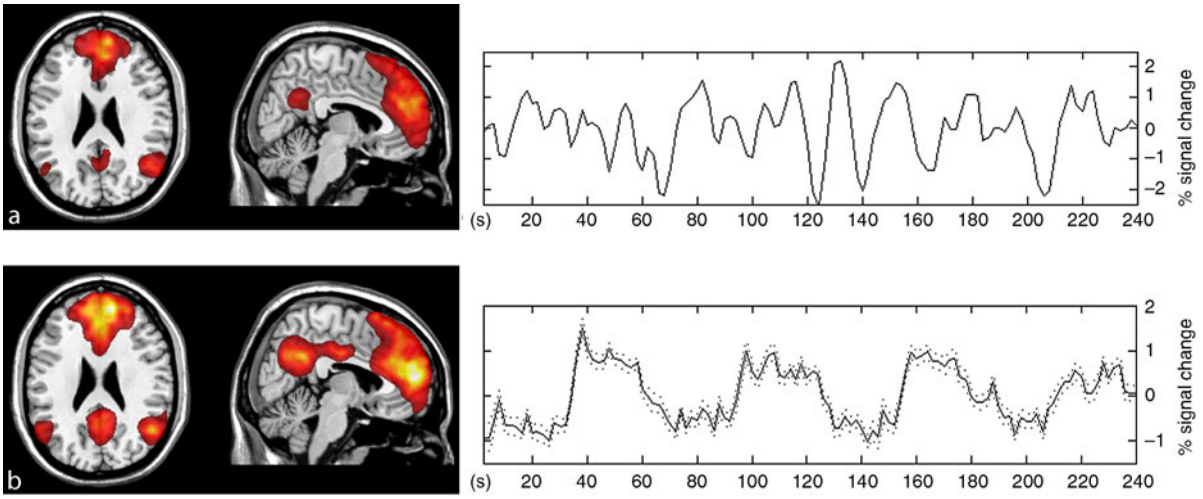
It was previously stated that the BOLD fMRI time series is influenced by a number of sources of physical and physiological noise. In the former case, this includes system noise that causes fluctuations in MR signal (e.g., signal drift) due to magnetic field inhomogeneities and other factors. In the latter case, this includes gross head motion artifacts, motion related to the cardiac (beat-to-beat) and respiratory (breath-to-breath) cycles, as well as slow variations in respiratory rate and volume, which change the pressure of arterial CO_2 – a potent vasodilator. Awareness of these various noise sources in BOLD fMRI studies has led to a range of methods to reduce or mitigate their influence, which continue to be improved upon and refined.



Magnetic Resonance Imaging (Functional). Fig. 4. Linearity of the hemodynamic response: events leading from the presentation of two stimuli to the generation of a summed BOLD signal. To a certain degree, the BOLD response to successive neural events can be predicted from the summed responses (superposition) to single neural events given an appropriate time delay between them. The figure assumes that stimulus 1 is presented 1 s before stimulus 2 and each stimulus evokes a response that alters CMRO2, cerebral blood flow, and CBV. The net effect of these physiological changes leads to the BOLD response for individual stimuli (**a** and **b**). The observed BOLD response (**c**) is a composite of the unobserved BOLD responses to the single stimuli. (Reproduced with permission from Brown et al. 2007. © 2007 Springer Netherlands.)

Pre-processing of the raw fMRI time-series, prior to statistical analysis, generally has two main goals: firstly, to reduce unwanted or uninteresting variability from data and; secondly, to prepare data for statistical analysis and inference given that many statistical tests applied in fMRI studies make assumptions that are met through such preprocessing steps. In practice, this involves modifying the raw data in a series of steps often including *image realignment* – to correct and to diagnose head motion artifact in a time series, *image normalization* – to transform data from different subjects into a common neuroanatomical space, *spatial smoothing* – to filter (or blur) the data to reduce spatial noise and to improve its normality for statistical parametric tests, and *temporal smoothing* – to remove low or high frequency noise sources, such as mentioned above.

There are a growing number of ways to perform statistical analysis in BOLD fMRI experiments. This has been assisted greatly by the development of publicly available neuroimaging analysis software packages, such as Statistical Parametric Mapping (http://www.fil.ion.ucl.ac.uk/spm/), FMRIB Software Library (http://www.fmrib.ox.ac.uk/fsl/FSL), Analysis of Functional Neuro Images (http://afni.nimh.nih.gov/). The majority of fMRI studies to date have adopted a conventional voxel-based mapping approach based on extensions of the general linear model for time-series analysis. The basic premise behind such approaches is that the observed fMRI data can be accounted for by a combination of several experimental (or model) parameters and uncorrelated (or independently distributed) noise. Given the high number of statistical tests performed (voxel by voxel) some correction factor for multiple



Magnetic Resonance Imaging (Functional). Fig. 5. The task consisted of four alternating 30 s control (C) and moral dilemma (D) condition blocks (CDCDCDCD). (Modified from Harrison et al. (2008) Proc Natl Acad Sci USA 105:9781–9789. © 2008 by the National Academy of Sciences of the USA.)

comparisons will generally be applied, leading to the generation of statistically thresholded "activation" maps related to the experiment at hand. This may be performed for the whole brain or specific regions of interest.

Other techniques, based on multivariate analysis techniques can also be used to investigate which brain areas are "activated" by a task or a stimulus in fMRI studies. These techniques, as opposed to the general linear model approach, are data driven and therefore do not require the specification of experimental models *a priori*. Another important distinction between this class of statistical tests and the former is that they are sensitive for testing not only "where" activation occurs in a given experimental context but also how different regions or networks of regions may interact or show interdependence in their activities over time (Fig. 5). Such relationships have been characterized as representing distinct forms of brain-functional connectivity, which has become a topic of specific interest with BOLD fMRI in recent years.

Major Strengths of the Method

- Is a safe, noninvasive, highly repeatable and widely available technique for measuring changes in brain activity in vivo.
- Has superior spatial resolution compared to other human neuroimaging techniques.
- Affords high flexibility in experimental design and data modeling.

Major Limitations of the Method

- Measures neuronal activity indirectly via changes in blood oxygenation levels.
- Has a temporal resolution in the order of seconds due to the nature of the hemodynamic response.
- Is susceptible to influences of non-neural changes in the body.

Definition

Structural and functional magnetic resonance imaging (structural MRI and fMRI, respectively) are medical imaging techniques widely used in radiology and neuroradiology. While structural MRI allows acquiring three-dimensional images of neuroanatomy with high spatial resolution and excellent soft tissue contrast, fMRI is applied to assess brain activity. fMRI provides information on current status and on neuropharmacological modulation of neuronal activity across the entire brain in a spatially and temporally resolved manner. Structural MRI and fMRI methods are readily translatable to clinical systems as they are inherently noninvasive and can therefore be applied in human subjects without exposure to radiation such as in nuclear imaging techniques. However, methodological constraints and limitations require careful interpretation of fMRI data. Today, both structural MRI and fMRI have emerged as powerful tools for neuropharmacological research and hold great potential for clinical applications.

Principles and Role in Psychopharmacology

MRI is a biomedical imaging technique applied in both research laboratories and radiology to visualize the structure and function of the body. MR images represent a weighted distribution of hydrogen atoms (protons) in living tissue, the major contribution being due to water constituting approximately 60–80% of tissue mass (Vlaardingerbroek and den Boer 1999). Hydrogen atoms possess an intrinsic magnetic moment. From a technical point of view, three key components are required to generate the MR signals allowing the formation of an image: the static magnetic field aligning the protons in the direction of the field, the radiofrequency (RF) coil(s) for excitation and reception of the MR signal, and the magnetic gradient field coils for spatial encoding of the MR signal. MRI systems measure the magnetic properties of the protons, which are influenced by electrical and magnetic characteristics of their environment. The local environment varies between tissues or the structures in which the protons are embedded in and are furthermore influenced by physiological processes such as diffusion, perfusion, or blood flow. Consequently, image contrast is governed by a number of MR parameters (Table 1), such as intrinsic relaxation rates (R_1, R_2, R_2^*), incoherent motion of water, such as diffusion or perfusion, coherent blood flow in major vessels and water exchange processes between cellular/interstitial fluid and water bound to macromolecules. MRI acquisition parameters can be adapted to emphasize the specific contrast optimal for the structure or the process of interest. In addition, tissue relaxation rates can be altered using exogenous contrast agents based on paramagnetic compounds, such as gadolinium chelates or iron oxide nanoparticles. The strong effect of contrast agents on relaxation rates is due to unpaired electron(s) contained in their electron shell, the magnetic moment of which is approximately 650 times higher than that of protons.

Structural MRI

Three-dimensional imaging, excellent spatial resolution, and superior soft tissue contrast render MRI the method

Magnetic Resonance Imaging. Table 1. Intrinsic MR contrast parameter and biological information derived.

Contrast-generating process	MRI parameter	Information derived
Longitudinal relaxation: return to magnetic equilibrium state	R_1 (=1/T_1)	Basic structural information: e.g., gray vs. white matter differentiation enhancement following contrast agent administration: e.g., blood–brain barrier integrity or retrograde axonal tracing
Transverse relaxation: Loss of phase coherence due to stochastic processes	R_2 (=1/T_2)	Basic structural information: sensitive to tissue water content edema formation, inflammation
Magnetic susceptibility: Loss of phase coherence due to magnetic field differences	R_2* (=1/T_2*)	Basic structural information: gray vs. white matter contrast, hemorrhages
		CBF and volume (using intravascular contrast agent) BOLD contrast
Incoherent motion, diffusion: Loss of phase coherence due to molecular diffusion	ADC FA	ADC: cellularity (intracelluar vs. extracellular volume fraction) FA: restricted anisotropic diffusion
Incoherent motion, perfusion: Loss of phase coherence due to flow in capillaries	F	Local tissue perfusion
Water exchange: Water exchange between two states of different water mobility	MTR	Macromolecule content: e.g., degree and integrity of myelination

ADC apparent diffusion coefficient (mm^2/s)
BOLD blood oxygen-level dependent (contrast)

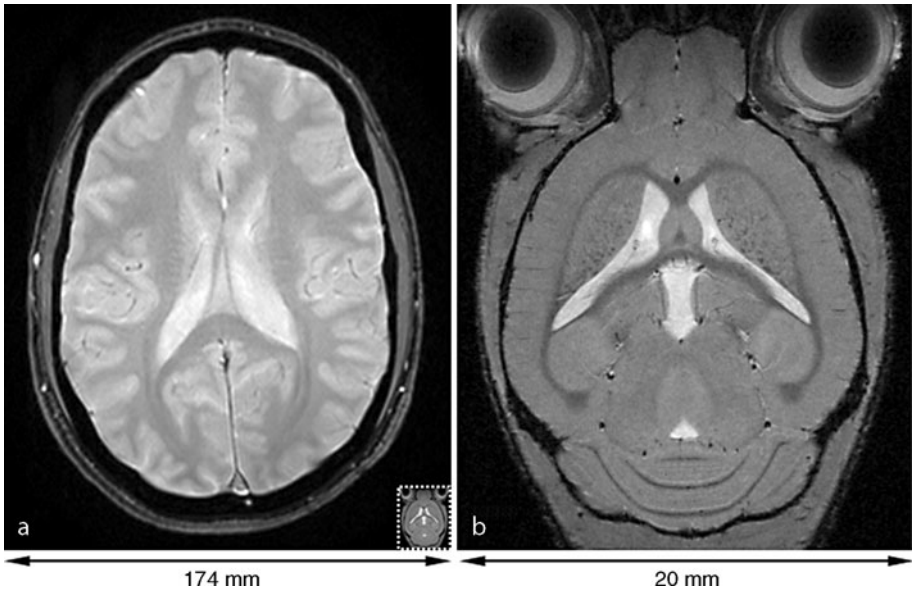
of choice for structural neuroimaging. A weak point of the method is its inherent low sensitivity, which has a negative impact on spatial resolution. Correspondingly, identifying small brain structures or assessing subtle/minor pathological alterations, putting high demands on spatial resolution, is challenging. Substantial efforts have been made in recent years to increase MR sensitivity by either moving to higher static magnetic field strengths or by refining RF detection devices, such as the cryogenic detection technology. State-of-the-art MR systems for routine clinical neuroimaging (Konarski et al. 2007) operate at 3 T allowing for spatial resolutions in the order of 1 mm^3 (Fig. 1a), while clinical research systems up to 7.0 T have been constructed. In contrast, the high spatial resolution required in rodent brain imaging led to the development of MR systems operating at up to 17.6 T. For example, the combination of high magnetic field strength (9.4 T) with cryogenic RF detection devices enabled the routine recording of high-resolution ($52 \times 52 \times 170$ m^3) mouse brain images (Fig. 1b) in a measurement time of 10 min (Baltes et al. 2009).

In structural MRI, usually morphometric comparisons between groups are performed using hypothesis-based selection of regions of interest (ROIs), which is a lengthy process and prone to evaluation errors. More recently, voxel-based morphometry (VBM) has been developed as a fully automated comparison of whole brains on a voxel-by-voxel basis. After spatial normalization of the brains to a stereotactic standard space, brain regions are compared with respect to differences in residual tissue concentrations rather than differences in shape. Clinical application of structural readouts using MRI cover a broad range of disorders from neurodegenerative (i.e., stroke and dementia) to neuropsychiatric diseases (American Psychiatric Association (APA) 2000) (e.g., ▶ schizophrenia, ▶ posttraumatic stress disorder (PTSD), or mood disorders, such as ▶ bipolar affective disorders). For example, VBM studies in schizophrenia generally confirmed and



Magnetic Resonance Imaging. Fig. 1. Visualization of neuroanatomical structures in the human (**a**) and in the mouse brain (**b**) put different demands on spatial resolution. While an in-plane resolution of 0.9 × 0.9 mm^2 in human subjects is sufficient for gray vs. white matter discrimination, a resolution of 52 × 52 m^2 is required in mouse brain to depict cortical structures, such as subfields of the hippocampus. For comparison of the dimensions, the mouse brain image (**b**) is depicted as inset in the human brain image (**a**) using the same scale. (Courtesy of R. Luechinger, PhD, University and ETH Zurich, Switzerland.)

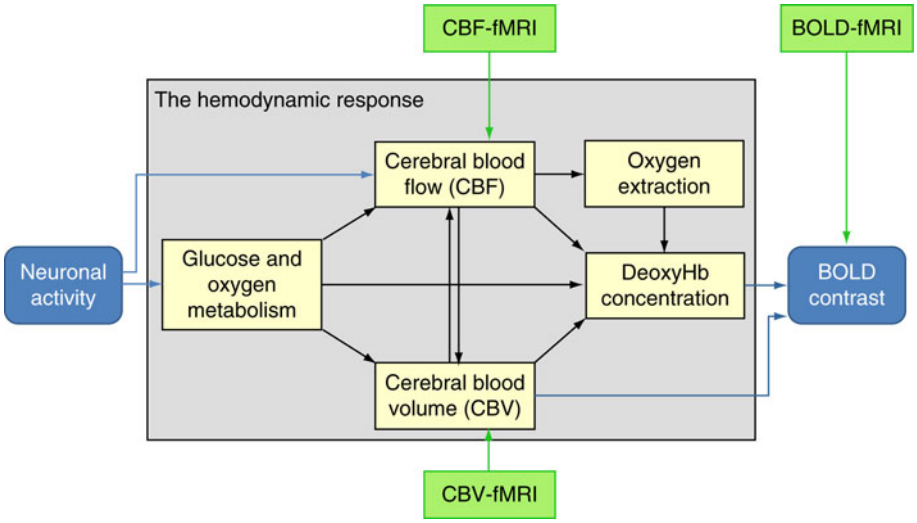
extended ROI-based studies showing less gray matter concentration in multiple cortical and subcortical regions (Pearlson and Calhoun 2007). In patients suffering, e.g., from bipolar disorders, structural MRI has been applied to assess neuroanatomical abnormalities between healthy subjects and patients. While overall brain volumes appeared to be normal, regional differences have been observed in prefrontal cortex, and subcortical and medial temporal structures involved in the behavioral network, which is known to be affected in bipolar disorders (Strakowski et al. 2005). Similarly, in preclinical MRI, morphometric readouts hold promise to phenotype rodent models of central nervous system (CNS) diseases with applications in mouse models of neurological disorders such as ► Alzheimer's disease (AD) or ► Huntington's disease or in rat models of schizophrenia. Its value for detection of subtle or diffuse morphometric abnormalities, i.e., in neuropsychiatric models that are predictive for disease progression or can serve as surrogate markers for end-stage disease status has to be further validated in carefully planned and analyzed longitudinal studies.

While structural MRI provides information on neuroanatomical alterations preceding or accompanying psychiatric diseases, fMRI allows assessing changes in neuronal activation patterns between healthy subjects and patients, which might be more closely related to the disease progression or effects of drug administration.

Functional MRI

Underlying Biological Processes

fMRI is widely applied in clinical and preclinical studies to assess brain function, keeping in mind that the MR method is sensitive to hemodynamic changes prompted by neuronal activity rather than the neuronal activation itself. Local neuronal activity leads to an increased consumption of oxygen and nutrients triggering an increase in local perfusion, i.e., regional cerebral blood flow (CBF) and cerebral blood volume (CBV) (Fig. 2). As the efficiency of oxygen extraction decreases with increasing flow rates, the venous blood contains more oxygenated hemoglobin in the activated state when compared with the resting state. The higher concentration of oxyhemoglobin, and correspondingly the lower concentration of paramagnetic deoxyhemoglobin during activation leads to a decrease in R_2^* relaxation rates, thus an increase in the MR signal. This mechanism, called blood oxygenation level dependent (► BOLD) contrast, has found widespread use in the neuroscience community to study brain function under physiological and pathological conditions. It is



Magnetic Resonance Imaging. Fig. 2. Schematic representation of the relationship between neuronal activity and the hemodynamic response function. fMRI allows to assess various processes involved such as changes in CBF, CBV, and changes in BOLD contrast. (Adapted from Martin and Sibson 2008.)

important to note that an intact neurovascular coupling is essential for the reliability of functional MRI signals.

To elucidate the complex mechanism of neurovascular coupling, further fMRI methods have been developed directly assessing the vascular response to neuronal activation such as CBF and CBV changes. Recently, MR arterial spin labeling (ASL) techniques have been described to measure regional CBF. For this purpose, the arterial blood flowing into the brain is magnetically labeled at the level of the common carotid artery. In this way, arterial blood can be used as endogenous contrast agent. Regional CBF values can be estimated from the difference of the MR signal intensities before and during labeling of the inflowing arterial spins taking the finite lifetime of the magnetically labeled state into consideration. ASL is independent of contrast agent administration and allows therefore continuous CBF monitoring. As CBF changes are supposed to be proportional to neuronal activity, ASL presents itself an attractive method for providing a more direct readout of neuronal activity than BOLD and CBV measurements, which are highly nonlinear. Furthermore, CBF measurements are less susceptible to magnetic field variations than BOLD fMRI based on fast-gradient echo sequences.

For the assessment of local CBV values, MRI methods have been developed using exogenous contrast agents with a long plasma half-life such as iron oxide nanoparticles leading to an increase in the R_2 and R_2^* relaxation rates. A few minutes after intravenous administration of the contrast agent, a steady-state concentration is reached. The relative change in local relaxation rates R_2 and R_2^* is proportional to the amount of contrast agent in the tissue and thus proportional to the local CBV. Subsequently, neuronal activity prompting local CBV changes can be detected by measuring relative changes in local relaxation rates R_2^*. As oxygen extraction decreases for increasing flow rates and the ► BOLD Contrast decreases at lower magnetic field strength, CBV measurements are more sensitive than fMRI based on the BOLD contrast.

Stimulation Paradigms

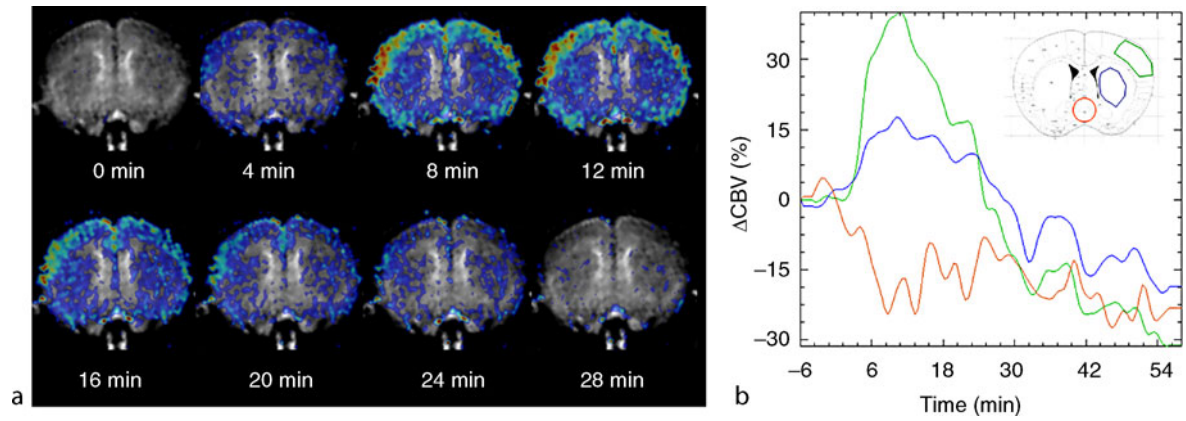
A key component of fMRI experiments is the ► Stimulation Paradigm applied to evoke brain activity. A variety of different stimuli ranging from no stimulation (resting-state fMRI) over thermal, sensory, mechanical, visual, or auditory to pharmacological stimuli have been used during fMRI studies. The rationale behind resting state fMRI is to investigate activation differences between a healthy control group and patients suffering, e.g., from schizophrenia (Pearlson and Calhoun 2007) as these experiments do not rely on the ability of the patient to perform certain tasks. Aside from resting state fMRI, which analyzes spontaneous activity/hemodynamic changes in the brain, fMRI studies always rely on at least two measurements comparing state A (e.g., the resting state) with state B (e.g., during stimulus-induced activation). When designing fMRI studies, it is important to consider the dynamics of the hemodynamic response to neuronal activity, which determines the time resolution that can be achieved in the experiment.

In ► Pharmacological fMRI (► phMRI), the functional response to ligand-induced receptor stimulation or

inhibition after drug administration is assessed throughout the brain using the above-described fMRI methods. Consequently, phMRI, like all fMRI methods, relies on intact neurovascular coupling and assesses the functional response induced by drug administration. In humans, phMRI involves BOLD signal acquisition before, during, and after the administration of a drug, while in animals CBF and CBV measurements are also widely established. phMRI studies in the rat measuring BOLD or CBV changes confirmed sufficient sensitivity to detect dose-dependent effects of systemically administered receptor ligands. Assessment of alterations in magnitude and spatial extend of neuronal activity induced by pharmacological targeting has been successfully demonstrated for various neurotransmitter systems such as the dopaminergic, ▶ opioid, ▶ GABAergic, glutamatergic, or cannabinoid system. Figure 3 shows an example of phMRI in the mouse. Acute administration of the $GABA_A$ receptor antagonist bicuculline led to region-specific CBV changes. The impact and potential of phMRI in the area of psychopharmacology will be discussed in the following for the example of mood and anxiety disorders. Investigations using in vivo neuroimaging techniques within the field of major (clinical) depression and anxiety disorders are largely dominated by measuring serotonergic (5-hydroxytryptamine; 5-HT) neurotransmission and receptor level and their response to medication treatment as alterations in serotonin neurotransmitter system have been clearly implicated in the pathophysiology of these two ▶ neuropsychiatric disorders. Based on the availability of radiolabeled 5-HT receptor ligands, distinct ▶ serotonin receptor populations have been imaged using positron emission tomography (PET) and single positron emission tomography (SPECT). On the other hand, the nature of serotonergic neurocircuitries can be investigated using phMRI by modifying endogenous neurotransmitter levels or manipulating their receptor activity by specific ligands. Most phMRI studies investigated the $5\text{-}HT_{2C}$ receptor system as one of the main targets for novel anxiolytic drugs. Among the different ligands used, meta-chlorophenylpiperazine (m-CPP), a mixed $5\text{-}HT_{1B/2C}$ receptor agonist, has been advanced as a useful pharmacological substance for fMRI studies of regional activation in rats and in human beings. Furthermore, the acute and chronic effect of SSRI on region-specific neuronal activation measured by BOLD-fMRI in human beings has been examined using citalopram or in the rats using ▶ fluoxetine. The literature on phMRI investigating specifically the $5\text{-}HT_{1A}$ receptor is rather sparse, but represents an attractive field of research given that $5\text{-}HT_{1A}$ autoreceptor desensitization is one of the suggested mechanisms of action of chronic antidepressants (i.e., ▶ selective serotonin re-uptake inhibitors, SSRIs) and might be responsible for the delayed onset of antidepressants under clinical conditions. Using CBV-fMRI, decreased activity across several brain areas of the rats was mapped with the strongest effects in ▶ hippocampus and septum after acute administration of the $5\text{-}HT_{1A}$ receptor agonist 8-OH-DPAT.

Data Analysis and Interpretation

The analysis of fMRI data turns out to be especially challenging because of the complex relationship between the physiological processes involved (Fig. 2) and,



Magnetic Resonance Imaging. Fig. 3. Example of phMRI in the mouse. CBV changes in the mouse brain during infusion of the $GABA_A$ receptor antagonist bicuculline. (**a**) Percentage ΔCBV activity maps of brain section +0.74 mm relative to the Bregma showing the highest activity in cortical areas. (**b**) Temporal profile for three different ROIs (see brain atlas inlet: green=cortex, blue=striatum, orange = control ROI) highlighting the region specificity of the induced CBV changes.

furthermore, the small signal changes detected in fMRI, e.g., BOLD signal changes in humans are in the order of 1–5%. For this reason, the fMRI analysis is often simplified by fitting a general linear model (GLM) based on a priori information of the stimulation paradigm convolved with an assumed hemodynamic response function. More sophisticated approaches incorporate the various processes associated with the hemodynamic response to form a biophysically plausible framework such as the balloon model (Buxton et al. 1998). However, phMRI aims at resolving neuronal networks and connectivities throughout the brain. As the functional relationship and the causal dependencies between different brain areas are a priori unknown, hypothesis-driven methods, such as GLM, might lead to false results or to a loss in sensitivity in activated areas. In this case, data-driven or exploratory approaches are assumed to be superior: these include independent component analysis (ICA) or methods detecting temporal or spatial correlations. For example, in wavelet-based cluster analysis (WCA), activated pixels are grouped according to their own activity pattern avoiding assumptions derived from the experimental design.

As phMRI methods monitor neuronal activity via neurometabolic or neurovascular coupling processes, careful interpretation of phMRI data is indicated taking various processes influencing the phMRI signal into account. Direct systemic effects of the drug administered or influences of the pathology on the vascular tone might lead to changes of the functional response measured by phMRI, which do not necessarily reflect changes in neuronal activity (Mueggler et al. 2002). Furthermore, one needs to keep in mind that phMRI detects brain regions showing hemodynamic changes, which usually exceed local regions of neuronal activity, thus overestimating the region involved, or neurons even project to distant brain regions, which do not reflect the underlying receptor distribution. In small rodents, phMRI is commonly carried out in anesthetized animals, in which the anesthetic might potentially interfere with the ligand–receptor interaction of interest.

The remaining topics with respect to fMRI data analysis and interpretation are the understanding of the functional signal changes acquired and their link to neuronal activity even in healthy subjects. The missing clear understanding of the fundamental process makes the interpretation of fMRI under pathological conditions even more complex. Furthermore, fMRI data analysis and interpretation is carried out on groups of healthy or diseased subjects. As described above, normalization of all brains of a group to a standard space reduces within-group difference, thus enhancing between-group difference and accordingly statistical significance of the differences (Konarski et al. 2007). The biological variability and the slightness of the signal changes hamper subject-specific interpretation or diagnosis of fMRI examinations.

Advantages and Limitations with Respect to Alternative Neuroimaging Modalities

The neuroimaging technique to be applied depends on the biomedical question to be addressed. Assessing structural information commonly requires high spatial resolution and adequate contrast for the structure of interest, while image acquisition time, typically in the order of several minutes, is not an issue because the anatomical structures can be assumed to be static during the data collection period. As alternative imaging modality, computerized tomography (CT) can be applied measuring X-ray attenuation by tissue. Both structural MRI and CT provide three-dimensional information with excellent spatial resolution and the accessibility to deep brain structures allowing to quantitatively document volumetric and morphological changes (Konarski et al. 2007). However, the advantage of structural MRI is completely noninvasiveness, thus enabling repeated measurements in longitudinal studies to monitor disease progression or therapeutic effects and superior soft tissue contrast.

In contrast, imaging of dynamic processes, such as brain perfusion, requires not only sufficient sensitivity to detect, but also sufficient temporal resolution to resolve the physiological changes under investigation. The time available for imaging is determined by the physiological process of interest, which has an impact on the fMRI method that can be applied and the spatial resolution that can be achieved. Alternative imaging modalities to fMRI are ► SPECT or ► PET. Both modalities are using exogenous contrast agents labeled with radionuclides, such as fluorine-18 for PET and iodine-123 for SPECT (Rudin 2005). Although PET is relatively expensive when compared with SPECT, it is superior in terms of sensitivity and spatial resolution, and provides inherently quantitative data. PET provides information on physiological (perfusion) and biochemical processes, such as neuronal glucose metabolism. With respect to SPECT and PET, fMRI is less sensitive, but provides information on functional consequences of drug administration in a spatially highly resolved manner. Due to their noninvasiveness, fMRI and nuclear imaging methods developed in small rodents are readily translatable to clinical applications.

The dimensions of small rodents further allow the use of fluorescent molecular tomography (FMT) as alternative neuroimaging method. In this method, a compound labeled with a fluorescent dye is administered. After specific binding of this reporter to the target and after clearance

of the unbound fraction, the fluorophor is excited using laser light in the near-infrared range (Rudin 2005). FMT is superior to MRI in terms of sensitivity, lower detection limits are in the nanomolar range, but provides relatively poor spatial resolution. However, in human subjects deep brain areas are not accessible due to the small penetration depth of light in the near-infrared range.

Future Directions

Noninvasive neuroimaging has been rapidly developing in the past decade, as various imaging modalities provide an overwhelming amount of information on functional neuroanatomy, neuronal activity, and neuronal networks. However, technical limitations such as low sensitivity in fMRI or poor localization in EEG prevented the assessment of an integrated view of the brain function. These issues have prompted the development of data fusion methods aiming to combine complementary information from different imaging modalities. For example, EEG data have been constrained using fMRI activation maps (Pearlson and Calhoun 2007). Although these methods hold great potential to improve data interpretation, one has to avoid unrealistic assumptions. Alternative approaches under development are trying to combine the strengths of two modalities such as the high sensitivity of molecular imaging with the high spatial resolution and localization of CT and MRI. Substantial efforts have been made to bring forward such hybrid imaging systems combining, e.g., CT-PET or MRI-PET for clinical applications. In small animal imaging, CT-FMT or MRI-PET solutions are also pursued.

Major and Minor and Mixed Anxiety-Depressive Disorders

Lawrence H. Price
Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, USA

Synonyms

Clinical depression; Depression; Unipolar depression

Definition

The depressive disorders comprise a spectrum of clinical syndromes characterized by persistent depressed mood or sadness, loss of interest (apathy), or loss of pleasure (anhedonia). These symptoms are to be distinguished from the transient feelings of unhappiness or sadness that constitute normal reactions to the disappointments or losses experienced in everyday life. The symptoms of depressive disorders cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and are not due to the direct physiological effects of a substance or a general medical condition. Depression is generally differentiated from bereavement, the expectable constellation of depressive symptoms

following the loss of a loved one, although depression may be diagnosed if such symptoms are unusually prolonged (e.g., more than 2 months) or are not characteristic of a "normal" grief reaction in the individual's culture. The depressive disorders are also to be distinguished from depressive *episodes* of ▶ bipolar disorder, which is diagnosed if the individual has ever had a manic, mixed, or hypomanic episode.

Role of Pharmacotherapy

Clinical Features, Etiology, and Pathogenesis

Recognition of depression as a distinct disease dates back at least as far as the Hippocratic writings of the fifth and fourth centuries B.C. Lifetime prevalence varies among diagnostic categories and according to the specific diagnostic criteria used, with risks for major depression ranging from 10 to 25% in women and 5 to 12% in men. Prevalence rates are unrelated to income, education, marital status, or ethnicity. Depressive disorders may have their onset at any age, but the average is in the mid- 20s. At least 60% of individuals with a single episode of major depression will have subsequent episodes. Major depression is associated with significantly increased mortality; up to 15% of individuals with severe illness die by ▶ suicide.

The etiology of depressive disorders is unknown. There is a familial pattern, with major depression 1.5–3 times more common in individuals with an affected first-degree biological relative; ▶ heritability based on twin studies is 40–50%. However, no single major gene locus has been shown to cause depression. Rather, genetic risk appears to involve multigenic and/or gene-environment interactions. The short allele of the serotonin transporter-linked polymorphic region (5-HTTLPR), in particular, has been most strongly implicated in gene-environment interactions leading to depression. Environmental risk factors include early-life abuse and neglect and major life stress.

The predominant theories of pathogenesis in depression have focused on monoamine neurotransmission and ▶ hypothalamic-pituitary-adrenal (HPA) axis dysfunction. Early monoamine theories posited simple deficiencies in ▶ serotonin or ▶ norepinephrine function, but such hypotheses have been superseded by complex formulations involving a wide array of intracellular and trans-synaptic signaling pathways. Similarly, while early HPA axis theories emphasized hyperactivity, more recent work suggests that derangements in this neuroendocrine system are more variable, and may be linked to abnormalities in neurotrophins (such as ▶ brain-derived neurotrophic factor (BDNF)) and ▶ neurogenesis. Other theories of pathogenesis have explored the role of reduced neurotransmission in the ▶ dopamine and ▶ GABA systems, altered glutamatergic neurotransmission, impaired ▶ endogenous opioid function, abnormal ▶ circadian rhythms, hypothalamic-pituitary-thyroid (HPT) axis dysfunction, monoamine–acetylcholine imbalances, cytokine-mediated neuroimmune abnormalities, deficient ▶ neurosteroids synthesis, and dysfunction of specific brain structures and circuits.

Diagnostic Categories

Major Depressive Disorder (Major Depression)

The diagnosis of major depression requires the presence of at least five of nine key symptoms during the same 2-week period, with at least one of the symptoms being either (1) depressed mood, or (2) loss of interest or pleasure. In addition to these, the other key symptoms are (3) significantly decreased or increased weight or appetite, (4) insomnia or hypersomnia, (5) psychomotor agitation or retardation, (6) fatigue or loss of energy (anergia), (7) feelings of worthlessness or guilt, (8) diminished concentration or indecisiveness, and (9) recurrent thoughts of death, suicidal ideation, or suicidal behavior.

Between 50 and 70% of individuals show clinically significant improvement with a given antidepressant. There is no compelling evidence of differential efficacy between drugs in unselected patients, and drug selection is usually based on a consideration of side-effect profiles. Selective serotonin reuptake inhibitors (▶ SSRIs) are the most frequently used first-line drugs for major depression. This group includes ▶ fluoxetine, ▶ paroxetine, ▶ sertraline, ▶ fluvoxamine, ▶ citalopram, and ▶ escitalopram. Common side effects of these drugs are constipation, diarrhea, dizziness, headache, insomnia, nausea, somnolence, and sexual dysfunction. Other frequently used classes of ▶ antidepressants are the serotonin-norepinephrine reuptake inhibitors (▶ SNRIs) and the norepinephrine reuptake inhibitors (▶ NARIs). The SNRIs include ▶ venlafaxine, desvenlafaxine, ▶ milnacipran, and ▶ duloxetine, which have side-effect profiles generally similar to the SSRIs. The NARIs include ▶ bupropion and ▶ reboxetine, with side effects that include dry mouth, insomnia, headache, nausea, constipation, tremor, and tachycardia; bupropion is less likely to cause sexual dysfunction than the SSRIs or SNRIs, but lowers the seizure threshold at high doses. The ▶ tricyclic antidepressants (TCAs) include ▶ amitriptyline, ▶ imipramine, ▶ clomipramine, ▶ nortriptyline, desipramine, protriptyline,

► trimipramine, amoxapine, and dothiepin. While the TCAs were the first class of drugs used to treat depression, they have largely been supplanted in that role by newer drugs because of their unfavorable side-effect profile (► anticholinergic effects, cardiovascular effects, somnolence, and tremor) and their high degree of lethality in overdose. Tetracyclic antidepressants, which include maprotiline, ► mirtazapine, and ► mianserin, constitute another group of less commonly used agents; maprotiline has side effects similar to the TCAs, whereas mirtazapine and mianserin are notable for causing somnolence, dry mouth, and substantial weight gain. The nonselective ► monoamine oxidase inhibitors (MAOIs), which include ► phenelzine, ► tranylcypromine, and ► isocarboxazid, are generally considered third- or later-line drugs, as they can cause life-threatening hypertensive or hyperpyrexic reactions when inadvertently combined with foods or drugs that enhance noradrenergic or serotonergic activity. More selective MAOIs, such as the reversible inhibitor of monoamine oxidase A (RIMA) ► moclobemide or the transdermal formulation of the MAO-B selective ► selegiline, are far less likely to cause such reactions. The triazolopyridine antidepressants, ► trazodone and its congener nefazodone, are now infrequently used as primary treatments for depression; trazodone can cause severe priapism, while nefazodone has been associated with rare fatal hepatic necrosis, and both drugs cause significant somnolence.

Major depression of mild to moderate severity may be treated with psychotherapy, with or without medication; ► cognitive-behavioral therapy and ► interpersonal psychotherapy, in particular, have been supported in controlled clinical trials. Milder cases of depression may also respond to complementary and alternative medical approaches, such as light (phototherapy), exercise, and herbal or dietary supplements (e.g., St. John's wort (*Hypericum perforatum*), omega-3 fatty acids, S-adenosine-L-methionine (SAMe)). Severe and treatment-resistant cases of depression are often managed with combinations of drugs or with ► electroconvulsive therapy. Rarely, stereotactic ablative neurosurgery, generally involving lesions in frontolimbic circuitry, is used in intractable cases. The role of newer neuromodulatory approaches, such as ► transcranial magnetic stimulation, ► vagus nerve stimulation, and ► deep brain stimulation, is currently under investigation.

Major Depressive Disorder with Psychotic Features (Psychotic Depression)

This form of depression is defined by the presence of either ► delusions or ► hallucinations, and is invariably severe; inpatient treatment is usually necessary because of profound functional impairment or intense suicidality. Psychotic features whose content reflects the typical depressive themes of personal inadequacy, guilt, disease, death, nihilism, or deserved punishment are considered mood-congruent; mood-incongruent psychotic features generally involve non-depressive persecutory delusions, thought insertion, thought broadcasting, or delusions of control. Pharmacotherapy usually involves the use of an ► antipsychotic in combination with an antidepressant. However, ECT is often required.

Major Depressive Disorder with Catatonic Features

Catatonia is diagnosed when at least two of five key symptoms are present, including (1) motoric immobility, such as catalepsy or stupor, (2) excessive purposeless motor activity (catatonic excitement), (3) extreme negativism (motiveless resistance to instructions or maintenance of a rigid posture against attempts to be moved) or mutism, (4) bizarre posturing, stereotypies, mannerisms, or grimacing, and (5) ► echolalia or ► echopraxia. Catatonic symptoms often respond acutely to ► benzodiazepines. However, since this syndrome generally occurs in the context of psychotic depression, treatment with an antipsychotic/antidepressant combination or ECT is usually necessary for sustained improvement.

Major Depressive Disorder with Melancholic Features (Melancholia)

The critical feature of this syndrome is profound anhedonia or lack of reactivity (not even transient mood improvement in response to positive events). In addition, at least three of six key symptoms are present, including (1) distinct quality of mood (different from usual feelings of sadness or loss), (2) morning worsening of mood (diurnal variation), (3) early morning awakening, (4) marked psychomotor retardation or agitation, (5) significant anorexia or weight loss, and (6) excessive guilt. Episodes of melancholia are usually severe, and patients with psychotic depression are usually melancholic. As the successor to the historical syndrome of endogenous depression, melancholia was originally defined in an attempt to identify those patients who would have a better response to somatic treatment than other patients. Subsequent research has failed to establish this preferential response, but has shown that melancholic patients are less likely than other patients to respond to placebo. Pharmacotherapy involves standard antidepressant drugs. Some authorities believe that first-generation drugs (i.e., TCAs and MAOIs) are more effective. Severe cases may require ECT.

Major Depressive Disorder with Atypical Features (Atypical Depression)

This syndrome is defined by the presence of mood reactivity (mood brightening in response to positive events) in conjunction with at least two of four key symptoms, including (1) significant weight gain or appetite increase, (2) hypersomnia, (3) leaden paralysis (heavy feelings in the limbs), and (4) a long-standing pattern of interpersonal rejection sensitivity. The diagnostic criteria for atypical depression reflect early efforts to identify a group of patients who would preferentially respond to MAOIs rather than TCAs. The importance of this distinction has receded as other, safer agents have supplanted the MAOIs, and treatment of atypical depression is now usually initiated with SSRIs or other second-generation antidepressants. However, ongoing research has generally supported the existence of meaningful neurobiological differences between atypical depression and melancholia (e.g., HPA axis hypoactivity in atypical depression vs. hyperactivity in melancholia).

Major Depressive Disorder with Postpartum Onset (Postpartum Depression)

Episodes of major depression whose onset is within 4 weeks of delivery are considered postpartum (as are similarly timed manic or mixed episodes). Diagnostic criteria are otherwise the same as for other depressive syndromes, although postpartum episodes are usually distinguished by symptom content that is focused on the infant. The mother may express excessive concern for the infant's well-being, feelings of being overwhelmed, fear of being responsible for the infant, hostility, or apathy. Psychotic symptoms may develop, in which case there may be a risk of infanticide. Postpartum depression must be distinguished from the transient mood lability ("baby blues") occurring in the first 10 days postpartum in up to 70% of women, which resolves on its own. Pharmacotherapy for postpartum depression involves standard antidepressant drugs, with antipsychotics if psychotic symptoms are present. All antidepressants are secreted in breast milk, but few specific adverse events have been reported, so benefits and risks of breastfeeding must be addressed.

Major Depressive Disorder with Seasonal Pattern (Seasonal Depression, Seasonal Affective Disorder)

Episodes of major depression are considered seasonal (as are manic or mixed episodes) if (1) there has been a regular temporal relationship between the onset of the episode and a particular time of year (for depression, usually fall or winter), (2) full remissions also occur at a characteristic time of year (usually spring), (3) in the last 2 years two episodes have occurred with the seasonal pattern, but no nonseasonal episodes have occurred, and (4) seasonal episodes substantially outnumber nonseasonal episodes over the individual's lifetime. The diagnosis is not made if seasonal psychosocial stressors (e.g., school or work) better account for the seasonal pattern. Seasonal depression is more common at higher latitudes and in younger individuals. Pharmacotherapy usually involves SSRIs or NARIs, although light therapy appears to be equally effective and is often used.

Minor Depressive Disorder (Minor Depression)

The diagnostic criteria for this syndrome are the same as those for major depression, but fewer symptoms are required. Thus, at least two, but less than five, of the nine key symptoms must be present during the same 2-week period, again with at least one of the symptoms being either depressed mood or loss of interest or pleasure. At present, these diagnostic criteria are considered investigational, and the nosological status of this syndrome is not established. There is only limited support for using pharmacotherapy in the management of minor depression, and while some studies suggest SSRIs may be of benefit, an especially careful assessment of risks and benefits should be undertaken.

Mixed Anxiety-Depressive Disorder (Mixed Anxiety-Depression)

This syndrome is defined by persistent or dysphoric mood lasting at least 1 month, accompanied by at least four of ten key symptoms lasting at least 1 month, including (1) difficulty in concentrating, (2) sleep disturbance, (3) fatigue, (4) irritability, (5) worry, (6) tearfulness, (7) hypervigilance, (8) anticipating the worst, (9) hopelessness, and (10) low self-esteem. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and are not due to the direct physiological effects of a substance or a general medical condition. In addition, criteria have never been met for major depression, ► dysthymic disorder, ► panic disorder, or ► generalized anxiety disorder, and criteria are not currently met for any other anxiety or mood disorder. As in the case of minor depression, mixed anxiety–depression is still considered an investigational diagnosis, and is not recognized in the official nomenclature. However, the greater symptom burden in mixed anxiety–depression supports a more prominent role for pharmacotherapy. SSRIs and SNRIs are preferred, as NARIs may lack efficacy and the side-effect profiles of other antidepressants are often

poorly tolerated in this population. Benzodiazepines are frequently used adjunctively, especially early in treatment.

Major Tranquilizer

Synonyms

Antipsychotic; Neuroleptics

Definition

A medication used in the treatment of psychotic disorders of any type with a particular emphasis on inducing sedation. The term is less used than its synonyms and is poorly characterized in pharmacological terms. It tends to be used less by psychiatrists than by nonspecialists.

Cross-References

- ▶ Antipsychotic Drugs
- ▶ First-Generation Antipsychotics
- ▶ Second and Third Generation Antipsychotics

MALDI

- ▶ Matrix-Assisted Laser Desorption Ionization

Malleability

Marijuana Dependence

► Cannabis Abuse and Dependence

Marplan

► Isocarboxazid

Mass Spectrometry

Synonyms

Mass spectroscopy

Definition

Mass spectrometry is an analysis technique that measures the molecular mass of an analyte. A mass spectrometer typically consists of three modules: (1) an ion source in which the convert sample is vaporized and ionized to make it analyzable; (2) a mass analyzer, which separates the sample components on the basis of their mass (more precisely their mass/charge ratios); (3) and a detector, which provides data for calculating the abundances of each ion present.

Matching Law

Definition

A behavioral allocation function that relates the rate of operant performance to the rate of reward delivery. The generalized matching law incorporates additional independent variables, such as the strength, amount, imminence, and likelihood of reward.

Maternal Deprivation Model

Definition

An animal model in which young rats are separated from their mother for a single period of 24 h. The most optimal day for separation is postnatal day 9. These animals develop a large number of schizophrenia-like phenomena in adulthood. Interestingly, most of these phenomena occur after puberty in accordance with the clinical literature on schizophrenia.

Mecamylamine

Definition
A nicotinic antagonist that is well absorbed from the gastrointestinal tract and crosses the ► blood–brain barrier.

Medazepam

Definition
Medazepam is a benzodiazepine that has anxiolytic, sedative, and anticonvulsant properties. It has a very long duration of action, mainly due to a long ► elimination half-life (36–200 h) and conversion to active metabolites including the benzodiazepines ► diazepam and

N-desmethyl-medazepam, both of which also are long-acting and also have long-acting metabolites. Like most similar compounds, medazepam is subject to ► tolerance, ► dependence, and ► abuse.

Cross-References
► Anxiolytics
► Benzodiazepines

Medial Forebrain Bundle

Definition
The MFB is a complex bundle of axons coming from the basal olfactory regions, the periamygdaloid region, and the septal nuclei, and passing to the lateral hypothalamus with some carrying on into the tegmentum. It contains both ascending and descending fibers. It is commonly accepted that the MFB is part of the reward system involved in the integration of reward and pleasure. Electrical stimulation of the MFB is believed to cause sensations of pleasure.

Medial Prefrontal Cortex

Synonyms
mPFC

Definition
A brain structure located in ► prefrontal cortex that receives dopamine input from the midbrain. It has been implicated in drug reward, behavioral inhibition, and stress reactivity.

Medical Herbalism

► Herbal Remedies

Medically Unexplained Symptoms

► Somatoform and Body Dysmorphic Disorders

Medicine

Synonyms
Drug; Human medicinal product

Definition
Any substance or combination of substances that may be used in or administered to human beings either with a view to restoring, correcting, or modifying physiological functions by exerting a pharmacological, immunological, or metabolic action, or to making a medical diagnosis.

Medicines Control

► Licensing and Regulation of Medicines

Medicines Regulation

Megakaryocytes

Definition
The megakaryocyte is a nucleated cell originating from the bone marrow and responsible for the production of platelets (thrombocytes), which are necessary for the process of hemostasis. The cytoplasm, exactly as platelets that bud off from it, contains alpha-granules and dense bodies.

Megalomania

► Delusional Disorder

Melanin-Concentrating Hormone

Definition
Lateral hypothalamic peptide involved in the regulation of feeding motivated behaviors including food intake. Like ► hypocretin/orexin, cells producing this peptide are located in the lateral hypothalamic region, but melanin-concentrating hormone (MCH)-producing cells do not co-express hypocretin/orexin.

α-Melanocyte-Stimulating Hormone

Definition
Cleaved product of the proopiomelanocortin pre-pro peptide. In the brain, this peptide is critical for the regulation of energy balance and genetic alterations that inactivate this peptide are associated with morbid obesity and insulin resistance.

Melatonin

Definition
Melatonin is a neurotransmitter that participates in the regulation of the sleep/wake cycle. It is produced endogenously and also available over-the-counter as an effective hypnotic for sleep onset.

Memantine

Definition
Memantine is used as an anti-dementia drug with some efficacy in the treatment of moderate to severe ► Alzheimer's disease. It reduces glutamatergic neurotransmission by acting as a low-affinity ► NMDA-receptor antagonist and this action is thought to underlie its protective effects against neuronal excitotoxicity. In addition to its anti-glutamate action, memantine also acts as a noncompetitive antagonist at serotonin 5-HT_3 and nicotinic acetylcholine receptors, and as an agonist at the dopamine D2 receptor; the role of these actions in the anti-dementia properties of the drug is unknown. Adverse side effects include confusion, dizziness, drowsiness, headache, insomnia or sleepiness, agitation, and hallucinations. In addition to Alzheimer's disease, memantine is currently being tested as a potential treatment for a number of other disorders. Preclinical studies as well as the clinical absence of withdrawal symptoms suggest that this drug has a low abuse potential.

Membrane Potential

Synonyms
Membrane voltage

Definition
A cell's membrane potential is the voltage difference across the plasma membrane that is present in all living cells.

Cross-References
► Intracellular Recording

Membrane Potential Recording

► Current Clamp

Membrane Voltage

► Membrane Potential

Memorial Delirium Assessment Scale

Synonyms
MDAS

Definition
The memorial delirium assessment scale (MDAS) is a 10-item, 4-point clinician-rated scale (possible range: 0 to 30) designed to quantify the severity of ► delirium, validated among hospitalized patients with advanced cancer and AIDS. Items included in the MDAS reflect the diagnostic criteria for delirium in the ► DSM-IV, as well as symptoms of delirium from earlier or alternative classification systems (e.g., DSM-III, DSM-III-R, ICD-9). The MDAS is both a good delirium diagnostic screening tool as well as a reliable tool for assessing delirium severity among patients with advanced disease. Scale items assess disturbances in arousal and level of consciousness, as well as in several areas of cognitive functioning (memory, attention, orientation, disturbances in thinking) and psychomotor activity. A cutoff score of 13 is diagnostic of delirium. The MDAS is designed to be administered repeatedly within the same day, in order to allow for objective measurement of changes in delirium severity in response to medical changes or clinical interventions. The MDAS has advantages over other delirium tools in that it is both a diagnostic as well as a severity measure that is ideal for repeated assessments and for use in treatment intervention trials.

Memory

Definition

Memory refers to the ability to recover information about past events or knowledge, the process of recovering information about past events or knowledge, as well as cognitive reconstruction. The brain engages in a remarkable reshuffling process in an attempt to extract what is general and what is particular about each passing moment.

Memory may be divided into short-term (also known as working or recent memory) and long-term memory. Short-term memory recovers memories of recent events, while long-term memory is concerned with recalling the more distant past.

Meprobamate

Synonyms
Miltown

Definition
Meprobamate is a sedative with a medium duration of action and is generally akin to the barbiturates used in the treatment of ► anxiety. It has largely been replaced by the benzodiazepines. Unwanted effects include sedation, headaches, paradoxical excitement, confusion, cognitive and psychomotor impairment, and confusion in the elderly. Interaction with ► alcohol can be hazardous. It depresses respiration and is toxic in overdose. Long-term use can induce ► dependence with severe withdrawal reactions. Recreational use and abuse can occur: it is a scheduled substance.

Cross-References
► Barbiturates
► Minor Tranquilizers

Meptazinol

Definition
Meptazinol is an opioid analgesic for use in moderate to severe pain. It is most commonly used to treat pain in obstetrics (childbirth). As a partial μ-opioid receptor agonist, its mixed agonist/antagonist activity results in a lower risk of dependence and abuse in comparison to full μ-agonists such as ► morphine. Meptazinol exhibits not only a short onset of action, but also a shorter duration of action relative to other opioids.

Mesolimbic System

Definition
Brain pathway that is dominated by dopamine projections branching to the subcortical ventral striatum (► nucleus accumbens) and to the ► prefrontal cortex.

Mesotelencephalic Dopamine Reward Systems

Synonyms
Brain reward systems; Dopamine reward systems

Definition
The mesotelencephalic dopamine system has three components, the nigrostriatal, mesolimbic, and mesocortical pathways consisting of cell bodies in the substantia nigra and ► ventral tegmental area that project to a number of regions including the ► nucleus accumbens, ► amygdala, striatum, and ► prefrontal cortex. These areas of the brain are strongly implicated in reward-related learning.

Meta-Analysis

Definition
A statistical technique for combining data from independent but methodologically similar studies to answer

related hypotheses and to estimate an overall effect across all the studies. Examples of its use include clinical trials and studies of behavioral and psychiatric genetics.

Metabotropic Glutamate Receptor

Synonyms
mGluRs

Definition
G-protein-coupled receptor for which glutamate is the endogenous ligand.

Metabotropic Glutamate Receptors 2 and 3

► Group II Metabotropic Glutamate Receptor

Meta-Phenylenediamine

Synonyms
m-PD

Definition
All microelectrode arrays sites are electroplated with meta-phenylenediamine (m-PD) by applying a potential of +0.5 V to the Pt sites versus a silver/silver chloride (Ag/AgCl) reference electrode (Bioanalytical Systems, RE-5) in a deoxygenated 0.05 M phosphate buffered saline (PBS, pH 7.1–7.4) with 5.0 mM m-PD. The m-PD forms a size-exclusion layer over the sites, blocking DA, ascorbic acid (AA), DOPAC, and other electroactive compounds.

Meta-Plasticity

Definition
Some forms of ► neuronal plasticity affect LTP and LTD, which are already forms of plasticity. Therefore, the term "meta-plasticity" was introduced.

Metergoline

► Methergoline

Methadone

Definition
Methadone is an opioid racemate drug that acts as an agonist on the μ opiate receptor and is the best-studied substance available for opioid maintenance in terms of clinical effectiveness reducing illicit opioid consumption and reducing high-risk behavior such as needle sharing and increasing rates of treatment retention.

Cross-References
► Opioid Dependence and Its Treatment

Methamphetamine

Synonyms
Desoxyephedrine; Methylamphetamine; N-methylamphetamine

Definition
Methamphetamine is a ► psychostimulant and sympathomimetic drug that has a blood ► half-life of 9–15 h. The primary metabolite of methamphetamine is ► amphetamine, a chemical that itself is a potent psychostimulant. Methamphetamine is clinically available for the treatment of obesity, ► narcolepsy, and in some cases ADHD. Methamphetamine is a highly potent drug of abuse, with its illicit use reaching epidemic proportions in several Western countries including North American, Asian, and Pacific regions. Chronic exposure to methamphetamine can lead to schizophrenia-like psychosis and ► neurotoxic degeneration of dopaminergic neurons.

N-Methyl-D-Aspartate Receptor

Synonyms
NMDA receptors

Definition
The N-methyl-D-aspartate receptor (NMDA) receptor is one of several subtypes of glutamate receptor. It is a voltage-sensitive ionotropic receptor (ligand-gated ion channel) that facilitates excitatory transmission of electrical signals between neurons by depolarizing the postsynaptic neuronal membrane. Although it is named after a selective agonist (NMDA), endogenous ligands for the receptor include glutamate or aspartate. Efficient channel

opening also requires binding by the co-agonist glycine and a positive change in transmembrane potential. Activation of NMDA receptors results in the opening of an ion channel that is nonselective to cations, allowing the influx of Na^+ and Ca^{2+} and the efflux of K^+. In addition to facilitating excitatory neurotransmission, NMDA receptors are thought to play a key role in ► synaptic plasticity, thereby having an important role in learning and memory.

Methylenedioxymethamphetamine (MDMA)

Iain S. McGregor[1], Murray R. Thompson[1]
Paul D. Callaghan[2]
[1]School of Psychology, University of Sydney, Sydney, NSW, Australia
[2]Radiopharmaceutical Research Institute, Australian Nuclear Science and Technology Organisation (ANSTO), Sydney, NSW, Australia

Synonyms

E; Eccie; Ecstasy; Hug drug; Love drug; Love hormone; 3,4 Methylenedioxymethamphetamine; XTC

Definition

MDMA is a popular recreational drug that is renowned for its ability to produce euphoria and unique prosocial effects. It is the best known and most commonly used member of the family of phenethylamines (substitutes for ► amphetamines) that are sometimes known as ► entactogens, empathogens, or the MDxx class of drugs. MDMA has multiple neurochemical effects, the most prominent of which is to promote the release of serotonin via an action on the ► serotonin transporter (SERT). The prosocial effects of MDMA have recently been linked to the release of the neuropeptide ► oxytocin. High doses of MDMA can cause long-term depletion of serotonin in the brains of laboratory animals, but whether this also occurs in humans and whether this leads to associated psychopathology such as ► depression and ► cognitive impairment remains unclear.

Pharmacological Properties

History

MDMA was first synthesized in 1912 by the company E. Merck. Although commonly thought to have been designed as an appetite suppressant, the original patent bears no record of this and simply states that MDMA was deemed to contain primary constituents for therapeutically active compounds. The first reported pharmacological study involving MDMA occurred in 1927 although basic toxicology studies were not undertaken until the 1950s. Further studies at the University of Michigan, supported by the US Army, reported LD_{50} values for five different species, with the lowest LD_{50} value found in dogs and the highest in mice.

The first systematic use of MDMA was as an adjunct to insight-oriented psychotherapy, with administration of MDMA producing an easily controllable altered state of consciousness with positive emotional and sensual overtones. The colloquial term for MDMA changed from "Empathy" as was used by therapists in the 1970s to "Ecstasy," emphasizing the drug's euphoric effects. Heavy media attention in 1985 sensationalized Ecstasy's euphoric effects and caused a surge in recreational use.

In 1986, MDMA became a Schedule 1 drug in the United States, deemed to possess no recognized therapeutic value. By the 1990s, ► Ecstasy had become intrinsically linked to the club and rave culture, with its use by groups of young people attending all-night dance parties where

vigorous dancing occurred to highly repetitive and hypnotic "techno" music. The popularity of MDMA has continued to grow to the point where it is now one of the most widely used illicit drugs in the world.

Mechanisms of Action

MDMA is a ring-substituted amphetamine, with a methylenedioxy group attached to the aromatic ring of amphetamine. It has multiple, complex pharmacological actions. The most important property is to potently release ▶ serotonin (5-HT) from axon terminals into the synapse and to inhibit 5-HT reuptake. To a lesser extent, MDMA also releases dopamine, noradrenaline, and acetylcholine. MDMA reverses the action of the SERT causing 5-HT stores from the neuron to be pumped into the synapse. An additional related action is to block the reuptake of 5-HT (▶ uptake), which further increases synaptic 5-HT concentrations. Pretreatment with SERT ligands including ▶ SSRIs (e.g., fluoxetine) prevents MDMA-induced 5-HT release in brain slices and in vivo. In addition to these effects on 5-HT efflux, MDMA-mediated inhibition of ▶ monoamine oxidase prevents the breakdown of 5-HT and other ▶ neurotransmitters such as dopamine, further contributing to elevated monoamine levels. A further effect of MDMA is to inhibit tryptophan hydroxylase (the rate-limiting enzyme for 5-HT synthesis). This effect may contribute to depletion of 5-HT stores in the days following MDMA use.

MDMA possesses two stereoisomers: (−)-MDMA has a higher affinity for postsynaptic 5-HT receptors while (+)-MDMA has a higher affinity for the SERT. The two isomers differ in their behavioral effects in rhesus monkeys and subjective effects in humans. These two isomers also differ in the rate in which they are metabolized across individuals which may result in large inter-individual differences in the overall response to MDMA.

MDMA also binds to various 5-HT receptors with moderate to high affinity. Receptor-binding studies indicate that MDMA possesses a high affinity for the 5-HT_2 family of receptors and a moderate affinity for 5-HT_1-type receptors. Activation of ▶ 5-HT_{1A} receptors largely acts to inhibit serotonergic cell firing although the resultant inhibitory effects on 5-HT release are overridden through MDMA-induced effects at the SERT in forebrain regions.

MDMA acts to increase synaptic ▶ dopamine levels, but these increases are generally smaller than the increases in 5-HT in any given region. MDMA-induced dopamine release may involve both an indirect ▶ 5-HT_{2A}-receptor mechanism as well as a direct action on the ▶ dopamine transporter (DAT). Dopamine levels are also augmented by an action of MDMA on the vesicular monoamine transporter (VMAT2) causing dopamine efflux from vesicular stores via carrier-mediated exchange.

MDMA also causes a significant release of ▶ norepinephrine via an interaction with the ▶ norepinephrine transporter (NET). ▶ Acetylcholine release also occurs in the prefrontal cortex and dorsal hippocampus following MDMA, and there is also the involvement of GABA, glutamate, nitrergic, and sigma ($\sigma 1$) systems. MDMA causes major endocrine changes (▶ neuroendocrine markers for drug action) including an increase in plasma oxytocin, vasopressin, cortisol, and prolactin.

Pharmacokinetics

Human ▶ pharmacokinetic studies show that MDMA's distinctive effects occur at doses of 1 mg/kg or above with peak MDMA serum concentrations observed 2 h post administration, coinciding with peak psychological effects. MDMA has nonlinear pharmacokinetics, with increasing doses resulting in unpredictable blood/body concentrations. Like most other psychoactive drugs, MDMA is primarily metabolized by the liver via the ▶ cytochrome P450 family of enzymes, with the 2D6 isozyme particularly implicated. However, MDMA has a very complex metabolic pathway in comparison to other amphetamine analogs, and this may explain the sometimes complex and unpredictable relationship between Ecstasy tablet intake and acute effects of the drug. The primary metabolites of MDMA in humans, HHMA and HMMA, are readily broken down in the body to ortho-quinones, highly reactive compounds that may lead to ▶ free radical-induced brain injury.

Neurotoxicity

Exposure to relatively high doses of MDMA can cause a long-lasting reduction in brain monoamine levels in a variety of animal species. While rats and primates show a primary reduction in brain 5-HT, mice show primary reductions in brain dopamine. Reductions in SERT density in cortical, limbic, and striatal regions has also been reported in many studies with rats and primates. Given that the SERT protein is primarily located in 5-HT axons, MDMA-induced axotomy has been invoked as the primary reason for this effect and has been confirmed in some histological studies. Abnormal 5-HT axonal immunoreactivity has been seen in primates 7 years post MDMA treatment. However, these pattern of findings do not confirm a neurotoxic effect in the classic sense. Gliosis is not typically observed following MDMA administration; nor is there any damage to serotonergic cell bodies. The widely discussed notion of MDMA-induced ▶ neurotoxicity therefore remains controversial (Baumann et al. 2007).

In addition to global SERT changes, alterations in the density of specific 5-HT receptor subpopulations can be seen following MDMA. Significant reductions in 5-HT_{2A} receptor density in cortical, striatal, thalamic, and hypothalamic regions have been reported in rats months after MDMA treatment, although opposite findings on 5-HT_{2A} receptor density have been reported in some human studies. ▶ 5-HT_{1B} receptor density was reduced in MDMA-treated rats in the globus pallidus, ▶ hippocampus, and medial thalamus but increased in the ▶ nucleus accumbens and lateral septum.

High ambient temperatures at the time of dosing, typical of the dance parties where MDMA is often taken, may exacerbate MDMA-induced 5-HT depletion. A ▶ neuroprotective effect of coadministered drugs (e.g., haloperidol, ketanserin, pentobarbitone, and various antioxidants) may result from an induction of hypothermia or by preventing the hyperthermic effects of MDMA. However, some drugs (e.g., ▶ cannabinoids) are protective independently of their body temperature effects.

Some human studies have found that Ecstasy users differ from controls on a range of measures related to 5-HT, including a reduction of cerebrospinal 5-HIAA levels and a blunted ▶ neuroendocrine responses to serotonergic ligands. Decreased global and regional SERT density in Ecstasy users have been reported in some ▶ PET imaging and ▶ SPECT imaging studies although these are generally modest effects and may recover with abstinence from the drug.

Positive Effects in Humans

MDMA induces a positive mood state in humans along with increased energy and euphoria, typical of amphetamine and its derivatives. However, MDMA users also report a unique sense of intimacy and empathy coupled with an increased feeling of closeness to others (▶ entactogen) that is not always typical of amphetamine (▶ social behavior). In addition, MDMA users also report mild ▶ hallucinogen-like enhancement of perceptions and sensations with augmented responses to touch and music. Unlike amphetamines, MDMA appears to have relatively low ▶ abuse potential in humans, perhaps due to rapid ▶ tolerance developing to the positive effects with repeated use.

SSRIs attenuate many of the acute psychological effects of MDMA in humans, consistent with a primary action of MDMA on SERT. SSRIs also reduce MDMA-induced heart-rate changes. Other studies showed that MDMA-induced perceptual changes and emotional excitation are partially mediated by post-synaptic 5-HT_{2A} receptors since these effects can be attenuated by ketanserin (Liechti and Vollenweider 2001).

The positive acute effects of MDMA in humans may involve other neurochemical systems. Thus, the ▶ antipsychotic drug ▶ haloperidol partially antagonized the positive and mania-like mood states induced by MDMA. In a recent laboratory study, the increased feeling of sociability after MDMA was associated with increased plasma levels of oxytocin in human subjects (Dumont et al. 2009).

Effects in Laboratory Animals

The acute effects of MDMA have been investigated in a diverse range of laboratory animal species. A key consideration in utilizing animal models is in establishing appropriate species-equivalent dosing levels to model human MDMA use (Green et al. 2009). This issue is still far from resolved with many animal studies using MDMA dose regimes that are in the extreme range. Species-specific ▶ pharmacokinetics also complicate the picture.

MDMA has amphetamine-like sympathomimetic effects, increasing blood pressure and heart rate. It exerts a powerful influence on body temperature, with the direction of change (hyperthermia or ▶ hypothermia) dependent upon the ambient temperature of the environment (Green et al. 2003). The hyperthermic response to MDMA appears in part to be reliant upon the mitochondrial uncoupling protein 3 (UCP-3) acting in striated myocytes. MDMA also produces peripheral vasoconstriction, further preventing heat loss.

Behaviorally, MDMA causes amphetamine-like ▶ hyperactivity and locomotor ▶ sensitization in rodent species. ▶ Intravenous self-administration of MDMA is seen in mice, rats, and nonhuman primates although rates are significantly less than that of other abused drugs such as the ▶ psychostimulants cocaine and methamphetamine. Self-administration of MDMA in rats is increased at high ambient temperatures, and this may be in part due to augmentation of MDMA-stimulated increases in dopamine and neuronal activation in reward-relevant brain regions. Rats will also show a ▶ conditioned place preference to MDMA, an effect that involves dopamine, ▶ opioid, and ▶ endocannabinoid systems.

In line with its characteristic prosocial effects in humans, MDMA reduces aggression and increases social interaction in rodents. In the ▶ social interaction test, rats spend increased times in adjacent contact following acute MDMA treatment, and this effect is also augmented at high ambient temperatures. This prosocial effect of MDMA is

reduced by oxytocin antagonists and is minimicked by the ► 5-HT_{1A} agonist 8-OH-DPAT (McGregor et al. 2008).

MDMA-Associated Hazards and Psychopathology

Hyperthermia and other components of the ► serotonin syndrome are the main acute hazards facing human MDMA users, particularly when the drug is taken in high doses and in hot environments. Despite considerable media attention, lethal effects of MDMA (taken alone) appear comparatively rare. However, combining MDMA with other serotonergic drugs (e.g., ► monoamine oxidase inhibitors) can be extremely dangerous due to the possibility of ► serotonin syndrome. Other problems for users relate to the fact that Ecstasy tablets do not always contain MDMA, with a wide range of adulterants reported in analytical studies.

Acute adverse psychological effects are occasionally reported with MDMA, most commonly ► anxiety and paranoia. A greater research focus, however, has been on possible lasting adverse psychological effects of MDMA use, effects that might be associated with serotonin depletion. In various studies, Ecstasy use has been linked to ► anxiety, ► depression, and ► mild cognitive impairment. However, many of these studies have inherent methodological problems. For example, Ecstasy users typically use other substances and coincident heavy cannabis use is a particularly troublesome confound in studies probing cognitive impairment after MDMA. There is also evidence that people with a preexisting childhood tendency toward anxiety and depression are more likely to become Ecstasy users, providing an additional confound. There is therefore a need for prospective longitudinal studies to control for premorbid psychiatric and cognitive problems in assessing MDMA-related harms. An example of this is the recent Netherlands XTC Toxicity (NeXT) study. This has uncovered subtle abnormalities in brain function in a sample of young persons taking MDMA for the first few times (de Win et al. 2008).

Preclinical studies are also important in addressing the issue of whether MDMA exposure has lasting adverse consequences. Consistent, lasting adverse effects have been reported in a number of behavioral tests in rodents pretreated with MDMA. These include increased anxiety as assessed in the emergence test and the ► elevated plus maze, increased depressive-like symptoms in the Porsolt test (► Depression: Animal Models), and impaired ► novel object recognition and ► spatial memory. The ► social interaction test has been found to be particularly sensitive to detecting lasting adverse effects of MDMA in rodents, with decreased social behavior detected even months after low-dose MDMA exposure. Many of the above long-term effects are seen with low-dose regimes of MDMA that do not deplete brain 5-HT. As yet, unspecified neuroadaptations in nonserotonergic brain systems may therefore underlie these lasting adverse effects (McGregor et al. 2008).

Therapeutic Uses

Despite concerns relating to the neurotoxicity and possible psychopathology associated with MDMA use, a number of reputable scientists have called for further study of the use of MDMA as a therapeutic for anxiety and depression and relationship issues. This marks something of a return to the original use of MDMA as a tool for assisting ► interpersonal psychotherapy in the 1970s and 1980s. The Multidisciplinary Association for Psychedelic Studies (MAPS) (http://www.maps.org/mdma/) is currently sponsoring small clinical trials of MDMA in several countries for the treatment of ► traumatic stress disorder, and are also sponsoring a study of MDMA for alleviation of anxiety linked to terminal cancer.

Conclusions

MDMA is a controversial drug with a unique and complex pharmacology. No other drug, with the possible exception of GHB (► sodium oxybate), has the capacity to produce such marked facilitatory effects on ► social behavior in humans and other animal species. It is therefore encouraging to see that recent psychopharmacological studies of MDMA have started to focus on the positive prosocial effects of the drug in humans (Bedi et al. 2009; Dumont et al. 2009), and not just on its possible adverse effects and neurotoxicity.

Despite a plethora of human and animal studies spanning more than two decades, experts cannot appear to reach a consensus on the relative harms associated with MDMA use: some claim MDMA is largely innocuous (Nutt 2009) while others proclaim its dangers (Parrott 2002). Fortunately, our overall knowledge of MDMA psychopharmacology continues to grow, as research studies involving both human Ecstasy users and laboratory animals given MDMA evolve in their sophistication, scope, and power. Perhaps given another decade of research, a greater consensus will emerge, and we will understand not only how MDMA acts in the brain to produce "chemical love" but also whether this is a good or a bad thing for the health of the individual.

Definition

Methylphenidate (MPH) is the most commonly prescribed psychostimulant for the treatment of attention-deficit hyperactivity disorder (juvenile and adult forms), although it has also been used in the treatment of narcolepsy and postural orthostatic tachycardia syndrome. It was first synthesized in 1944 and is chemically related to cocaine; it was originally formulated as a mixture of two racemates, 80% (±)-erythro and 20% (±)-threo, though its efficacy was later realized to derive from the threo isomer. Like most psychomotor stimulants, it acts to enhance ▶ dopamine release and block reuptake with additional effects on ▶ noradrenaline reuptake; it is not thought to affect central serotonin directly, unlike the prototypical psychomotor stimulant ▶ amphetamine, or ▶ cocaine. Its main cognitive effects are to reduce ▶ fatigue, enhance ▶ attention, and reduce ▶ impulsivity. Experimental studies in non-sleep-deprived healthy humans have indicated beneficial effects on ▶ working memory, leading to its current reputation as a "▶ cognition enhancer." Its mode of action on cognition is probably in fronto-striatal circuits as shown from human imaging and animal studies. Its relatively slow onset of action when taken orally may well contribute to its relative lack of abuse potential in the conventional sense, although it has recently been shown to be a popular "cognition enhancer" in college students where it is sometimes called "Vitamin R." Adverse effects of methylphenidate include slight growth retardation, appetite suppression, and, occasionally, motor tics. Long-term effects are largely unknown, although it has been suggested to "protect" ADHD juveniles from future drug abuse.

Pharmacological Properties

Several newspapers in the US recently reported the contention that healthy people should have the right to boost their brains with psychoactive drugs, drugs that are normally described for disorders such as attention deficit disorder (ADD), ► attention deficit/hyperactivity disorder (ADHD), ► narcolepsy, and memory-impairment in older individuals (► dementia). College students are already taking Ritalin as a ► cognitive enhancer before exams to help them study better, and some students contend that "We should welcome new methods of improving our brain function" and that doing it with pills is no more morally objectionable than eating right or getting a good night sleep (Houston Chronicle, December 8, 2008). But what do we know about this psychoactive drug?

Psychoactive drug use is a practice that dates back to prehistoric times. A psychoactive drug is a central nervous system (CNS) stimulant that modulates consciousness, perception, mood, and behavior. There is archeological evidence of the use of psychoactive drugs as far back as several thousand years ago. These drugs were used therapeutically as medication, for ritual and spiritual purposes, as well as recreationally to alter one's mood and to get "high." Because psychoactive drugs elicit changes in consciousness and mood, the user feels alert, joyful, pleasant, and becomes euphoric. Many psychoactive drugs are abused despite the risks of negative consequences, that is, ► dependence. Methylphenidate belongs to this family of drugs.

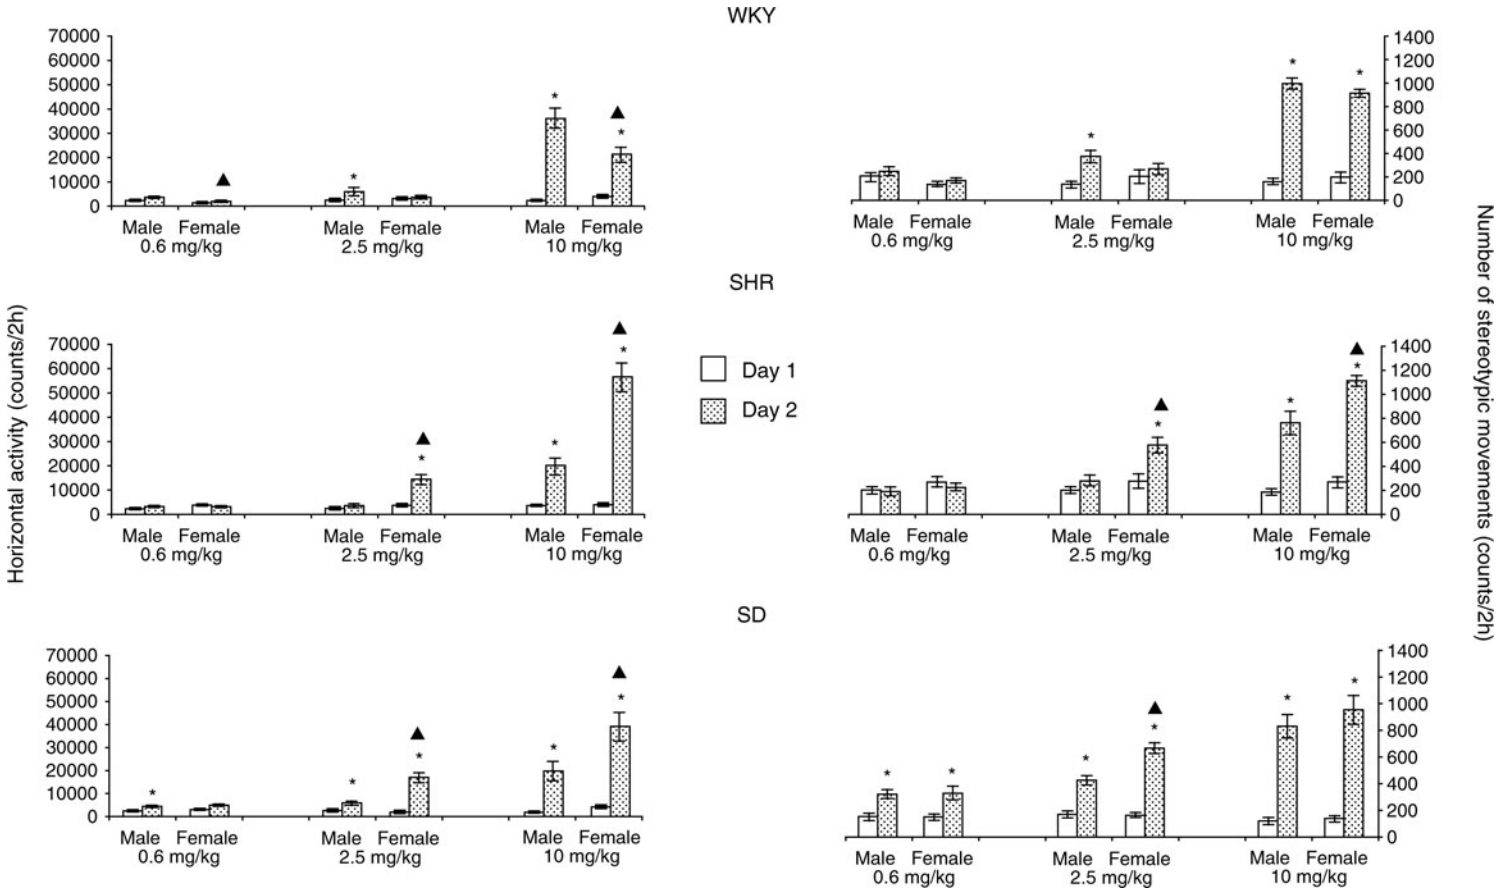
What is methylphenidate? MPD is one of the most prescribed psychostimulants for the treatment of children and adults with ADHD. ADHD is characterized by a persistent pattern of inattention and/or hyperactivity, with impulsivity more often displayed and more severe than is typical for individuals at a comparable level of development. ADHD is a developmental disorder that affects as much as 5–15% of school-aged children in the US (Kollins et al. 2001). Methylphenidate is a CNS stimulant that is structurally closely related to ► amphetamine. The neuropharmacological profile of methylphenidate is also similar to that of ► cocaine (Volkow et al. 1999). The drug was first synthesized in 1944 and was used initially as an analeptic for several types of barbiturate-induced coma. It was later used as a drug to improve memory in elderly patients. Since then, its usage has been extended to improve alertness and attention in children and adults with emotional, behavioral, and learning difficulties. Methylphenidate is highly effective in treating ADHD. Methylphenidate may also be useful in providing relief from intractable pain in narcolepsy and chronic fatigue. When methylphenidate is given orally, it is absorbed from the intestinal tract and has a half-life time of about 1 h with equally short duration and efficacy (Solanto 2000). Its peak level following injection (systemic) is faster and is reached in 8–20 min post injection (Kuczenski and Segal 1997), a pattern that is similar to systemic cocaine and amphetamine administration (Volkow et al. 1999). When methylphenidate is given systematically, it binds with similar affinity to the ► dopamine transporter (DAT) and has a potency (K_i=200) similar to cocaine (K_i=224) (Kuczenski and Segal 1997). The relationship between drug doses (milligrams of hydrochloride salt/kilogram of body weight) and percentage occupancy of DAT is identical for cocaine and methylphenidate in rodents and humans (Gatley et al. 1999). The dose and route of administration are important because the features of the behavioral and neurochemical responses to the drug are dependent on the speed of the drug to reach the peak level, that is, the rise time of drug concentration (Kuczenski and Segal 1997). Peak levels of methylphenidate following intravenous (i.v.), intraperitoneal (i.p.), and oral administrations were 8–20 min, 15–28 min, and 60–90 min, respectively (Gerasimov et al. 2000). Similar peak levels of i.v., i.p., and oral administrations were obtained following amphetamine and cocaine (Gerasimov et al. 2000). The ability to reach the peak level in a short time (i.v., 8–30 min) is one of the main

factors in eliciting adverse effects such as its euphoria, ▶ tolerance, and ▶ sensitization. Stimulants have been abused for both "performance enhancement" and for recreational purposes. For the former, they suppress appetite, facilitate weight loss, increase wakefulness, and increase focus and attention. Their euphoric effects usually occur when the stimulants are crushed and inhaled through the nose or injected. Methylphenidate is absorbed and metabolized via de-esterification to ritalinic acid and released into urine within 48 h. Brain concentrations of methylphenidate exceed that of plasma, since the psychostimulant is concentrated in catecholamine systems with free passage across the ▶ blood-brain barrier. Methylphenidate has a rapid uptake in the brain similar to amphetamine and cocaine, but differs from amphetamine and cocaine in that the rate of clearance from the brain is much slower. Intravenous (i.v.) or intranasal administration of methylphenidate is associated with a higher mortality rate than cocaine or amphetamine use, and every year more adolescents and young adults use (or misuse) the drug in these routes of administration. The outcome of methylphenidate treatment results primarily in dopamine (DA) release and inhibits the reuptake of DA, norepinephrine (NE), and serotonin (5-HT) (Kuczenski and Segal 1997). Like cocaine, methylphenidate is an indirect catecholamine agonist, since it does not stimulate the catecholamine receptors directly but rather facilitates the action of the catecholamine (Volkow et al. 1999). The therapeutic effects of methylphenidate in the treatment of ADHD has been attributed to its ability to increase the efflux of these neurotransmitters (Askenasy et al. 2007; Dafny and Yang 2006) by binding to their transporters and blocking the reuptake of these neurotransmitters. This causes increases in extracellular DA, NE, and 5-HT levels (Kuczenski and Segal 1997), which has an effect that has been linked to its reinforcing properties (Solanto 2000; Volkow et al. 1999). Methylphenidate has moderate effects on the peripheral circulatory system. In rats, methylphenidate administration in low doses (2.0–5.0 mg/kg) stimulates locomotor activity (Fig. 1) and elicits behavioral sensitization (Fig. 2.). In higher doses (10.0 mg/kg and higher), it stimulates stereotypical behavior and tolerance (Dafny and Yang 2006). The therapeutic effects of stimulants such as methylphenidate and amphetamine are achieved by slow and steady increases of DA, NE, and 5-HT which are similar to natural production by the brain. The most commonly prescribed medication for ADHD patients include amphetamine (e.g., Adderall, a mixture of amphetamine salts), methylphenidate (i.e., Ritalin, which is short acting), and formulations such as Concerta that release methylphenidate over a longer period of time.

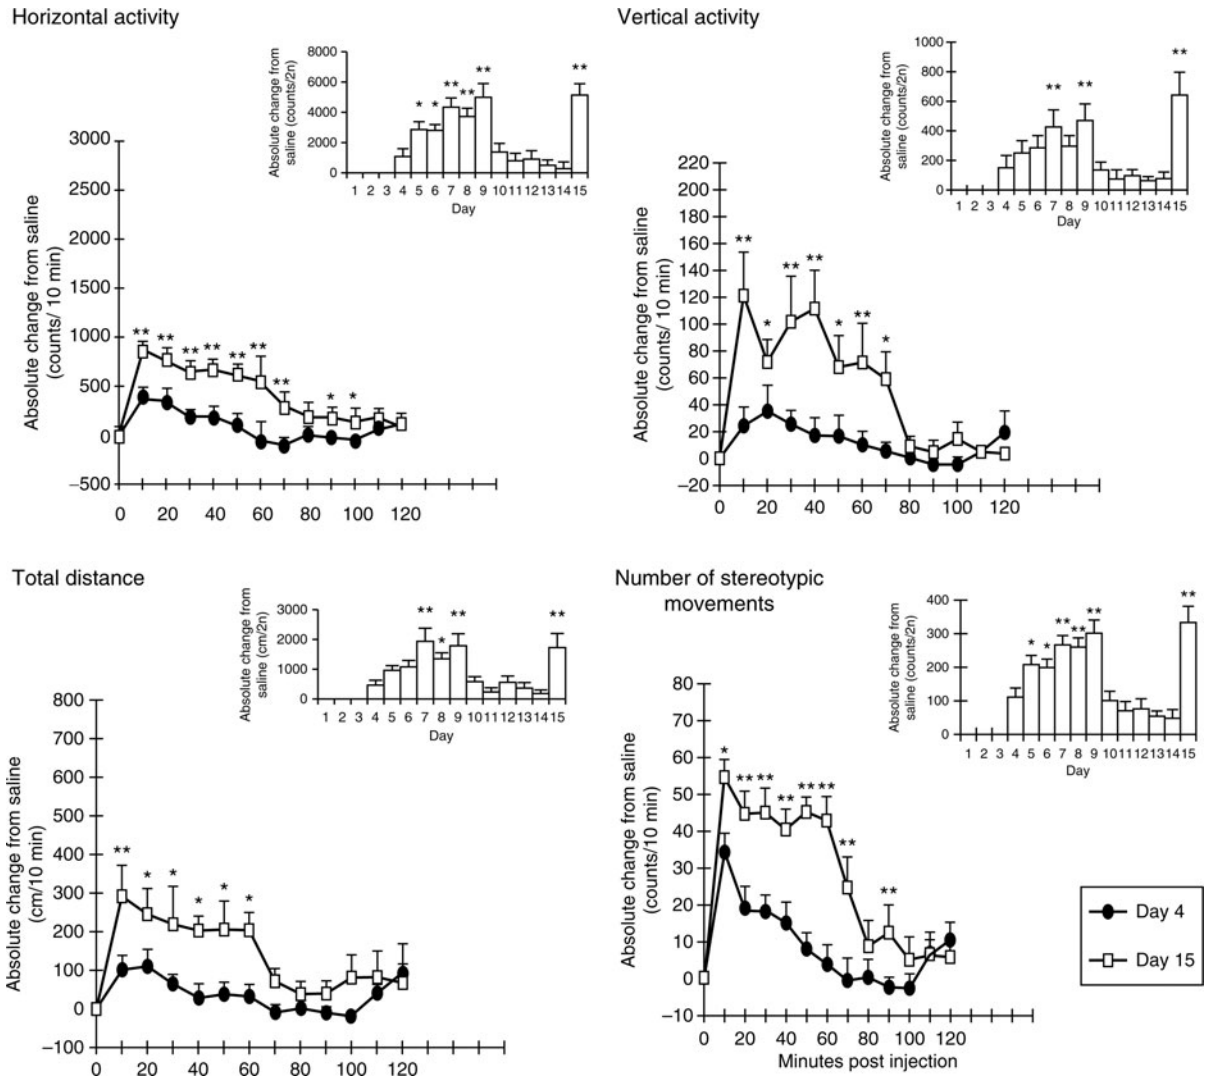
Domestic sales of methylphenidate in the US showed an increase of almost 500% in the last decade. The therapeutic benefits of methylphenidate treatment for ADHD are clear. Moreover, concerns exist that during adolescent years, crucial neurodevelopment occurs with the production and elimination of numerous neuronal synaptic connections, that is, synaptic pruning. Children with ADHD who are going through neurodevelopmental processes are treated with methylphenidate for extended periods of time. Chronic treatment with psychostimulants such as methylphenidate and amphetamine can modulate these neurodevelopmental processes critically, which in turn may alter the body's homeostasis. Any modulation produced by such psychopharmacological intervention in a still-developing brain should generate significant public health concerns. Additional concerns are raised that psychostimulant therapy given to adolescents and young adults may result in an increased risk for behavioral disorders (Robinson and Berridge 1993), while other reports have shown that psychostimulant treatment in adolescents with ADHD protects them from later substance use. These contradictory reports call for basic in-depth studies to resolve this critical issue. Animal models using behavior and neuronal recordings following acute and chronic methylphenidate treatment can be used to clarify this contradiction.

Animal Models for Studies of Methylphenidate

Methylphenidate is the drug most often used for treating children and adults with ADHD, for many years. It is expected that these patients would be used to study the prolonged effects of methylphenidate on their physiological and behavioral properties. However, there are ethical, methodological, and economic factors that limit research on children and adults exhibiting ADHD and on the therapeutic effects of methylphenidate. Therefore, research uses animal models for the understanding of the disorders. Researchers deal with a simpler system, which yields data that may be easier to interpret than that of a clinical case. In addition, animal models offer the possibility of understanding neurobiological processes that cannot be readily studied in humans. The question is which animal, and if a rat is selected, which strain? It has been argued that the most adequate model to study the physiological properties of methylphenidate is the one that best mimics a clinical case of ADHD and is able to predict aspects of ADHD behavior. There are differences between different strains of rats in the susceptibility to psychostimulants and their chronic effects such as tolerance or sensitization. Each strain of rats comprises a different gene pool. This results in different susceptibilities to



Methylphenidate and Related Compounds. Fig. 1. The figure summarizes the dose-response of acute methylphenidate injection on the horizontal activity and the number of stereotypic activities of female and male WKY, SHR, and SD rats, using the open field assay. Each group consists of $N=8$ and was given saline on experimental day 1 and methylphenidate on experimental day 2. The 0.6 mg/kg methylphenidate failed to elicit any changes in the horizontal activity of female and male WKY and SHR groups, while this low dose of methylphenidate significantly increased the horizontal activity of male SD rats (Fig. 1 – *left column*). The 2.5 mg/kg methylphenidate given i.p., increased significantly (*$P<0.05$) only the horizontal activity of male WKY and SD rats and female SHR and SD rats (Fig. 1 – *middle column*), as compared to that of the saline control group. Female SHR and SD exhibited significantly (Δ $P<0.05$) greater increase in activity compared to their male counterparts. The highest methylphenidate dose (10.0 mg/kg) induced robust increase in locomotor activity when compared to baseline. * – indicates significant ($P<0.05$) difference when comparing the animal group to its control day, that is, experimental day 2 to experimental day 1. Δ indicates significant ($P<0.05$) difference between the sexes of each rat strain.



Methylphenidate and Related Compounds. Fig. 2. This figure demonstrates behavioral sensitization. The embedded histograms in the upper right corner depict the total change from the baseline activity in the initial 2-h following injection at all administration times. The numbers indicate the experimental days. The figure summarizes 15 consecutive recordings ($N=8$) of four different locomotor activity indices. The locomotor recording of three control days (baseline) was set arbitrarily as 0. Following the control days, six single daily injections of 2.5 mg/kg methylphenidate (i.p.) were given at 07:00, and followed by 5 days of washout. Finally, a re-challenge injection of 2.5 mg/kg methylphenidate (i.p) was administered on experimental day 15. In all the four locomotor indices, the activity on experimental day 15 was significantly elevated as compared to the recording on experimental day 4 (1st day of methylphenidate injection). In the temporal graphs, the filled circles are the recordings after saline injection, while the squares denote the locomotor activity after 2.5 mg/kg methylphenidate.

psychostimulants by different strains, and the long-term effects of the drug (sensitization or tolerance) can also be different in each strain.

Since no biological marker for ADHD has yet been identified, diagnosis of ADHD is presently based only on behavioral symptoms. Many suggested ► animal models of ADHD exist, including rats selected from a general population, rats reared in social isolation, rats exposed to environmental pollutants, rats that have undergone neonatal anoxia, rats that have undergone hippocampal X-irradiation in infancy, rats that have undergone neurotoxic brain lesions, Naples High/Low excitability rats,

and knockout mice. There are also genetic models, including the spontaneously hypertensive/hyperactive rat (SHR) strain, which was bred from progenitor Wistar Kyoto (WKY) rats (Dafny and Yang 2006). The SHR is a rat strain hyperactive in a variety of behavioral characteristics that are comparable to the behavior of children with ADHD, including motor and cognitive impulsiveness, impaired sustained attention, hyperactivity, and reduced DA function. Therefore, the SHR strain is used most often in ADHD/methylphenidate studies. Most investigators who study the properties of drugs on animals do so in the belief that their work will ultimately be relevant to people.

Behavioral Models for Drug Dependence and Abuse

The concept of drug ► abuse liability is related operationally to the ability of a drug to support ► self-administration. There are only two studies that investigated the self-administration behavior of methylphenidate (Askenasy et al. 2007) and they reported that methylphenidate supported self-administration behavior. They conclude that the reinforcing effects of methylphenidate were similar to those of amphetamine and cocaine. The ► conditioned place preference paradigm is an experimental procedure in which, after training, an animal develops a preference for certain environment by virtue of its association with the rewarding state induced by a drug. The procedure consists of a box that is divided into two compartments that are qualitatively different from each other, for example in texture, color, smell, and connected to each other via a chamber that acts as a gateway between the compartments. The studies paired the drug (methylphenidate) with the less preferred compartment and they demonstrated that methylphenidate induced CPP in drug naïve rats (Askenasy et al. 2007).

Age differences in methylphenidate effects: The response to psychostimulants was reported to vary with age (Dafny and Yang 2006). During normal development, overproduction of synaptic connections and receptors occurs and follows by their pruning or competitive elimination. The marked overproduction and elimination of synapses and receptors during adolescence may serve as a permissive factor for a number of behavioral/psychiatric disorders, including ADHD (Andersen and Teicher 2000). Between 5 and 15 years of age, in humans, synaptic density in the frontal cortex decreases by approximately 40%. The time course and nature of ADHD parallel the pattern of overproduction and regressive synaptic elimination described earlier. Some adverse consequences of neuronal development in children were reported. Adolescent rats are affected differently by catecholaminergic agonists when compared with adult rats. It was reported that adolescent rats exhibited an attenuated behavioral response, while adult rats exhibited an increase in behavioral response to psychostimulants (Laviola et al. 1995). Rats exposed to methylphenidate during the period equivalent to human adolescence experienced behavioral changes that endured into adulthood, which suggests that methylphenidate does have a neurobiological effect in adolescents that modulates the "normal" development to adulthood (Dafny and Yang 2006). Studies of cocaine-induced behavioral ► sensitization in developing animals have yielded conflicting results, depending upon the age tested, the drug maintenance dose, the intervals between the repetitive drug treatment, and the challenge dose. Adolescent rats showed behavioral sensitization to the locomotor activating effects of cocaine, whereas different locomotor sensitization profiles were found in adult rats (Laviola et al. 1995). However, others have reported that younger animals treated chronically with stimulants rarely exhibited behavioral sensitization and that when sensitization occurred, it persisted for a shorter period of time.

When adolescent and adult rats were compared to their responses following chronic stimulant, adolescent rats showed alterations in psychopharmacological sensitivity which apparently did not rely on age-specific decreases in brain drug availability, but rather appeared to be related to alterations in CNS sensitivity (Laviola et al. 1995). It was also reported that adult rats repeatedly exposed to methylphenidate during adolescence were significantly more vulnerable to cocaine, as determined by increased self-infusion of psychostimulants and increased motor activity. This suggests that adult responses to cocaine are altered following childhood methylphenidate exposure. The ontogeny of brain/behavior relationship during the period between preadolescence, adolescence, and attained sexual maturity needs to receive more attention.

Sex Differences in Methylphenidate Effects

Biomedical investigation has been conducted almost exclusively on male subjects. The reason for excluding females as subjects in the research is that they have greater biological complexity than males due to their reproductive cycle. It has only recently become evident that the gonadal steroid hormones have multiple functions. Furthermore, sex-related differences are often controversial and not documented. Differences in the response to cocaine and amphetamine are reported to be sex-dependent. Observations of ► sex differences in response to drug treatment may be due to drug ► pharmacokinetics, particularly drug metabolism. The neural systems mediating the behavioral response to psychomotor stimulants are sexually dimorphic and are modulated by genes

and pituitary and gonadal hormones. For example, estrogen enhances the acute behavioral and neurochemical responses to dopamine (DA), amphetamine, and cocaine in female rats. The effects of gonadal hormones are postulated to have important implications for gender differences in the acute and chronic responses and in the susceptibility of addiction to psychomotor stimulants. There are also remarkable gender differences in the behavioral expression of ADHD patients (Andersen and Teicher 2000). For example, ADHD is more often diagnosed in males than in females and is 2–9-fold more prevalent in males. Females with ADHD may be more severely affected than males, as female ADHD subjects tend to have a higher genetic loading for the disorder. It was hypothesized that there is an extensive overproduction of DA receptors in the male striatum and NAc during prepubertal development, which may help to explain why males are often afflicted with ADHD because dopaminergic activity increases in these regions can produce hyperactivity and stereotypical behavior. Sex differences in ADHD may also be attributed to sex differences in DA receptor density. Striatal D_2 receptor density in males increases to $144 \pm 26\%$ in between 35 and 40 days, while that in females increases only to $31 \pm 7\%$. The rise in striatal DA receptors in males parallels early development of ADHD motor symptoms (Dafny and Yang 2006).

In general, females were more sensitive than males to methylphenidate, cocaine, and amphetamine. The development of behavioral sensitization to these drugs was a function of sex-specific alterations in the sensitivity to psychostimulants. In addition, accumulating evidence indicates that the antecedents, consequences, and mechanisms of drug abuse and addiction are different in females and males. It was reported that adult female rats were more seriously addicted to psychostimulants and express a more rapid behavioral sensitivity to chronic exposure of these drugs compared to their male counterparts. This sexual dimorphism was only observed in adult rats, suggesting that gonadal hormones secreted in adulthood may modulate the responsiveness to psychostimulants (Dafny and Yang 2006).

Mianserin

Definition
Mianserin is a tetracyclic second-generation ► antidepressant with combined serotonergic–noradrenergic mechanism of action. It increases serotonergic (5HT) and noradrenergic (NA) neurotransmission by acting as an antagonist mainly at 5-HT_2 and α2 presynaptic and somatodendritic auto- and hetero-receptors. This drug also has a strong antihistaminic effect but, unlike the ► tricyclic antidepressants, it has almost no anticholinergic and cardiotoxic properties. In addition to its antidepressant effects, mianserin also has anxiolytic, sedative-hypnotic, antiemetic, and appetite-enhancing effects. Clinical effects of mianserin usually become noticeable after 1–3 weeks of treatment. Common side effects include dizziness, blurred vision, drowsiness, weight gain, dry mouth, and constipation while more serious adverse reactions may include hypomania, fainting, seizures, and hematological problems. As with other antidepressants, abrupt or rapid discontinuation of mianserin therapy may induce withdrawal effects, such as rebound depression, anxiety, panic attacks, anorexia, and insomnia.

Brain microdialysis; Intracerebral microdialysis

Definition
Brain microdialysis is a sampling technique developed to study the concentration of chemical solutes (mainly neurotransmitters) in the extracellular compartment of the brain by means of implanting a tubing of dialysis membrane. During the last decades, the necessity to measure the release of neurotransmitters in vivo in the central nervous system (CNS) has prompted the development of innovative techniques for sampling the extracellular fluid in the brain of experimental animals. Historically, one of the methods that evolved for this purpose was the push–pull perfusion which involved the stereotaxic insertion of a push–pull cannula into a selected area of the brain. Being an open flow system, push–pull perfusion allowed a direct contact of perfusion fluid with brain tissue, which often caused tissue damage, microbial and blood contamination, etc. To circumvent such drawbacks, a semipermeable membrane was attached to the cannula tip and this device was called dialysis bag or dialytrode. This was soon replaced by a more straightforward approach, the intracerebral dialysis, in which the dialysis bag was substituted by a hollow fiber, the dialysis membrane (Ungerstedt 1984).

Principles and Role in Psychopharmacology
The term dialysis refers to the passage of small molecules through a semipermeable membrane, a process driven by a concentration gradient. The endogenous substances diffuse out of the extracellular fluid into the perfusion

medium. On the other hand, exogenous compounds can be infused locally through the dialysis probe and reach the brain compartment through this concentration gradient. Unlike push–pull perfusion, dialysis is based on a closed flow system. Therefore, only a single perfusion pump is needed. The probe is constantly perfused with a physiological solution at a low flow rate (typically <2 µL/min) and perfusate samples are then collected for further analysis. Due to its relative ease of use, microdialysis has become the technique of choice for the in vivo analysis of neurotransmitters in the extracellular compartment of the brain of experimental animals. Its use has been fundamental in the identification of the mechanism of action of numerous psychoactive drugs. In particular, microdialysis has enabled to clarify neuronal elements (neurotransmitters, receptors) and brain networks affected by two of the most important drug classes in psychiatry: ► antidepressants and ► antipsychotics (Artigas and Adell 2007).

The low concentration of endogenous neurotransmitters in the extracellular brain space has been one of the main difficulties associated with the dialysis technique. The development of highly sensitive ► high-performance liquid chromatographic (HPLC) methods has made possible the increasing use of the microdialysis technique for the in vivo analysis of nanomolar concentrations of neurotransmitters and their metabolites (usually at higher concentrations) in brain. Capillary electrophoresis has also been successfully applied to the analysis of amino acids and amines. However, the need to sample for relatively long periods of time (typically >10 min) is one of the main drawbacks of microdialysis, compared with other in vivo techniques assessing brain function, such as electrophysiology and ► electrochemical techniques.

The dialysis membrane constitutes a real barrier between the perfusion fluid and the interstitial brain space, which usually excludes the transport of large molecules that may interfere with the substances of interest in the analytical procedure. Furthermore, enzymes that could cause a breakdown of the neuroactive compounds are also prevented from being picked up by the dialysate. The implant and functioning of microdialysis probes may cause tissue reactions ranging from an excessive washout of neurotransmitters and metabolites if flow rates are too high, to glial reaction surrounding the probe that may act as an actual barrier for the passage of components from the extracellular brain space to the inner part of the microdialysis probe. These aspects need to be examined in detail while establishing the experimental protocols. In particular, the effect of flow rate and duration of experiments need to be carefully assessed.

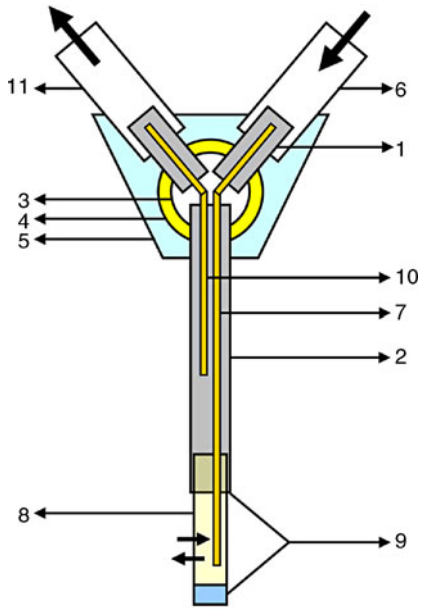
Methodology

Microdialysis probes are implanted stereotaxically in the brain of anesthetized animals. The coordinates for rat or mouse brain are usually taken from the corresponding atlas (Franklin and Paxinos 1997; Paxinos and Watson 2005). This allows a theoretical precision of 0.1 mm in the placement of microdialysis probes, although the actual precision is impaired due to individual variations in the size and shape of brain of experimental animals.

Once the dialysis probe has been positioned in the area of the brain to be studied, flushing with artificial cerebrospinal fluid (CSF) is recommended in order to check the integrity of the membrane. Then, the probe is secured to the skull with anchor screws and dental cement.

Construction of a Dialysis Probe

At present, the type of dialysis probe most commonly used has a concentric structure (Fig. 1). This kind of probe has been used in a wealth of experimental research



Microdialysis. Fig. 1. Schematic representation of a concentric microdialysis probe made up of the following components (see text for details): 27 gauge stainless steel tubing (1), 25 gauge stainless steel tubing (2), epoxy resin (3 and 9), dental cement (4), hot-melt adhesive (5), polyethylene tubings (6 and 11), fused silica capillary tubings (7 and 10), and dialysis membrane (8). Small arrows indicate the interchange process through dialysis membrane. Larger arrows indicate the direction of perfusion fluid.

because it is well suited for reaching deep structures and/or small nuclei of the brain. A detailed description of the materials and suppliers can be found in Adell and Artigas (1998). Briefly, the body of the probe is made up of 20-mm long 25 gauge stainless steel tubing. The inflow and outflow tubes threaded through the 25 gauge tubing consist of fused silica capillary tubing of 0.11 mm OD, 0.04 mm ID. The upper exposed end of fused silica tubings are inserted into a 7-mm piece of 27 gauge (0.41 mm OD, 0.20 mm ID) stainless steel tubing. The junction of the 27 and 25 gauge stainless steel tubings is sealed with epoxy glue and covered with dental cement to harden the assembly. Sampling of monoaminergic neurotransmitters usually requires a dialysis membrane consisting of a regenerated cellulose hollow fiber (0.17 mm OD, 0.15 mm ID), with a molecular weight cutoff of 6,000 Da, which is placed over the protruding lower portion of the inlet fused silica tubing and glued with epoxy resin to the inside surface of the 25 gauge stainless steel tubing. The tip of the hollow fiber is sealed also with epoxy glue. The length of the dialysis membrane exposed to the tissue varies according to the brain area to be examined. Finally, the 27 gauge protective steel tubes are friction-fitted with 20-mm lengths of polyethylene tubing of 0.61 mm OD, 0.28 mm ID to facilitate the connection of the probe to the perfusion pump and outflow line. These polyethylene and steel tubes are secured together with hot-melt glue.

Perfusion Fluids

One of the crucial aspects in microdialysis studies is that the composition of the perfusion medium must be physiological, i.e., isotonic with respect to that of the interstitial space. However, several fluids are being used currently that differ in their electrolytic composition/concentration (reviewed by Benveniste and Hüttemeier 1990). With little variation, the fluids used to perfuse dialysis probes are those derived from Krebs–Ringer solutions or artificial CSF. Typically, the concentration of Ca^{2+} ions in the perfusion fluid may vary from the physiological 1.2 mM–3.3 mM. Since Ca^{2+} ions are essential for the process of exocytosis, some authors have used higher concentrations to stimulate transmitter release. Although the buffering capacity of the extracellular fluid for some cations such as K^+ and Ca^{2+} is high, differences in the ionic composition of the perfusion and interstitial fluids may alter the responsiveness of neurons.

Other perfusing solutions also contain glucose to prevent its depletion from the interstitial space produced by the continuous drainage of dialysate. Glucose addition to the perfusion fluid also provides the essential nutrient for neurons to cope with the cell damage and disruption of the ▶ blood-brain barrier caused by probe implantation. However, the concentration of lactate, pyruvate, aspartate and glutamate in rat cortical dialysates is similar when the perfusion fluid contains 0 or 3 mM glucose, which suggests that the presence of glucose does not play a critical role in neuronal metabolism during microdialysis experiments. In addition, it should be kept in mind that the presence of glucose may favor bacterial growth in the perfusion fluid, thus altering the extraction of neurotransmitters.

One common problem inherent to most microdialysis studies is the very low concentration of neurotransmitters in the dialysate caused by efficient mechanisms of removal from interstitial space, such as reuptake or enzymatic degradation. To circumvent this complication, an uptake blocker or an inhibitor of enzymatic breakdown is included in the perfusion medium. In the absence of such agents, the extracellular concentration of a transmitter (but not of its metabolites) reflects the balance between the processes of release and inactivation. However, in the presence of such agents, the release component is amplified and this has to be taken into consideration while interpreting dialysis results. For example, the use of an uptake blocker may allow to detect changes in the extracellular level of transmitters that otherwise may be overlooked. The most common compounds added to the perfusion fluid are uptake inhibitors such as ▶ citalopram for serotonin, ▶ nomifensine for dopamine, desipramine for norepinephrine, and ▶ physostygmine or neostygmine to block the enzymatic degradation of acetylcholine.

However, the use of such agents can complicate the interpretation of results, as the higher neurotransmitter concentration they induce may result in the activation of terminal autoreceptors in nerve endings, which usually results in a negative feedback affecting neurotransmitter synthesis and release. On the other hand, the addition of ▶ acetylcholinesterase inhibitors, which increase the concentration of acetylcholine in dialysates, has been shown to influence markedly the interaction between cholinergic and dopaminergic brain systems. Therefore, these modified perfusion fluids must be used with caution, as they may alter the function of drugs whose mechanism of action is examined.

The choice of an appropriate flow rate for the perfusion (usually ranging between 0.1 and 2 μL/min) is an important practical point for several reasons. The relative recovery of neurochemical compounds through dialysis membranes declines as the flow rate increases. High flow rates generate a concentration gradient and compounds can be carried away from the extracellular space with the subsequent enrichment of dialysate samples so that the absolute recovery per time unit is greater. However, such

a washing effect may reduce the tone on terminal autoreceptors and, therefore, alter the dynamics of the release process.

For all of the above reasons, low flow rates are preferred in order to approach ideal dialysis conditions and maximize the recovery of transmitter substances from the interstitial space. Flow rates of 0.25–3 μL/min provide a sample volume of 5–60 μL per 20-min fraction, which can be collected in plastic microvials and is easy to handle for further analysis by HPLC procedures.

Quantitative Aspects

Different attempts have been made to calculate the extracellular concentration of neurotransmitters stemming from the level obtained in dialysate samples. The simplest method is to calibrate the probes for in vitro recovery. To this aim, the probes are immersed in a beaker filled with a known concentration of the substances of interest dissolved in the perfusion fluid. The ratio between the concentration of the substance in the probe effluent and in the medium provides the recovery value of such a substance. The term "absolute recovery" refers to the total amount of a compound that passes into the perfusion fluid per unit of time, whereas "relative recovery" describes the concentration of a compound in the dialysate relative to that in the perfusion medium expressed as a percentage value. The flow rate of the perfusion fluid is inversely related to the relative recovery and the magnitude of absolute recovery is limited by perfusion flow rate. It is important to note herein that the absolute recovery is proportional to the concentration of the substance outside the dialysate, whereas the relative recovery is not. In addition, the calibration in vitro of the probes depends on the temperature and physicochemical stability of the compounds to be analyzed. The validity of these calibration procedures is based on the assumption that the conditions in vitro and in vivo are similar. However, the brain interstitial space is a more complex matrix and the tortuosity of the diffusion created by cell membranes and the drainage of endogenous compounds induced by the continuous perfusion are factors that must be taken into consideration.

Several refined mathematical models have been described to determine the actual concentration of transmitters in the extracellular compartment of the brain, yet they are usually too complex to be used routinely in neuropsychopharmacology research. A more practical approach was reported in which the dialysate concentration of a neurotransmitter is measured at different flow rates and extrapolated to a flow rate of zero (Justice 1993). With no net flow, the dialysate is in equilibrium with the extracellular fluid. Therefore, the level found at zero flow should represent the actual in vivo concentration of the transmitter.

Finally, it should be considered that, for many applications, the knowledge of the in vivo concentration of a transmitter is not necessary. Instead, the change with respect to baseline level is what actually matters and is to be related to the mechanism of action of drugs.

Statistical Analysis of Data

The working hypothesis usually tested in microdialysis experiments tests whether a physiological or pharmacological manipulation affects the concentration of a transmitter in dialysate samples. Typically, the experimental approach consists in the collection of several pretreatment samples until stable baseline values are attained. Then, drugs are administered or animals are subjected to certain procedures (e.g., stress, forced motor activity, behavioral manipulation, etc.) and a number of posttreatment samples are collected. These temporal data series are often analyzed by means of analysis of variance (ANOVA) for repeated measures followed by appropriate *post hoc* tests to compare pre- and posttreatment periods. In more complex experiments (e.g., when assessing the effects of different drug doses or in various areas of the brain), the use of two-way ANOVA for repeated measures is better suited, with dose (or region) as the independent factor and time (or treatment) as the dependent variable. AUCs of the posttreatment periods can be also calculated as an integrated estimate of drug action and compared by means of one- or two-way ANOVA.

Neural Origin of Transmitters in Dialysate

In order to determine the neural origin of neurotransmitter efflux measured in dialysis experiments, several specific criteria must be fullfilled. First, basal transmitter release from nerve terminals has to be impulse-dependent. This is usually assessed by the addition of the sodium channel blocker tetrodotoxin, which impairs the release of the transmitter. A second requirement for the neuronal origin of a putative transmitter is its disappearance or decrease from dialysate, when Ca^{2+} is omitted from the perfusion medium. The basis for such an action is that the impulse-dependent release of a transmitter by exocytosis is dependent on the availability of extracellular Ca^{2+} (Augustine et al. 1987). Finally, the ability of elevated concentrations of K^{+} to depolarize neural structures and stimulate the output of transmitters has been taken as an additional criterion for their neural provenance.

Working Practices

As detailed in the preceding sections, microdialysis is only a sampling procedure. The combination with appropriate

analytical techniques has made it possible to monitor changes in the concentration of small molecules in the interstitial space of the CNS. In addition, researchers have devised a number of different experimental approaches to exploit the capabilities of this technique.

Local Administration of Chemicals and Drugs

Due to the ability of the microdialysis membrane to allow the passage of small molecules in both directions, microdialysis probes have been used to deliver chemicals in restricted areas of the brain by reverse dialysis. Ions or pharmaceutical agents known to affect neural function can be dissolved in the perfusion fluid and delivered to the brain structures of interest, provided that the molecular weight cut-off of the membrane is appropriate. Changes in the concentration of transmitters can thus be monitored locally or distally, by means of a second dialysis probe implanted in an area anatomically or functionally related to the brain structure in which the first probe is located (see Section 7.3).

When appropriate amounts of chemical agents or drugs have to be dissolved in the perfusion fluid, it is important to check that they do not alter pH or osmolarity of the fluid. Usually, once stable baseline values are obtained, the standard dialysis fluid is replaced by one containing the compound(s) of interest. This procedure may be particularly useful when examining the effects of substances with a poor penetration into the brain or when assessing regional differences in the effects of drugs.

Quantitative effects of drugs in vivo can be estimated through ► ED_{50} values calculated after local application of drugs. The ED_{50} values obtained in this manner are by no means comparable to those obtained using cell cultures, membranes, synaptosomes, or other in vitro preparations. Several factors account for these differences, including (1) the recovery of the dialysis membrane, usually much lower than 100%; (2) the diffusion of chemicals within the brain once they have crossed the dialysis membrane and the tortuosity of the neural tissue; (3) the continuous drainage of applied drugs by the CSF; and (4) the unspecific binding to cell membranes, particularly of lipophilic molecules. All these factors contribute to reduce the actual concentration of drugs reaching the active sites in the brain, dramatically. In contrast, in vitro drug affinities for receptors/transporters are calculated under almost ideal conditions, i.e., with enriched preparations and unlimited access of the chemicals to their cellular targets, generally at equilibrium and under nondegrading conditions.

Systemic Administration of Drugs

Experiments involving the systemic administration of drugs constitute the vast majority of the applications of microdialysis. In such experiments, however, appropriate controls must be carried out, because the procedure of drug delivery or the vehicle used may change transmitter function due to the associated stress or the sensitivity of some neuronal groups to sensory stimuli. The changes in the concentration of transmitters in an area of the brain after systemic administration of drugs do not necessarily parallel those found after their local application. In general, when drugs are applied locally, larger concentrations are needed to reach effects similar to those obtained after systemic application. This possibly reflects a better distribution of drugs administered systemically through the diffuse network of brain capillaries. Another factor frequently ignored is the fact that the diffusion of a chemical agent delivered by reverse dialysis is limited to a small portion of the brain tissue surrounding the dialysis probe. In contrast, the changes in the extracellular concentration of the transmitter in the same area after systemic administration of a drug results from an integrated response of the whole CNS, i.e., local and transynaptic effects.

Dual Probe Models

Experiments carried out with two or more probes implanted in the same animal present two distinct advantages. First, such an approach allows to reduce the number of animals used in a single experiment and, second, it is ideal to examine functional interactions between different brain areas. This latter asset was first employed for dopamine and serotonin systems to study how the release in terminal areas is regulated by the activity at the level of cell bodies. This was possible because the cell bodies of those neuronal systems are tightly packed in the midbrain substantia nigra, ventral tegmental area, and raphe nuclei. Therefore, the local application of drugs known to interact with receptors or transporters located on these monoaminergic cell bodies induces changes of the release of the transmitter in projection areas. Dual probe microdialysis studies have been extremely helpful for the study of the functional connections between different brain areas and the transmitter/receptors involved (Adell and Artigas 1991; Santiago et al. 1991).

Coupling to Electrical Stimulation

Similar to the experiments described in the previous section, electrical stimulation coupled with microdialysis in distal areas has been used to assess the existence of functional connections between brain areas. This is usually achieved by inserting an electrode in an area containing the cell bodies of a certain transmitter system and a dialysis probe in the corresponding projection areas. For instance, the electrical stimulation of the substantia nigra

or the raphe nuclei results in an enhanced release of dopamine and serotonin, respectively, in projection areas. Similar experimental procedures combining electrical stimulation and microdialysis have been used to study the modulatory role of ► prefrontal cortex on dopaminergic and cholinergic activity in subcortical structures such as the dorsal striatum or the ► nucleus accumbens.

Advantages and Limitations of Microdialysis

Since its first applications, microdialysis has become increasingly popular to study brain function. The use of alternative in vivo procedures such as push–pull perfusion or voltammetry has remained constant or even declined during last years. A comparison between microdialysis and voltammetry reveals that microdialysis is applicable to most types of small molecules whereas the use of voltammetry is limited to easily oxidizable compounds such as catecholamines and serotonin. Moreover, microdialysis appears to be simple to use on a routine basis and can easily be applied to study freely moving animals.

Table 1 summarizes some of the advantages and limitations of microdialysis. Certainly, microdialysis is by no means a definitive method for the assessment of the active transmitter concentrations in the brain. Yet, it has a number of advantages over its predecessor, the push–pull perfusion, which have led to a more widespread use. The main limitations of microdialysis are the size of the probes and the tissue damage caused by their insertion. For certain applications, size may not be a problem (e.g., to assess the effects of drugs in large brain regions). However, the study of physiologically- or pharmacologically-induced changes of transmitters in small nuclei may pose some constraint because a larger proportion of neurones is damaged.

Finally, the low amount of certain neurotransmitters in brain dialysates makes it necessary to collect samples every 20 or 30 min, a time scale which is far from that of neuronal events. This may not be a problem in pharmacological studies because most drugs reach peak levels at a time compatible with the usual periods of sampling of 20 or 30 min. This enables to follow up drug-induced transmitter changes. However, microdialysis may not be suitable for the study of the effects of neuronal stimulation on transmitter release at a physiological time scale. Recent advances in the detection of very low concentration of certain transmitters with capillary electrophoresis have permitted a considerable shortening of the sampling periods. Yet, this is still far from the scale at which neuronal excitation or inhibition is associated to the release of a transmitter. It is hoped that future methodological and technical developments will overcome some of these limitations.

Microdialysis. Table 1. Advantages and limitations of the microdialysis technique.

Advantages	Easy to use routinely Easy manufacture of probes No enzymatic degradation of transmitters in samples Coupling to chemical methods of analysis (HPLC, mass spectrometry, capillary electrophoresis, etc.) Possibility of local administration of drugs Possibility of concurrent determination of drugs after systemic administration Dual probe approaches Possibility of concurrent recording of electrical activity Concurrent study of behavior in freely-moving animals
Limitations	Invasive procedure: causes neuronal death and reactive gliosis Limited spatial resolution Limited temporal resolution Analytical difficulties with some transmitters Low membrane recoveries with high molecular weight compounds

Microelectrode Arrays

Synonyms
MEA

Definition
Ceramic-based multisite microelectrode arrays (MEAs; 15 μm × 330 μm or 20 μm × 150 μm recording sites) with platinum recording sites and polyimide insulation that have been recently described (Hascup et al., 2007). The triangular design of the microelectrodes yields a microelectrode array ranging in thickness from 37 to 125 μm and an overall length of 8–10 mm. These arrays are wire bonded to printed circuit board holders that adapt MEA's for measures in brain slices and studies in anesthetized and awake mice, rats, and nonhuman primates. More than 20 varieties of geometries ranging from 4 to 16 Pt recording sites have been designed.

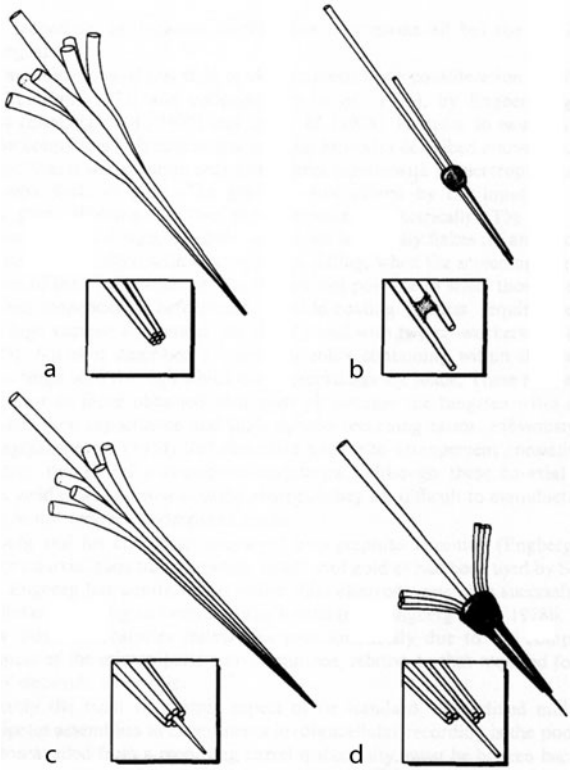
Synonyms
Iontophoresis

Definition
The term microiontophoresis is derived from the ancient Greek term *phoretikos*, which refers to the production or induction of movement. Microiontophoresis is a technique with which drugs and other ionized particles can be ejected in very small amounts from solutions contained in glass micropipettes. This ejection is accomplished by applying a voltage across the micropipette and causing the electrode to become polarized. Ionized particles in solution migrate in the applied field and will be ejected from the tip as they carry the current into the tissue. This technique is widely used to determine the effects of various substances on firing parameters of both central and peripheral neurons and muscles. In investigating the phenomenon of synaptic transmission at the neuromuscular junction, during the 1950s, this technique became very popular. A technique appropriate for the study of synaptic pharmacology was first realized by Nastuk (1953) and was later developed by del Castillo and Katz (1955), and it consisted essentially of the microiontophoretic method, i.e., movement of charged particles produced by an electric current, restricted to a micropipette with a tip diameter of the order of 1 μm. Thus, solutions of ► acetylcholine chloride were used, and by passing a suitable current to this solution, acetylcholine ions could be ejected from the 1 μm orifice onto a correspondingly localized area of subsynaptic membrane at the neuromuscular junction. Later, Curtis and his colleagues adopted this technique for studying the mammalian central nervous system (CNS) (Curtis and Eccles 1958b). The experiments of Curtis and coworkers, however, involved an important modification of the original method, in that this group used ► multibarrel micropipettes. In the production of these, several lengths of tubing are fused together and then pulled so as to produce a single collective tip, but with each barrel having its own orifice. Multibarrel micropipettes are usually composed of five to seven barrels (Fig. 1). Usually, the central barrel is the recording electrode, whereas the other side barrels contain drug solutions (Fig. 1). As the drug molecules would tend to diffuse from solution in the pipette tip into the extracellular environment, it is necessary to apply a small current to reduce that efflux. This is known as a "holding" or "retaining" current (Fig. 2). It is also a usual practice to include a barrel containing sodium chloride solution, which can be used to control the effects of the current itself. This may be done either by periodically passing through the control barrel the same current used for drug ejection or by passing continuously a current adequate to cancel out the instantaneous sum of ► ejecting and ► retaining currents passing through the drug-containing barrels. This is known as "current balancing." The use of microiontophoresis is suitable for any ionized molecule, but nonionized compounds can be ejected by the closely related variant "electro-osmosis," which is attributable to the presence of an electrical "double



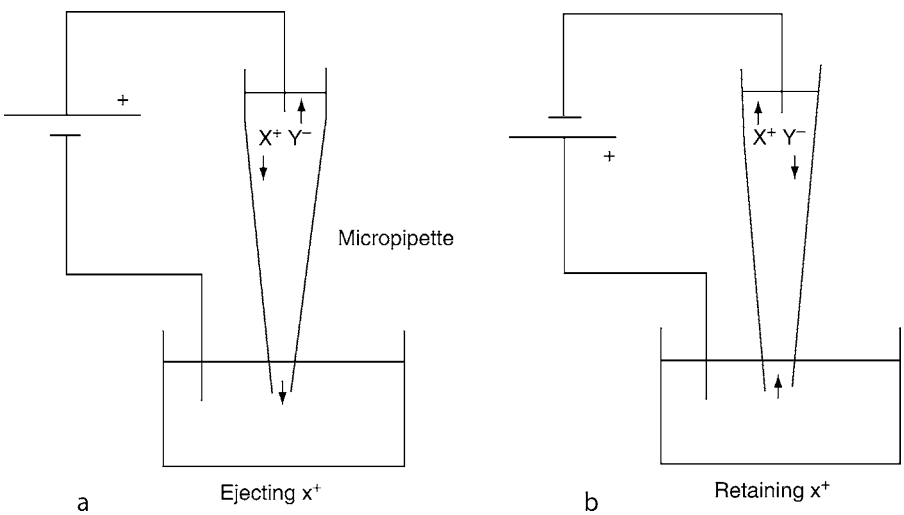
Microiontophoresis and Related Methods. Fig. 1. Examples of different types of multibarrel micropipette assemblies used in microiontophoretic experiments. (**a**) Standard 7-barrel assembly in most common use, introduced first by Curtis. (**b**) Twin, or parallel micropipette. (**c**) Co-axial assembly. (**d**) Staggered tip multibarrel. (From Hicks, 1984.)

layer" within the barrel tip. When an aqueous solution is in contact with glass, negative ions are tightly adsorbed on the glass surface, leaving the bulk of solution carrying a net positive charge. The passage of positive (or outward) current then causes the ejection of a small volume of solution containing the compound of interest (Fig. 2). It should be noted, however, that this mechanism has nothing to do with the osmotic pressure of a solution or the establishment of any osmotic gradient. The term electroosmosis derives simply from the fact that the driving force is the movement of the *solvent,* not the solute, just as the case of osmotic movements across a semipermeable membrane. An alternative method of applying both ionized and nonionized compounds from micropipettes is the use of pressure. A suitable source of pressure, usually a cylinder of compressed gas, is connected to the open end of a micropipette barrel. Pressure usually up to 20 pounds per square inch (p.s.i.) will eject fluid from a 1 µm pipette tip. One advantage of micropressure ejection is that it can be applicable to all compounds; however, it is not devoid of problems and artifacts and is unlikely to replace microiontophoresis as a microapplication method.

Principles and Role in Psychopharmacology

General Principles

Each barrel of a micropipette assembly to be used for drug ejection is filled with a solution of the ionized compound and the solution is connected to the iontophoresis machine by a suitable lead, which is in contact with the drug solutions. The establishment of a potential difference



Microiontophoresis and Related Methods. Fig. 2. Schematic diagram of a micropipette that contains a salt X^+Y^-, showing the direction of current necessary to eject (**a**) and retain (**b**) the ion X^+. (From Hicks, 1984.)

between the drug solution and the medium surrounding the barrel tip will then cause the movement of ions through the solution and out of the pipette tip (Fig. 2). A chief advantage of the microiontophoretic method is that it is possible to examine the effects of drugs on single neurons in vivo without affecting the whole nervous system or other physiological responses, such as those that may occur when drugs are administered systemically (Aghajanian 1972). If a voltage is applied to a solution, ions and charged molecules will migrate toward and away from the source of the imposed electrical field depending on the sign of their net charge. This phenomenon is the fundamental principle of microiontophoresis: the desired charged particles are ejected from the mouth of one barrel of a multipipette assembly by appropriately charging the interior of that barrel (Fig. 2). An outward current will cause the "ejection" of positively charged ions, and an inward current flow, the ejection of negatively charged particles. If the pipette assembly is positioned close to a neuron, so that the recordings of its activity can be made through another electrolyte-filled barrel, drugs may be ejected and their pharmacological effects are inferred by the resulting changes in the rate and/or ► firing pattern.

The Transport Number and the T_{50} Value

An important technical consideration for experiments employing microiontophoresis is the transport number. The transport number is a measure of the amount of drug released from the micropipette by iontophoretic expulsion and it is important, because it helps one to evaluate dose–response relations between different compounds, and it can also provide some indication of the absolute potency of compounds. The transport number varies for individual compounds and is based on the interaction of the following variables: their solubility, the extent of their dissociation in solution, their polarity, and the nature of the external medium into which the drugs are administered. The transport number may be formally described by the following equation:

$n = R_i ZFi^{-1}$, where

n = apparent transport number of the drug ion,

Z = valency,

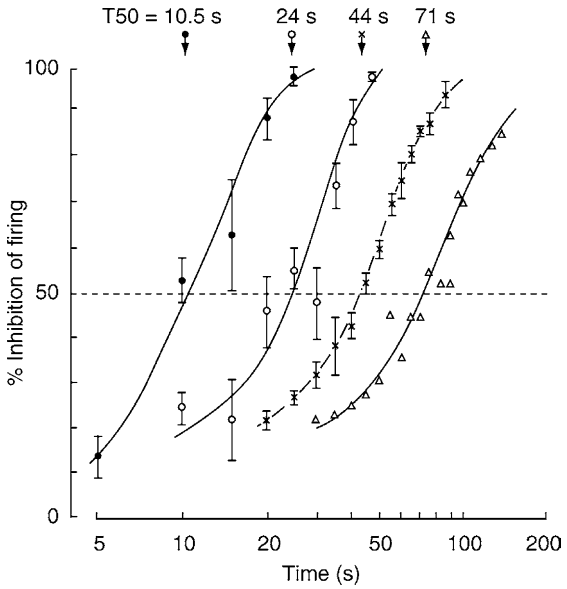
F = Faraday's constant, in Coulombs

i = intensity of ► ejecting current, in nanoamperes, and

R_i = rate of microiontophoretic release (which is equivalent to total release minus the sum of the rate of steady-state spontaneous release and where applicable, the release due to electro-osmosis).

During microiontophoresis, the total number of ions transported is related in a direct manner to the amount of current applied to the solution, according to Faraday's law. However, only a certain proportion of the charge imposed is carried by the ion species of interest. This value, which is "n," the transport number, is not constant for a given material but will vary not only from pipette to pipette, but also, to a lesser extent, between different barrels of the same micropipette assembly containing identical solutions. Despite these inconsistencies, it remains valid that under steady-state conditions, drug release from micropipettes conforms to Faraday's law: the amount of drug released is proportional to the magnitude of current passed (Hicks 1984).

Another important parameter to consider when interpreting microiontophoretic data is the T_{50} value, which is the time taken for a response to reach 50% of its maximum (Fig. 3). The basis for this procedure is the hypothesis that each individual response to an agonist may be considered as a cumulative dose–response relationship



Microiontophoresis and Related Methods. Fig. 3. Time courses of inhibition of neuronal firing following microiontophoretic application of GABA with four different currents, 20 nA (filled circle), 10 nA (o), 5 nA (×), and 2 nA (open triangle). Each curve was obtained from the same neuron at a depth of 957 μm in the middle suprasylvian gyrus of the cat cortex. The neuron was driven by continuous microiontophoretic application of L-glutamate (20 nA). Each of the points for 20, 10, and 5 nA applications of GABA is the mean ± SEM of three values obtained from three separate applications of the same current of GABA. The values of T_{50} shown are the times taken to achieve 50% inhibition of neuronal firing. (From Hill and Simmonds (1973) Br J Pharmacol 48:1–11.)

reflecting the gradual increase in tissue concentration of drug during the ejection period. If a series of such responses are obtained, reaching the same maximum amplitude, they can be readily characterized by the T_{50} value (Fig. 3). Moreover, T_{50} value is easier to measure accurately than a response size. Thus, it can be very difficult to obtain reproducible graded response amplitudes to some very potent compounds such as amino acids. Any changes in ▶ firing rate during a response, which ideally should be of the plateau variety, may further complicate any assessment of the response size, whereas in the determination of T_{50} values, all responses increase to the same maximal level, which may be 100% inhibition or a clear maximal plateau of excitation tending toward overdepolarization.

Microiontophoresis in the Central Nervous System

It is now more than 50 years since Curtis and Eccles (1958a, b) first employed the technique of microiontophoresis in the CNS. Microiontophoresis has provided so far a great contribution in the identification of the central effects of neurotransmitters, including glutamate, aspartate, γ-aminobutyric acid (GABA), noradrenaline, serotonin, dopamine, and a variety of neuropeptides (enkephalins, cholecystokinin, neurotensin, tachykinins). Microiontophoresis also allows the histological confirmation of the sites of electrophysiological recordings, and the neuroanatomical determination of pathways by applying dyes, markers, and materials, which are carried by axonal transport for tracing fiber tracts. Alterations in neuronal sensitivity due to the influence of anesthetic compounds have been monitored when pharmacological agonists have been tested using microiontophoresis.

Applications

The largest number of studies has been concerned with the central nervous system. These studies have yielded information on: (1) the qualitative sensitivity of neurons to putative neurotransmitters and drugs; (2) quantitative estimates of variations and sensitivity in different CNS regions or of different cell types and the following lesions or the administration of drugs; (3) the pharmacology of transmitter receptors; (4) the effects of modifier of putative transmitter effects (antagonistic or enhancing substances) on synaptic transmission; and (5) the mechanisms and ionic conductances underlying transmitters effects.

Excitatory Amino Acids

Some of the earliest iontophoretic studies demonstrated marked excitatory activity of several simple dicarboxylic acids, including L-glutamic and L-aspartic acids (Curtis and Watkins 1960). Responses to some of these amino acids, especially ▶ glutamate and aspartate, terminate rapidly when an ejecting iontophoretic current is switched off. It is unclear to what extent this is due to the kinetics of iontophoresis or reflects the presence of rapid and efficient uptake processes. Some authors have reported long-lasting changes of cortical neuronal firing following iontophoresis of glutamate sufficient to at least double the resting firing rate. The development of a series of potent amino acids analogs with very high agonist potency led to the discovery of NMDA and non-NMDA glutamate receptors. This discovery was strengthened by additional findings that phosphonate analogs of amino acids, such as 2-amino-5-phosphonovaleric acid (AP-5) blocked the effects of NMDA, but not of quisqualic and kainic acids.

Inhibitory Amino Acids

Both glycine and ▶ GABA act as potent inhibitors of neuronal activity in the CNS, usually causing ▶ hyperpolarization associated with increased membrane conductance to chloride. Glycine is selectively antagonized by strychnine, whereas the effects of GABA are blocked by picrotoxin and bicuculline. Microiontophoretic experiments showing potentiation of the inhibitory effects of GABA by ▶ benzodiazepines were among the earlier experimental evidence for the modulatory action of these drugs on ▶ $GABA_A$ receptors (Gallagher 1978).

Acetylcholine

Almost every region of the brain has been examined for its sensitivity to iontophoretically applied cholinergic agents. Most of the earlier work in vivo was concerned primarily with establishing the direction of responses to cholinomimetics and whether the effects involved muscarinic or nicotinic receptors. Many studies examined only cells encountered randomly in a particular brain region, but others have often succeeded in relating the direction of responses to cholinomimetics with some specific function. In the cerebral cortex deep pyramidal tract, cells are excited by ▶ acetylcholine. Several authors have also described an inhibitory action of acetylcholine, largely muscarinic in nature, in more superficial levels of the cortex and an excitatory action, which appears to have a predominant nicotinic pharmacology, in the same superficial layers. Some authors have shown that acetylcholine enhances the stimulus-evoked responses of visually driven cortical units, without affecting the overall excitability of the cell. Thus, orientation and direction specificity of neurons is preserved and increased relative to the non-preferred responses. This phenomenon is reminiscent of the effects of some amines, which can also increase the

signal-to-noise ratio by potentiating evoked activity and suppressing background.

Noradrenaline

Early microiontophoretic studies have shown that ► noradrenaline would cause a depression of neuronal firing in the cat cerebral cortex, and a large number of experiments have revealed similar responses in most areas of the CNS. This inhibition often seems to involve a voltage-dependent hyperpolarization accompanied by an increased membrane resistance, although a decreased membrane resistance was found on neurons of the locus coeruleus in slice preparation in vitro. The biochemical basis of this hyperpolarization has been the subject of much argument. Although it was originally suggested that they may be mediated by an increase in the intracellular concentration of cyclic AMP, some group failed to reproduce these findings. Overt excitatory effects of noradrenaline have also been observed in many areas of the CNS. Neuronal responses to iontophoretic application of noradrenaline, apparently excitatory as well as inhibitory, can be enhanced by antidepressants. However, this potentiation can occur even after the loss of most amine-containing terminals, and it may be restricted to certain layers of the cortex. The pharmacology of responses to iontophoretically applied noradrenaline has been extensively studied. Some authors have postulated that, in the neocortex, excitatory responses to noradrenaline are mediated by α_1-adrenergic receptors, whereas inhibitory responses occur through β-adrenergic receptors. Activation of α_2-adrenergic receptors does also elicit inhibitory responses.

Dopamine

► Dopamine was first tested iontophoretically in the cerebral cortex, where profound suppression of spontaneous cell firing was observed. This action has been confirmed by several authors, although excitatory effects have also been reported. Much attention has been centered on the effects of dopamine in the neostriatum where its action is usually inhibitory in the caudate nucleus. Bunney and Aghajanian (1976) have performed a laminar analysis of amine responses in the rat cerebral cortex. They found that neurons in layers II and III, which receive a dense noradrenergic projection, were more sensitive to noradrenaline than dopamine, whereas the reverse pattern was noted in layers V and VI, which receive a greater dopamine-containing projection. These authors also reported that desipramine, a selective inhibitor of noradrenaline reuptake, would enhance noradrenaline responses in layers II and III, but not in deeper layers, while benztropine enhanced dopamine responses only in layers V and VI. Dopamine receptors are present not only on innervated cells but also on the dopaminergic neurons themselves: the so-called ► autoreceptors. Activation of such receptors by dopamine or apomorphine causes marked inhibition of cell firing, and these effects are blocked by neuroleptic drugs. Microiontophoretic studies of dopamine response pharmacology have mostly proved consistent with behavioral and neurochemical work. Phenothiazines, for example, block dopamine but not noradrenaline responses in the cerebral cortex and the striatum. Iontophoretically applied ► α-flupenthixol can also block the effects of dopamine, although intravenously administered α-flupenthixol or ► pimozide did not modify neuronal responses to iontophoretic dopamine.

Serotonin

There is an extensive scientific literature regarding the effects of microiontophoretically applied ► serotonin on different areas of the central nervous system. Indeed, the microiontophoretic technique contributed substantially to the elucidation of the physiology and pharmacology of the central serotonergic system. Thus, an important factor controlling the activity of central serotonergic neurons is neuronal feedback inhibition. This is thought to be a homeostatic response, which, under physiological conditions, acts to compensate for increases in synaptic availability of serotonin. Thus, as the concentration of serotonin increases in the brain, the activity of central serotonergic neurons correspondingly decreases. The mechanism underlying this feedback regulation is both local or intrinsic to the raphe region (where serotonergic cell bodies are located) and through a feedback loop from postsynaptic target neurons. Serotonin released in the raphe region from dendrites and possibly from axon terminals appears to inhibit serotonergic neurons by activating somatodendritic autoreceptors, which produces hyperpolarization of the cell membrane *via* an increase in potassium conductance. Historically, the first drug reported to exert a preferential action on the 5-HT autoreceptor was LSD (lysergic acid diethylamide) applied microiontophoretically on the dorsal raphe nucleus of rats. Subsequently, several other hallucinogenic indoleamines, notably 5-MeODMT (5-methoxy-*N*,*N*-dimethyltryptamine), were found to share this property with LSD. Since that time, several highly selective 5-HT_{1A} agonist compounds such as 8-OH-DPAT have been synthesized and shown to suppress the firing of serotonergic neurons with potencies comparable with, or even greater than, that of LSD. On the basis of electrophysiological data, the serotonin autoreceptor has been characterized as the 5-HT_{1A} subtype. Microiontophoretic technique also contributed to

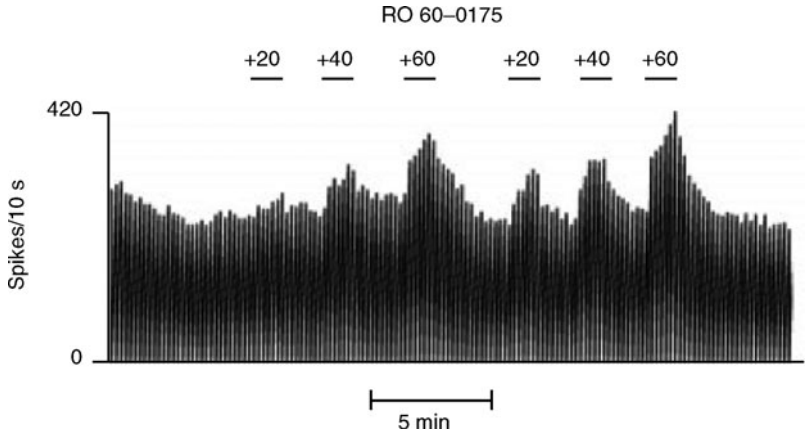
characterize the action of serotonin agonists and antagonists and to elucidate the physiological role of serotonin receptor subtypes such as 5-HT_{1B}, 5-HT_{2A}, and 5-HT_{2C}. As regards the 5-HT_{2C}, it was found that this receptor subtype exerts a tonic inhibitory influence on the activity of dopamine-containing neurons in the substantia nigra pars compacta and the ► ventral tegmental area. Apparently, this inhibitory effect is mediated through the activation of nondopaminergic (presumably GABA-ergic) neurons in the substantia nigra pars reticulata. Thus, it was recently shown that microiontophoretic application of 5-HT_{2C} receptor agonists stimulates the basal activity of nondopaminergic (presumably GABA-ergic) neurons in the substantia nigra pars reticulata (Invernizzi et al. 2007) (Fig. 4). By using microiontophoresis, it was also found that serotonin exerts a tonic inhibitory influence on the activity of noradrenergic neurons in the locus coeruleus.

Opiates and Opioids

Microiontophoresis has proved exceedingly valuable for opiate system studies, since it allows the testing of discrete units activated by noxious or nonnoxious stimuli in the same preparation. In most such studies, the applied opiates have depressed noxious stimulus-evoked activity, although usually in parallel with the effects on spontaneous or chemically induced firing. Microiontophoresis has also been proved as a popular means for comparing qualitatively opiate responses in normal and opiate-tolerant animals. Thus, inhibitory responses to ► morphine were encountered less frequently in the neocortex of morphine-tolerant rats than in controls. It was shown that iontophoretically applied ► naloxone would elicit a large increase of firing in the locus coeruleus noradrenergic neurons in morphine-tolerant rats, presumably as a correlate of the withdrawal phenomenon in such animals. Also, opioid peptides have been tested iontophoretically in many regions of the central nervous system. Opioid peptides were found to excite hippocampal neurons; however, these effects were apparently mediated through an indirect action on transmitter release or to a naloxone-sensitive depression of local inhibitory interneurons.

Peptides

Microiontophoretic or pressure ejection has been used to apply a wide range of endogenous and synthetic peptides to neurons in vivo and in vitro. However, partly because of the lack of selective antagonists, there has been little progress in relating the observed responses to a physiological role, and as a result, attention has been concentrated on the mechanism of the observed responses, and potential interactions with neurotransmitters. ► Substance P, for example, appears to interact selectively with acetylcholine. Microiontophoretic substance P has also been found to enhance the response of spinal cord neurons to noxious stimulation but not innocuous ones, in some cases leading to the occurrence of responses in initially unresponsive units. Some excitatory effects of substance P can be mimicked by capsaicin, also applied iontophoretically. It was also reported that the excitatory effect of substance P on noradrenalin-containing neurons in the locus coeruleus is blocked by the selective antagonist [D-Pro^2, D-$Trp^{7,9}$] substance P. Thyrotropin releasing hormone (TRH) has been found to enhance the excitatory effects of acetylcholine on cortical neurons,



Microiontophoresis and Related Methods. Fig. 4. Representative rate histogram showing the effect of the selective 5-HT_{2C} receptor agonist RO 60-0175 on the basal activity of a nondopaminergic (presumably GABA-ergic neuron) of the rat substantia nigra pars reticulata. Microiontophoretic application of RO 60175 causes excitation of basal neuronal activity, which is proportional to the amount of the ejecting current applied (numbers above each bar in nA). (From Invernizzi et al. 2007.)

with no effects on resting firing rate. ▶ Somatostatin exerts a potent excitatory effect on hippocampal neurons. ▶ Cholecystokinin (CCK) and ▶ neurotensin are also frequently excitatory while angiotensin has excitant properties, which appear to be restricted to the subfornical organ and related structures. However, it is important to point out that peptides present special problems for microiontophoresis. Larger molecules tend to be adsorbed on to charged surfaces, which include the internal wall of a micropipette tip. Some peptides may also undergo denaturation or degradation during iontophoretic experiments. This problem may be exacerbated if very high currents are applied for long periods of time through high resistance tips, in that any change of local temperature may have a major impact on the stability of a peptide.

Advantages and Disadvantages of Microiontophoresis

The original microiontophoretic technique was developed for answering questions concerned with synaptic transmission and the neuromuscular junction. Using this preparation, it is a simple matter to microscopically examine the muscle fiber being studied, to determine the distance of the micropipette from the tissue, and to have ready access to known synaptic inputs. These advantages are not valid for the CNS. Nevertheless, with some further precautions and considerations, the technique has been used successfully in the CNS for about 50 years. It is important to consider other potentially confounding technical factors limiting the utility of microiontophoresis, as it is used in central investigations. Of primary concern is the site of drug administration relative to cell soma, where the strongest depolarizing or hyperpolarizing influences are manifested, and the dendritic field, where synaptic influences are normally expressed and where antagonists of transmitters must accumulate to modify trans-synaptic excitations. Another consideration for central investigations also concerns the spatial distribution of drugs in the CNS. Since the CNS is densely packed with cells, microiontophoretically administered compounds cannot affect single neurons in isolation. This must be kept in mind when interpreting the data.

Conclusions

Microiontophoresis, an experimental technique introduced more than 50 years ago, prompted a great impetus to the study of the physiology and pharmacology of the central nervous system. By mimicking the synaptic function, it provided a crucial step in establishing the physiological role of most neurotransmitters, including amines, amino acids, and neuropeptides. Although it is now considered by some as a "classical" neurophysiologic approach to the study of central nervous system, it is likely that it will still contribute substantially to the progress of neuroscience.

MEOS

Definition

Secondary pathway of alcohol metabolism in the liver, which plays a pronounced role during heavy and sustained drinking.

Midazolam

Definition

Midazolam is an ultra short-acting benzodiazepine derivative with potent anxiolytic, amnestic, hypnotic, anticonvulsant, skeletal muscle relaxant, and sedative properties. It is considered an ultra short-acting benzodiazepine, with an ► elimination half-life of about 2 h. It is used in some countries for the short-term treatment of insomnia and in many countries as a premedication before surgery. Intravenous midazolam is indicated for procedural sedation (often in combination with an ► opioid, such as ► fentanyl), for pre-op sedation, for the induction of general anesthesia, and for sedation of ventilated patients in critical care units.

Mild Cognitive Impairment

Josef Marksteiner, Irene Adelt
Department of Psychiatry and Psychotherapy, LKH Klagenfurt, Klagenfurt, Austria

Definition

Mild cognitive impairment (MCI) is a relatively recent term. It is used to describe individuals who have ► cognitive impairments beyond that expected for their age and education, but that do not interfere significantly with their daily activities (Petersen et al. 1999). The criteria for MCI are shown in the next section. It is considered to be a transitional stage between normal aging and various types of ► dementia. Although MCI can present with a variety of symptoms, when memory loss is the predominant symptom it is termed "amnestic MCI" and is frequently seen as a risk factor for Alzheimer's disease (AD) (Morris et al. 2001). Individuals who have impairments in cognitive domains other than memory are classified as nonamnestic single- or multiple-domain MCI. Subtype of MCI may influence rates of progression to dementia and has a major influence on subsequent type of dementia diagnosis (Yaffe et al. 2006).

Studies clearly suggest that MCI patients tend to progress to probable Alzheimer's disease at a significantly higher rate than healthy individuals of the same age. It is important that people with cognitive impairment are diagnosed as early as possible, so that they can benefit from therapeutic interventions.

Criteria for MCI

The criteria for MCI are those previously proposed by Petersen et al. (1999)

- Presence of a subjective memory complaint
- Preserved general intellectual functioning
- Demonstration of a memory impairment by cognitive testing
- Intact ability to perform activities of daily living
- Absence of dementia

The revised MCI criteria are those proposed by the Stockholm Group consensus.

- Presence of a cognitive complaint from either the subject and/or a family member
- Absence of dementia
- Change from normal functioning
- Decline in any area of cognitive functioning
- Preserved overall general functioning but possibly with increasing difficulty in the performance of activities of daily living

Role of Pharmacotherapy

Epidemiology and Risk Factors

People with MCI are more likely to develop Alzheimer's or other dementias than are those without cognitive impairment. In fact, about half the people with MCI will progress to ► Alzheimer's disease within 5 years. In the general population, the prevalence of MCI was estimated to be about 3% (Ritchie et al. 2001). In the same population, a prevalence rate of about 18% was reported for age-associated cognitive decline, which is a similar concept as MCI but is related to normal cognitive aging processes rather than incipient dementia. Most of the studies described an increase in prevalence of MCI with age. A higher prevalence rate of MCI has been found in females.

Vascular diseases were identified as risk factors for MCI in some studies. Patients, particularly in general hospitals, represent a high-risk group for MCI, since risk factors like cardiovascular diseases are quite common (Bickel et al. 2006). MCI is also positively associated with stroke and peripheral arterial obstructive disease.

Depressive symptoms are highly prevalent among elderly MCI subjects and in cognitively normal elderly individuals. These symptoms are associated with an increased risk of developing MCI (Ravaglia et al. 2008).

Depressive symptoms may also increase the conversion rate from MCI to ▶ dementia (Barnes et al. 2006). A synergistic interaction between ▶ apolipoprotein E genotype (epsilon3/epsilon4 or epsilon4/epsilon4) and depression was reported with regard to the incidence of MCI (Geda et al. 2006). Association between MCI and apoE allele 4 status largely depends on MCI subtype. For Alzheimer's disease, the apoE allele 4 status is probably the most established risk factor.

Symptoms

How do the memory difficulties in MCI differ from those of normal aging? Numerous studies have examined the cognitive performance of patients with MCI. In general, information on cognitive performance over time is essential for definition of MCI to substantiate a worsening over time. Neuropsychological examinations have demonstrated that, in general, these patients are impaired on tests of memory compared with age-matched healthy individuals. Forgetting things that are usually remembered may be a first symptom of MCI patients. MCI may encompass deficiencies in any or all of the following categories: language, visuospatial ability, for example, placement of things in time and space becomes more difficult; executive function, for example, decision making becomes more challenging; ▶ episodic memory, for example, what happened yesterday. A general recommendation for individuals concerned about their memory would be to discuss these concerns with their physician.

MCI patients may report distinct difficulties in other areas of cognition, such as naming objects or people and complex planning tasks. These symptoms are comparable, but less severe, than the neuropsychological deficits found for Alzheimer's disease, especially for amnestic MCI. A careful interview may reveal that the MCI patient has mild difficulties with daily activities. These problems should be confirmed by a significant other.

People with MCI may also experience:

- Depression
- Irritability
- Anxiety
- Aggression
- Apathy

Diagnosis

In general, a lot of research has focused upon techniques to try to improve ways of identifying people with MCI. The diagnosis of MCI requires considerable clinical judgment, which consists of a comprehensive clinical assessment, including clinical observation, laboratory examinations, neuropsychological assessment, and neuroimaging. These examinations are also performed to rule out any alternate diagnosis which may lead to cognitive impairment. A similar assessment is usually performed for the diagnosis of Alzheimer's disease or other types of dementia.

As part of physical examination, neurological examination checks for signs of ▶ Parkinson's disease, strokes, tumors, or other medical conditions that can impair memory as well as physical function.

Laboratory Tests

Simple blood tests can rule out physical problems that can affect memory, such as vitamin B-12 deficiency or an underactive thyroid gland.

Neuroimaging

There is emerging evidence that magnetic resonance imaging (MRI) can observe deterioration, including progressive loss of gray matter in the brain, from MCI to Alzheimer disease. MRI-based volumetric measurements of medial temporal lobe structures can discriminate between normal elderly control subjects and patients with Alzheimer's disease. The extent of medial temporal lobe atrophy distinguishes probable Alzheimer's disease and amnestic MCI from healthy subjects. Neuroimaging also helps to monitor disease progression from a diagnosis of MCI to different stages of AD. Furthermore, MRI or CT is necessary to rule out the possibility of a tumor, evidence of stroke, or bleeding which could also cause some of the symptoms seen in MCI patients.

Biomarker

Currently, a lot of research is done with biomarkers in Alzheimer's disease and in MCI patients. A promising area of research for biochemical diagnosis of AD and mixed forms of dementia is the analysis of cerebrospinal fluid (CSF) Biological markers can serve as early diagnostic indicators, and as markers of preclinical pathological change. They are likely to take on an increasingly important role in the diagnosis and monitoring of AD, and probably also in MCI. Some biomarkers are currently in the process of implementation as outcome variables. In a large multicenter study, the CSF biomarkers Aβ42, T-tau, and P-tau could predict with good accuracy which MCI patients will develop AD, which is a finding that was previously found in smaller studies (Mattsson et al. 2009). The sensitivity and specificity and ease of use are the most important factors that ultimately define the usefulness of a biomarker for diagnosis.

Neuropathology

MCI often causes the same types of brain changes seen in Alzheimer's disease or other forms of dementia. The difference between MCI and other types of dementia lies in the extent of these changes. The available data suggests that MCI is associated with the early stages of the neuropathological changes that are found in the lesions of AD; including the accumulation of neuritic ▶ plaques, neurofibrillary tangles, synaptic and neurotransmitter associated deficits, and significant neuronal cell death. There is evidence suggesting that while amnestic, MCI patients may not meet the neuropathologic criteria for Alzheimer's disease, and these patients may be in a transitional stage of evolving Alzheimer's disease.

Treatments and Drugs

In general, there is no cure for MCI. There are several medications as well as many nonmedication approaches that can potentially improve MCI-related symptoms. Treatment of coexisting conditions, such as high blood pressure or depression, may help reduce cognitive problems. As MCI may represent a prodromal state to clinical Alzheimer's disease, treatments proposed for Alzheimer's disease, such as antioxidants and ▶ cholinesterase inhibitors have also been tested for MCI. Patients with MCI are frequently being treated with "off label" cholinesterase inhibitors and ▶ memantine, as well as other possible cognition-enhancing drugs.

Acetylcholinesterase-inhibitors (AChEIs) and Memantine

Randomized, placebo-controlled trials examining the therapeutic value of ▶ acetylcholinesterase-inhibitors (AChEIs) have been performed during the last years. All of them have had a negative outcome with regard of the primary outcome parameter which was to prevent the conversion from MCI to real Alzheimer's disease. Negative results have also been obtained with steroidal or anti-inflammatory compounds or antioxidants. As these compounds are thought to target the early steps in the pathophysiological cascade of dementia, the negative results are disappointing. So far, no disease modifying drugs with a proven efficacy are available for the treatment of MCI patients. As a consequence of these largely negative studies, there is no proven treatment or therapy for MCI. For example, ▶ rivastigmine failed to stop or slow progression to Alzheimer's disease or on cognitive function for individuals with MCI (Feldman et al. 2007). Donepezil showed only minor, short-term benefits. During the first year of a 3-year study, the rate of progression from MCI to Alzheimer's was significantly lower in the people who took ▶ donepezil (Petersen et al. 2005). However, that difference disappeared by the end of the study. A recent study showed that depression is predictive of progression from amnestic MCI to Alzheimer's disease, and treatment with donepezil delayed progression to AD among depressed subjects with amnestic MCI (Lu et al. 2009). Also ▶ galantamine has not changed the conversion rate from MCI to Alzheimer's disease, but may increase the risk of sudden death from heart attacks and strokes when used in people who have MCI (Winblad et al. 2008). However, several clinical trials are in progress to determine if any medications will prevent or delay the rate of progression from MCI to dementia.

High Blood Pressure Drugs

People who have MCI are also more likely to have problems with the blood vessels inside their brains. High blood pressure can worsen these problems and cause memory difficulties. Therefore, antihypertensive drugs are under investigation of whether they can reduce the conversion rate from MCI to dementia. But also because of other medical complications, it is essential to keep blood pressure at normal levels.

▶ Antidepressants

Depression is common in people who have MCI, and depression, itself, can cause memory problems. Treating ▶ depression may help to improve memory. However, the studies to date were of short duration, and it is not clear whether there is a longer-term benefit associated with antidepressant treatment. Further studies are needed to investigate the role of antidepressants in depressed MCI patients, especially whether they can reduce the conversion rate from MCI to dementia.

Antioxidants

The antioxidant vitamin E may help to protect brain cells from the oxidative stress that appears to play a role in dementia, but it works no better than placebo in relieving the symptoms or delaying the progression of MCI. Ginkgo appears to improve memory and concentration in older adults with no major memory problems, but it is still uncertain if ginkgo can reduce the memory problems associated with MCI.

Physical Activity

Observational studies have shown that physical activity reduces the risk of cognitive decline. In a ▶ randomized controlled trial of a 24-week physical activity intervention, participants in the intervention group improved suggesting that a 6-month program of physical activity

provided a modest improvement in cognition over an 18-month follow-up period (Lautenschlager et al. 2008). In general, study results are to a certain extent controversial whether physical activities can prevent or reverse MCI. Nevertheless, physical activity can be part of a healthy lifestyle for older people with or without MCI.

Conclusion

The concept of MCI is currently of high interest. A number of studies have been dealing with different aspects of MCI with regard to diagnosis and therapeutic strategies. Upto now, no drug is licensed for the indication of MCI. However, there is hope that new compounds may be efficacious in the treatment of MCI to reduce the conversion rate from MCI to dementia.

Mismatch field; MMN

Definition

Mismatch Negativity (MMN) is similar to the P300 in that it is an event-related potential component seen when subjects are presented with a rare or "deviant" stimulus in a train of frequent or regular stimuli. It can be found using stimuli in a variety of sensory modalities but has been most researched using auditory or visual stimuli. The deviant stimuli can vary from the frequent ones in any way, for example, tone, pitch, loudness. Unlike the P300, subjects do not need to be paying conscious attention to the stimuli. MMN is a negative potential observed over fronto-central scalp with a typical latency of 150–250 ms after the onset of the deviant stimulus.

Misoprostol

Synonyms

Cytotec

Definition

Misoprostol is an FDA-approved drug for the prevention of nonsteroidal anti-inflammatory drug-induced gastric ulcers. Misoprostol is also widely used by obstetricians and gynecologists for the induction of labor, therapeutic abortion, and the early termination of pregnancy.

Chemically, misoprostol is a synthetic prostaglandin E1 analogue. The most commonly reported adverse effects of misoprostol are: diarrhea, abdominal pain, nausea, and headache.

Mitochondrial Complex Chain

Definition
Mitochondria provide the energy source of cells by synthesis of adenosine triphosphate (ATP). A series of enzymes and cofactors (complexes I – V) in the inner membrane of the mitochondrion oxidize carbohydrates to release electrons that drive the proton pumps necessary to provide the energy for ATP synthesis. A range of drugs and toxins act on these enzyme complexes to disrupt or enhance energy production via the mitochondrial electron transport chain, affecting cell metabolism and ultimately cell survival.

Mobile phase

Definition
The mobile phase is the buffer that is pumped through the chromatographic column. All chemicals used to prepare the buffer should be of at least HPLC grade, and they should be made up using ultrapure, HPLC-grade, water. In addition, the buffer should be thoroughly filtered which is best achieved by vacuum filtration. This has the benefit that it also removes dissolved gas in the mobile phase that otherwise can come out of solution causing minute air bubbles to form. These get lodged in the column, with resultant adverse effects on the separation, or pass through to the detector, where they make irregular baseline noise, and rapid spikes.

Moclobemide

Synonyms
Aurorix; Manerix

Definition
Moclobemide is an antidepressant that inhibits reversibly and preferentially MAO-A, introduced in 1977, but not approved by the FDA in the USA. It is mainly used in the treatment of ► major depression and ► social anxiety, and it is claimed to have a favorable side-effect profile, but with equal effectiveness to ► tricyclic antidepressants and ► SSRIs within 1 week of treatment. It is rapidly absorbed and has a relatively short ► half-life, but the CNS effects persist for many hours, and it is considered safe.

Modafinil

Michael Minzenberg
University of California, Davis School of Medicine, Imaging Research Center, Sacramento, CA, USA

Synonyms
2-[(diphenylmethyl)sulfinyl]acetamide

Definition
Modafinil is a non-amphetamine ► psychostimulant currently FDA-approved for the treatment of sleepiness in ► Narcolepsy and shift-work sleep disorder.

Pharmacological Properties
Modafinil (brand name Provigil) is a racemate, with the two enantiomers being approximately equipotent in behavioral effects, but different in ► pharmacokinetic profile. The R-enantiomer (armodafinil) reaches higher

plasma concentrations than the racemic form between 6 and 14 h after administration, with a longer duration of wake-promoting activity in healthy adults. Modafinil is readily absorbed after single or multiple oral doses, reaching peak plasma concentrations 2–4 h after administration. The presence of food in the gastrointestinal tract can slow the rate of absorption but does not affect the total extent of absorption. Steady-state plasma concentrations are achieved between 2 and 4 days with repeated dosing. It is highly lipophilic, and approximately 60% bound to plasma proteins, primarily albumin. Major pharmacokinetic parameters are independent of doses in the range of 200–600 mg/day. The major circulating metabolites, modafinil acid and modafinil sulfone, do not exert any significant activity in the brain or the periphery. The ▶ elimination half-life is approximately 12–15 h, and single daily dosing is adequate and common in clinical practice. Elimination occurs primarily in the liver, via amide hydrolysis and, to a lesser extent, by ▶ cytochrome P450-mediated oxidation. Excretion occurs in the urine, with less than 10% of the oral dose excreted as the unchanged drug. Elimination is slowin the elderly or in individuals with hepatic or renal impairment. Some drug-drug interactions are apparent with modafinil. In vitro, modafinil exerts a reversible inhibition of CYP2C19, a smaller but concentration-dependent induction of CYP 1A2, 2B6 and 3A4, and a suppression of 2C9 activity. There are significant interactions of modafinil with ethinylestradiol and ▶ triazolam, though not with ▶ methylphenidate, dextroamphetamine, or warfarin.

Neurochemical Effects of Modafinil

Modafinil Effects on Catecholamine Systems

Modafinil is structurally unrelated to ▶ amphetamine, with a differing profile of pharmacological and behavioral effects. While the in vitro potency of modafinil in binding either the ▶ dopamine transporter (▶ DAT) and ▶ norepinephrine transporter (▶ NET) is low relative to methylphenidate, ▶ bupropion, or benztropine, modafinil shows DAT occupancy comparable to ▶ methylphenidate at clinically relevant doses (Madras et al. 2006).

Modafinil has a complex profile of effects on central dopamine (▶ DA) and norepinephrine (NE) systems, lacking many neurochemical and behavioral effects observed with amphetamine administration. For instance, in contrast to amphetamine, modafinil does not significantly affect DA release or turnover; it shows negligible effects on cerebral cortical blood flow and shows different patterns of metabolic activation compared to amphetamine; it does not produce behavioral stereotypies or rebound hypersomnia; and in healthy humans, modafinil has effects on the resting EEG that are distinct from amphetamine. Nevertheless, a parenteral administration of modafinil does raise extracellular DA levels in the rat ▶ prefrontal cortex (de Saint Hilaire et al. 2001), and in the caudate nucleus of narcoleptic dogs, though only minimally in the rat ▶ hypothalamus (de Saint Hilaire et al. 2001). It causes a modest increase in DA in the accumbens after intraperitoneal doses up to 300 mg/kg. In rat brain slices, modafinil inhibits the activity of ▶ ventral tegmental area DA neurons, an effect that appears to be mediated by D2 receptors. This suggests that modafinil inhibits DA reuptake, leading to DA cell body ▶ autoreceptor activation, to diminish DA cell firing. Modafinil effects on wakefulness are abolished in DAT knockout mice. In a rodent ▶ drug discrimination paradigm, modafinil partially generalizes to a cocaine-like stimulus; in addition, modafinil effects on activity levels in mice are modestly attenuated by D1 receptor antagonism, though not by D2 antagonism. Modafinil reduces blood prolactin levels in humans, without effects on blood growth hormone or thyroid stimulating hormone. Overall, these findings suggest that modafinil effects on arousal and behavioral activity are at least partly mediated by synaptic DA, but in a manner differing from that of amphetamine, and possibly favoring corticostriatal over subcortical limbic circuits.

Modafinil also elevates extracellular NE levels in ▶ prefrontal cortex (along with DA) and hypothalamus. Pretreatment with α-adrenergic receptor antagonists diminishes modafinil-induced increases in arousal and activity in rats and monkeys. However, modafinil does not reduce cataplexy in dogs or humans with narcolepsy, a feature that is similar to other DAT inhibitors, and in contrast to α1B receptor agonists and NET inhibitors. In addition, pretreatment with low doses of the α2 antagonist ▶ yohimbine potentiates modafinil-induced wakefulness and activity, whereas higher doses attenuate the activity increases. This biphasic response to yohimbine suggests that low doses may preferentially block the inhibitory terminal α2 autoreceptor to enhance NE release and thus augment postsynaptic adrenergic receptor activation by modafinil, whereas higher doses also block postsynaptic α2 receptors, attenuating modafinil effects. These findings make it likely that postsynaptic α2 receptors mediate some of the behavioral effects of modafinil. Importantly, modafinil also augments pupillary dilation parameters in a manner consistent with phasic activity of locus coeruleus neurons. This effect may also be mediated through α2 receptor activation; in this case, those receptors (autoreceptors) are located on locus coeruleus cell

bodies. Modest attenuation of modafinil-induced arousal and activity has also been observed after pretreatment with the β-blocker ▶ propranolol, suggesting that postsynaptic β receptors also mediate these modafinil effects.

Taken together, these varied findings suggest that modafinil may potentiate both DA and NE neurotransmission. It appears likely that the elevations in extracellular NE observed after modafinil are responsible for the majority of the adrenergic receptor-mediated effects, which may involve α2, α1, and β receptors. D1 and D2 receptors probably also mediate modafinil effects on cognition and behavior. In addition, however, Wisor and Eriksson (2005) have proposed that the elevated synaptic DA resulting from DAT inhibition may lead to DA activation of adrenergic receptors. There remains the possibility that enhanced DA in the ▶ prefrontal cortex results from competition with increased NE levels for binding to the NET, which plays an important role in terminating DA action in the prefrontal cortex. DA has an affinity for cloned mouse α1B receptors that is on the same order of magnitude as NE and DA can activate adrenergic receptors in various brain regions. These observations suggest a mechanism whereby the modafinil inhibition of DAT inhibition may be related to adrenergic receptor-mediated behavioral effects.

Modafinil Effects on GABA, Glutamate, and Serotonin Systems

Modafinil also has consistent effects on central ▶ glutamate and gamma amino-butyric acid (▶ GABA) neurotransmitter systems. The regional effects on extracellular glutamate occur at ascending doses in this order: thalamus = hypothalamus < striatum = hippocampus. Glutamate levels in the globus pallidus and substantia nigra are unchanged after the highest doses administered. These effects on glutamate may interact with adrenergic mechanisms.

Modafinil also causes a dose-dependent decrease in extracellular GABA. These regional GABA effects occur at ascending doses in this order: cortex < striatum/pallidum = hypothalamus < thalamus = hippocampus = substantia nigra = nucleus accumbens.

The effects on extracellular GABA may be mediated by modafinil effects on other neurotransmitter systems Cortical GABA effects require intact catecholamine neurons. In addition, modafinil elevates extracellular serotonin (5HT) in the frontal cortex, central nucleus of the amygdala, and dorsal raphe nucleus, but minimally in the hypothalamus. Modafinil and the 5HT reuptake inhibitors ▶ fluoxetine, ▶ paroxetine, and ▶ imipramine mutually enhance the effects of each other on elevations in cortical 5HT. Taken together, this literature suggests that modafinil effects on GABA are at least partly mediated by 5HT. Ultimately, modafinil effects on GABA may be mediated by adrenergic effects on 5HT activity.

Modafinil Effects on Orexin and Histamine Systems

The clinical efficacy of modafinil in narcolepsy, a condition characterized by deficient orexin (▶ hypocretin) in the brain, suggests that modafinil may have clinically relevant effects on this neurochemical system. Modafinil does activate orexin cells in the perifornical area of mice and rats. However, modafinil induces wakefulness more potently in orexin knockout mice than in wild-type mice, with similar patterns of Fos-immunoreactivity. In addition, modafinil does not bind to the orexin 1 receptor and retains effects on both extracellular striatal DA and wake-promoting activity in orexin 2 receptor-deficient narcoleptic dogs. Therefore, modafinil effects on arousal do not appear to be mediated through the orexin system, and the precise role of orexin in the cognitive and clinical effects of modafinil remains unknown. Modafinil also elevates extracellular histamine (HA) in the anterior hypothalamus. However, a direct injection of modafinil into the tuberomamillary nucleus (the site of HA cell bodies) does not affect HA release. Given the multiple effects on catecholamines, 5HT and GABA described earlier for modafinil, it appears likely that modafinil effects on HA are mediated by one or more of these other neurotransmitter systems.

Effects of Modafinil on Cognition

Studies in rodents indicate that modafinil can improve ▶ working memory performance in a dose- and delay-dependent manner, and that the processing of contextual cues is also enhanced with modafinil. These effects may be augmented with sustained dosing regimens. In healthy humans (with or without undergoing sleep deprivation), working memory, recognition memory, ▶ sustained attention, and other tasks dependent on cognitive control (and on function of the prefrontal cortex) are enhanced with modafinil. Some evidence suggests that the magnitude of modafinil effects in healthy adults may depend on underlying cognitive abilities. Those with high general intellectual abilities, or high performance in specific cognitive domains, appear to exhibit less improvement after modafinil, suggesting that these individuals already experience optimal levels/patterns of catechalamine activity in the modulation of cognition. Among psychiatric populations, there is now consistent evidence that modafinil (in well-tolerated dosing regimens) improves attention and response inhibition in children and adolescents with attention-deficit/hyperactivity disorder (▶ ADHD). These

improvements in cognition may form the basis for clinical efficacy in ADHD. Among adult psychiatric patients, modafinil improves several cognitive functions dependent on the prefrontal cortex in ► schizophrenia, ► major depression and adult ADHD, with some null findings reported in schizophrenia. However, these studies have significant limitations evident in their design. The range of clinical samples and cognitive functions that are subject to modafinil treatment study is expected to expand in the future.

Clinical Effects of Modafinil

Modafinil has consistently shown efficacy in measures of alertness in narcolepsy and shift-work sleep disorder, in ► randomized, double-blind placebo-controlled studies. In these studies, modafinil has shown efficacy in open-label extension phases extending for as long as 136 weeks, and it has been well tolerated, with no evidence of significant adverse events or abuse. Modafinil has also been evaluated for the treatment of ► fatigue and sedation in a number of other neurological and medical conditions, including multiple sclerosis, idiopathic ► Parkinson's disease, chronic fatigue syndrome, polio, HIV infection, ► dementias, obstructive sleep apnea, post-anesthetic sedation, and fibromyalgia, with generally favorable but somewhat mixed results (Ballon and Feifel 2006).

Among studies of adult psychiatric patients, two studies of patients with ► major depression have found significant improvements in mood symptoms on modafinil compared to placebo, and modafinil has been associated with greater rates of abstinence in cocaine-dependent adults. It also shows clinical efficacy in adults with ADHD. In contrast, adjunct modafinil has shown modest and inconsistent efficacy for symptoms of schizophrenia, though these studies have been plagued by small sample sizes and other methodological limitations.

In childhood/adolescent ADHD, modafinil improves parent, teacher, and clinician ratings of ADHD symptoms in several short-term (4–9 weeks), randomized, double blind, placebo-controlled trials, at mean doses ranging from 195 to 368 mg daily.

Throughout these clinical trials, modafinil has been well tolerated. However, case reports have appeared describing significant adverse events in routine clinical use of modafinil, including the exacerbation of psychosis, acute mania, clozapine toxicity, premature ventricular contractions, and irritability and verbal aggression. Nonetheless, these events have not been observed at a significant rate in modafinil-treated patients compared to placebo-treated patients in clinical trials and no serious (e.g., life-threatening) sequelae have ensued in these reported isolated cases. Modafinil also appears to have a relatively low potential for abuse, which may be a function of its pharmacodynamic profile and/or its physical properties, being insoluble in water and unstable at high temperatures, which minimizes its bioavailability upon smoking or intravenous use. Nonetheless, careful clinical judgment should be exercised in the decision to initiate therapy with modafinil, with particular attention to both its side-effect profile and its potential for drug–drug interactions.

Definition

Monoamine oxidase inhibitors (MAOIs) inhibit the enzyme MAO, of which there are two major isoforms, MAO-A and MAO-B.

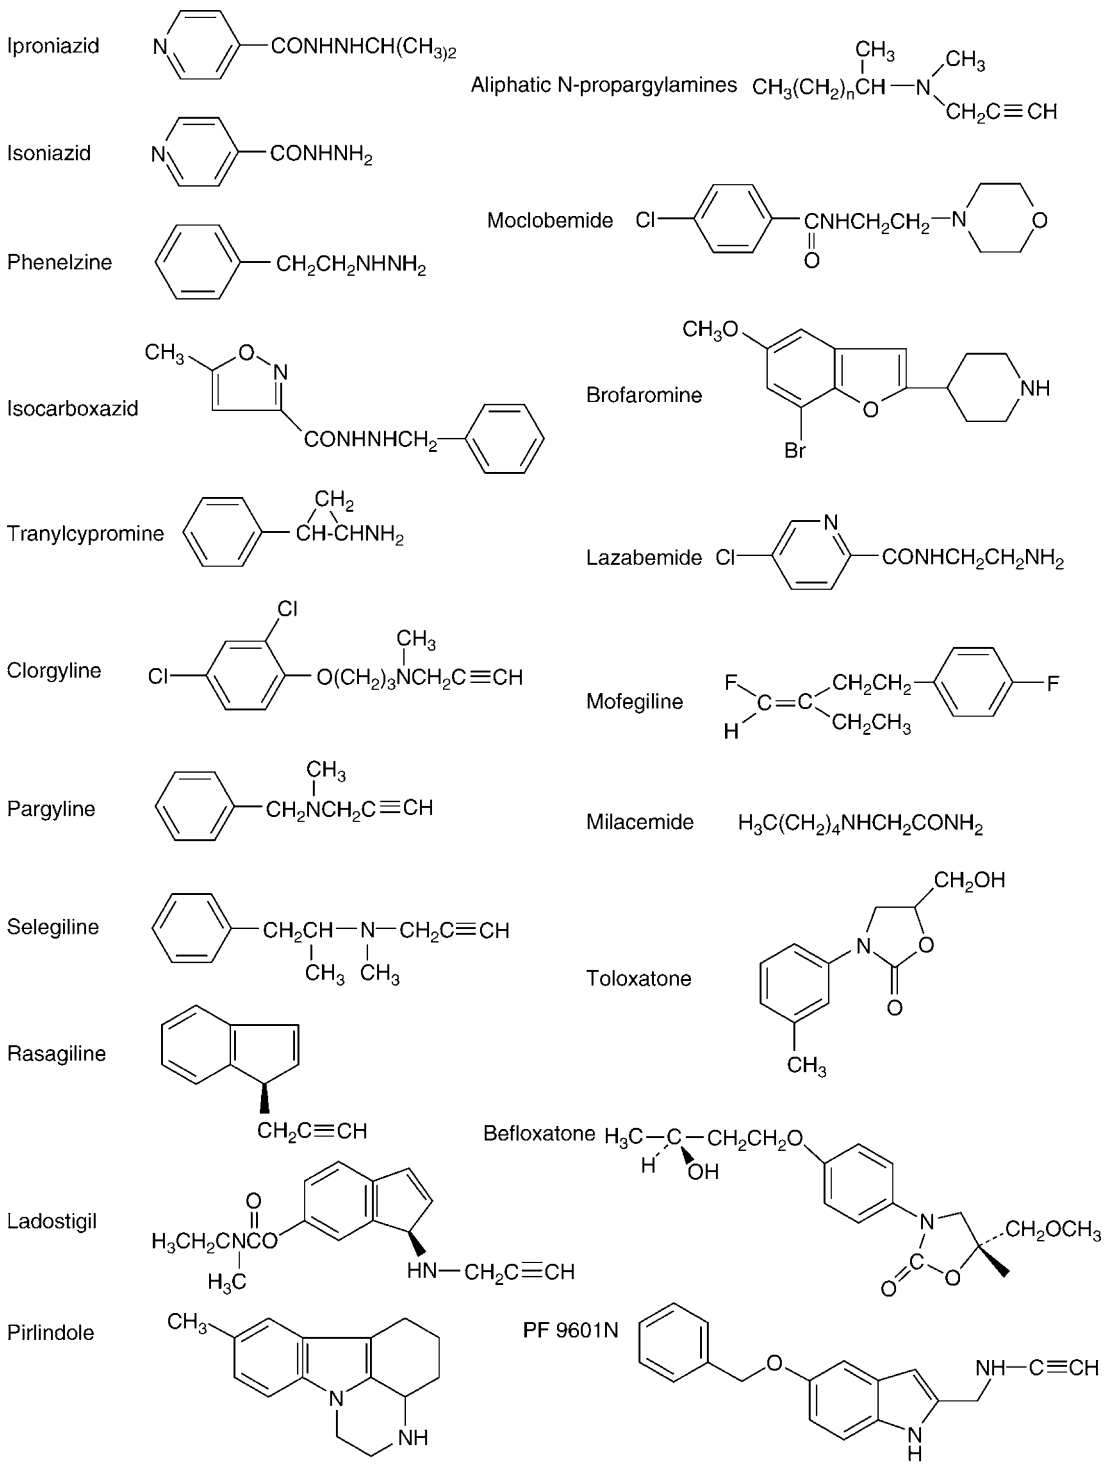
Pharmacological Properties

History

MAOIs were originally developed as ► antidepressants because of their ability to restore brain levels of the biogenic amines ► noradrenaline and 5-hydroxytrytamine (or ► serotonin), both of which are thought to be functionally deficient in depression. Yet, several of these drugs have also proven useful in the treatment of ► panic disorder, ► social anxiety disorder, ► eating disorders, pain syndromes, ► Parkinson's disease, and ► Alzheimer's disease. MAOIs are no longer first-line drugs for most depressive or anxiety disorders. However, they do remain important agents when first- or second-line drugs prove to be ineffective or intolerable, and are especially effective in ► atypical depression and depression associated with anxiety, panic, or phobias (Kennedy 1994; Kennedy et al. 2005). The MAOIs may be classified according to selectivity (for either the MAO-A or MAO-B isoform) and reversibility (reversible or irreversible) (see Kennedy et al. 2005; Stahl and Felker 2008 and Youdim et al. 2006). Noradrenaline and serotonin are preferred substrates for MAO-A, while β-phenylethylamine and benzylamine are selective for MAO-B. Selective inhibitors of MAO-A and MAO-B include clorgyline and l-deprenyl, respectively. Figure 1 and Table 1 show several MAOIs, some of which are currently available clinically, and others that are used only pre-clinically or are at various stages of development.

Side Effects

While the inhibition of MAO-A is required for antidepressant activity, clinically used irreversible inhibitors of MAO prevent the inactivation of dietary sympathomimetic amines, such as tyramine, by MAO-A in the gut wall and by MAO-A and MAO-B in the liver. The resulting increase in systemic tyramine stimulates the release of noradrenaline from sympathetic varicosities in the vascular wall. This also occurs with clorgyline, despite its lack of effect upon hepatic MAO-B. As a consequence of MAO-A inhibition, noradrenaline accumulates and produces a series of symptoms, usually starting with headaches and, if not dealt with appropriately, potentially culminating in a hypertensive crisis. This adverse effect is called the "cheese effect," so-named because it was originally observed in patients taking MAOIs who had ingested foods



Monoamine Oxidase Inhibitors. Fig. 1. Some monoamine oxidase inhibitors and their structures.

Monoamine Oxidase Inhibitors. Table 1. Some monoamine oxidase inhibitors and their actions.

Generic	Reversible/irreversible selectivity
Iproniazid	Irreversible, nonselective
Isoniazid	Irreversible, nonselective
Phenelzine	Irreversible, nonselective
Isocarboxazid	Irreversible, nonselective
Tranylcypromine	Irreversible, nonselective
Clorgyline	Irreversible, MAO-A selective
Pargyline	Irreversible, MAO-B selective
Selegiline	Irreversible, MAO-B selective
Moclobemide	Reversible, MAO-A selective
Brofaromine	Reversible, MAO-A selective
Lazabemide	Very slowly reversible, MAO-B selective
Mofegiline	Irreversible, MAO-B selective
Milacemide	Partially reversible, nonselective
Toloxatone	Reversible, MAO-A selective
Befloxatone	Reversible, MAO-A selective
Pirlindole	Reversible, MAO-A selective
Rasagiline	Irreversible, MAO-B selective
Ladostigil	Irreversible, MAO-B selective
PF 9601N	Irreversible, MAO-B selective
Aliphatic N-propargylamines	Irreversible, MAO-B selective

Table modified from Kennedy et al. 2005

such as aged cheeses that have a high tyramine content. This food–drug interaction can occur with some of the MAOIs used currently in the clinic, including ▶ tranylcypromine, ▶ phenelzine, and ▶ isocarboxazid (all of which act as irreversible inhibitors of both MAO-A and MAO-B). Thus, when patients receive a prescription for such MAOIs, they should be informed by their physician and pharmacist of the foods that should be avoided while on these medications (Stahl and Felker 2008).

Concern about the food–drug interaction mentioned above led to the development of selective MAO-B inhibitors such as l-deprenyl (▶ selegiline) as putative antidepressants. However, this selectivity for MAO-B meant that l-deprenyl did not exhibit antidepressant effects until selectivity was lost at higher doses that also caused irreversible MAO-A inhibition. Nonetheless, l-deprenyl is used in the treatment of Parkinson's disease and has been demonstrated to have ▶ neuroprotective properties in a large number of neurotoxicity tests in vivo and in vitro (Tatton and Chalmers-Redman 1996; Youdim et al. 2006). In fact, the neuroprotective actions of this drug have stimulated considerable research into related drugs as potential neuroprotective agents (▶ rasagiline is an example of productive research in this area). Transdermal selegiline has recently been reported to be effective as an antidepressant (Culpepper and Kovalick 2008; Stahl and Felker 2008); under these conditions, the drug is delivered directly into the systemic circulation, thereby avoiding extensive first-pass metabolism and reaching the brain in sufficiently high concentrations to inhibit both MAO-A and MAO-B.

In a further effort to develop antidepressants that would not precipitate the cheese effect, reversible inhibitors of MAO-A (RIMAs) were developed. ▶ Moclobemide, a competitive RIMA available clinically for several years, retains antidepressant properties, but the risk of a hypertensive crisis is reduced since dietary tyramine can still compete with moclobemide for the active site on MAO-A. RIMAs have a further advantage over irreversible inhibitors in that after cessation of treatment with the latter drugs, a period of approximately 2 weeks is required before MAO fully recovers (following the synthesis of new enzyme). In the case of RIMAs, the recovery of enzyme occurs as inhibitors are cleared from the body and is usually complete in 2–5 days. This is an important consideration when shifting a patient to a drug regimen that would otherwise be contraindicated because it would result in elevated levels of serotonin (e.g., a ▶ selective serotonin reuptake inhibitor [SSRI]).

Although a hypertensive crisis is a feared adverse effect associated with irreversible MAOIs, this is usually the result of a food–drug or drug–drug interaction. Paradoxically, orthostatic hypotension is a more common adverse cardiovascular effect with MAOIs. ▶ Serotonin syndrome may result if an MAOI is given with another drug that also increases the availability of serotonin (see Table 1). ▶ Insomnia can be a problem with tranylcypromine (an MAOI with a structure similar to that of amphetamine), and the irreversible MAOIs can produce weight gain, peripheral edema, and ▶ sexual dysfunction (Kennedy et al. 2005). A discontinuation syndrome (arousal, mood disturbances, and somatic symptoms) may occur with phenelzine or tranylcypromine if they are discontinued abruptly.

Drug–Drug Interactions

In addition to the food–drug interaction mentioned earlier, drug–drug interactions must be taken into consideration when prescribing MAOIs; some of these may be life

Monoamine Oxidase Inhibitors. Table 2. Potential drug–drug interactions involving monoamine oxidase inhibitors.

Interacting drugs	Examples	Possible result
Drugs that stimulate the release of or inhibit the reuptake of noradrenaline at sympathetic neurons; decongestants	Amphetamines, methylphenidate, ephedrine, phenylephrine, phenylpropanolamine, pseudoephedrine, oxymetazoline, some antidepressants, tramadol, sibutramine, phentermine	Hypertension
Drugs metabolised by monoamine oxidase	Phenylephrine (oral), sumatriptan, citalopram	Hypertension, increased serum levels of sumatriptan, citalopram
Drugs that inhibit serotonin reuptake	SSRIs, clomipramine, imipramine, meperidine, dextromethorphan, propoxyphene, venlafaxine, chlorpheniramine, brompheniramine, tramadol	Serotonin syndrome, confusion, agitation, hypomania, sweating, myoclonus, fever, coma, possible fatality
Serotonin agonists	Sumatriptan	Serotonin syndrome
β-Blockers		Increased hypotension, bradycardia
Oral hypoglycemics		Increase hypoglycemic affects

Table modified from Kennedy et al. 2005 and Stahl and Felker 2008

threatening. These potential drug–drug interactions are summarized in Table 2.

Metabolism

Most of the MAOIs are metabolized extensively, and various ► cytochrome P450 (CYP) enzymes are involved in this metabolism (see Kennedy et al. 2005).

Beyond Inhibition of MAO

The MAOIs are multifaceted drugs and have been reported to bind to a wide variety of other enzymes, receptor systems, and uptake pumps that may contribute to their therapeutic and/or adverse effects. Depending on the MAOI involved, interactions with the following have been reported: other amine oxidases; various transaminases, decarboxylases, dehydrogenases, cytochromes P450 (CYPs); biogenic amine receptors and transporters; imidazoline binding sites; and sigma receptors (Holt et al. 2004). Several MAOIs also cause marked increases in brain levels of ► trace amines such as β-phenylethylamine and ► tryptamine, both of which can affect the normal function of classical neurotransmitter amines such as noradrenaline, dopamine, and serotonin. There has been extensive interest in recent years in the possible neuroprotective effects of MAOIs and their potential for the treatment of neurodegenerative disorders. For example, the MAO-B inhibitors l-deprenyl and rasagiline are neuroprotective and are used as anti-Parkinsonian drugs and, to a lesser extent, as therapeutic agents in Alzheimer's disease (Youdim et al. 2006). In many cases, these neuroprotective actions appear to be independent of the inhibition of MAO. l-Deprenyl and rasagiline have been reported to prevent the initiation of apoptotic cascades by up-regulating the anti-apoptotic protein Bcl-2 and down-regulating pro-apoptotic proteins such as Bad and Bax, and to prevent the activation and nuclear localization of glyceraldehyde-3-phosphate dehydrogenase (Youdim et al. 2006). Preliminary reports indicate that l-deprenyl might be useful for the treatment of negative symptoms in ► schizophrenia. Phenelzine has been shown to provide neuroprotection in an animal model (global ischemia) of stroke, and its contribution to neuroprotection might rely on actions as diverse as the inhibition of ► GABA transaminase (GABA-T) and the elevation of brain GABA, the elevation of brain ornithine, and the sequestration of toxic aldehydes such as 3-aminopropanal and acrolein (Baker et al. 2007; Sowa et al. 2004). Although unrelated to MAO, semicarbazide-sensitive amine oxidase (SSAO) is inhibited by some MAOIs (e.g., phenelzine). SSAO has been the subject of extensive research in the areas of

inflammation, neuropsychiatry, and cardiovascular complications of diabetes in recent years, and might play a role in Alzheimer's disease-related pathology (Jiang et al. 2008).

The RIMA moclobemide has been reported to have anti-Parkinsonian activity and neuroprotective effects in a model of cerebral ischemia. Both tranylcypromine and phenelzine have been shown to increase the expression of ► brain-derived neurotrophic factor (BDNF) in rat brain after chronic administration. Clorgyline (an irreversible inhibitor of MAO-A), like l-deprenyl and rasagiline, contains an N-propargyl moiety, and has been reported to be neuroprotective in vitro and in vivo (Baker et al. 2007), albeit at doses lower than are required to inhibit MAO. Increased activity and expression of MAO have been reported in Alzheimer's disease, suggesting that MAOIs should be investigated more thoroughly as adjunctive drugs in this neuropsychiatric disorder. Ladostigil, a drug that combines the properties of rasagiline with anticholinesterase activity, is currently in phase II clinical trials for treatment of Alzheimer's disease (Youdim et al. 2006), while related drugs that also possess iron-chelating properties or inhibitory potency versus ► glutamate release are in preclinical development.

In summary, although MAOIs are not currently used extensively in mood and anxiety disorders because of clinically relevant food–drug and drug–drug interactions, they continue to have an important place in the treatment of psychiatric and neurological disorders and are exciting keys to the development of future drugs with potential neuroprotective activity.

Monoamines

Definition

Monoamines (so-called because they have one organic substituent attached to the nitrogen atom) include ► serotonin, ► norepinephrine, and ► dopamine, all of which are neurotransmitters that are important in the pathophysiology and treatment of psychiatric disorders. Monoamines are subdivided into ► catecholamines and ► indoleamines.

Mood Disorders

Synonyms

Affective disorders

Definition

Depressive, manic, and hypomanic disorders like ► major depression, ► mania, hypomania, ► bipolar disorder, ► dysthymia, or cyclothymia.

Mood Stabilizers

Guy M. Goodwin
University Department of Psychiatry, Warneford Hospital, Headington, Oxford, UK

Synonyms

Long-term treatments for bipolar disorder

Definition

Mood stabilizers are pragmatically defined by their clinical efficacy in ▶ bipolar disorder. Bipolar disorder is a complex condition as it is expressed as episodic periods of contrasting mood disturbance – ▶ mania and ▶ depression – and its long-term or maintenance treatment must prevent new episodes of both. Any medicine that achieves this can be said to be a mood stabilizer.

Pharmacological Properties

History

The first mood stabilizer was ▶ lithium. It was discovered over 60 years ago by guided serendipity. Lithium salts of urea were found by an Australian doctor John Cade to be sedative in animals. He had reasoned that urea itself was an active component, but realized that, in fact, lithium was unexpectedly tranquilizing. Immediate trials in patients with ▶ mania suggested acute efficacy and subsequent experience showed that lithium could markedly modify the course of bipolar disorder (then called manic-depression) in the long term. The effects were anecdotally so dramatic for some extremely disabled patients that a group of psychiatrists and scientists, led most notably by Mogens Schou, quickly became self-proclaimed lithium enthusiasts and by the 1960s, had influenced practice in many parts of the world. The history of lithium's acceptance was interrupted by highly vocal criticism of the methodology of its early adopters. While the critics were right about the methodology, they were wrong about lithium (which they proclaimed on equally little evidence to be a dangerous yet inactive placebo). Subsequent trials have repeatedly shown that lithium is an effective medicine for the prevention of relapse (especially to the manic pole) in bipolar disorder (Geddes et al. 2004). Where the illness starts with and tends to relapse to the manic pole, lithium can produce remarkable mood stability. However, such success is seen in only about 30% of patients with the severe form of the disorder. Therefore, for many patients, other mood stabilizers are required to meet their unmet needs.

▶ Valproate and ▶ carbamazepine are also often described as mood stabilizers, although the evidence is weaker than for lithium. Both also tend to be most active against mania.

There is also good evidence for ▶ antipsychotics in mood stabilization (Mahli et al. 2005): ▶ quetiapine acts against both poles of the illness. It also turns out that other agents can be effective in long-term treatment against, for example, the manic pole of the illness, without having an important impact on depression (e.g., ▶ aripiprazole, ▶ olanzapine, and ▶ risperidone), and vice versa (e.g., ▶ lamotrigine). Some authors have argued for extending the term mood stabilizer to include medicines with all these effects. Even more loosely, there was at one time a tendency to extend the term mood stabilizer to include ▶ anticonvulsants, effectively by extrapolation from the examples of ▶ valproate and ▶ carbamazepine. In the case of ▶ topiramate and ▶ gabapentin, subsequent clinical trials proved to be negative. There seems little advantage to a more liberal definition except for marketing the drugs.

Mechanism of Action

It follows from the definition that there are no pharmacological properties that define mood stabilizers as a class. Moreover, our understanding of the neurobiology of mania and depression remains highly provisional. However, the fact of clinical efficacy has often preceded an understanding of mechanism and has been a major driver to further research. Thus, the individual medicines effective in stabilizing mood have a variety of effects defined for the most part in animal experiments.

Lithium inhibits the phosphoinositide second-messenger system in the brain and peripheral tissues. This may be the basis for its therapeutic (and nontheraputic) effects, although it has not been investigated as fully as might be expected. There are also some effects on the ▶ monoamine function in the brain, which have weak parallels with better-defined psychotropic drugs like ▶ antidepressants and antipsychotics. In recent years, interest has been directed to downstream cellular changes in transcription factors and other molecular pathways that may mediate ▶ neuroprotection. Lithium has some actions in common with valproate in these cellular models.

The net actions of the anticonvulsants are variously pro-GABAergic and antiglutamatergic. The efficacy of lamotrigine in bipolar depression is of particular interest

given its lack of neurotoxicity at effective doses and selective effects on membrane polarization and glutamate release. ► Glutamate is increasingly implicated in the neuronal circuits that are believed to regulate mood, and there is an evolving pharmacology targeted on the glutamate system. Whether this next generation of molecules will be effective is still an open question.

The antipsychotics that can prevent long-term relapse in bipolar disorder have a common action in blocking dopamine receptors. However, most have additional actions on serotonergic function in the brain and; in the specific case of quetiapine, an active metabolite that appears to block noradrenergic reuptake, a property shared with a number of antidepressants. Whether these effects, in addition to dopamine blockade, are important remains an open question.

► Pharmacokinetics

Lithium provides an unusual example for psychopharmacology of a drug whose plasma levels are routinely monitored in clinical practice. It is necessary because the drug has a narrow therapeutic ratio: in other words, the difference between a blood level that is just effective and that which can poison the patient is relatively small. For efficacy, 0.5 mmol/L is regarded as the minimum effective level in plasma taken 18 h after the last dose of lithium. Levels over 1.5 mmol/L are potentially toxic and definitely not recommended. The commonest well-tolerated level is around 0.7 mmol/L, although slightly higher levels (0.8–1.0 mmol/L) are often recommended. Choice of level should always be informed by any symptoms the patient describes. A variety of effects can limit doses to those achieving well below 1.0 mmol/L.

Although not routinely used to guide treatment, levels of valproate and carbamazepine are often available because of their use in epilepsy. A valproate level between 50 and 125 g/mL has been associated with acute response in mania. Importantly, because combined treatments are so often necessary in bipolar patients, carbamazepine promotes enzyme induction and can lower the levels of a range of other agents (including the contraceptive pill); hence, higher doses of comedication may often be necessary. Conversely, valproate approximately doubles the availability of lamotrigine, thus halving the dose required for efficacy.

In the elderly, it is common for the required dosage to be substantially less than those used in younger people. Side effects are an important guide, as ever, to what the dosage should be. The highest *well-tolerated* dose (whatever the actual figure) is usually the best choice in bipolar disorder.

Tolerability and Safety

In general, mood-stabilizing medicines have to be reasonably well tolerated because patients are expected to take them week in and week out for many years – often indefinitely. There is a tendency for doctors to underestimate the adverse impact of medicines on their patients. The most important adverse subjective effects of psychotropic drugs that are used to treat bipolar disorder tend to be tiredness, sedation, and weight gain. In addition, lithium can produce tremor, increased urine volumes, and thyroid dysfunction. Attention to minimizing these problems (by optimizing doses) is essential for good adherence to prescribed medicines.

Weight gain was formerly seen as a largely cosmetic problem. It is now realized to be a much more important because obesity combined with lack of exercise and smoking is associated with the so-called metabolic syndrome. This is a composite term for biochemical, blood pressure, and weight indices associated with older age and higher body mass index. It is the prelude to diabetes, coronary heart disease, and stroke. Several antipsychotics used to treat bipolar disorder, including ► clozapine, ► olanzapine, and ► quetiapine are particularly associated with increased weight gain and the risk of dyslipidaemia, hypercholesterolaemia, and elevated glucose. In an increasingly obese population, this is a growing concern and requires active prevention wherever possible and treatment of risk factors.

In pregnancy, there is a risk of teratogenicity from several of the medicines used as mood stabilizers. Thus, especially in the first 3 months of fetal development, drugs may interfere with the formation of the most complex organs. The neural tube and heart are especially vulnerable. Lowest risks appear to be associated with the antipsychotics. Higher ► teratogenic risks are associated with lithium and especially the anticonvulsants (valproate > carbamazepine > lamotrigine).

Decisions about the use of medication in pregnancy by women with bipolar disorder are always difficult. Sudden discontinuation (Goodwin, 1993) or switching medicines risks destabilizing mood and precipitating relapse of the bipolar disorder. Treatment of an acute episode in a pregnant woman may be both highly stressful and require much higher doses of psychotropic drugs than would be required for prophylaxis.

Treatment issues also arise postpartum. Childbirth greatly increases the risk of relapse in patients with bipolar disorder in the weeks and months after delivery. Bipolar women with a previous history of a severe postpartum episode (puerperal psychosis) and bipolar women with a

family history of puerperal psychosis will have a >50% risk of severe relapse. Medication given to prevent this outcome will often appear in breast milk and have potential consequencies for the neonate.

Conclusion

The term mood stabilizer is in common use, even though it imprecisely describes what such medicines do and certainly does not define a meaningful pharmacological action or even set of actions. The strictest definition, proposed by Bauer and Mitchner (2004) is prophylaxis and the prevention of recurrence *and* evidence of short-term efficacy for both poles of the illness. Lithium may just meet the criterion despite its relative weakness against depression; quetiapine certainly does but clinical experience is less. Therefore, for any agent to be called a mood stabilizer, we probably need to know how it performs in comparison to lithium in the long term. We also need to be able to gauge its relative effects against the manic and depressive poles of the illness.

Medicines that reduce the risk of relapse to mania and/or depression in bipolar patients can contribute to mood stability, whatever we call them. Some contemporary uses of the term are overinclusive. However, mood stability is a goal that patients, their families, and attending doctors share. If a medicine helps, then doctors are more likely to prescribe it and patients are more likely to take it. In other words, the term mood stabilizer is chosen to be comforting and persuading. This does not detract from the scientific challenge to understand the mechanisms underlying mood stabilization and how we improve treatment.

Morris Water Maze

Synonyms

Morris water navigation task

Definition

The Morris water maze was developed by Richard Morris (Morris 1984) and is used to assess ► spatial learning in rats and mice. The apparatus comprises a pool of varying diameter, typically 1.2–2m (smaller for mice) and depth of approximately 60 cm which is filled with opaque water and contains a hidden platform. The animal is placed in the pool at different starting points and swims to the hidden platform (there are many variations of this to assess, e.g., ► working memory, daily learning, ► delayed match to sample). There are no intramaze cues and the dominant strategy in relocating the hidden platform is thought to be truly spatial. The main measure for the water maze is the latency to find the platform. In order to control for search strategies, other measures can be taken, including time spent in each quadrant during the main trials and probe trials (where the platform is removed), and analyses of the path length. The advantages of the Morris water maze are the rapid acquisition of the task, the ability to assess learning and performance, markers of motivation, and motor ability (e.g., swim speed), and the innate motivation of rats to want to find the platform without being distressed.

Motor Activity and Stereotypy

Stephen C. Fowler
Department of Pharmacology and Toxicology 5036 Malott Hall, Schieffelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, USA

Synonyms

Exploratory behavior; Locomotor activity; Motor activity; Repetitious behavior; Repetitive behavior; Spontaneous activity; Stereotypy

Definition

Motor activity generally refers to a laboratory animal's horizontal movements within an enclosure that permits the use of a variety of methods for quantifying such

movements. The term is rarely used in the context of laboratory animals exercising in running wheels or on treadmills.

Stereotypy refers to abnormally repetitive behavior that reflects dysfunction of nervous system induced by drugs (especially those that elevate brain ▶ dopamine levels), brain lesions, genetic mutations, or environmental circumstances (e.g., wild animals in captivity). Depending on the context in which the term is used, stereotypy or stereotyped behavior may include specific features of locomotor activity (e.g., moving predominantly in the same direction along the inside perimeter of an enclosure) or may be restricted to repetitive behaviors that primarily occur in the absence of locomotion (e.g., rhythmic head movements, known as focused stereotypy; gnawing on the wire-mesh floor of a cage, known as oral stereotypy).

Impact of Psychoactive Drugs

The locomotor activity assay is one of the most frequently used procedures in the initial exploration of a drug's putative psychoactive effects. Typically, a mouse or rat is administered a fixed dose of a drug and is then placed in an enclosure with a flat floor large enough to enable free movement of several body lengths in any direction in the horizontal plane. A human observer or an instrument is used to quantify the distance an animal moves. Other species-typical rodent behaviors, such as grooming or rearing, may also be recorded depending on the objective of the research, the recording method, and other experimental conditions. Comparisons of a variety of techniques for measuring locomotor activity can be found in Fowler et al. (2001). The success of locomotor activity as a drug assay depends largely on the fact that most types of mice and rats spontaneously engage in "exploratory" behaviors, when placed in environments new to them. As it moves from place to place in the new environment, a mouse or rat uses its sensory organs and information processing endowments to learn the available species-relevant attributes of the environment. Importantly, the study of drug effects on spontaneously expressed behavior is economical because the experimenter does not need to impose any preconditions on the animals (e.g., neither food restriction nor explicit training in a specific task, etc.) in order to assure that easily measurable amounts of species-typical behavior will occur in placebo-treated animals ("controls"). The behavioral output of controls then affords a baseline condition with which the effects of drug treatments can be compared. Depending on type of drug, drug dose, amount of experience in the environment, amount of experience with the drug, duration of the observation period, route of drug administration, lighting conditions, time of day, and many additional variables, the drug treatment may increase, decrease, or have no effect on measures of locomotor activity compared to control performance. When interpreting the results of these kinds of experiments, one should keep in mind the fact that *a priori* suppositions about a drug's "stimulant" or "depressant" activity may not be confirmed in a straightforward manner. For example, the drug, ▶ pentobarbital, which in clinical terms is described as a "sedative-hypnotic," increases locomotor activity in rodents at low doses and decreases or abolishes locomotor activity at higher doses as an anesthestic dose level is neared. The ▶ psychomotor stimulant drug, d-amphetamine sulfate, also increases locomotor activity in rats at doses around 1.0 mg/kg, but at doses around 5.0 mg/kg of ▶ amphetamine produces a focused stereotypy syndrome characterized by the absence of locomotion and the concurrent expression of rapid rhythmic head movements. In research situations where *a priori* information about a drug is lacking, a relatively wide range of doses should be used in locomotor activity assays to detect lower-dose increases and higher-dose decreases in locomotor activity.

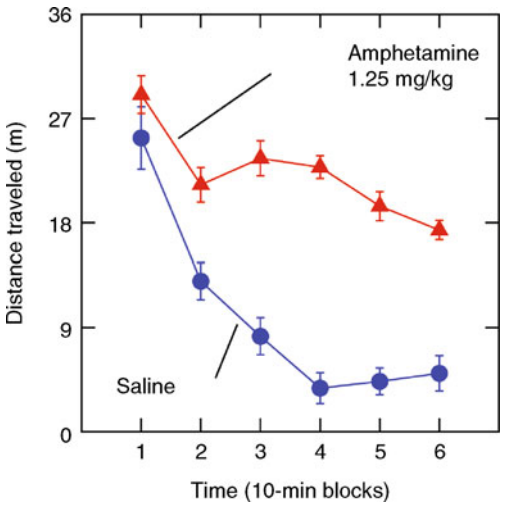
Amphetamine-Induced Locomotor Activity: Illustrative Data

Figure 1 provides data illustrating increased locomotor activity induced by amphetamine. The measure of locomotor activity was the ▶ distance traveled during six 10-min time blocks in a 1-h recording session. Distance traveled was calculated from the rats' center of force x–y coordinates as the rats moved on the 28 cm × 28 cm load plate of a ▶ force-plate actometer (Fowler et al 2001). The saline group exhibited rapid ▶ habituation during the first 40 min, and the distance traveled remained low for the remainder of the hour. Compared with the saline group, the amphetamine-treated rats showed significantly more locomotor activity at all but during the first 10-min interval, the standard errors of the mean (sem) overlapped. The curvature in the amphetamine plot between block 2 and block 6 is likely the result of changes in the brain level of amphetamine. Brain ▶ microdialysis studies have shown that intraperitoneally administered d-amphetamine sulfate reaches a peak level at about 22–26 min after injection and is eliminated with a half-life of about 40–45 min. During the sixth time block (see Fig. 1), the amphetamine group exhibited more distance traveled than the control group in every time block except the first, suggesting that amphetamine continued to induce abnormally high levels of locomotion 1 h after treatment. Given that the time-related diminution of locomotion in the control group is a representative example

of habituation, one can hypothesize that amphetamine, at least in part, produced elevated levels of locomotor activity by interfering with the habituation process. A well designed experiment with ► cocaine, a psychomotor stimulant with many pharmacological effects similar to those of amphetamine, supports this hypothesis (Carey et al. 2003). Thus, the increased locomotor activity induced by a variety of CNS-active drugs is not simply a "motor effect," because the multiple sites of action of such drugs reside in multiple anatomical loci that perform information processing, associative, and motivational functions, as well as motor functions.

Amphetamine-Induced Focused Stereotypy

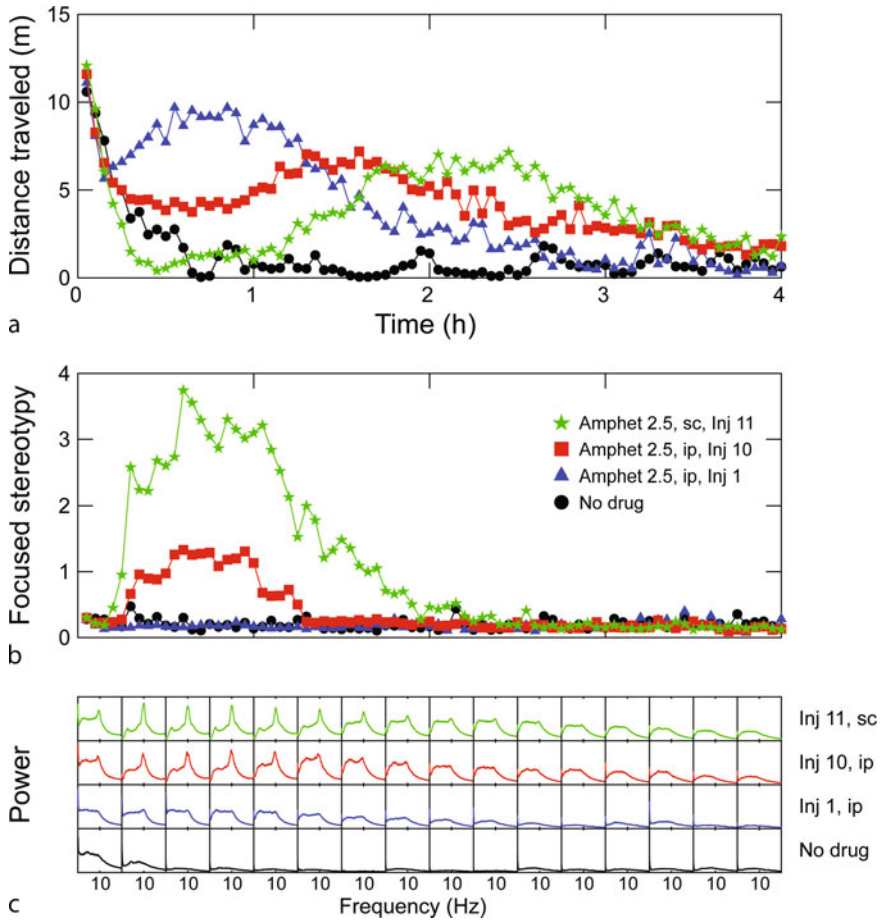
In male Sprague Dawley rats, the first experience with a 2.5 mg/kg, ip, dose of amphetamine will induce an increase in locomotor activity in a large majority of the subjects compared to the untreated controls (see Fig. 2).



Motor Activity and Stereotypy. Fig. 1. Effect of d-amphetamine sulfate on locomotor activity in two separate groups (n=8) of male Sprague Dawley rats. The amphetamine was injected intraperitoneally a few seconds before the rats were individually placed in a dark force-plate actometer for a 1-h recording session. Data are based on the rats' first exposures to the apparatus. The saline group exhibited habituation during the first 40 min, and distance traveled remained low for the remainder of the hour. Compared to the saline group, the amphetamine-treated rats showed hyperactivity throughout the hour. Over the entire hour the saline group mean distance traveled was 59.71 m (s.e.m. 7.23 m), and the amphetamine-treated group traveled 133.51 m (s.e.m. 6.59 m).

However, when given repeatedly, the same dose of amphetamine predominantly evokes, a syndrome characterized by an absence of locomotion accompanied by rapid head movements that have been described as "sniffing" and/or "head bobbing". This syndrome is focused stereotypy or the "stationary phase" of the amphetamine response, and it has been observed in observation arenas as large as 3.0 m × 3.5 m (Schiorring 1971).

The focused stereotypy score in Fig. 2 was calculated by combining a quantitative measure of spatial confinement with the variance of vertical force variation within the boundaries of the space used (see Fowler et al. 2007a for details). This score is low for a sleeping animal (high spatial confinement but low force variance because of a lack of "in-place" movements). The focused stereotypy score is also low when spatial confinement is low (movements are dispersed across the floor), despite the presence of high force variance associated with ambulation. When spatial confinement is pronounced and force variance is also high, a high focused stereotypy score is obtained. In Fig. 2, the switch from first-dose locomotor stimulation to tenth-dose substantial focused stereotypy (Fig. 2, panel b) can be appreciated by comparing the distance traveled data of Injection 1 (panel a, triangles) with the same measure for Injection 10 (panel a, squares), during the second 30 min of the session. Correspondingly, during the same time period, the focused stereotypy scores after Injection 1 were near zero, but averaged higher than 1 after Injection 10. This change in response topography from locomotion to stationarity and focused stereotypy is the result of a ► sensitization process, whereby rats become more sensitive to amphetamine or other psychomotor stimulants as repeated dosing ensues. After injection 10, distance traveled (see Fig. 2, panel a, squares) did not drop to no-drug levels because three rats did not make a complete switch to focused stereotypy and continued to display substantial locomotor activation. However, all but one of the eight rats after the tenth injection showed a *decrease* in distance traveled compared to Injection 1. The aberrant rat actually exhibited evidence of sensitization of locomotor response, as suggested by its 67.9% *increase* in distance traveled between injection 1 and 10. Two important points can be made from these observations: (1) Individual differences in response to drugs are to be expected, especially when genetically heterogenous outbred strains of rats are used, and (2) when amphetamine or similar drugs are under study, at doses near the threshold for expression of focused stereotypy, the observed behavioral effect may be in opposite directions, with a subset of rats showing increased locomotor activity and another subset exhibiting locomotor suppression.



Motor Activity and Stereotypy. Fig. 2. Measures from a force-plate actometer showing how the behavioral effects of d-amphetamine sulfate at 2.5 mg/kg depends on time after treatment, amount of experience with the drug, and the route of administration. After experiencing a 4-h habituation session (black circles, panels a and b), in subsequent sessions eight male Sprague Dawley rats received injections (Inj) of amphetamine eleven times, 3–4 days apart. The first ten injections were given ip, and the 11th injection (green stars) was administered sc in the same volume and dose as the previous ip injections. Panel (**a**) shows distance traveled for successive 3-min periods in the 4-h recording session. In panel (**b**) are plotted, also in 3-min intervals, group mean focused stereotypy scores for the indicated treatment conditions. Panel (**c**) shows the group mean power spectra of the vertical force variations over 15-min periods for the same treatments. The distinctive spectral peaks near 10-hz in the red and green power spectra reflect the rhythm of the head movements of focused stereotypy.

Another important point is that a univariate (i.e., single-dependent-variable method such as distance traveled) approach to behavioral pharmacology with ▶ indirect-acting dopamine agonists can easily lead to erroneous interpretations of a drug's effects. For example, if one did not have a stereotypy score (Figure 2, panel b) and relied only on the distance traveled information (Figure 2, panel a), one may erroneously conclude that, between Injection 1 and Injection 10, ▶ tolerance (decrease in distance traveled) had occurred instead of sensitization.

Effect of Route of Administration on Focused Stereotypy

An 11th injection of 2.5 mg/kg amphetamine was given, but this injection was by the subcutaneous route (sc). Figure 2 (panels a and b, stars) shows that changing the route of administration from ip to sc intensified and lengthened the expression of focused stereotypy. Gentry et al. (2004) also found more pronounced focused stereotypy for 3.0 mg/kg sc ▶ methamphetamine compared to the same dose given ip. The group mean increase in

focused stereotypy after the sc injection resulted from (1) a recruitment of the three previously low-stereotypy rats to full stereotypy and (2) all five rats that were already expressing focused stereotypy had higher scores after sc amphetamine treatment compared to the previous ip treatment with the same dose. ► Pharmacokinetic studies (Gentry et al. 2004) have shown that sc compared with ip amphetamine in male Sprague Dawley rats reaches a lower peak blood concentration, takes longer to reach its peak, and is eliminated more slowly (i.e., longer duration of action). Thus, the pharmacokinetic data indicating a longer duration of action for sc compared to ip administration of amphetamine are consistent with the behavioral data shown in Fig. 2 (in panels a and b, compare behavioral measures for injections 10 and 11). However, neither the reported pharmacokinetic time-to-peak nor peak level achieved is in accord with the behavioral data. In Fig. 2 (panel b), focused stereotypy scores began to rise earlier in the session for the sc injection than for the ip injection (opposite the pharmacokinetic later rise in concentration), and the sc-related focused stereotypy scores reached a substantially higher level than those seen for the ip injection (again, opposite the lower pharmacokinetic peak for sc dosing). While no explanation is yet available for this difference in the stereotypy-evoking efficacy of the ip and sc injection methods, the empirical data show that route of administration can substantially influence the focused-stereotypy-inducing effects of amphetamine.

Rhythmicity of Head Movements During Focused Stereotypy

During the expression of amphetamine-induced focused stereotypy, not only are the head movements observably repetitive they are also strongly rhythmic (Fowler et al. 2001; Fowler et al. 2007a). Application of signal processing techniques, such as ► power spectral analysis, to a rat's variations in vertical force recorded with a force-plate actometer shows that the head movements of focused stereotypy have a tightly regulated rhythm near 10 Hz (Hz=cycles/s). Panel c in Fig. 2 presents group mean power spectra that were calculated for each 15 min interval in the 4-h session. Once the expression of focused stereotypy begins in male Sprague Dawley rats, the near 10-Hz rhythm can be continuously sustained for an hour or more (see Fig. 2, panel c, top row of functions, frames 2, 3, 4, and 5 from left to right). The near 10-Hz rhythm has been recorded in rats separately treated with four different indirect-acting dopamine agonists: amphetamine, ► nomifensine, ► methylphenidate, and cocaine. The precision of rhythm regulation in rats expressing focused stereotypy rivals or exceeds that of consummatory licking (7.0 Hz), hindlimb scratching behind the ear (8.0 Hz), within-bout vibrissal whisking (e.g., 7.0 Hz), or grooming (forepaws/face/head: 7.2 Hz; flank-licking: 3.6 Hz). The existence of these species-typical rhythmic reflexes invite the conjecture that the head-movement rhythm of amphetamine focused stereotypy is also reflexive. Both the atypical ► antipsychotic drug, ► clozapine, and the α-1 noradrenergic antagonist, ► prazosin, have been shown to slow the head-movement rhythm of amphetamine-induced focused stereotypy without abolishing the overall syndrome (Fowler et al. 2007a). The frank ► rhythmicity of amphetamine-induced head movements adds a new measurable dimension to the focused stereotypy response, and experimental analyzes of rhythm production and modulation may provide insights into the neurotransmitter systems and neuroanatomical loci that mediate drug-induced stereotypy.

Locomotor Activity and Stereotypy in ► Drug Self-Administration Experiments

Measurements of locomotor activity and stereotypy in rodents have been used in drug-self-administration research in at least two different ways. One way exemplified by the work of Piazza et al. (1989), used the locomotor activity response to a novel environment (i.e., a 170-cm perimeter, 10-cm wide circular track with photobeams to detect the rats' locomotion) to analyze individual differences in rats' susceptibility to acquiring amphetamine self-administration later in another environment. Piazza et al. (1989) found that rats with a relatively low level of locomotor response to novelty did not acquire the amphetamine self-administration nose-poke response, while those rats exhibiting higher amount of locomotor activity acquired the response. This rodent-based experiment was one of the first to suggest that behavioral response to novelty and susceptibility to drug-abuse-like behaviors are correlated. A second way that locomotor activity and stereotypy have been combined with self-administration research is illustrated by an experiment that used a force-plate actometer as the floor of a self-administration chamber where five lever-presses by rats resulted in an intravenous cocaine infusion in a 24-h "binge" session (Fowler et al. 2007b). The work provided measures of rotational behavior ("circling in the same direction"), distance traveled, power spectra of the vertical force of movements (as in panel c of Fig. 2), and focused stereotypy in order to determine whether or not self-administered cocaine produced the same kind of unconditioned behaviors that are elicited by noncontingently administered bolus doses of cocaine. The results showed that all six

rats displayed behaviors typical of noncontingently administered ▶ bolus doses. The average duration of active cocaine intake was 14.7 h (±1.8 h). During this time, rats rotated in the same direction an average of 1206.5 (±372.7) times, traveled an average of 914.6 m (±65.9 m), and exhibited a power spectral peak near 10 Hz during 32.0% (±8.4%) of the active binge duration. These data show that locomotor activity and focused stereotypy are major behavioral manifestations of self-administered cocaine and raise the possibility that unconditioned behaviors evoked by indirect-acting dopamine agonists contribute to the reinforcing effects of psychomotor stimulant drugs.

Differences in Expression of Stimulant-Induced Behaviors in Rats and Mice

Although it is difficult to offer accurate generalizations that are valid for all strains of rats or mice, mice tend to move more than rats, and mice tend to have shallower locomotor activity habituation functions than rats. Response topographies of stimulant-induced stereotypies of rats and mice have similarities and differences. Generally, amphetamine and other indirect-acting dopamine agonists, in sufficient doses, evoke some degree of spatial confinement in both rats and mice. Also, after very high doses of these drugs, most types of laboratory rats and mice exhibit self-injury (usually biting the dorsal wrist area sufficiently to cause bleeding and exposure of subcutaneous structures). Despite these similarities, the topography of the focused stereotypies in rats and mice can be very different in appearance. For example, while rats exhibit a complete and enduring arrest of locomotion during focused stereotypy, mice tend to retain a substantial locomotor component in their stereotypy response. Typically, mice observed in force-plate actometers do not display the narrow-band head-movement rhythm, characteristic of the rat response to a 5.0 mg/kg dose of amphetamine. Different stereotypy topographies in mice and rats make it difficult if not impossible to devise a rating scale that can be used to quantify stereotypies equally well in both species. Comparing stereotypies in rats and mice is further hindered by the heterogeneity among inbred strains of mice in their responses to amphetamine and other psychomotor stimulants. For example, BALB/cJ mice show a low-dose *decrease* in their locomotor activity response to 1.0 mg/kg amphetamine, and at a higher dose of 10.0 mg/kg, BALB/cJ mice exhibit vertical leaping ("popping") behavior. C57BL/6J, DBA/2J, 129SvJ, and C3H/HeJ mice exhibit neither low-dose suppression of locomotor activity nor higher-dose vertical leaping behavior.

Neurobehavioral Interpretations and Clinical Importance of Stereotypy

Stereotyped behaviors are generally thought to reflect the dysfunction of the central nervous system (Robbins et al. 1990; Teitelbaum et al. 1990). Persons with mental retardation, autism, schizophrenia, Tourette's syndrome, Huntington's disease, or obsessive compulsive disorder (OCD) often exhibit excessively repetitious and apparently purposeless behaviors as do persons who have used excessive amounts of amphetamine over multi-day periods. Substantial clinical and experimental evidence points to ▶ dopamine as the brain neurotransmitter with a major role in the expression of stereotyped behavior in the aforementioned clinical abnormalities. In rodent studies of the behavioral effects of psychomotor stimulants, links have been established between dopaminergically innervated subcortical structures and expression of increased locomotor activation and stereotypy induction. Dopamine agonists are thought to induce locomotor activity by acting on the ▶ nucleus accumbens, while actions of the drugs on the caudate/putamen are believed to be critical for the expression of focused stereotypy. In the clinic, dopamine receptor-blocking drugs (e.g., the antipsychotic drug ▶ haloperidol) can be effective in suppressing the spontaneously occurring stereotypies, such as hand flapping, in persons with autism. In the laboratory, most, but not all, antipsychotic drugs can block the expression of amphetamine-induced focused stereotypy. Although a massive amount of empirical evidence implicates a role for dopamine in the evocation of locomotor activity and the expression of stereotyped behavior, much remains to be discovered about dopamine's interaction with a multiplicity of other neurotransmitters (e.g., glutamate, GABA, acetylcholine, serotonin, neuropeptides) and their receptors in the nucleus accumbens, caudate/putamen, and elsewhere in the brain. Given the large number of drug targets located in these brain regions, the measurement of pharmacologically induced locomotor activity and stereotypy is likely to continue to be important in the conduct of psychopharmacology research for many decades to come.

Movement Disorders Induced by Medications

Thomas R. E. Barnes
Department of Psychological Medicine, Imperial College, London, UK

Synonyms

Antipsychotic-induced movement disorders; drug-induced motor syndromes; EPS; Extrapyramidal side effects

Definition

Discussion of medication-induced movement disorder generally refers to the side effects of ► antipsychotic medication which affect motor behavior. However, other drugs, such as lithium, valproate, antidepressants, and psychostimulants like amphetamine, can cause movement problems, principally tremor. Patients developing antipsychotic drug-induced movement disorders exhibit a range of neurological phenomena: ► dyskinesia, ► dystonia, parkinsonian features including bradykinesia, tremor and rigidity, and restless movements as part of antipsychotic-induced akathisia. While some motor syndromes such as parkinsonism, acute dystonia, and acute akathisia are more common during acute drug treatment, others

such as tardive dyskinesia, tardive dystonia, and chronic akathisia are more common with long-term treatment. The motor phenomena exhibited by those developing these disorders can cause functional impairment and be socially stigmatizing; and parkinsonism, akathisia, and dystonia also have mental manifestations that can be unpleasant and distressing (Owens 1999). Further, the disorders can confound clinical assessment of the psychotic illness. For example, features of parkinsonism such as bradykinesia overlap phenomenologically with symptoms of depression and negative symptoms, while akathisia may be misdiagnosed as anxiety or an exacerbation of psychotic symptoms.

Role of Pharmacotherapy

The four main diagnostic categories of ► extrapyramidal side effects (EPS) associated with antipsychotic medication are ► parkinsonism, ► akathisia, ► dystonia, and ► tardive dyskinesia. The pathophysiology of these movement disorders involves the dopamine D2 receptor-blocking properties of antipsychotic drugs. However, it should be noted that both parkinsonism and dyskinesia are observed in antipsychotic-naive patients with first-episode psychoses, suggesting that such movements reflect a neuro-dysfunction intrinsic to the pathophysiology of schizophrenia (Pappa and Dazzan 2009). While EPS were relatively common with the ► first-generation antipsychotics (FGAs: such as chlorpromazine, fluphenazine, haloperidol, and trifluoperazine), one of the main claims for ► second-generation antipsychotics (SGAs: such as aripiprazole, clozapine, olanzapine, quetiapine, and risperidone) has been a lower risk of developing such disorders, although the individual SGAs vary in their liability for EPS burden. Clinical trials and ► meta-analyses (Leucht et al. 2003) suggest that while SGAs have a lower liability for acute EPS and tardive dyskinesia when compared with haloperidol, even at low dosage, the evidence that this is the case in relation to other FGAs in moderate dosage is less convincing. Further, the common use of high dose or combined SGAs, or combined SGAs and FGAs, in clinical practice may compromise any such advantage. Parkinsonism and akathisia remain major problems despite the widespread use of SGAs. With regard to tardive dyskinesia, the evidence suggests a lower risk with SGAs (Correll and Schenk 2008), but prospective, longitudinal studies of SGAs as monotherapy are required to quantify the risks of tardive dyskinesia with particular drugs.

Parkinsonism

Antipsychotic-induced parkinsonism (sometimes called "pseudoparkinsonism") usually occurs within days of beginning antipsychotic treatment or after a dosage increase. It comprises a triad of bradykinesia, rigidity, and tremor. Bradykinesia is probably the core feature, and manifests itself as difficulty with the initiation of movements and slowness and interruption of the normal flow of movement. When tested by passive movement of the limbs, muscle rigidity may be revealed as being of the lead-pipe (i.e., stiffness that is uniform throughout the range of movement) or cogwheel (i.e., a ratchet-like resistance) type. Other clinical signs include a mask-like expression, lack of spontaneous gesture, and a reduction in the normal arm swing when walking. Subjectively, patients experience slowed thinking ("bradyphrenia"), fatigue, weakness and stiffness, and sometimes apathy, and diminished interest and initiative. There is some evidence that the development of parkinsonism may indicate an increased risk of developing tardive dyskinesia later.

While drug-induced parkinsonism mimics idiopathic ► Parkinson's disease, it is rather more an akinetic rigid syndrome, with the classical resting tremor being relatively uncommon. Nevertheless, the coincidental onset of idiopathic Parkinson's disease should be borne in mind as a differential diagnosis, and if this is suspected because of the nature of the clinical presentation, or because the signs and symptoms prove to be persistent after antipsychotic discontinuation, a neurology referral may be indicated.

Treatment options include reduction of the dose of the causal, or suspected, antipsychotic, or switching to another with evidence for a lower risk of parkinsonism. Prescription of an ► antimuscarinic agent (also called ► anticholinergic or antiparkinsonian) may be useful (Barnes and McPhillips 1996). The anticholinergic agents most commonly used are as follows:

► Benzatropine (benztropine) mesylate –0.5–6 mg/day by mouth in one to two divided doses; can be sedative so if one dose is greater, administered at bedtime. Tablets are not available in the United Kingdom.

► Trihexyphenidyl hydrochloride (benzhexol hydrochloride) –1–2 mg daily, increased gradually; usual maintenance dose 5–15 mg daily in three to four divided doses, to a maximum of 20 mg daily.

► Orphenadrine hydrochloride –150 mg a day by mouth in divided doses initially, titrated slowly upwards if necessary. Usual dose range is 150–300 mg daily in divided doses.

► Procyclidine hydrochloride –2.5–5 mg by mouth up to three times a day initially, titrated slowly upwards if necessary. Usual maximum is 30 mg a day in divided doses.

Biperiden –2 mg by mouth, one to two times a day.

Anticholinergic drug prescription should be regularly reviewed, partly because parkinsonism can wane

spontaneously, and after 3 months or so there may no longer be a need for such treatment, and partly because antimuscarinic drugs are associated with their own unwanted effects such as blurred vision, headaches, dry mouth, increased heart rate, difficulty in urinating and constipation, as well as confusion and disorientation, inability to concentrate, and memory impairment. The elderly are at greater risk of anticholinergic side effects.

Akathisia

► Akathisia is characterized by a subjective feeling of inner restlessness and objectively by increased restless movement (Barnes 1992). These movements are not dyskinetic (involuntary, repetitive movements) but rather resemble normal patterns of restless movement. Most typically, they involve the legs, for example, walking on the spot, pacing around, or shuffling and tramping of the legs when sitting. When required to sit or stand still, patients can experience a mounting sense of tension and a compulsive desire to move in an attempt to gain some respite. The clinical significance of akathisia relates not only to the subjective dysphoria and unease experienced, but also its adverse influence on medication adherence, and its status, like parkinsonism, as a possible risk factor for tardive dyskinesia.

Treatment options include reduction of the dose of the causal antipsychotic, or switching to another with evidence for a lower risk of akathisia. Low-dose ► propranolol (initially 20 mg bd) or other lipophilic beta-blockers, an anticholinergic drug (e.g., procyclidine, see above), or a ► benzodiazepine (e.g., diazepam 2–4 mg tds) may be helpful. The evidence base for such interventions is limited, though strongest for propranolol or other lipophilic beta-blockers (Miller and Fleischhacker 2000). Note that the beta-blockers are contraindicated in those with asthma or peripheral vascular disease. Taylor et al. (2007) also cite evidence for a possible reduction in symptoms with low-dose ► clonazepam, diphenhydramine (an antihistamine), and $5HT_2$ antagonists such as cyproheptadine, ► mirtazapine, ► trazodone, and ► mianserin.

Dystonia

► Dystonia is defined as sustained muscle contractions causing twisting and repetitive movements or abnormal postures, which can be painful. Acute dystonia usually occurs early in drug treatment and is short-lived, although it can be distressing and frightening. It can also occur as an antipsychotic drug-withdrawal phenomenon. Tardive dystonia occurs late in the treatment, tends to be persistent, and in severe cases can be disabling and disfiguring. The neck, and jaw and tongue are the most common sites to be affected by the muscle spasms, but trunk and limbs can also be involved.

With regard to *treatment options for acute dystonia*, the intervention of choice is an anticholinergic drug (Barnes and McPhillips 1996), for example, procyclidine (see above for oral administration if symptoms are mild. Also by intramuscular or intravenous injection as an emergency treatment for acute drug-induced dystonia, 5–10 mg), benzatropine (see above for oral administration if symptoms are mild, but this drug may also be given intramuscularly or even intravenously as an emergency treatment for acute drug-induced dystonia: 1–2 mg repeated if symptoms reappear, to a maximum of 6 mg daily), orphenadrine (see above for oral administration if symptoms are mild), or trihexyphenidyl hydrochloride (see above for oral administration). Patients may be given an oral antimuscarinic drug to take prn ("as required") should there be any signs of recurrence within the next few days. Other drug treatments advocated include antihistamines, such as diphenhydramine and benzodiazepines, such as ► diazepam (Owens 1999).

With regard to *treatment options for tardive dystonia*, clinicians should first consider the differential diagnosis, including ► idiopathic torsion dystonia or secondary dystonia associated with conditions such as ► Huntington's disease or Wilson's disease. Further, there is some overlap with the features of tardive dyskinesia, with which tardive dystonia may coexist. The most common phenomena are sustained, forced, involuntary closing of the eyelids (blepharospasm), twisting of the neck to one side (torticollis) or drawing the head back (retrocollis), and involvement of the laryngeal and pharyngeal muscles affecting speech and swallowing.

The condition can be hard to treat. Withdrawal of antipsychotic medication is not usually a realistic clinical option for people with an established psychotic illness. Switching to an antipsychotic with a lower liability for EPS may be helpful in a proportion of cases over time, and the best evidence is for clozapine. There are also several specific drug treatments that may be beneficial:

Dopamine-depleting agents (► tetrabenazine, ► reserpine) are used in low dose, and have a reasonable evidence base to support their efficacy. They have a range of potentially unpleasant side effects including drowsiness, parkinsonism, depression, and orthostatic hypotension, although tetrabenazine has a lower side-effect burden than reserpine.

There is evidence for benefit with anticholinergic agents, sometimes in high dosage, although the relevant studies have yielded mixed results, and use of these drugs runs the risk of exacerbating any co-existing tardive dyskinesia.

Benzodiazepines (such as clonazepam), which have muscle relaxant properties, are also commonly used.

For focal tardive dystonia which has not responded to standard measures, local injection of botulinum A toxin into the affected muscle by a neurologist with experience of the technique may be effective.

Tardive Dyskinesia

► Tardive dyskinesia is a syndrome of abnormal involuntary movements, repetitive and stereotypic in nature and commonly referred to as choreiform (i.e., rapid, jerky). The condition usually appears late in the course of treatment, and is partly related to advancing age and possibly the psychotic illness for which the antipsychotic medication is prescribed. Tardive dyskinesia most commonly affects the oro-facial muscles; characteristically a combination of movements is observed, including chewing, tongue twisting and protrusion, and lip smacking and puckering. But virtually all parts of the body can be involved including the trunk and limbs, and respiratory muscles. The condition is most pronounced when patients are aroused and tends to ease during states of relaxation. The abnormal involuntary movements of tardive dyskinesia can result in considerable social and physical disability, although patients are usually unaware of them.

Treatment options include reducing the dosage of the antipsychotic or switching to an SGA with evidence for a low liability for tardive dyskinesia, particularly if the patient has been receiving an FGA. Limited data from small studies do not provide convincing evidence of the value of these approaches (Soares-Weiser and Rathbone 2005), but clozapine is probably the antipsychotic most likely to diminish dyskinetic movements in patients with existing tardive dyskinesia. Discontinuing antimuscarinic agents may also be a worthwhile therapeutic option, given the evidence that such drugs can worsen tardive dyskinesia, but the available evidence does not allow for any confident statement on the likely effects of such a strategy.

A range of other potential anti-dyskinetics have been tested (Owens 1999; Taylor et al. 2007), including dopamine depleters (e.g., tetrabenazine, reserpine, oxypertine), cholinomimetic agents (e.g., choline, lecithin, deanol), GABA agonists (e.g., sodium ► valproate, gamma-vinyl GABA), calcium channel blockers (e.g., diltiazem, verapamil), and vitamin E (alpha-tocopherol). But none has the strength of evidence for efficacy or data on adverse effects that would allow for a clinical recommendation as a treatment for tardive dyskinesia (Soares and McGrath 1999).

MR Image Analysis

Definition

Unlike, for example, X-ray or computer tomography (CT), MR images usually do not provide absolute values of MR contrast parameters, as such measurements are

accompanied with long acquisition times that are not acceptable in clinical applications. For this reason, MR quantification is mostly based on relative measurements in comparison to a defined reference such as baseline data acquired under normal or resting conditions, or data derived from a healthy control group.

In functional MRI, small and relative signal changes caused by the hemodynamic response to changes in neuronal activity are assessed. Sophisticated analysis methods are essential to detect these small changes ranging from approaches that incorporate prior knowledge from the stimulation paradigm applied to solely data-driven or exploratory methods.

Muscarinic Cholinergic Receptor Agonists and Antagonists

Michael E. Ragozzino, Holden D. Brown
Department of Psychology, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

Muscarinic agonists; Muscarinic antagonists

Definition

Muscarinic acetylcholine receptors represent one of the two classes of receptors that mediate the actions of acetylcholine in the nervous system and certain body parts. Muscarinic acetylcholine receptors were so named owing to their greater sensitivity to ► muscarine over ► nicotine. Muscarinic agonists activate and antagonists block, muscarinic acetylcholine receptors at an orthosteric or ► allosteric site.

Pharmacological Properties

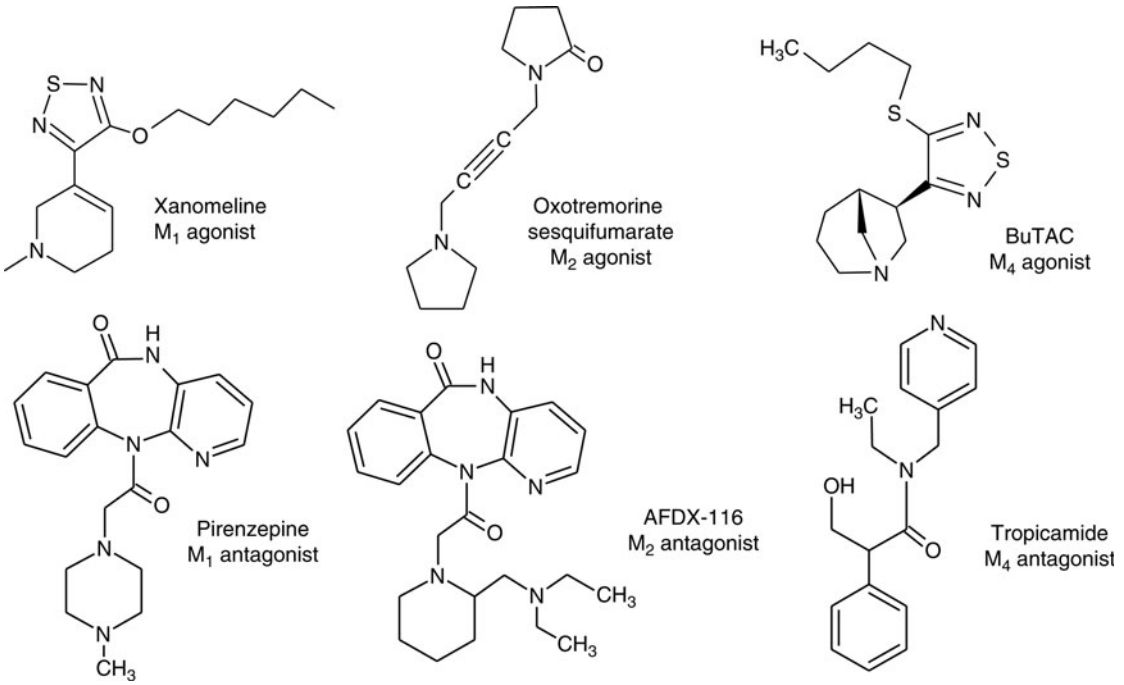
Muscarinic cholinergic receptors are ► G-protein coupled receptors that are ubiquitously expressed in the central nervous system. There are different muscarinic receptor subtypes referred to as M_1–M_5, when a receptor subtype is described based on pharmacology, and m_1–m_5, when based on their molecular properties. The M_1, M_3, and M_5 muscarinic receptor subtypes are coupled with G_q proteins resulting in the mobilization of intracellular calcium. The M_2 and M_4 muscarinic receptor subtypes are linked to G_o proteins with the activation of these receptors producing a decrease of intracellular cyclic AMP. Antibodies specific to the muscarinic acetylcholine receptor proteins indicate that the m_1, m_2, and m_4 receptors are most abundant in the brain (Levey et al. 1991). The m_1 receptor is most concentrated in the neocortex, ► hippocampus, ► striatum, and ► amygdala. These receptors are found to be postsynaptic. The m_2 receptor is most abundant in the basal forebrain, thalamus, neocortex, and striatum. These receptors are located on cholinergic terminals and are also located postsynaptically. The m_4 receptor has its highest density in the striatum and hippocampus. These receptors are found postsynaptically, as well as presynaptically, on cholinergic neurons. The m_3 and m_5 receptors are sparser in the brain, with the m_3 receptor being the most common in the neocortex, thalamus, and hippocampus, while the highest density of m_5 receptors is located in the substantia nigra. It appears that these receptors are present postsynaptically.

The identification of different muscarinic receptor subtypes has led to interest in developing muscarinic agonists and antagonists that target a specific type of muscarinic receptor. The development of selective receptor subtype compounds arises in part to understand the function(s) of muscarinic acetylcholine receptor subtypes. This work has been carried out predominantly in animal models. Interest in the development of drugs that target specific muscarinic receptors has also emerged because various neurodegenerative and psychiatric disorders have shown alterations in specific muscarinic acetylcholine receptor subtypes.

The effects of muscarinic agonists and antagonists that prefer one type of muscarinic acetylcholine receptor to the other subtypes are described in the following text. The focus is on M_1, M_2, and M_4-preferring drugs because most compounds developed preferentially act at these muscarinic receptor subtypes (see Fig. 1).

M_1 Muscarinic Receptor-Preferring Drugs

There has been considerable effort in the development of pharmacological agents that selectively act at the M_1 muscarinic acetylcholine receptor, in particular M_1 muscarinic agonists. This is, in large part, because of studies indicating that M_1 muscarinic acetylcholine receptors are altered in ► Alzheimer's disease and ► schizophrenia (Langmead et al. 2008). Both of these conditions are marked by cognitive deficits and thus there has been an



Muscarinic Cholinergic Receptor Agonists and Antagonists. Fig. 1. Chemical structures of muscarinic M_1, M_2 and M_4 agonists and antagonists.

interest in developing selective M_1 muscarinic agonists to alleviate the cognitive deficits in these conditions. A recent double-blind placebo-control study using xanomeline, a muscarinic M1-preferring agonist, in schizophrenic patients showed significant improvement in overall positive and negative symptom ratings, along with enhanced verbal learning with only mild side effects (Shekhar et al. 2008). Several M_1 muscarinic-preferring agonists have been developed, which have shown learning and memory benefits in animal models, but overall, have not fared as well in clinical trials (Langmead et al. 2008). This is likely due to the lack of high selectivity for the M_1 muscarinic acetylcholine receptor leading to the activation of other muscarinic receptor subtypes and unwanted side effects, e.g., nausea, diarrhea, sweating, and salivation.

Some of the strongest evidence suggesting that M_1 muscarinic receptors support learning and memory comes from experiments examining the effects of M_1 muscarinic-preferring antagonists in animal models. For example, systemic administration of M_1-preferring receptor antagonist, dicyclomine impairs both learning and memory in a variety of behavioral paradigms. Infusions of the M_1-preferring antagonist pirenzepine into specific brain regions of the rodent impair learning or memory (Tzavos et al. 2004). Taken together, several experiments indicate that the blockade of M_1 muscarinic acetylcholine receptors in various brain areas impairs learning and memory indicating that M_1 muscarinic acetylcholine receptors may support several forms of learning and memory.

A main limitation of compounds such as pirenzepine and dicylomine is that they do not exhibit a strong selectivity for M_1 muscarinic receptors compared to the other muscarinic receptor subtypes. Another approach to studying muscarinic receptor activity is through the use of snake toxins that bind to specific muscarinic receptor subtypes. Muscarinic-toxin 7 (MT-7) is one such compound that exhibits greater selectivity for the M_1 muscarinic receptor over other subtypes. Because MT-7 acts as a more selective M_1 muscarinic receptor antagonist compared to that of pirenzepine and dicyclomine, it has been used to study the role of M_1 muscarinic receptors in learning. A recent experiment demonstrated that injections of MT-7 into the rodent dorsomedial striatum does not affect the initial learning of a spatial discrimination, but specifically impairs spatial reversal learning (McCool et al. 2008). Thus, the results from the blockade of M_1 muscarinic receptors indicate that this muscarinic receptor subtype is important for learning, memory, and behavioral flexibility.

Consistent with numerous studies demonstrating that compounds which preferentially block M_1 muscarinic receptors impair learning and memory, treatment with M_1 muscarinic-preferring agonists have shown to facilitate learning and memory. The drug, McN-A-343, is often considered to be a M_1 muscarinic-preferring agonist. Although there is limited muscarinic receptor subtype selectivity for this drug, there is evidence that the drug enhances spatial working memory.

There are several M_1 muscarinic agonists that have been reported to have cognitive benefits in preclinical tests. Furthermore, the activation of M_1 muscarinic acetylcholine receptors may have neuroprotective effects by reducing the amyloid-beta peptide and tau protein associated with plaques and neurofibrillary tangles, respectively. However, M1-preferring agonists have failed or led to significant side effects in clinical trials. Xanolemine, talsaclidine, and WAY 132983 are all examples of compounds that have shown to have pro-cognitive benefits but led to unwanted side effects. The limitations of these drugs that act at the ► orthosteric site of the M_1 muscarinic acetylcholine receptor, likely results because these agents do not display a strong selectivity for the M_1 muscarinic acetylcholine receptor compared to the other muscarinic receptor subtypes.

A new generation of M_1 muscarinic agonists are being developed that act at the allosteric site of the M_1 muscarinic acetylcholine receptor (Langmead et al. 2008). These newer compounds hold further promise for clinical effectiveness because the allosteric binding site for agonists does not seem conserved among the other muscarinic acetylcholine receptor subytpes. Thus, the development of selective allosteric agonists at the M_1 receptor site may be effective in reducing cognitive deficits while minimizing unwanted side effects.

M_2 Muscarinic Receptor-Preferring Drugs

Another pharmacological approach to modify brain cholinergic activity has been through M_2 muscarinic acetylcholine receptors. Some M_2 muscarinic acetylcholine receptors are found to be heteroreceptors in different brain regions. However, many M_2 receptors act as autoreceptors providing negative feedback at cholinergic terminals. The localization of M_2 muscarinic acetylcholine receptors on cholinergic neuron terminals has led to the examination of M_2-preferring antagonists on brain acetylcholine activity and cognitive function. In particular, M_2-preferring antagonists enhance brain acetylcholine efflux as measured by *in vivo* ► microdialysis (Ragozzino et al. 2009). Furthermore, the administration of M_2-preferring antagonists such as SCH 72788, BIBN99, AF-DX 116, or methoctramine given either systemically or centrally improve memory ► consolidation, as well as ► working memory on a variety of tasks (Lazaris et al. 2003). To provide more direct evidence that changes in acetylcholine output are related to learning, a study demonstrated that the infusion of the M_2-preferring agonist, oxotremorine sesquifumarate, into the dorsomedial striatum simultaneously blocked a behaviorally induced increase in striatal acetylcholine output and impaired reversal learning. These effects were reversed by the M_2-preferring antagonist, AF-DX 116. Thus, the blockade of M_2 muscarinic acetylcholine receptors can provide a mechanism for modulating brain acetylcholine release and cognitive functioning (Ragozzino et al. 2009).

The clinical use of M_2 muscarinic acetylcholine receptor antagonists is suggested in diseases involving cholinergic degeneration and cognitive impairment, such as ► Alzheimer's disease (Langmead et al. 2008). A number of compounds have been developed that exhibit significant selectivity for the M_2 muscarinic acetylcholine receptor. One of the serious drawbacks about using a M_2 muscarinic antagonist as a drug therapy is that M_2 muscarinic receptors are located in the heart where they slow heart rate. Thus, treatment with a M_2 muscarinic antagonist can lead to tachycardia.

M_4 Muscarinic Receptor-Preferring Drugs

The M_4 muscarinic acetylcholine receptor is another muscarinic acetylcholine receptor subtype in which there is significant interest in developing selective agents to generate novel treatments for both ► schizophrenia and ► Parkinson's disease. Despite interest in the M_4 muscarinic acetylcholine receptor, there are a relative lack of compounds that are highly selective for this muscarinic receptor subtype. Comparable to developing new targets for the M_1 muscarinic receptor, the development of positive allosteric modulators for the M_4 muscarinic receptor holds promise in generating novel treatments for various disorders and diseases.

Interest in the M_4 muscarinic acetylcholine receptor related to schizophrenia has evolved from findings indicating hyperactivity of the neurotransmitter dopamine in the striatum is observed in schizophrenia (Langmead et al. 2008). Moreover, the activation of M_4 muscarinic acetylcholine receptors may inhibit striatal dopamine efflux. PTAC and BuTAC are two compounds that are M_4-preferring agonists. These drugs have shown to reduce apomorphine-induced ► prepulse inhibition (Jones et al. 2005), a paradigm commonly used to screen the effectiveness of antipsychotic drugs. As with many other muscarinic agonists, these drugs do not display a strong selectivity for the M_4 muscarinic acetylcholine receptor (Langmead et al.

2008). Therefore, there is a real possibility of producing unwanted side effects with such treatments.

Interest in the M_4 muscarinic acetylcholine receptor related to ► Parkinson's disease is also related to dopaminergic–cholinergic interactions in the striatum. Owing to the reduced striatal dopamine activity in Parkinson's disease, treatment with a M_4 muscarinic acetylcholine receptor antagonist may have benefits in enhancing dopaminergic transmission and reducing symptoms in the disease. In support of that idea, tropicamide, a muscarinic acetylcholine receptor antagonist with moderate binding selectivity for the M_4 muscarinic acetylcholine receptor subtype, suppresses tremulous jaw movements in rats, a model of Parkinson's disease, without significant impairment on memory tasks (Betz et al. 2007). Several other compounds that have a high affinity for the M_4 muscarinic acetylcholine receptor and show selectivity over other muscarinic acetylcholine receptor subtypes may prove beneficial in the treatment of Parkinson's disease (Böhme et al. 2002).

Conclusions

Muscarinic acetylcholine receptors are found throughout the central nervous system. There are various neurodegenerative disorders, as well as psychiatric disorders that exhibit abnormalities in muscarinic acetylcholine receptor function. These various diseases and disorders often exhibit altered muscarinic acetylcholine receptor function for specific muscarinic receptor subtypes. Thus, the development of compounds that are selective for the different muscarinic receptor subtypes provides an opportunity for novel treatments that can reduce severe impairments in cognitive or motor functioning.

Muscarinic Receptors

Synonyms

mAChR

Definition

► G-protein-coupled acetylcholine receptors found in the plasma membranes of certain neurons and other cells. They play several roles, including acting as the main end receptor stimulated by acetylcholine released from postganglionic fibers in the parasympathetic nervous system.

Mutant

► Transgenic Organism

Mutant Animal

► Genetically Modified Animals

Myelination

Definition

A process by which axonal trees of major projection neurons (i.e., neurons that project to distant brain regions) are sheathed in myelin, a fatty membrane produced by surrounding neuroglial cells. This myelin sheathing insulates the propagation of action-potentials, the electrical signals that convey information from the cell body to the axonal synaptic terminals, from nonspecific dissipation in the neuropil. Myelin sheathing reduces the energy requirements while increasing the speed of long-range information relays in the brain.

Nafion

Definition

A perfluronated ion exchange resin that allows the passage of cations (such as biogenic amines) and precludes the passage of anions (such as metabolites of biogenic amines and ascorbic acid).

Naloxone

Definition

Naloxone is one of the best-known opioid receptor antagonists that shows high affinity for ► μ-opioid receptors in the CNS and as result of blockade of these receptors often produces rapid onset of withdrawal symptoms in opiate-dependent subjects. Naloxone also blocks with a lower affinity, at κ- and δ-opioid receptors. It is used clinically to counteract the effects of opioid overdose, for example, heroin or morphine overdose, where it is most commonly injected intravenously.

Cross-References

► Naltrexone
► Opioid Antagonist

Naltrexone

Synonyms

ReVia; Vivitrol (injectable)

Definition

Naltrexone is an ► opioid receptor antagonist and is known to bind to all three opioid receptors (mu, delta, kappa) as a function of the dose administered. Approved in oral form (ReVia®) in 1994 for the treatment of alcohol dependence, naltrexone appears most effective in reducing heavy drinking and is believed to act by blocking some of the reinforcing properties of ► alcohol. Problems with compliance led to the development of a long-acting (30 days) injectable form of naltrexone (Vivitrol®), approved in 2006.

Nanospray

► Electrospray Ionization

Narcolepsy

Definition

A chronic disorder of sleep characterized by excessive daytime sleepiness and sudden onset of sleep, without the normal transition through lower levels of arousal, and with an altered circadian pattern. Individuals with narcolepsy often experience cataplexy, which refers to sudden attacks of muscular weakness, often brought on by strong emotional states.

Narcotics Prison Farm

Synonyms

Federal medical center, Lexington; Lexington narcotics farm

Definition

The U.S. Narcotics Prison Farm was established in 1935 in Lexington, Kentucky, as a prison hospital for drug addicts and was operated by the U.S. Federal Bureau of Prisons and the Public Health Service. Inmates were either committed by courts to serve sentences at the Farm or voluntarily admitted themselves. Patient/prisoners received treatment for their substance abuse problem and were given new employment skills by working on the farm or on related jobs. The Narcotics Prison Farm was home to the Addiction Research Center, a significant research center focused on the study of drug abuse and dependence, particularly opioid dependence, using the inmate population. Research of this type on prisoners is rarely conducted today because of ethical concerns, although prisons remain important locations for the study of treatment programs.

Selective noradrenergic reuptake inhibitors

Definition

Selective ► Norepinephrine Reuptake Inhibitors (selective NRIs) are a group of drugs that exert action primarily by the inhibition of norepinephrine reuptake at the norepinephrine transporter protein. The affinity of a drug for such a receptor can be expressed mathematically as the dissociation constant (K_i). To be considered as a selective NRI, the binding affinity of the most occupied receptor, in this case the norepinephrine reuptake pump, must be at least tenfold higher than the binding affinity of the next most occupied receptor. Parenthetically, the lower the K_i value, the higher the affinity of the drug for the receptor. Ki values for the selective NRIs are compared in Table 1.

Pharmacological Properties

Agents that meet the criteria for selective NRIs include ► reboxetine, ► atomoxetine, viloxazine, and several secondary amine ► tricyclic antidepressants (TCAs) (e.g., desipramine). The history, ► pharmacokinetics, and the efficacy of reboxetine, atomoxetine, and viloxazine will be described together, as they are most similar in mechanism of action, having little affinity for receptors other than norepinephrine. Secondary amine TCAs and ► bupropion, a dual ► dopamine and norepinephrine reuptake inhibitor, will be discussed separately within the context of this essay. Safety and tolerability will be described for the selective NRI class as a whole.

Reboxetine, Atomoxetine, and Viloxazine

History

Reboxetine holds the distinction of being the first truly selective norepinephrine reuptake inhibitor and has been used in the treatment of clinical ► depression, ► anxiety disorders, and ► attention deficit disorders. It is licensed for use in several countries but is unavailable in the USA (Fleishaker 2000). Reboxetine has been denied approval

5HT-T serotonin transporter (i.e., uptake pump), $5HT_{1A}$ – serotonin 1A receptor, Alpha 1 – adrenergic alpha 1 receptor, M1 – cholinergic muscarinic receptor, D_2 – dopamine 2 receptor, H_1 – histaminic 1 receptor, NET – norepinephrine reuptake transporter, DT – dopamine reuptake pump.

by the US Food and Drug Administration (FDA) multiple times (Page 2003). Viloxazine has also been unable to gain FDA approval. As first reported in 1976 by Lippman and Pugsley, viloxazine was found to inhibit norepinephrine reuptake in the hearts of rats and mice, but unlike previously discovered agents such as ► imipramine, did not have similar actions in brain tissues. Since that time, more research has been conducted suggesting possible benefits in conditions including ► depression, ► narcolepsy, nocturnal enuresis in children, and alcoholism. Another selective NRI, atomoxetine, is the first nonstimulant drug approved for the management of symptoms secondary to attention deficit hyperactivity disorder (► ADHD). Initially, studies were conducted to evaluate the efficacy of atomoxetine in depression, but these studies were stopped in 1990 as the manufacturer was focusing efforts on a more promising agent for the same indication, ► fluoxetine. Interestingly, the drug was originally named tomoxetine but was changed to atomoxetine after the FDA raised concerns about possible confusion with the previously marketed drug tamoxifen, an agent used in the treatment of breast cancer.

Mechanisms of Action

Antidepressants modulate various neurotransmitter systems involved in mood. Reboxetine selectively inhibits the neuronal reuptake of norepinephrine, which is believed to mediate its antidepressive effects. In contrast to secondary amine TCAs (desipramine) and maprotiline, reboxetine lacks affinity for alpha 1, histaminergic, and muscarinic receptors, and has extremely limited serotonergic properties.

Atomoxetine is closely related in structure to reboxetine. Administration of atomoxetine results in an increase of norepinephrine in the ► prefrontal cortex, an area of the brain associated with attention and memory. An increase of norepinephrine at this site is thought to correlate with improvement in target symptoms of ADHD.

► Pharmacokinetics

Reboxetine is metabolized by cytochrome P450 (CYP) 3A4. Inhibitors of CYP 3A4 could potentially increase reboxetine plasma levels, while potent CYP3 A4 inducers will reduce the plasma concentrations of reboxetine. Reboxetine undergoes hydroxylation, oxidative dealkylation, and oxidation of both the parent compound and its metabolites, with subsequent renal elimination. Patients with hepatic impairment or renal impairment (defined as a creatinine clearance of <50 mL/min) should be started on initial doses of 2 mg twice daily, with maximum daily doses of 6 mg.

The ► metabolism of atomoxetine also warrants discussion, as the ► half-life is largely dependent on CYP 2D6. For extensive metabolizers the reported half-life is approximately 5 h, as compared to poor metabolizers (roughly 7% or Caucasians and 2% of African Americans) where the half-life could be prolonged up to 20 h (Caballero and Nahata 2003). Dose adjustment may be warranted when using atomoxetine in combination with CYP 2D6 inhibitors. As reboxetine, atomoxetine, and viloxazine have only weak serotonergic activity, these agents can be safely used in combination with ► selective serotonin reuptake inhibitors (SSRIs) with virtually no overlap in mechanism of action, although metabolic drug interactions may occur.

Efficacy

Reboxetine has not been granted approval in the USA due to a lack of compelling evidence of efficacy. A meta-analysis of four short-term (4–8 week), double-blind, multicenter trials was published in 2002. The ► Hamilton Depression Rating Scale was used as the primary assessment tool. In these studies, improvements were observed in psychomotor retardation, cognitive disturbance, anxiety, and insomnia. Interestingly, depressive symptoms were not discussed, leaving the reader to question the efficacy of reboxetine in the treatment of mood symptoms. Reboxetine in total daily doses of 8–10 mg may be effective in the management of depressive symptoms (Ferguson et al. 2002).

Atomoxetine should be considered as a treatment option in ADHD patients who do not tolerate stimulants, especially if insomnia and impact on growth are areas of concern. When the administration of atomoxetine is started, it can take 2–4 weeks before a therapeutic effect is appreciated, a timeframe that is comparable to other selective NRIs. This latency period could be viewed as a disadvantage of atomoxetine, as the effects of stimulants, such as ► methylphenidate, occur within 1–3 h of achieving an effective dose. Atomoxetine does not have ► abuse potential and is not labeled in the USA as a controlled substance. These features make it a particularly appealing choice over stimulants in the treatment of patients who have a history of ► substance abuse disorders.

Few advantages of viloxazine over other selective NRIs have been reported, although viloxazine may be a less cardiotoxic alternative to imipramine.

Tricyclic Antidepressants (TCAs)

History

Several TCAs are considered to be selective NRIs, including ► nortriptyline, ► lofepramine with its active metabolite desipramine, protriptyline, and the tetracyclic agent maprotiline (Preskorn 2009). TCAs were developed from ► phenothiazines to be used as possible sedatives, antihistamines, analgesics, and antiparkinsonian drugs in the 1950s (Brunton et al. 2006). Imipramine, the first TCA developed, was tested in 500 patients with various psychiatric disorders. Of the patients who were tried on ► imipramine, only depressed patients with psychomotor retardation treated daily for 1–6 weeks showed improvement in symptoms (Domino 1999).

Mechanism of Action

Unlike reboxetine, atomoxetine, and viloxazine, TCAs bind to a variety of receptors in addition to the norepinephrine reuptake pump, including serotonin reuptake pumps, muscarinic acetylcholine receptors, histamine 1 receptors, norepinephrine alpha 1 receptors, and fast Na channels (Table 2). Activity at these receptor sites is more prominent with ► tertiary than secondary amine TCAs, and is responsible for efficacy as well as side effects.

Pharmacokinetics

► Pharmacokinetics of TCAs that are considered to be selective NRIs are similar. They are well absorbed from the gastrointestinal tract independently of food. First-pass metabolism accounts for 40–50% of the total metabolism that occurs in the intestine and the liver.

The main pharmacokinetic drug–drug interactions take place on plasma proteins involved in the distribution of the medication, and during hepatic metabolism involving enzymes CYP 450. TCAs have a high affinity for plasma proteins and share this trait with other medications such as ► phenytoin, ► valproic acid, aspirin, and warfarin. If used concomitantly with these agents, displacement from the plasma proteins can occur, thus increasing the unbound form to toxic levels, although this mechanism is more theoretical than actual. CYP 450 enzymes involved in the metabolism of TCAs include 2D6, 2C19, 1 A2, and

NARI Antidepressants. Table 2. TCA receptor binding profile. (Adapted from Preskorn 2009.)

Receptor	Effect associated with blockade	
Histamine 1 (H1)	Sedation Antipruritic effect	Increase of appetite and weight
Muscarinic receptor	Dry mouth Sinus tachycardia Constipation	Urinary retention Memory impairment
Serotonin 5HT2 uptake pump	Antidepressant Nausea	Loose stools Insomnia Anorgasmia
Serotonin HT2C	Antianxiety Decrease of motor restlessness	Appetite decrease
Serotonin HT3	Decreases nausea	Decreases vomiting
Fast Na + channels	Delayed repolarization leading to arrhythmia, seizures, delirium	

3A3-4, with the 2D6 enzyme pathway identified as the rate-limiting step in the elimination of TCAs. Inducers and inhibitors of the enzymes aforementioned can increase or decrease the metabolism of TCAs, causing either inadequate levels with poor therapeutic response or increased levels leading to toxicity (Preskorn et al. 2004).

Efficacy

There are multiple double-blind placebo-controlled studies showing the effectiveness of TCAs in treating acute depression. The therapeutic response usually starts with the improvement of somatic symptoms. The main indication for protriptyline (dose 15–60 mg/day), nortriptyline (75–150 mg/day), desipramine (75–200 mg/day), and maprotiline (75–225 mg/day) is the treatment of depression in adults, but nortriptyline is also used as a treatment for neuropathic pain, nocturnal enuresis, and as a second-line treatment in attention deficit hyperactivity disorder in children, adolescents, and adults. Currently, lofepramine is not approved for use in the USA, but is used for the treatment of depression and anxiety in Europe.

TCA serum levels can be used as a clinical guide to achieving adequate therapeutic response. TCAs have a narrow therapeutic index and therapeutic drug monitoring (TDM) is needed to assure safe use of TCAs (Janicak et al. 2001). The optimal therapeutic plasma concentrations of desipramine and nortriptyline are 50–150 ng/ml.

Bupropion

History

► Bupropion has a long and complex history. First discovered in 1969 by Mehta, bupropion was granted approval as an antidepressant by the FDA in 1985 under the trade name Wellbutrin. Prior to marketing, subjects involved in clinical trials were reported to experience increased risk of seizures. At the time of approval, doses up to 900 mg daily were used. Subsequently, marketing was halted and further research revealed that the risk of seizures was dose dependent. Bupropion was released in 1989 with a lower maximum daily dose and more strict contraindications for use. Since that time, bupropion has become widely prescribed for depression and has also been granted indications for smoking cessation and, as an extended-release form, for seasonal affective disorder.

Mechanisms of Action

Bupropion is not a true selective NRI as it exhibits more potent reuptake of dopamine than norepinephrine. Bupropion has only weak serotonergic activity (Table 1).

Pharmacokinetics

Currently, bupropion is available in three dosage forms: an immediate-release tablet intended to be taken thrice daily, a sustained-release tablet to be taken twice daily, and an extended-release form to be taken once daily. In April of 2008, the FDA approved a fourth form of bupropion. Previous forms have all shared the same hydrochloride salt form, but the newest version differs in that it is bupropion hydrobromide. It is not commercially available now, but will be marketed in the USA as Aplenzin™ as a once-daily dosage form. Caution should be used when bupropion is used concomitantly with drugs dependent on CYP 2D6 for clearance, as doses $\geq$300 mg of bupropion can cause appreciable inhibition of drugs metabolized by this CYP enzyme.

Efficacy

Bupropion has proven to be effective for the treatment of depressive symptoms as monotherapy. It is also used off-label as an adjunct antidepressant, particularly in patients who have only partially responded to SSRIs. Additionally, bupropion has been evaluated in the management of symptoms associated with ADHD, but to date does not have an indication for this disorder.

Selective NRI – Safety and Tolerability

The side-effect profiles of reboxetine, atomoxetine, and viloxazine can be attributed to the unwanted effects of norepinephrine, as activity at other receptors is limited. The concept of selectivity can thus be a bit deceiving. While an agent such as reboxetine is selective for the neurotransmitter ► norepinephrine, its activity is nonselective in terms of distribution, contributing to effects not only in the brain but in the body as well (Table 3). In the limbic system, the stimulation of noradrenergic receptors has been correlated with agitation. Acute stimulation of norepinephrine receptors in the brainstem and spinal cord can contribute to elevations in blood pressure, although the extent of these elevations does not appear to reach clinical relevance in most cases. Such elevations have been reported with atomoxetine use. In most cases, the side effects that are present with selective NRIs lessen over time. The most frequent side effects of reboxetine include dry mouth, constipation, urinary retention, blurred vision, headache, drowsiness, dizziness, excessive sweating, and insomnia. When looking at these side effects, one might associate dry mouth, constipation, urinary retention, and blurred vision with anticholinergic activity, but as was already mentioned, reboxetine does not directly block muscarinic cholinergic receptors. Instead, anticholinergic-like effects are the result of norepinephrine receptor stimulation in the sympathetic nervous system, which in turn causes a reduction of parasympathetic cholinergic tone, frequently referred to as sympathomimetic effects. This is observed clinically in the fact that reboxetine, atomoxetine, and viloxazine are generally better tolerated than tertiary amine TCAs, which elicit full effects at these receptor sites. In addition to anticholinergic effects, TCAs are linked to lethal cardiac arrhythmias, seizures, and neurotoxicity associated with elevated serum TCA levels. Toxic levels are generally accepted as >500 ng/ml for desipramine and nortriptyline.

Selective NRIs should be used cautiously in several patient populations. The potential of antidepressants to lower the seizure threshold is a class effect, and as such, all drugs in this class should be used with caution in patients with seizure disorders. Bupropion is contraindicated in patients who have epilepsy or concomitant medical conditions that may lower the seizure threshold, including the active discontinuation of ► alcohol or ► benzodiazepines

NARI Antidepressants. Table 3. Noradrenergic pathways. (Adapted from Stahl 2004)

Beginning of the pathway	Projecting to	Control of
Locus Coeruleus	Frontal cortex Alpha-2 receptor	Attention Concentration Cognition Libido increase
Locus Coeruleus	Frontal cortex Beta-1 receptor	Mood
Locus Coeruleus	Limbic cortex	Energy Fatigue Emotions Psychomotor agitation and retardation
Locus Coeruleus	Cerebellum	Tremors
Locus Coeruleus	Brainstem	Blood pressure
Locus Coeruleus	Spine Alpha-2	Pain modulation
Spinal sympathetic neurons	Heart Beta-1 receptor	Heart rate
Spinal sympathetic neurons	Urinary Bladder Alpha-1	Bladder emptying

and eating disorders. Daily doses greater than 450 mg of bupropion are associated with increased incidence of seizure.

As a class, selective NRIs depend on hepatic function for proper metabolism. Caution should be used, and dosage adjustments may be warranted, in hepatic insufficiency. In 2004, the FDA mandated that a warning be added to the atomoxetine drug label following two reports in which patients with no documented liver insufficiencies presented with elevated bilirubin levels and hepatic enzymes.

Selective NRIs are contraindicated with ▶ monoamine oxidase inhibitors (MAOIs). Concurrent use can result in increased catecholamine concentrations, which present, clinically, as hypertensive crisis, confusion, and seizures. Reboxetine has the ability to block the neuronal uptake of tyramine and, as a result, would theoretically be protective against hypertensive crisis secondary to the dietary ingestion of tyramine. As the threshold and duration of these effects are unknown, the combination of reboxetine and MAOIs should be avoided.

The effects of selective NRIs have not been extensively studied in pregnancy or breast-feeding, and should be used only when it is determined that the benefits outweigh the potential risks. Currently, maprotiline is the only selective NRI that is classified as pregnancy category B. Bupropion was previously classified as ▶ pregnancy category B but this labeling was changed by the FDA to category C. All other selective NRIs are category C, with the exception of nortriptyline, which is classified as category D due to its increased risk of teratogenicity, and therefore should be avoided in pregnancy.

The FDA mandated the addition of a ▶ black box warning disclosing the risk of suicide in children and adolescents in October 2004 and later extended the warning to include young adults. Close monitoring for suicidal ideation or changes in behaviors is warranted in patients who are started on therapy, particularly during the first few months of therapy or following dosage changes. Along with the warning, manufacturers in the USA must provide Patient Medication Guides that are to be given to the patient with all prescriptions for antidepressants.

Conclusion

In summary, selective NRIs can be divided into two main categories: those that have primary activity only on norepinephrine receptors such as reboxetine, atomoxetine, and viloxazine, and those that have significant activity at other receptor sites in addition to norepinephrine, including secondary amine TCAs, maprotiline, and bupropion. With respect to the first group, the effects of norepinephrine activity alone result in increased alertness and concentration. For this reason, atomoxetine is beneficial in treating symptoms associated with attention deficit disorders. Agents with solitary norepinephrine activity, such as reboxetine and viloxazine, have not been overwhelmingly advantageous in the treatment of depressive symptoms. When looking at the second group, it appears that activity at other receptor sites including serotonin and dopamine, may be beneficial in the treatment of depressive symptoms. This interpretation is supported by the fact that the TCAs and bupropion result in more robust clinical response when used to treat depressive illness.

N-Back Test

Definition

In this test, subjects are presented with a series of stimuli (e.g., spatial locations, visual objects, letters, etc.) and required to decide whether the current stimulus is the same as the stimulus seen *n* trials back. In variants of this test, subjects have to respond to the current trial with the stimulus presented *n* (e.g., two) trials back.

Necrosis

Definition

A term used to define the mechanism by which cells die due to the degradative action of enzymes. Necrosis follows an initial causative factor such as ischemia, a neurotoxin, or injury.

Cross-References

Negative Reinforcement Theory

Definition

Like positive reinforcement, negative reinforcement increases the likelihood that a behavior associated with it will be continued. However, a negative reinforcer is an unpleasant stimulus that is removed after a behavioral response. Negative reinforcers can range from uncomfortable physical sensations to actions causing severe physical distress. Taking drug to relieve the withdrawal distress is, arguably, an example of negative reinforcement. If a person's withdrawal syndrome (stimulus) goes away after taking drug (behavior), then it is likely that the person will seek for drug as soon as the first withdrawal discomfort will appear in the future.

Negative Reinforcer

Definition

An aversive event whose removal follows an operant response.

Negative Symptoms Syndrome

Synonyms

Deficit symptoms syndrome

Definition

A syndrome that involves the lacking of a number of mental features or capacities that would be expected to be present in a healthy individual. These features and capacities include: the ability to sustain an adequate level of attention during tasks, activities, or social encounters; a full range of genuine, appropriately responsive, and appropriately sustained affect; an adequate quantity of spontaneous speech that contains objective content and that is delivered without disruptive delays in either initiating or sustaining the speech; an appropriate level of attention and caring concerning grooming and personal hygiene; an appropriate level of motivation and persistence concerning work, school, or other productive activities; an appropriate level of energy for initiating and sustaining activities, and capacity for self-starting and self-direction; an appropriate level of interest and investment in, and pleasure derived from, enjoyable or recreational activities; and an age-appropriate interest in, and

capacity for, friendship, cooperation, and interpersonal closeness or intimacy.

Nemonapride

Definition
Nemonapride is a first-generation (typical) antipsychotic drug that belongs to the benzamide class approved in Japan for the treatment of schizophrenia. It is a potent dopamine antagonist with high affinity for D_2, D_3, and D_4 receptors. In addition, it is a potent 5-HT_{1A} receptor agonist and has relatively high affinity for sigma receptors, with little affinity for 5-HT_{2A} receptors. It can induce extrapyramidal motor side effects and has a propensity to elevate prolactin secretion, but it displays generally low toxicity.

Nerve Growth Factor

A. Claudio Cuello
Department of Pharmacology, McGill University, Montreal, Quebec, Canada

Definition
Nerve growth factor (NGF) is a protein primarily responsible for the differentiation and survival of sympathetic and ► spinal cord primary sensory neurons in the peripheral nervous system and for the differentiation and survival of cholinergic neurons of the basal forebrain during the development of the nervous system and responsible for the maintenance of their neuronal phenotype after maturity. NGF has other broader effects over endocrine and inflammatory mechanisms.

Pharmacological Properties

Preamble
NGF was the first molecule identified as having well-defined trophic actions over cells of the nervous system. Following the discovery of NGF, a plethora of other proteins with differential trophic effects over PNS or CNS neurons has also been identified. The discovery of NGF introduced the concept that neuronal survival, differentiation, and growth are controlled by ► trophic factors and initiated a major research field in the neurosciences and neuropharmacology.

History
The discovery and identification of NGF is one of the most fascinating chapters in the history of neuroscience. The immediate roots of this discovery can be found in the pioneering investigations of Rita Levi-Montalcini and Viktor Hamburger who demonstrated that the grafting of sarcoma tumors in chick embryos elicited a remarkable hypertrophic growth of spinal cord primary sensory and sympathetic ganglia with an ingrowth of the corresponding nerves into the sarcoma (Levi-Montalcini 1987). The possibility that a "diffusible factor" was responsible for such a remarkable neurotrophic response was consecutively investigated *in vitro* by Rita Levi-Montalcini who, while in Rio de Janeiro, demonstrated that the culture media of sarcoma tissue induced a remarkable "halo" of radially outgrowing neurites emerging from the ganglia. These powerful microscopic images have remained iconic, given these dramatic effects and their significance. Stanley Cohen and, later, Rita Levi–Montalcini, serendipitously identified similar trophic

effects with material extracted from snake venom glands and from rodent submaxillary glands. These highly purified preparations allowed them to establish the proteinaceous nature of NGF, and to generate antibodies for immunoneutralization and biological characterization. Later, these preparations allowed Angeletti and Brashaw to establish NGF's amino acid sequence. Because of these pioneering findings, the Nobel Prize in Medicine was granted in 1986 to both Rita Levi-Montalcini and Stanley Cohen. A family of NGF-like molecules (the neurotrophins) and their receptors was consequently identified after these seminal contributions.

Neurobiology and Mechanisms of Action

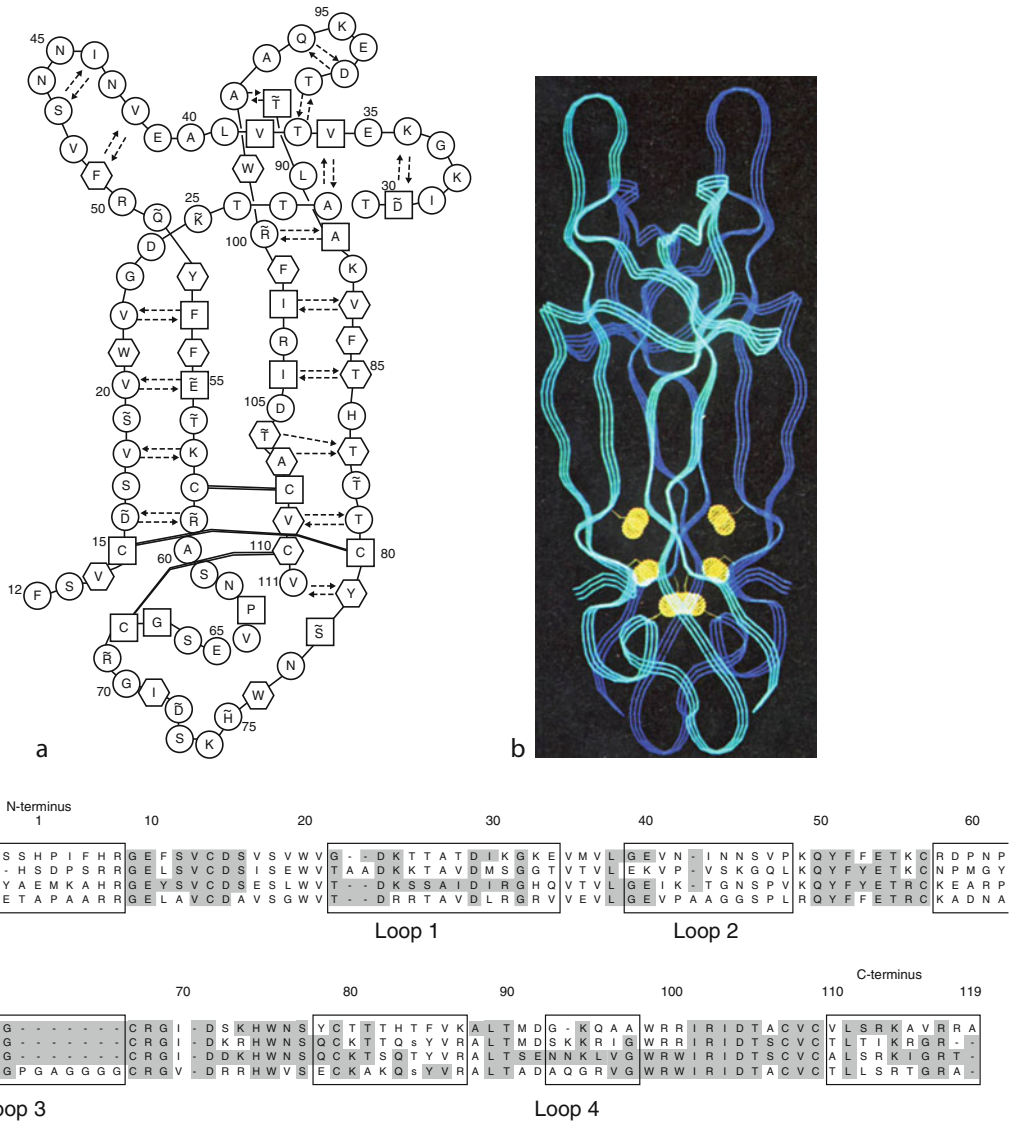
It is currently known that NGF is a member of the so-called neurotrophin family of trophic factors which is composed of NGF, brain derived neurotrophic factor (BDNF), and the neurotrophins, NT3 and NT4/5. These proteins have a high degree of homology with NGF and their tertiary structure reveals antiparallel strands and four hairpin loops. Three disulfide bridges known as a "cysteine knot" maintain the 3D configuration. The neurotrophins can be differentiated from each other principally by the amino acid sequence of their hairpin loops, which apparently grants them their biological specificity (Skaper 2008). The neurotrophins have subunit molecular masses in the range of 12–14 kDa and are found as noncovalently linked homodimers of approximately 26 kDa. The 3D molecular structure of NGF and its relative homology with other members of the neurotrophin family is represented in Fig. 1.

Three main high-affinity receptor tyrosine kinases have been identified and referred to as TrkA, TrkB, and TrkC, responding preferentially to NGF, BDNF, and NT3 respectively, and NT4 to NT4. While NGF acts fairly narrowly on TrkA, some overlap regarding receptor responses can be expected of the rest of the neurotrophins (Chao 2003; Kaplan and Miller 2000; Skaper 2008), as illustrated in Fig 2.

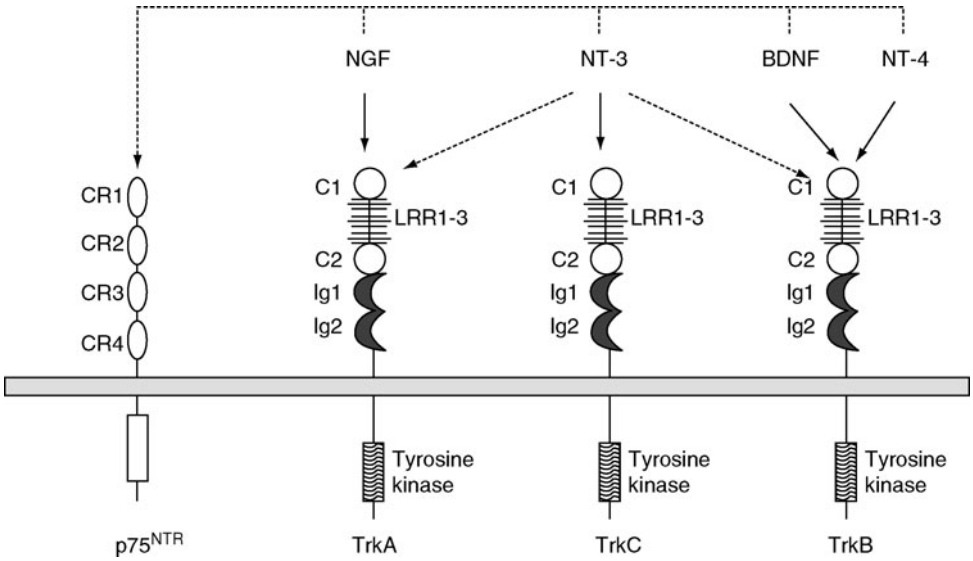
These receptors are mainly responsible for the diverse and specific neurotrophic responses elicited by the neurotrophins over defined groups of CNS and PNS neurons. An ubiquitous and less discriminating "co-receptor," p75 neurotrophin receptor (NTR), appears to act cooperatively with Trk receptors in eliciting neurotrophic actions. However, in certain conditions, in the absence of Trk receptors, $p75^{NTR}$ are thought to mediate cell death via apoptotic mechanisms, acting cooperatively with the sortilin receptor (Nykjaer et al. 2004), a receptor for neurotensin, which is also present in NGF-rich CNS regions. Both TrkA and $p75^{NTR}$ receptors are nowadays considered to be high-affinity receptors for NGF. NGF is generated by a variety of tissues and cell types. In the mature CNS, it is mainly produced by neurons located in target regions for NGF-dependent neurons (target derived trophic support) where their axonal branches and presynaptic boutons terminate. NGF is synthesized as a larger precursor molecule, preproNGF, whose signal peptide is cleaved in the endoplasmic reticulum to produce proNGF. ProNGF is a secreted molecule and is the most abundant molecular species of NGF in the adult CNS. It is the preferred ligand of the $p75^{NTR}$/sortilin complex. It can also bind TrkA, but with weaker affinity than mature NGF (Fahnestock et al. 2004). The mature form of NGF (mNGF), on the other hand, is most likely generated extracellularly and binds more tightly to TrkA. The biological activities of proNGF and NGF are determined by the relative levels of TrkA and $p75^{NTR}$ (Masoudi et al. 2009). The best-characterized biological actions of mNGF are its neurotrophic effects. These are achieved by mNGF binding to monomeric or homodimeric TrkA receptors and also to hetero-TrkA-$p75^{NTR}$ complexes; dimeric complexes result in higher ligand-receptor affinity (Fig. 3).

Synthesis, Release, and Metabolism of NGF

As indicated earlier, mature and biologically active NGF is the immediate product of a larger precursor protein, proNGF. Western blot analysis reveal that the predominant form of NGF in the adult CNS is proNGF (Fahnestock et al. 2001). It has been proposed that proNGF can be cleaved intracellularly by the action of furin converting proNGF into NGF. However, the degree to which the "conversion" of proNGF into mNGF takes place intra or extracellularly is debatable. Studies with transfected cell lines have shown that a furin-resistant form of proNGF can be released into the extracellular space and induce cell death via the activation of $p75^{NTR}$ (Lee et al. 2001), possibly when TrkA levels are low. Cell biology studies indicate that the secretion of NGF is activity-dependent. *Ex-vivo* studies with superfused cerebral cortex tissue of adult rats have revealed that proNGF is the molecular form released in an activity-dependent manner, following depolarization or neurotransmitter stimulation (Bruno and Cuello 2006). These studies also indicate that in the adult and fully differentiated nervous system, the conversion of proNGF occurs in the extracellular space by the coordinated action of plasminogen and tissue plasminogen activator (tPA) producing plasmin which converts proNGF into mNGF (Bruno and Cuello 2006). Mature NGF and corresponding activated TrkA receptor are internalized in endosomal vesicles, which are transported retrogradely by axonal processes from nerve terminals to perinuclear regions of neurons, where the



Nerve Growth Factor. Fig. 1. (**a**) Schematic representation of the β-NGF monomer subunit highlighting structurally important residues. Bold, absolutely conserved residues for all NGF and NGF-related sequences. Squares, buried residues in the β-NGF subunit with a relative side-chain. The hexagons represent residues involved in the dimer interface as identified using computer imaging techniques. The side-chain of the residue participates in a hydrogen bond with either a side-chain or a main chain atom. The main chain hydrogen bonds involved in the β-sheet structure are displayed as arrows, pointing in the direction of the donor acceptor. The cysteine knot is shown as three solid lines linking six cysteine residues near the bottom of the molecule (From McDonald et al. (1991) Nature; with author's and publisher's permission). (**b**) Ribbon representation of the β-NGF dimer. The cyan and dark blue ribbons each represent a subunit. The Sγ atom for each half-cystine residue is also shown drawn as a sphere. (From McDonald et al. (1991) Nature; with author's and publisher's permission). (**c**) Structure-based sequence alignment of the neurotrophins. Numbering refers to the sequence of mature human NGF. Positions are numbered from the first residue in each neurotrophin. Note that, because of differences in the lengths of the N-termini of the different neurotrophins, homologous positions in different molecules do not have equivalent numbering. Conserved residues are shaded and low sequence homology (boxes) and sequence of hairpin loops are represented. Dashes indicate gaps introduced for the sake of alignment. (From Skaper 2008. CNS Neurol Disord Drug Targets; with author's and publisher's permission.)



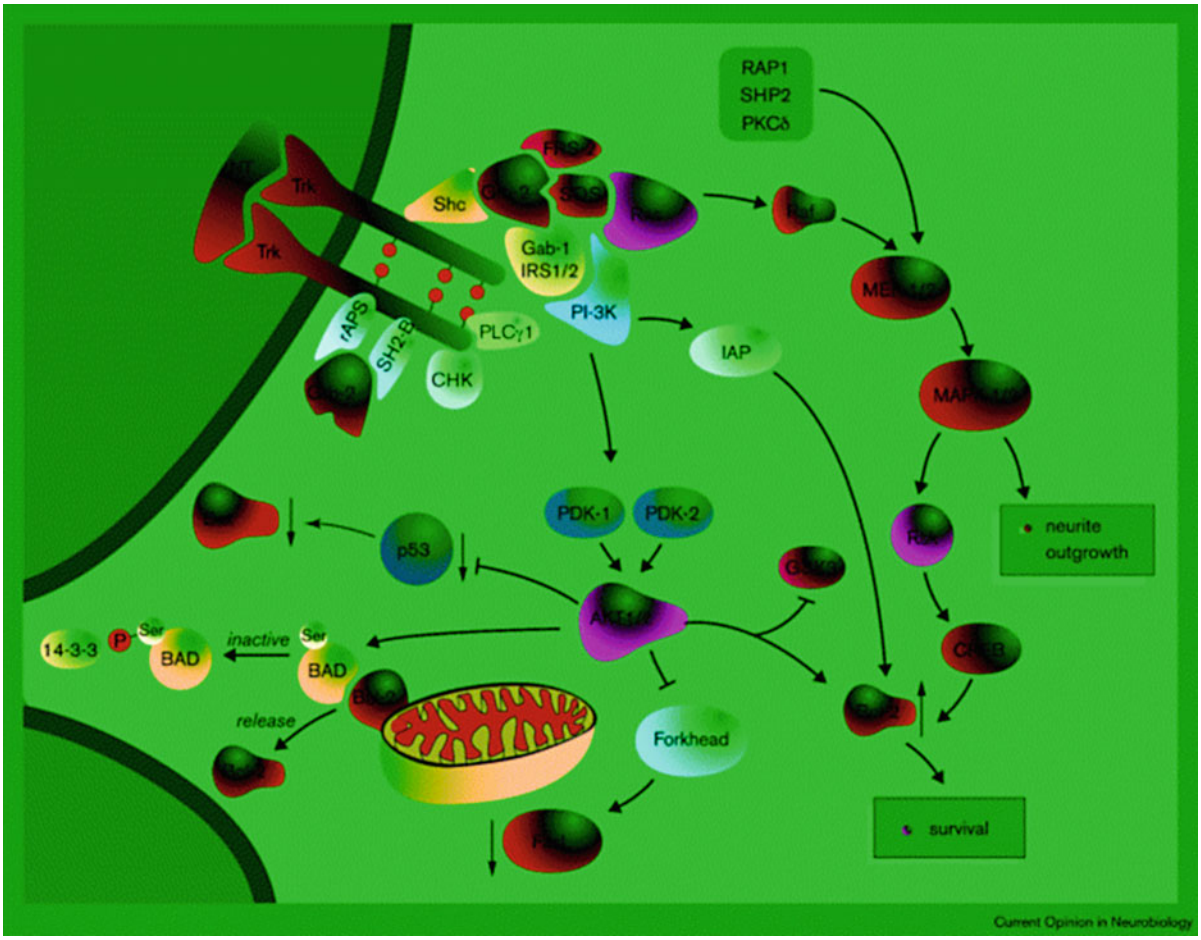
Nerve Growth Factor. Fig. 2. Neurotrophins and their receptors. The neurotrophins display specific interactions with the three Trk receptors: NGF binds TrkA, BDNF and NT-4 bind TrkB, and NT-3 binds TrkC. In some cellular contexts, NT-3 can also activate TrkA and TrkB albeit with less efficiency. All neurotrophins bind to and activate $p75^{NTR}$. CR1-CR4, cysteine-rich motifs; C1/C2, cysteine-rich clusters; LRR1-3, leucine-rich repeats; Ig1/Ig2, immunoglobulin-like domains. (From Skaper 2008. Drug Targets. CNS Neurol Disord; with author's and publisher's permission.)

vesicles continue signaling via the Erk-CREB pathway (Grimes et al. 1996). These studies also indicate that the metalloproteinase MMP9 rapidly degrades and inactivates any remaining mNGF, which is not bound to the cognate receptor (TrkA) and rapidly internalized.

The above metabolic pathway involving plasmin for the maturation of NGF and MMP9 for its degradation has been pharmacologically validated *in vivo,* showing that the inhibition of tPA results in the brain accumulation of proNGF and, conversely, the inhibition of MMP9 in the accumulation of mNGF (Bruno and Cuello 2006). Fig. 4 illustrates the activity-dependent release of proNGF and its consequent conversion to mature NGF, binding to its cognate receptors and its eventual degradation in the extracellular space as well as the protease cascade and endogenous inhibitors.

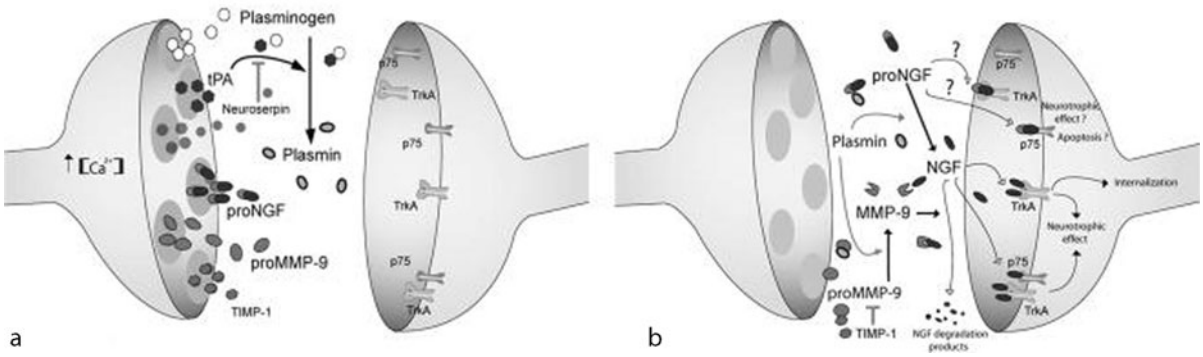
The best-defined and most dramatic actions of the endogenously generated NGF are illustrated during embryonic stages and the early postnatal period. In brief, in *in vitro* conditions, the deprivation of NGF support leads to cell death of NGF-dependent embryonic neurons, typically small-size spinal cord primary sensory and ▶ sympathetic neurons. The early studies on the deprivation of NGF trophic support were performed by immunoneutralization with anti-NGF polyclonal antibodies and more recent studies were done with NGF knock-out (KO) or NGF-deficient animal models. Mice lacking NGF or TrkA (KO models) do not survive beyond weeks after birth. The phenotype of NGF(−/−) or TrkA(−/−) mice is one of dramatic loss of NGF-dependent spinal cord sensory neurons and sympathetic neurons, but with a lesser effect on NGF-dependent forebrain neurons. However, mice carrying a single NGF allele have shown marked atrophy of forebrain cholinergic neurons of the nucleus basalis and medial septum. The most accepted view is that during development, the presence of NGF in defined target areas will attract axonal growth to the sites of termination (synapses in the CNS) and secure the eventual survival of NGF-dependent neurons (Sofroniew et al. 2001).

Many of the concepts derived from investigations on embryonic tissue have been applied to the adult nervous system. Thus, the concept of "target derived" NGF support of CNS neurons in the adult brain was readily accepted. It was shown early on that axotomy of the septal-hippocampal cholinergic pathway in the adult brain resulted in the loss of the corresponding NGF sensitive cholinergic neurons. Their recovery by the application of NGF was interpreted as an indication of a similar NGF-dependency for neuronal survival in the adult and fully differentiated CNS. However, the substantial excitotoxic destruction of the target tissue (hippocampus),



Nerve Growth Factor. Fig. 3. Trk signaling pathways regulating survival and neurite growth in neuronal cells. Neurotrophin (NT) binding to Trk stimulates receptor transphosphorylation, resulting in the recruitment of a series of signaling proteins to docking sites on the receptor. These proteins include Shc, which activates Ras through Grb-2 and SOS, FRS-2, rAPS, SH2-B and CHK, which participate in activating MAPK, and PLC-γ1 and CHK bind to phosphorylated Tyr 785. MAPK activity is also regulated through Raf, Rap 1, SHP-2, and PKCδ . The MEK and MAPK pathway is thought to regulate neurite growth and survival. Trk activates PI-3K through the RAS and the Gab-1/IRS-1/IRS-2 family of adapter proteins. PI-3K activity stimulates the activities of PDK2, which in turn activate Akt. The targets of PI-3K/Akt anti-apoptotic activity, including BAD, Forkhead, GSK-3, Bcl-2 IAP, and the p53 pathway involved in cell death. (From Kaplan and Miller 2000. Curr Opin Neurobiol; with author's and publisher's permission.)

while sparing their axonal input, resulted in atrophy, but not cell death, of the NGF-dependent cholinergic neurons of the medial septum, unequivocally demonstrating that NGF in the adult is key for the maintenance of neuronal phenotype, but not survival (Sofroniew et al. 2001). A similar NGF-dependency for the phenotypic characteristics of cholinergic neurons of the nucleus basalis has also been amply documented (Cuello 1994). Further confirmation of the essential role of NGF in the maintenance of the CNS cholinergic phenotype in the mature brain is provided by the evidence that blocking "endogenous" NGF function through the application of either antibodies mapping out the ligand (NGF) or NGF mimetic peptides with antagonist actions over the receptor (TrkA) in the cerebral cortex of adult rats results in the loss of preexisting cortical cholinergic synapses (Debeir et al. 1999). Such an observation indicates that the "steady-state" number of CNS cholinergic synapses is dependent on a continuous supply of endogenous NGF, in line with the classical Hebbian concept that brain activity unleashes a



Nerve Growth Factor. Fig. 4. Schematic representations of events leading to proNGF conversion into mNGF and its degradation. Neuronally stored proNGF, plasminogen, tPA, neuroserpin, proMMP-9, and TIMP-1 would be released into the extracellular space upon neuronal stimulation. Released tPA would induce the conversion of plasminogen to plasmin, where its activity is tightly regulated by secreted neuroserpin. The generated plasmin would convert proNGF into mature NGF and activate proMMP-9 into active MMP-9. Mature NGF would interact with its cognate receptors (TrkA and $p75^{NTR}$) or suffer degradation by activated MMP-9. (From Bruno and Cuello 2006. PNAS; with author's and publisher's permission.)

growth-dependent synaptic efficacy. While the evidence for a target-derived action of NGF is strong, it is not clear whether endogenous NGF can also act in a paracrine fashion. However, it has been shown both in rodents and primates that exogenously applied NGF can also act in a paracrine fashion (Tuszynski et al. 2005), a concept (see below) which might have therapeutic applications.

NGF Pharmacology

Both NGF purified from submaxillary glands and genetically engineered recombinant forms of NGF have been successfully applied in a large variety of *in vitro* and *in vivo* experimental models. Both forms have been shown to be equally effective. In most *in vitro* models, NGF displays trophic effects at concentrations as low as 10^{-13} M. In the adult CNS, the recovery of target-deprived or lesioned NGF-dependent neurons can be achieved with the application of doses as low as 1 μg/kg/daily typically administered in the cerebrovascular space for period of a week or longer. The drawback of the application of the NGF protein resides in its broad actions over a large variety of target cells and tissues in the CNS and periphery, its rapid proteolytic degradation and the difficulty with which it crosses the ▶ blood-brain barrier (BBB) for potential CNS reparative applications.

A number of strategies have been explored to develop smaller molecular weight compounds with NGF agonist or antagonistic actions. The initial efforts have involved the testing of NGF diverse fragments, then synthesis of cyclic-peptides mimicking NGF loops and lately, the use of dimeric peptide-mimetic molecules. The majority of these molecules displayed some TrkA antagonistic actions in either *in vitro* or *in vivo* conditions (Longo et al. 2007; Skaper 2008). A recently developed dimeric NGF mimetope named D3 has been shown to display similar efficacy to NGF in recovering the CNS cholinergic phenotype and correcting memory impairments of aged and cognitively impaired rats (Bruno et al. 2004). Whether analogous low molecular weight compounds capable of crossing the BBB will find therapeutic applications remains to be established.

NGF in Health and Disease

The multifaceted aspects of NGF have been repeatedly signaled by Rita Levi-Montalcini, Luigi Aloe and collaborators and they would indicate the possible involvement of NGF in a multitude of functions beyond the classical neurotrophic effects. Two areas of potential therapeutic applications have been given the most attention. These are the potential reparative effects of NGF in ▶ Alzheimer's disease (AD) and the control of the NGF proinflammatory/pronociceptive effects in the periphery.

It is well established that the experimental, exogenous application of NGF in the cerebrovascular space can rescue the cholinergic phenotype and memory functions in the axotomy model of the septo-hippocampal pathway and in the model of retrograde degeneration of nucleus basalis neurons following large stroke-type lesions of the cerebral cortex (Cuello 1994). Furthermore, CNS cholinergic axonal sprouting and synaptogenesis have resulted from the application of NGF in rodent and primate animal models (Cuello 1994). Likewise, it has been

shown that NGF is capable of reversing the well-known age-related CNS cholinergic atrophy. Since ► acetylcholine is known to play a key role in higher CNS functions such as attention, learning and memory, and since this transmitter system is the most vulnerable to AD neuropathology, it was naturally considered early-on as a possible trophic factor for reparative therapy for this neurodegenerative disease. The first therapeutic attempts in AD were made by the intracerebral application of highly purified murine NGF. Despite anecdotal cognitive improvements, these trials were interrupted as the patients developed an unacceptable weight loss and pain. More recently, application of NGF has been restricted to the forebrain in order to overcome these undesirable effects. This has been done in the knowledge that NGF, besides acting as a "target-derived" neurotrophin, also displays paracrine trophic effects. Thus, autologous fibroblasts genetically modified to express human NGF have been grafted in the area of the nucleus basalis in a limited number of AD sufferers (Tuszynski et al. 2005). The drawback of this approach is the invasive nature of the procedure. The development of small molecular weight TrkA agonists capable of crossing the BBB and eliciting neuroregeneration without the activation of pain receptors or provoking loss of body weight would be a desirable objective.

AD pathology occurs concurrently with a marked atrophy of NGF-dependent ► basal forebrain cholinergic neurons. However, in AD there are no signs of a diminished synthesis of NGF, but on the contrary, an elevation of the NGF precursor, proNGF, has been consistently reported (Fahnestock et al. 2001). This creates the paradoxical availability of an abundance of NGF precursor along with cholinergic atrophy. This can now be explained by the finding of an altered metabolism of NGF in AD such that the conversion of proNGF to mNGF is impaired and the degradation of mNGF exacerbated. Such circumstances could offer a conceptual framework for a less invasive pharmacological strategy to correct the NGF dysmetabolism observed in AD.

As noted by Levi-Montalcini and Aloe and observed by others, NGF is capable of recruiting/activating mast cells and inducing an inflammatory response in animal models and in arthritic tissue in the human (Watson et al. 2008). Furthermore, there is good evidence that NGF is elevated in a variety of severe pain conditions in humans. These include arthritis, chronic cystitis, and pancreatitis. The application of NGF or the overexpression of NGF in transgenic animal models results in hyperalgesia and even allodynia. The production and release of NGF is stimulated by a variety of cytokines and inflammatory reagents present in damaged or inflamed tissues. In turn, NGF acts in a pro-inflammatory fashion by recruiting mast cells and facilitating mast cell degranulation. The pronociceptive effects of NGF are thought to be elicited mainly by the stimulation of TrkA receptors present in small diameter spinal cord primary sensory afferents of type Aδ and C. These fibers contain and release either substance P or calcitonin gene related peptide (CGRP), or both. NGF stimulates the production and release of these pronociceptive peptides orthodromically in the spinal cord (first CNS pain signal) and antidromically in the periphery, facilitating further plasma extravasation and mast cell degranulation(Watson et al. 2008). NGF modulates a number of ligand- and voltage-gated ion channels participating in nociception. In particular, NGF enhances the synthesis, membrane expression, and density of the ligand-gated transient receptor potential cation channel of the vanilloid subfamily, member 1 (TRPV1). This receptor responds to capsaicin and a number of noxious stimuli and agents released by injured tissue such as bradikinin. It also sensitizes spinal cord primary sensory fibers to nociceptive stimuli. In consequence, NGF has "feed forward" properties in enhancing and prolonging both inflammation and pain. A number of pain-controlling strategies aimed at blocking NGF actions in the periphery have been explored. Thus, chimeric molecules with dimeric TrkA domains fused to the constant region (Fc) of human IgG domains have been shown to be effective in controlling pain and inflammation in the carrageenan-inflamed rat hind limb model, when injected locally. However, the large molecular size and immunological reactions are potential drawbacks for the clinical application of this molecule. More recently, a recombinant and refolded protein with the amino acid sequence of the d5 domain of TrkA has been shown to be equally effective in a variety of preclinical models. The clinical application of such an approach has not, as yet, been explored. Antibodies against NGF are known to control nociceptive effects. The development of a monoclonal antibody capable of reducing pain and inflammation in a number of preclinical models including bone fractures has encouraged the humanization of these antibodies for further, ongoing, clinical trials with some apparent success (Watson et al. 2008). Small molecular weight molecules acting as NGF antagonists on TrkA receptors may also find an application on this front (Skaper 2008).

Definition

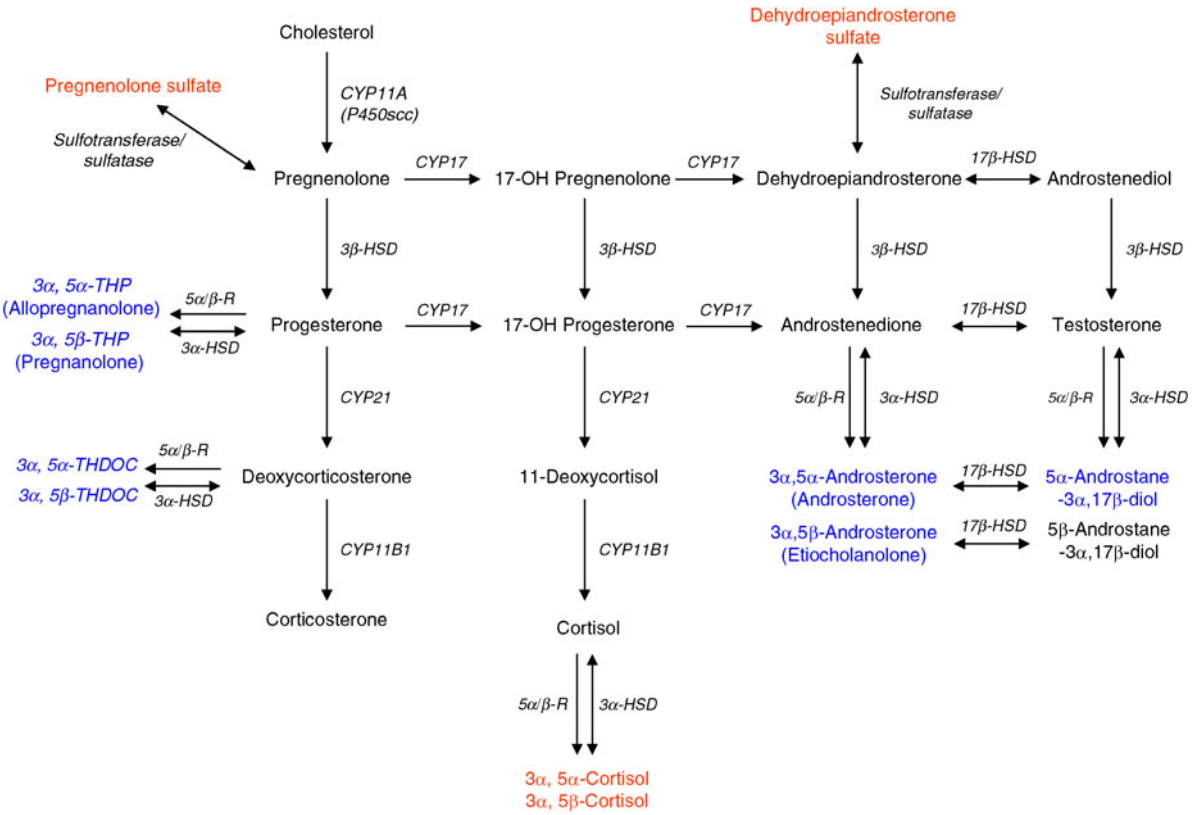
This essay delineates the pharmacological, physiological, pathological and therapeutical relevance of ► neuroactive steroids. These steroids are endogenous or synthetic compounds that can cross the ► blood–brain barrier and rapidly alter neuronal excitability via membrane receptors. We focus on neuroactive steroids that have specific binding sites on γ-aminobutyric acid type-A (► $GABA_A$) receptors which directly influence both synaptic and

extrasynaptic transmission and indirectly alter many physiological processes including ► hypothalamic–pituitary–adrenal (HPA) axis function, inflammation, and myelin formation. Neuroactive steroid levels are modulated by stress, ovarian cycle, pregnancy, as well as numerous pharmacological agents. We summarize the sites of neuroactive steroid actions, the systemic and molecular consequences of these actions, and the potential therapeutic relevance of their effects for neuropsychiatric disease.

Pharmacological Properties

Neuroactive steroids are a class of endogenous neuromodulators that influence brain processes in fundamental ways that affect mood, behavior and all organ systems controlled by brain function. Pioneering work from Baulieu and collaborators in the early 1980s demonstrated the persistence of substantial amounts of pregnenolone, progesterone, dehydroepiandrosterone (DHEA) and their sulfate metabolites in the brain of adrenalectomized/gonadectomized animals. This suggests that the brain was capable of local synthesis of these steroids that were thus termed ► Neurosteroids. Subsequent studies have shown that neurons and glial cells in the brain have the ability to locally synthesize neurosteroids *de novo* from cholesterol (Baulieu 1998). The biosynthetic pathway for neuroactive steroids is shown in Fig. 1. Neuroactive steroids with inhibitory activity on neurons are shown in blue while steroids with excitatory activity on neurons are show in red.

The classical action of steroid hormones is to regulate transcriptional activity and protein biosynthesis over minutes to hours via interaction with nuclear steroid receptors. However, neuroactive steroids have the ability to rapidly (milliseconds to seconds) alter the neuronal excitability by binding to membrane receptors such as ion channels or receptors in the plasma membrane (see Paul



Neuroactive Steroids. Fig. 1. Biosynthetic pathway for neuroactive steroids. While neuroactive steroids with inhibitory activity on neurons are shown in blue, neuroactive steroids with excitatory activity on neurons are show in red. *3α,5α-THP* (3α,5α)-3-hydroxypregnan-20-one; *3α,5β-THP* (3α,5β)-3-hydroxypregnan-20-one; *3α,5α-THDOC* (3α,5α)-3,21-dihydroxypregnan-20-one; *3α,5β-THDOC* (3α,5β)-3,21-dihydroxypregnan-20-one; *3β-HSD* 3β-hydroxysteroid dehydrogenase; *5α/β-R* 5α/5β-reductase; *3α-HSD* 3α-hydroxysteroid dehydrogenase; *17β-HSD* 17β-hydroxysteroid dehydrogenase.

and Purdy 1992, for review). Neuroactive steroids may include any steroid that acts on membrane receptors in brain to alter physiological properties of neurons. These steroids include glucocorticoids, ► estrogens, progesterone, DHEA, as well as the 3α,5α-reduced metabolites of progesterone and deoxycorticosterone that are the primary focus of this essay.

GABAergic Neuroactive Steroids

The 3α,5α- and 3α,5β-reduced metabolites of progesterone, deoxycorticosterone, DHEA and testosterone enhance ► GABAergic transmission and produce inhibitory neurobehavioral effects (see Morrow 2007, for review). The most studied are the progesterone metabolite (3α,5α)-3-hydroxypregnan-20-one (3α,5α-THP or allopregnanolone) and the deoxycorticosterone metabolite (3α,5α)-3,21-dihydroxypregnan-20-one (3α,5α-THDOC or allotetrahydrodeoxycorticosterone). The demonstration of the GABAergic activity of these endogenous compounds (Majewska et al. 1986) initiated decades of further studies, including recognition of their nanomolar potency at ► $GABA_A$ receptor. In contrast, the excitatory neuroactive steroids include the sulfated derivatives of pregnenolone and DHEA, as well as the 3α,5α- and 3α,5β-reduced metabolites of cortisol. While these latter steroids are weak inhibitors of the $GABA_A$ receptors, both pregnenolone sulfate and DHEA sulfate also act as weak ► N-methyl-d-aspartate (NMDA) receptor agonists (micromolar potency).

Pharmacological Activity

Systemic administration of GABAergic neuroactive steroids exerts a variety of pharmacological activities. In the 1940s, Hans Selye reported the sedative, anesthetic and anticonvulsant actions of progesterone. However, in the mid 1980s it was discovered that these properties are due to its GABAergic metabolites (see Rupprecht 2003, for review). Likewise, 3α,5α-THP, 3α,5α-THDOC and their precursor progesterone have potent, dose-dependent, sleep-inducing properties in rats while the 5β-isomer, 3α,5β-THP (pregnanolone) has soporific and anesthetic properties in humans. Moreover, progesterone has been found to ameliorate the symptoms of catamenial epilepsy, a seizure disorder associated with the cyclical variations of steroid hormones during the menstrual cycle. Presently, clinical trials are under way in humans to investigate the antiepileptic activity of the synthetic, neuroactive steroid ganaxolone.

Progesterone and its metabolites, 3α,5α-THP and 3α,5α-THDOC, have ► anxiolytic, antidepressant-like and analgesic properties in animal and human studies. 3α,5α-THP (both after intracerebroventricular and systemic administration) has anxiolytic properties in several different animal models of anxiety-like behavior, such as light–dark transition test, ► open-field test, mirrored chamber test and the ► elevated plus-maze. Similar anxiolytic effects have been found for 3α,5α-THDOC and 3α,5β-THP. In addition to the GABAergic neuroactive steroids, lower doses of pregnenolone sulfate are also anxiolytic, while higher doses are ► anxiogenic, likely due to a combination of mechanisms including metabolism to progesterone and its metabolites. Likewise, DHEA and DHEA sulfate also have anxiolytic activity in mice. Progesterone and 3α,5α-THP have antidepressant-like properties in the Porsolt swimming test and the tail suspension test in rats. Systemic administration of 3α,5α-THP, 3α,5α-THDOC and progesterone also induces analgesic effects in rats, as measured by decreased-pain sensitivity to the tail-flick test. Furthermore, progestins and androgens, respectively, activate and inhibit feminine ► sexual behavior of rodents via their GABAergic metabolites 3α,5α-THP and the 5α-reduced testosterone metabolite (3α,5α,17β)-androstane-3,17-diol.

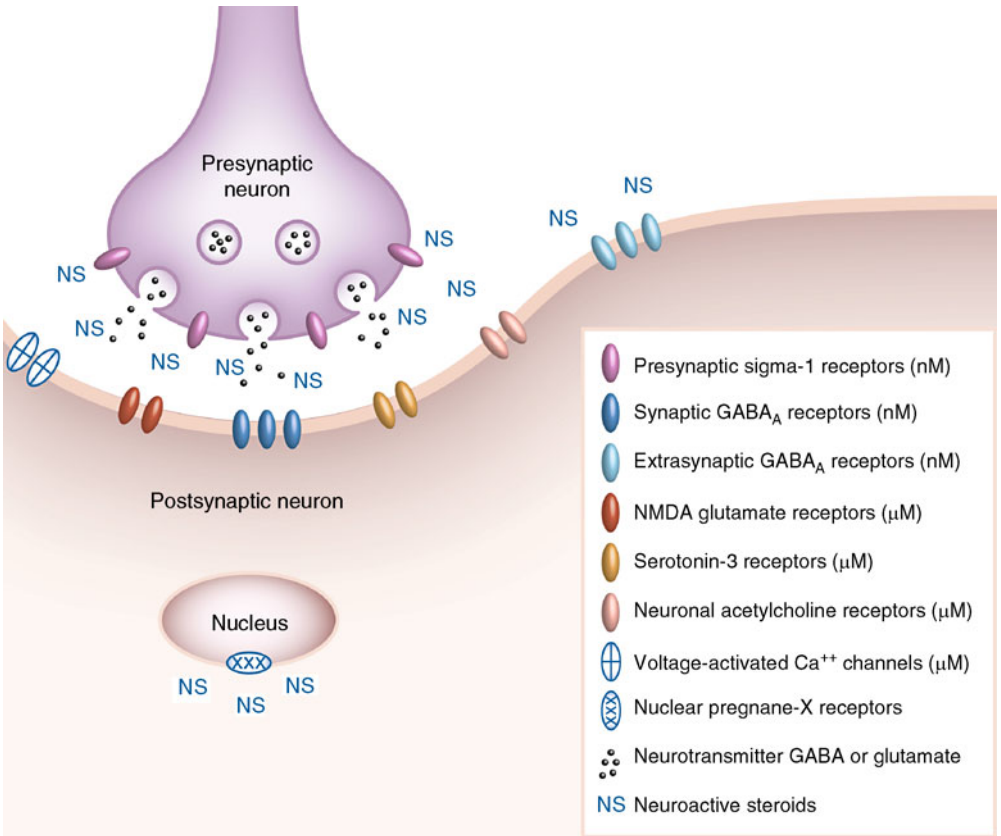
Neuroactive steroids, like various ► drugs of abuse, can have rewarding properties too (see Biggio and Purdy 2001, for review). 3α,5α-THP and (3α,5α,17β)-androstane-3,17-diol appear to have reinforcing properties via $GABA_A$ receptor activation. In addition, 3α,5α-THP and other GABA agonist neuroactive steroids modulate ethanol intake in animal models of ethanol self-administration, increasing consumption when administered at low doses or when modulating low levels of ethanol intake and reducing consumption when administered at high doses or for modulation of high levels of ethanol intake. Furthermore, ethanol-dependent rats show enhanced $GABA_A$ receptor sensitivity to 3α,5α-THP and 3α,5α-THDOC. Further, ethanol-dependent rats are sensitized to the anticonvulsant actions of neuroactive steroids, suggesting that the above class of compounds may be therapeutic during ethanol withdrawal. Indeed, neuroactive steroid therapy may have advantages over benzodiazepine therapy since ► benzodiazepines exhibit ► cross tolerance with ethanol.

In the past decade, studies have shown that 3α,5α-THP has neuroprotective and neurotrophic effects (see Schumacher et al. and Mellon in Morrow 2007). 3α,5α-THP reduces brain swelling and inflammatory cytokines after traumatic brain injury, suggesting a role for neuroactive steroids in the inflammation process. In addition, progesterone and its GABAergic metabolites have neuroprotective effects after traumatic brain injury, spinal cord injury, or cerebral ischemia, and promote remyelination

after peripheral nerve damage. While estradiol has also been shown to promote neurogenesis, DHEA sulfate and 3α,5β-THP hemisuccinate are neuroprotective in experimental models of ischemia and stroke, respectively. Furthermore, 3α,5α-THP, DHEA and DHEA sulfate also have antiapoptotic effects.

Mechanisms and Sites of Action

The sites of action of both excitatory and inhibitory neuroactive steroids are depicted in Fig. 2. The inhibitory actions of the GABAergic neuroactive steroids are mediated by synaptic and extrasynaptic $GABA_A$ receptors. These steroids interact with $GABA_A$ receptors via specific binding sites on α subunits that allosterically modulate binding to GABA and benzodiazepine recognition sites (Hosie et al. 2006). $GABA_A$ receptor function is enhanced by potentiation of GABA-mediated Cl^- conductance as well as direct stimulation of Cl^- conductance in both ►voltage clamp studies and [$^{36}Cl^-$] flux studies. $GABA_A$ receptors appear to have multiple neurosteroid recognition sites that likely reflect distinct recognition sites on $GABA_A$ receptor subtypes. Neuroactive steroids modulate both synaptic and extrasynaptic $GABA_A$ receptors with lower potency at synaptic receptors that contain γ2 subunits and higher potency at extrasynaptic receptors that contain δ subunits (see Belelli and Lambert 2005, for review). These steroids also have modulatory actions at serotonin type-3 receptors neuronal ►nicotinic



Neuroactive Steroids. Fig. 2. Sites of action of inhibitory and excitatory neuroactive steroids. The inhibitory actions of GABAergic neuroactive steroids are mediated by synaptic and extrasynaptic γ-aminobutyric acid type-A ($GABA_A$) receptors. The excitatory actions of sulfated steroids such as pregnenolone or dehydroepiandrosterone (DHEA) sulfate are partially mediated by direct, but low potency, activation of NMDA receptors and inhibition of $GABA_A$ receptors. Pregnenolone sulfate also potently inhibits GABA or glutamate release at nerve terminals. These effects are mediated by presynaptic sigma-1 receptors. Neuroactive steroids have modulatory actions at serotonin type-3 receptors, neuronal nicotinic acetylcholine receptors and voltage-activated calcium channels, albeit with micromolar potency at these sites. Another site of action includes the nuclear pregnane-X receptor that regulates P450 enzymes and steroid hormone levels across many tissues.

acetylcholine receptors and voltage-activated calcium channels, albeit with micromolar potency at these sites (see Rupprecht 2003, for review).

Studies of the structural requirements for neuroactive steroid activity at $GABA_A$ receptors include 3α reduction and 5α/5β reduction of the A ring as well as hydroxylation of C21. The 5β-reduced metabolites of progesterone and deoxycorticosterone, 3α,5β-THP and 3α,5β-THDOC, are equipotent modulators of GABAergic transmission. Humans synthesize these 5β-reduced neuroactive steroids and the concentrations of 3α,5β-THP are physiologically relevant and are comparable with those of 3α,5α-THP in human plasma and cerebrospinal fluid. In addition, 3α,5α- and 3α,5β-reduced cortisol have antagonist properties at both GABA and neurosteroid recognition sites of $GABA_A$ receptors, and these compounds are the most abundant metabolites of cortisol in human urine.

The excitatory actions of sulfated steroids such as pregnenolone or DHEA sulfate are partially mediated by direct, but low potency, interactions with ► NMDA receptors (Fig. 2). Pregnenolone sulfate also potently inhibits GABA or ► glutamate release at different neuronal sites, effects that are blocked by sigma-1 receptor antagonists and therefore thought to be mediated by these receptors. Another site of action includes the nuclear pregnane-X receptor that regulates P450 enzymes and steroid hormone levels across many tissues, but there are no effects of the excitatory or inhibitory neuroactive steroids on nuclear progesterone or ► glucocorticoid receptors.

Physiological Significance

Stress and HPA Axis Activation

► Stress increases plasma and brain levels of GABAergic neuroactive steroids in rodents (Purdy et al. 1991). In rat brain, the increase in 3α,5α-THP reaches pharmacologically significant concentrations in brain between 50–100 nM that is sufficient to enhance $GABA_A$ receptor activity and produce behavioral effects. Similarly, stress or ► corticotropin-releasing factor (CRF) infusion elevates 3α,5α-THP levels in human plasma. The increase in neuroactive steroid levels elicited by stressful stimuli appears to be mediated by activation of the HPA axis, since it is no longer apparent in adrenalectomized animals. Although adrenalectomized animals exhibit no circulating concentrations of 3α,5α-THP and 3α,5α-THDOC, brain levels are still detectable, suggesting that brain synthesis may play an important role in neuroactive steroid actions. In addition, anxiogenic drugs that inhibit GABAergic transmission, activate the HPA axis and produce stress which in turn increases brain and plasma levels of 3α,5α-THP.

The activation of HPA axis in response to acute stress increases the release of CRF from the ► hypothalamus that stimulates the release of adrenocorticotropic hormone (ACTH) from the pituitary, which, in turn, stimulates the adrenal cortex to release glucocorticoids and the GABAergic neuroactive steroids. Glucocorticoids provide negative feedback upon the hypothalamus and pituitary. Likewise, GABAergic neuroactive steroids inhibit CRF production and release, ACTH release, and subsequent corticosterone levels following stress in rodents. The ability of these steroids to reduce HPA axis activation may play an important role in returning the animal to homeostasis following stressful events. The restoration of hypothalamic and pituitary homeostasis may be critical for the maintenance of normal responses to subsequent stress challenges.

Ovarian Cycling

Neuroactive steroid concentrations vary throughout the ovarian cycle in both rodents and humans. 3α,5α-THP levels are increased in rodent brain and plasma during estrus. Likewise, increased circulating levels of 3α,5α-THP have been reported during the luteal phase of the menstrual cycle in women, and treatment with oral contraceptives prevents this increase. Neuroactive steroid concentrations are also dramatically elevated during pregnancy in both rats and women. Rat studies have shown that levels of progesterone and 3α,5α-THP decrease immediately before parturition and return to control levels 2 days after parturition. These abrupt changes in steroid concentrations may contribute to postpartum depressive symptoms. Levels of 3α,5α-THP remain low throughout development and increase immediately before puberty in both humans and rodents. Moreover, 3α,5α-THP levels decline during menopause in women (see Smith et al. in Morrow 2007).

Modulation by Pharmacological Agents

Numerous psychoactive drugs induce an increase in the brain and plasma concentrations of GABAergic neuroactive steroids and their precursors in rats (see Biggio and Purdy 2001 for review). For instance, systemic administration of ethanol increases the brain and plasma concentrations of 3α,5α-THP and contributes to ethanol actions in rats (VanDoren et al. 2000). Likewise, acute administration of psychotropic drugs like ► caffeine or ► nicotine induces a dose- and time-dependent increase in the brain and plasma concentrations of 3α,5α-THP and its precursors pregnenolone and progesterone in rats. All these effects are mediated by activation of the HPA axis, since ethanol, caffeine and nicotine do not alter neuroactive steroids in adrenalectomized rats.

In contrast, chronic ethanol consumption or chronic administration of nicotine to rats does not increase neuroactive steroids. However, ethanol dependence induces adaptations in HPA axis function, with blunted neuroactive steroid responses to stress or to ethanol challenge in both animals and humans. Furthermore, while cigarette smoking in humans does not alter the HPA axis response to pharmacological challenges, serum 3α,5α-THP levels are positively correlated with the nicotine metabolite cotinine, suggesting they may be higher in heavy smokers.

Several other drugs of abuse including ► cocaine, ► morphine, Δ9-tetrahydrocannabinol and γ-hydroxybutyric acid also activate the HPA axis. While acute administration of morphine, Δ9-tetrahydrocannabinol and γ-hydroxybutyric acid increased cerebral cortical levels of 3α,5α-THP, cocaine had no effect at doses that normally increase corticosterone levels. Cocaine may inhibit neuroactive steroid synthesis since other precursor steroids are elevated. For the most part, these drug-induced elevations of 3α,5α-THP levels are dependent on HPA axis activation. Further studies are needed to determine if the effects of acute administration are reversed by chronic exposure or whether humans exhibit elevations under conditions of drug abuse.

Neuroactive steroid concentrations are increased by several drugs that are used to treat ► mood disorders, and it is hypothesized that this increase may contribute to their therapeutic efficacy (see Girdler et al. in Morrow 2007 for review). Acute injection of ► fluoxetine, ► reboxetine, ► venlafaxine or ► imipramine increases the cerebrocortical and plasma concentrations of progesterone and its metabolites 3α,5α-THP and 3α,5α-THDOC in rats. Fluoxetine, ► paroxetine and ► sertraline may increase 3α,5α-THP levels by a direct action on the 3α-hydroxysteroid dehydrogenase enzyme that promotes the formation of neuroactive metabolites. Moreover, chronic treatment with fluoxetine increases cerebrospinal fluid concentrations of 3α,5α-THP of depressed patients. Treatment with other antidepressants, like ► amitriptyline, ► clomipramine, viloxazine, ► nortriptyline, ► mirtazapine and ► lithium, also induced an increase in circulating 3α,5α-THP levels that was associated with improved symptomatology in depressed patients. Other drugs that are used to treat mood disorders, including lithium and ► carbamazepine also increase brain levels of 3α,5α-THP in rats.

The atypical antipsychotic drugs, ► clozapine and ► olanzapine increase the brain and plasma concentrations of pregnenolone, progesterone and their metabolites, 3α,5α-THP and 3α,5α-THDOC, as well as the serum levels of corticosterone (see Payne et al. 2008 for review). The increase in neuroactive steroids is prevented by adrenalectomy, suggesting the involvement of HPA axis activation. In contrast, the typical antipsychotics, ► risperidone and ► haloperidol, induce a modest increase in serum progesterone and corticosterone levels, but do not alter brain 3α,5α-THP. Pregnenolone is elevated in the postmortem brain of patients with ► schizophrenia, though it is unknown if this is secondary to the disease or antipsychotic treatment. Nonetheless, elevations of pregnenolone and the GABAergic neuroactive steroids may contribute to the therapeutic efficacy of clozapine and olanzapine in patients with schizophrenia.

Regulation of $GABA_A$ Receptors

Changes in neuroactive steroid levels that occur *in vivo* under physiological conditions such as puberty, ovarian cycle, pregnancy or lactation are associated with changes in ► $GABA_A$ receptor function and expression (see Smith et al. in Morrow 2007). Likewise, the chronic administration of progesterone, 3α,5α-THP or oral contraceptives to rats also results in changes in $GABA_A$ receptor subunit function and expression. The onset of puberty is associated with abrupt increases in 3α,5α-THP levels and a marked increase in α4 and δ subunit expression in the mouse. Furthermore, administration of 3α,5α-THP, which is normally anxiolytic, increases anxiety in pubertal female mice, perhaps via decreased outward currents at the highly expressed α4βδ $GABA_A$ receptors. The diestrus phase of the mouse ovarian cycle is accompanied by elevated levels of progesterone and 3α,5α-THP, as well as increased expression of the δ subunit and decreased expression of the γ2 subunit of the $GABA_A$ receptor, with consequent increase in tonic inhibition and decreased seizure susceptibility and anxiety.

The regulation of $GABA_A$ receptor subunit expression during pregnancy in rodents is complicated by differential changes across different brain regions. However, the increase in neuroactive steroid levels observed during pregnancy appears to be consistently associated with a decrease in γ2 subunit expression in several regions. This decrease is reversed during lactation when neuroactive steroid levels normalize. More recently, it has been found that the expression of δ subunit is also decreased during pregnancy in mice and this decreased expression is associated with decreased activity of the receptor. Moreover, δ subunit knockout mice exhibit anxiety- and depression-like maternal behavior during the postpartum period, suggesting that δ subunit plasticity may be relevant to the development of postpartum depression (see Smith et al. in Morrow 2007).

Pharmacological treatment with steroids also has the ability to alter $GABA_A$ receptor subunit expression. Thus, administration of oral contraceptives to female rats is associated with increased expression of γ2 subunit mRNA and peptide, decreased levels of pregnenolone, progesterone and 3α,5α-THP, and increased anxiety-like behavior. Likewise, progesterone or 3α,5α-THP administration to female rats increased expression of α4 and δ subunits and decreased expression of the α1 subunit in the ► hippocampus, but the effects are no longer observed after 4–5 days, suggesting a compensatory mechanism to counteract the effects of continued steroid exposure on $GABA_A$ receptors. Furthermore, steroid withdrawal from long-term exposure of both progesterone and 3α,5α-THP results in marked increases in α4 and δ subunit expression in the hippocampus with subsequent changes in receptor function, sensitivity to ► benzodiazepines, and increased anxiety and seizure susceptibility (see Smith et al. in Morrow 2007).

Pathological Significance

Neuroactive steroid concentrations are altered in various pathological conditions including ► depression, premenstrual ► dysphoric disorder, alcoholism and schizophrenia (Morrow 2007; Payne et al. 2008). However, the pathological significance of these alterations remains a matter of speculation. Because neuroactive steroids contribute to regulation of the HPA axis response to stress and are modulated by drugs that are used as medications for neuropsychiatric disease, neuroactive steroids may play a homeostatic role that both reflects and influences the allostatic state of the person and contributes to the wide range of symptomatology associated with all of these disease states.

Patients with major depression have elevated cortisol levels, hypersecretion of CRF and suppression of feedback mechanisms marked by blunted dexamethasone suppression of cortisol levels. Some neuroactive steroid concentrations are decreased in patients with major depression as well as in ► animal models of depression, and administration of antidepressant-specific serotonergic reuptake inhibitors increases these neuroactive steroids in patients and in rodent brain and plasma (see Rupprecht 2003, for review). This increase might be mediated by a direct effect of specific serotonergic reuptake inhibitors on the biosynthetic enzyme 3α-hydroxysteroid dehydrogenase that produces GABAergic neuroactive steroids or by increased serotonin neurotransmission that stimulates the release of CRF to activate the HPA axis. The acute anxiolytic and antidepressant-like effects of neuroactive steroids, demonstrated in rodent models, may be important for prevention and recovery from major depression. Hence, neuroactive steroids may contribute to the therapeutic efficacy of antidepressant medications by contributing to GABAergic inhibition, modulation of the HPA axis, as well as the unknown mechanisms that underlie their acute antidepressant-like activity.

Neuroactive steroid levels are also altered in premenstrual dysphoric disorder, although the literature is controversial with reports of increases, decreases, and no change in 3α,5α-THP plasma levels (see Girdler in Morrow 2007). Differences in analytical methods, diagnostic criteria or presence of other comorbid psychiatric disorders might account for these discrepancies. Premenstrual dysphoric disorder results in dysregulation of the HPA axis and sympathetic nervous system responses to stress. Furthermore, these patients have a blunted 3α,5α-THP response to stress. Women with a history of depression, regardless of premenstrual dysphoric disorder symptoms, also had a blunted 3α,5α-THP response to stress. All this experimental evidence emphasizes the important link between HPA axis function and neuroactive steroid levels in the maintenance of homeostasis and healthy brain function.

Like depression, alterations in HPA axis responsiveness are found in alcoholism during drinking and abstinence (see Morrow in Morrow 2007). ACTH and cortisol secretion increased during ethanol intoxication and acute alcohol withdrawal, but attenuated responsiveness of the HPA axis is found in both drinking and abstinent alcohol-dependent patients. Alcohol-dependent patients have low cortisol and 11-deoxycortisol basal levels, and have a reduced cortisol response to exogenous ACTH challenge. Moreover, they have attenuated ACTH and cortisol responses after pituitary stimulation by ovine or human CRF. Altered cortisol and ACTH responses to ovine CRF and naloxone have also been found in sons of alcoholics. The levels of the GABAergic neuroactive steroids have not been studied under these conditions, but are likely to be impacted since both human and animal studies show that neuroactive steroid responses to stress or HPA axis activation are blunted when ACTH or glucocorticoid responses are blunted. Basal levels of the GABAergic neuroactive steroid 3α,5α-THP are reduced during ethanol withdrawal in humans, when circulating cortisol levels are elevated. Furthermore, abstinent alcoholic patients show a blunted pregnenolone sulfate response to adrenal stimulation and a delayed deoxycorticosterone response to ovine CRF challenge, supporting the idea that blunting of the HPA axis also impacts the GABAergic neuroactive steroid responses to stress in alcoholics.

The levels of neuroactive steroid precursors pregnenolone and DHEA as well as 3α,5α-THP have been studied in postmortem brain of patients with schizophrenia (see Payne et al. 2008, for review). Pregnenolone and 3α,5α-THP were present in human postmortem brain tissue at considerably higher concentrations than typically observed in serum or plasma. Pregnenolone and DHEA levels were higher in both posterior cingulate and parietal cortex of subjects with schizophrenia versus control subjects. 3α,5α-THP levels tended to be decreased in parietal cortex in subjects with schizophrenia when compared with control subjects. Furthermore, pregnenolone, DHEA and 3α,5α-THP levels determined in human postmortem brain in these investigations are known to be physiologically relevant and therefore may have a functional impact on pathophysiology and not merely represent an epiphenomena. In addition, neuroactive steroid induction represents a potential mechanism contributing to the efficacy of clozapine and olanzapine, which in turn increase plasma pregnenolone and 3α,5α-THP levels in rodents. Clinical evidence suggests antipsychotic properties for neuroactive steroids. Progesterone administration ameliorates symptoms of postpartum psychosis in women. Furthermore, adjunct treatment with pregnenolone or 17β-estradiol improves schizophrenia symptomatology in both men and women. Most recently, two independent studies show that pregnenolone improves cognition and negative symptoms in patients with schizophrenia. These findings suggest that neuroactive steroids are candidate modulators of schizophrenia pathophysiology and/or therapeutics.

Progesterone and its GABAergic metabolites promote the viability of neurons in the brain and spinal cord. Neuroprotective effects have been documented in animal models of traumatic brain injury, experimentally induced ischemia, spinal cord lesions and Nieman–Pick type-C disease (see Schumacher et al. and Mellon in Morrow 2007). It is unknown if GABAergic neuroactive steroid levels are deficient or contribute to the etiology of these diseases, but their ability to promote recovery suggests a role in pathophysiology. Indeed, progesterone had remarkable efficacy in a clinical study of traumatic brain injury where it dramatically reduced mortality and increased recovery of function. This is a new area of avid investigation that will likely lead to a better understanding of the role of neuroactive steroids in health and disease.

Therapeutic Potential of Neuroactive Steroids

The preceding sections have alluded to the therapeutic potential of GABAergic neuroactive steroids and their precursors for behavioral disorders that involve anxiety, dysregulation of the HPA axis, ▶ cognitive impairment and brain inflammation. Many neuropsychiatric disorders exhibit these attributes as components of different syndromes that may contribute to severity of disease or recovery under standard treatment protocols. Therefore, neuroactive steroids might be considered as primary or adjunctive therapy that supports normal brain function and cognition, normalization of HPA axis function and the reduction of inflammatory processes that contribute to neuronal dysfunction and cellular death. Since brain inflammation is implicated in depressive disorders, alcoholism, brain lesions, traumatic brain injury and possibly cognitive disorders such as schizophrenia and ▶ Alzheimer's disease, the use of neuroactive steroids or precursors may ameliorate this component of the pathology and thereby support recovery or disease management.

Few neuroactive steroid compounds are under development for neurological or psychiatric disease, despite the data reviewed here. No GABAergic neuroactive steroids are presently approved for clinical use in any disease, therefore compounds are not readily available for clinical testing. The precursor pregnenolone is commercially available as a nutritional supplement and therefore, little impetus exists for clinical trials sponsored by the pharmaceutical industry. The GABAergic neuroactive steroids could also have abuse or dependence potential, and this factor increases the risk of untoward effects – a deterrent to investment in the development of new compounds. Despite these limitations, clinical trials are underway for traumatic brain injury, schizophrenia, alcoholism and anxiety and depressive disorders. Indeed, stimulation of steroidogenesis by direct activation of the 18-kDa cholesterol translocator protein has recently been shown to have therapeutic potential for anxiety disorders, without the side effects concomitant with the use of benzodiazepine anxiolytics (Rupprecht et al. 2009). In addition, ongoing basic research may uncover the role of GABAergic transmission, sigma receptors or pregnane-X receptors in the therapeutic efficacy of neuroactive steroids in animal models. Further studies are needed to evaluate the therapeutic potential of neuroactive steroids.

Definition

"Neurodegeneration" is a common expression and most frequently it is not defined in manuscripts dealing with what authors think it is or could be. An important question is how we define aging, and it is often difficult to differentiate between age-related processes and neurodegenerative ones. This includes neuronal systems that are vulnerable to aging but also to degenerative pathology, and this may happen in certain brain regions while others are spared. Degeneration (in one system only or in several ones?) thus may start with only a functional disturbance triggered by dose-related genetic aberrations or by environmental circumstance.

This article focuses on a classical neurodegenerative disorder for which aging is a major risk factor but with significant differences between the pathology of Alzheimer's disease and the physiological aging process. Thus, we regard this article as a "teaching example." But in addition, Alzheimer's disease presents many pathological features and mechanism which are unspecific, that is, they are common in many neurodegenerative disorders, such as Parkinson's disease, etc. For example, we present many pathological processes which are a general basis of

"neurodegeneration," such as loss of adenosine triphosphate (ATP), disturbances of the respiratory chain activity, disturbances of the energy metabolisms, apoptosis, and ► reactive oxygen species (► ROS).

Impact of Psychoactive Drugs

Among all dementia (see DeDeyn and Pemberton; this volume) ► Alzheimer's disease (AD) is the most frequent dementia disorder in old age. In origin, AD can be divided into two different forms. (1) A very small proportion of 1% or less of all Alzheimer cases is caused by missense mutations in presenilin 1 and 2 on chromosomes 14 and 1, respectively, or in the amyloid precursor protein (APP) gene on chromosome 21, leading to autosomal dominant familial AD with an early onset (Rocchi et al. 2003). These currently known three types of mutations are involved in both the overexpression and abnormal cleavage of APP, and increased formation of its derivative amyloid peptide(s) (e.g., $A\beta_{1-40;\ 1-42;\ 1-43}$) being the inevitable starting point for the disease process of familial AD in the form of the cause–effect principle (► β-amyloid cascade hypothesis) (2). In contrast, millions of people worldwide suffer from sporadic AD, and no such mutations were found as yet for this dementia form. However, two susceptibility genes may contribute to the development of sporadic AD: (1) a ► single nucleotide polymorphism in the gene coding for 11β-hydroxysteroid dehydrogenase I that may amplify the glucocorticoid action in the brain; (2) allelic abnormalities of the apolipoprotein E (APOE) 4 gene on chromosome 19 involved in the lipid transport in the brain and in the metabolism of the plasma membrane constituent cholesterol.

Morphologically, AD is characterized by cell loss in susceptible brain regions, extracellular deposition of β-amyloid containing neuritic ► plaques and ► neurofibrillary tangles mainly composed of hyperphosphorylated tau protein.

Beside the above risk factors, aging has been found to be the main risk factors for AD.

A multitude of inherent variations in fundamental metabolic processes are set into motion at the cellular, molecular, and genetic levels which result from functional imbalances of regulative systems such as

- Energy production (reduced) and energy turnover (increased)
- Insulin action (reduced) and cortisol action (increased)
- ► Acetylcholine action (reduced)
- ► Noradrenaline action (increased) indicative of an increased sympathetic tone, in brain areas due to environmental stress, which in addition causes hypercortisolemia via chronic disturbance of the hypothalamic–pituitary–adrenal axis
- Formation of ROS (increased) and capacity of their degradation (reduced)
- Loss of membrane lipids and shift of unsaturated fatty acids in membranes in favor of saturated fatty acids
- Dysregulation of intracellular pH
- Shift of gene expression profile from anabolic site (reduced) to catabolic site (increased)

to name the functionally most important ones. These variations/shifts may indicate an uncoupling of synchronization of biological systems that may correspond to increased entropy, that is, increased mess-up of a biological system. Smaller additional internal or external events, even one that is ineffective in itself, may change biological and/or biophysical properties of the aging brain. Such events may shift a system in a stepwise manner to increased entropy/decreased criticality ending in a catastrophic reaction (disease) (Hoyer and Froelich 2007; Hoyer and Plaschke 2004).

Physiologically, the mature mammalian brain uses the nutrient glucose exclusively to ensure its structure and function. From the ► glycolytic glucose metabolite fructose-6-phosphate (F-6-P), UDP-*N*-acetylglucosamine (UDP-GlcNAc) is formed and used for protein *O*-glycosylation, for example, for ► tau protein (Hart 1997). The metabolite acetyl-CoA serves as the source of the generation of (1) the neurotransmitter acetylcholine for learning and memory processes and (2) the membrane constituent cholesterol in the 3-hydroxy-3 methyl-glutaryl-CoA cycle. Finally, the energy-rich compound ATP is formed which is essential to most cellular and molecular activities. A hierarchy of ATP-utilizing processes has been proposed in the following order: protein synthesis > RNA/DNA synthesis > Na^+ cycling > Ca^{2+} cycling > proton leak. The position in this hierarchy may be determined by the sensitivity of each process to changes in energy charge.

Highly ATP-dependent processes are (Hoyer and Froelich 2007)

- Sorting, folding, transport, and degradation of proteins
- Maintenance of pH 6 in the endoplasmic reticulum/Golgi apparatus
- Heat shock protein-guided transport across the latter compartments
- Axonal transport of proteins
- Regulation of the conformational state of insulin degrading enzyme
- Maintenance of intracellular/extracellular ion homeostasis

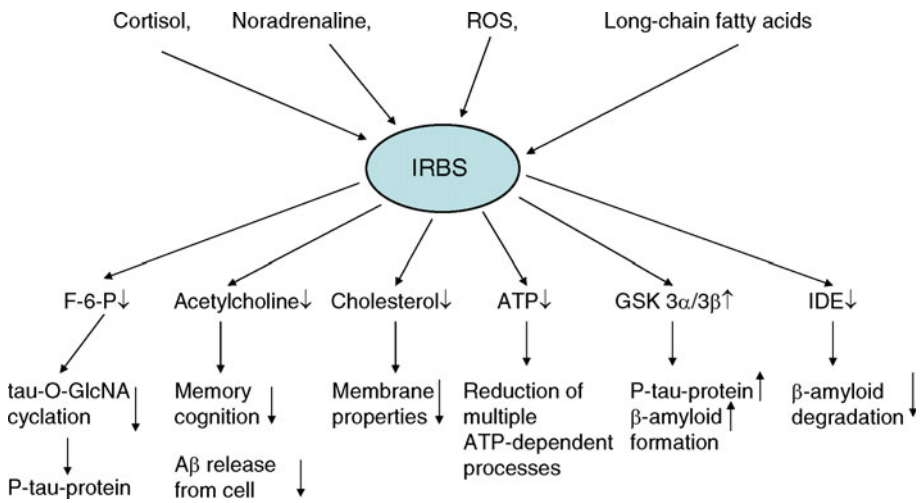
- Maintenance of biophysical membrane properties
- Maintenance of a membrane potential in neurons
- Regulation of synaptic membrane composition
- Maintenance of synaptic transmission
- Control of the metabolism of both APP and tau protein

β-amyloid deposits as a hallmark of AD tell us they are important. However, in contrast to familial AD, it has to be proven yet that the mismetabolism of APP and the increased formation of the derivative β amyloid contribute to the generation of sporadic AD. Recent evidence has been provided that an ► insulin resistant brain state (► IRBS) may play a pivotal role in the generation of the latter dementia form (Grünblatt et al. 2007; Riederer and Hoyer 2006; Salkovic-Petrisic et al. 2006). Several age-related candidates may contribute to the causation of an IRBS:

- Increased concentration of cortisol that may cause neuronal insulin receptor desensitization by inhibition of its tyrosine residues phosphorylation
- Increased activity and metabolism of noradrenaline and increased concentration of cAMP that lead to the decrease of the receptor's tyrosine kinase activity
- Increased concentration of ROS (the uncharged species hydrogen peroxide) that may persistently inhibit the activity of phosphotyrosine phosphatase, thus inhibiting its dephosphorylation and rendering the insulin receptor ineffective
- Increased concentration of long-chain fatty acids that may reduce insulin's receptor binding

An IRBS may induce diverse abnormalities in cellular and molecular brain metabolism (Hoyer 2004) (Fig. 1), among which is the reduction of glucose metabolism including the compound F-6-P, acetyl-CoA, and ATP. F-6-P decrease favors tau hyperphosphorylation; the fall of acetyl-CoA diminishes the formation of both acetylcholine and cholesterol. The reduction of the former decreases the cellular release of APP via its muscarinic receptors; likewise, learning, memory, and cognitive capacities decline. The reduction of cholesterol in the cell membrane changes its properties and may, thus, damage receptor function. The deficit in ATP has a cascade-like effect on diverse ATP-dependent cellular and molecular processes (see above) which may damage cell functions and may jeopardize the survival of the cell. The compromised insulin signaling downstream of the insulin receptor may activate glycogen synthase kinase-3α/β which may result in hyperphosphorylated tau protein and increased production of β-amyloid (Hoyer 2004). The reduced insulin signal may downregulate IDE resulting in a reduced capacity to degrade β-amyloid and, thus, favoring its cellular accumulation.

In contrast to the hereditary form of AD, sporadic AD may be considered to be a complex and self-propagating metabolic brain disease showing predominating abnormalities in oxidative/energy metabolism including decreases in the formation of both acetylcholine and cholesterol finally ending in the formation of neuritic plaques and neurofibrillary tangles. Therefore, a "rational" therapy may be based upon different strategies.



Neurodegeneration and Its Prevention. Fig. 1. Candidates which may induce an insulin resistant brain state (IRBS) and a survey of diverse effects thereafter.

According to all available information about the pathology of sporadic AD, it is evident that multiple drug regimes are necessary in order to come closer to a "disease modifying" treatment strategy. Therefore, multifunctional drugs are necessary to be developed. While the development of anti-Alzheimer (dementia) drugs involves all currently known pathological principles driven by globally acting industry as well as smaller companies and start-up companies, the concept of developing multifunctional drugs is still the one followed by relatively few (Riederer and Gerlach 2009). Worldwide enormous capacity focuses developments into (1) new substances to inhibit acetylcholine esterase or to block glutamatergic *N*-methyl-D-aspartate (NMDA) receptor subunits. Currently, several drug companies develop novel compounds as ▶ acetylcholine esterase inhibitors and also various types of glutamatergic receptor antagonists (Riederer and Gerlach 2009). Other strategies are related to nicotinergic and muscarinergic receptor subtype modulation (see Ragozzine; this volume). These are not expected to be ▶ disease-modifying strategies. The therapeutic potency, side effects, and adverse reaction profile of receptor subtype specific nicotinic and muscarinic drugs still have to be evaluated. (2) There is profound knowledge about the β-amyloid pathology. Based on this, many companies try to develop (1) protein aggregation inhibitors, (2) β- and γ-secretase inhibitors, or (3) vaccination strategies against Aβ-induced plaques (see Le Sage and Pentel; this volume). For the latter, caution is suggested if the data from Holmes et al. (2008) are taken into consideration. These postmortem human brain studies performed on AD patients who have deceased after vaccination with AN 1792 give evidence that reduction of plaque load is not correlated with any cognitive improvement. However, it has been suggested that vaccination at progressed stages of AD comes too late. Therefore, early vaccination strategies are envisaged.

Much less efforts are taken into the reduction of tau-protein related pathology. The reason might be that the focus has been on amyloid because of the proven genetic link between AD and amyloid in the admittedly small number of familiar AD cases.

Current pharmacotherapeutic strategies of sporadic AD consist of supplementation of central acetylcholine deficit by acetylcholine esterase inhibitors (see Newhouse; this volume) and by an ▶ NMDA receptor antagonist. In addition to this standard therapy, other options for interfering with pathological mechanisms are antioxidants to defeat the action of ROS (vitamins-A, -E and -C or Ginkgo biloba). All these therapeutic interventions together are suitable to improve the ▶ quality of life of AD patients for about 1–2 years, but they are unable to reduce or even halt the progression of this devastating disorder.

Antioxidative drug developments are of more general interest as oxidative stress is proven in all neurodegenerative disorders. The same holds true for anti-inflammatory drug developments.

One aspect that, at least in our minds (see above), deserves more attention is influencing the "glucose metabolism." Drug-related interactions are given by (1) α- and β- (PPAR) γ-agonists, (2) glycogen synthase kinase (GSK)-3-α and -β-inhibitors, as well as (3) inhibitors of advanced-glycation-end (AGE) product biosynthesis or inhibitors of AGE-receptors. It is to hope that part of such research will come from antidiabetic research and respective drug developments. Influencing the "IRBS" is right now the most plausible mode of action to causally treat sporadic AD (Grünblatt et al. 2007; Riederer and Hoyer 2006; Salkovic-Petrisic et al. 2006).

There is still a debate about cholesterol, hypercholesterolemia (as measured in plasma/serum), and the use of antihypercholesterolemia directed drugs, statins. As we have pointed out earlier (Hoyer and Riederer 2007) it is necessary to distinguish between the peripheral and central cholesterol-related pathology. There is no question that the treatment of peripheral hypercholesterolemia is useful to reduce and avoid, for example, cardiovascular disturbances. Chronic increase of plasma/serum cholesterol may also disturb the functioning of brain capillaries and thus may provoke β-amyloid pathology within the capillaries epithelium. If so, "peripheral" antihypercholesterolemia treatment by peripherally acting statins may be useful. Experimental proof for this working hypothesis, is, however, still lacking.

As peripheral cholesterol does not pass the ▶ blood-brain barrier, knowledge about soluble and membrane-bound cholesterol in brain regions involved in the pathology of sporadic AD is speculative. While there is evidence for (1) reduced cholesterol in membranes undergoing degeneration and (2) disturbed membrane fluidity based on an imbalance of the cholesterol/fatty acid ratio, there is no data available to judge the role of soluble neuronal/extraneuronal cholesterol. In case of such lack of knowledge, it is not justified to use centrally acting statins, as they may lead to worsening of AD if used in a chronic treatment design. In line with this are all the negative outcomes of prospective clinical studies using statins for sporadic AD (Hoyer and Riederer 2007).

However, all pharmacotherapeutic actions are too late to be effective as "disease-modifying" or even neuroprotective or neurorestorative strategy (see Rhodes and Green; this volume). Therefore, development of biomarkers in

order to detect early phases of pathological development, for example, in the population of "► mild cognitive impaired patients" or even earlier on the basis of "health-control check-ups" is as important as drug development. In fact, there is current effort by both basic/clinical research and industrial interest to get this dual concept into a reality (Riederer and Gerlach 2009).

Conclusion: While early phases of familiar AD show a deficit in glucose consumption but unchanged O_2 consumption, thus giving no evidence for an energy deficit, in later phases of familiar AD a loss of energy may be assumed. In contrast, sporadic AD is based on multiple pathological mechanisms, the more causally related disturbances in the metabolism of glucose and energy being still underestimated by molecular biological and genetic approaches. As such development of multifunctional drugs deserves apparent urgency.

Neurodevelopmental Hypothesis

Definition

The neurodevelopmental hypothesis suggests that ► schizophrenia results from abnormalities in neuronal connectivity, which arise during fetal life but are not expressed until the onset of illness.

Neuroendocrine Markers for Drug Action

R. H. De Rijk, E. R de Kloet
Department of Medical Pharmacology, Leiden Amsterdam Centre for Drug Research and Leiden University Medical Center, 2300 RA Leiden, The Netherlands

Definition

The ► hypothalamic-pituitary-adrenal (HPA) axis is a neuroendocrine system that coordinates adaptation of body and brain function to environmental demands: i.e., day- and sleep-related events and ► stressors (Chrousos and Gold 1992). The hormones of the HPA axis operate in a feedforward cascade from hypothalamic ► corticotropin releasing hormone (CRF) and vasopressin via pituitary ► adrenocorticotropin hormone (ACTH) to adrenocortical secretion of glucocorticoids in the circulation. Glucocorticoids in turn feedback on brain and pituitary to shut down the activated HPA axis. In this chapter the mechanism underlying HPA axis functioning is first described, and subsequently the different tests being used to evaluate HPA axis reactivity. Then, specific psychiatric disorders characterized by dysregulation of the HPA axis are discussed and genetic and early life susceptibility factors are referred to. The chapter concludes with an analysis of HPA axis responses that may serve as predictors for the efficacy of psychoactive drugs in humans.

Impact of Psychoactive Drugs

HPA Axis Regulation

Corticotrophin releasing hormone on factor (CRF) and its co-secretagogue vasopressin (AVP) organize the behavioral, sympathetic, and neuroendocrine response to daily- and sleep-related events and stressors (de Kloet et al. 2005). The neuroendocrine response proceeds via the hormones of the HPA axis, e.g., hypothalamic CRF and AVP, pituitary ACTH, and adrenal glucocorticoids. CRF, AVP, and POMC peptides also have elaborate ► neuropeptide networks in the limbic-midbrain which modulate the processing of circadian and stressful information (Herman et al. 2003). Additionally, many neurotransmitter systems influence dynamically at several levels the activity of the HPA axis. These include among others ► GABA, ► glutamate, monoamines, neuropeptides, and gas-based messengers. More recently, the ► endocannabinoid system has been proposed to exert an inhibitory action on HPA axis activation.

Under basal conditions the hormones of the HPA axis are released in hourly pulses (Lightman et al. 2008). The magnitude of these pulses changes during day and night with the largest amplitude at the start of the activity period. Awakening triggers an additional distinct HPA response. The pulsatile HPA axis pattern shows gender differences. The frequency of the pulses alters during chronic stressful or inflammatory conditions. The ultradian rhythm becomes disordered during Cushing and Addison's disease and during the aging process. The pulse generator resides in the hypothalamus, but its nature is unknown and pulses are amplified on the adrenal level. Frequency encoding is a common mechanism in information processing by hormonal systems and evidence is accumulating that resilience in target tissues depends on pulsatile exposure to glucocorticoids.

Superimposed on the ultradian rhythm is the response to stressors. In fact, it has been shown in rats that the magnitude of the HPA axis response depends on the phase of the rhythm: corticosterone responses were larger when a stressor is experienced at the ascending rather at the descending phase. The onset, duration, and magnitude of the HPA axis response is affected by the previous experience, and, in particular, early life events are potent stimuli capable to program the reactivity of the axis to stressors in later life. The most profound psychological stressors are characterized by loss of control, no information, and no prediction of upcoming events combined with a sense of fear and uncertainty. This condition results in a profound and long-lasting activation of the HPA axis.

Receptors

The actions of the various HPA axis hormones are mediated by receptors. CRF has a high affinity to the CRF-1 receptors and a lower affinity to the CRF-2 receptors, which have actually their own privileged ligands urocortin II and III. CRF-1 receptors are on pituitary corticotrophs and have a discrete localization in limbic-midbrain circuitry: such as e.g., in the amygdala, where CRF promotes emotional arousal. Activation of the CRF-2 receptor ligands produces complimentary responses. There is evidence that CRF-1 and CRF-2 receptors mediate different phases of the ► stress-response from activation to later adaptations. CRF-1 antagonists have been developed which suppress fearful and emotional responses in animals and humans (Ising et al. 2007). These antagonists potentially represent a new generation of ► anxiolytic and/or ► antidepressant agents that have an action mechanism within the stress system.

AVP binds to AVP-1 receptors regulating the pressor response, to AVP-2 receptors mediating its antidiuretic action in the kidney, and to AVP-3 receptors in pituitary corticotrophs inducing ACTH release. These AVP receptors are also localized in discrete brain regions. The oxytocin receptor which is localized in central ► amygdala, ventromedial nucleus, ventral subiculum, and olfactory tubercle also displays high affinity to AVP. Peptides such as AVP and OT have long been known to act potently in ► fear conditioning paradigms and have an important modulatory function in psychosocial aspects of behavior.

The glucocorticoids cortisol (man) and corticosterone (man and rodent) readily penetrate the brain and bind to two types of nuclear receptors: high affinity mineralocorticoid receptors (MR) and lower affinity glucocorticoid receptors (GR), which are colocalized in high density in the limbic system. These nuclear receptors also have lower affinity membrane variants that can mediate rapid actions of glucocorticoids in brain. The action of glucocorticoids mediated by the two types of receptors operates in complimentary fashion. The low and high affinity MR are involved in appraisal processes and involved in the onset of the stress response, while the termination of the stress response is facilitated via the GR types (negative feedback) and the way the stressful experience is handled and stored in the memory for future use.

An organism is healthy and resilient when the HPA axis is readily activated as long as it is also turned off efficiently. If coping with stress fails HPA axis regulation is compromised, CRF is usually hyperactive, and stress-induced glucocorticoid secretion can be inadequate or excessive and prolonged. Psychoactive drugs that interact with the stress neurocircuitry in the limbic-midbrain have

the potential to modulate HPA axis regulation, either by direct interaction with the "core" of the HPA axis or indirectly by modulation of afferent pathways. Recovery of HPA axis responsiveness and pulsatility by, e.g., antidepressants precedes recovery from depression.

Testing of HPA Axis Reactivity

Cortisol, the human's principal glucocorticoid, binds in plasma to serum albumin and with higher affinity to corticosteroid binding globulin or transcortin. Hence, total cortisol can be measured as index for adrenocortical output; free cortisol is considered to be the biologically active fraction. Currently, the free cortisol concentration is often determined in saliva, which can be obtained by a much less stressful procedure than blood via venipuncture. In 24 h urine cortisol and 17-ketosteroids (17-OHCS) are measured and are an index for daily production.

Basal values of cortisol are often reported, but these levels must be judged with care. In single measurements, hourly pulses of the hormone may produce variable data unless temporal patterns are measured. Moreover, the amplitude of the cortisol pulse displays a strong circadian rhythm producing high levels of the hormone during awakening and low levels from usually 11.00 p.m. to 5.00 a.m. Finally, 30 min after awakening a sharp rise in cortisol is observed on top of the circadian rhythm. This rise is called the cortisol awakening response (CAR).

Chemical challenges of the HPA axis date back to the 1970s, when administration of 1 mg dexamethasone was used to test the negative feedback capacity of the HPA axis; this is the so-called dexamethasone suppression test (DST). Glucocorticoid receptors (GR) in the pituitary corticotrophs are probably the primary target of dexamethasone, which at these low dosages is hampered to penetrate the brain by multi drug resistance P-glycoprotein located in the ►blood brain barrier. Lower doses of dexamethasone of 0.5 mg and even 0.25 mg can detect more subtle differences in negative feedback function.

An extension of the DST, the combined dexamethasone–CRF challenge was developed as a pharmacological test of reactivity of the HPA axis, further amplifying differences in dexamethasone sensitivity. The principle of the test is that the individuals receive dexamethasone at 23.00 p.m. and then the next afternoon the pituitary–adrenal response to a CRF injection is measured. The CRF in this test enhances escape from dexamethasone suppression. Several other pharmacological challenges of the HPA axis have been developed and applied. To test the integrity of the pituitary gland, ovine CRF or AVP was administrated to depressed patients. Furthermore, ACTH challenges are being performed often using high (250 μg) or low (1 μg) dose Synacthen (synthetic ACTH), to test synthesis and secretion of corticosteroids by the adrenal cortex.

Physical challenges of the HPA axis may involve, for example, strenuous exercise for 20 min on a tread-mill under controlled conditions of O_2 usage and CO_2 production. This condition results in a profound activation of the HPA axis. Such conditions in which energy metabolism is challenged usually are accompanied by a profound increase in adrenal sensitivity to ACTH.

Psychological challenges characterized by lack of control and lack of social support trigger the largest ACTH and cortisol response. The ►Trier Social Stress Test (TSST) is a well-established psychosocial stress test (Dickerson and Kemeny 2004). This test involves a public speaking and mental arithmetic task which needs to be performed in front of an audience and camera, and results in a large increase in ACTH, cortisol and sympathetic activity.

Hypo- and Hypercortisolistic States

Health and resilience are characterized by a reactive HPA axis that is readily turned on and off. Several disease states have been associated with changes in basal and activated HPA axis responses. Thus, *hyper*cortisolemic states usually enhance the risk for infection because of suppression of the immune system. Examples are Cushing syndrome, melancholic depression, ►panic disorder, ►anorexia nervosa, sleep deprivation, ►addiction, and malnutrition. Alternatively, *hypo*cortisolism enhances the risk for inflammatory disorders because the cortisol action is insufficient to restrain the initial stress reactions. Examples are Addison's disease, atypical depression, chronic fatigue syndrome, fibromyalgia, ►post traumatic stress disorder (PTSD), and autoimmune diseases.

Common functional genetic variants that are associated with changes in HPA axis reactivity have been described (DeRijk 2009). Most evidence for specific genetic components is provided by ►single nucleotide polymorphisms (SNPs) in the MR- and GR-genes found to modulate both negative feedback and stress-induced activity of the HPA axis. Importantly, these SNPs in the MR- and GR-genes also associate with aspects of ►depression, indicating their importance as vulnerability factors. Alternatively, a trait defect might be acquired as a result of unfavorable environmental circumstances, particularly during early life (Champagne et al. 2009). These so-called "programming" effects cause changes in the expression of MR and GR with consequences for HPA axis reactivity, neuronal activity, and behavior. In addition, also gender and aging have been found to modulate HPA axis reactivity.

Depression

In depressed patients, basal plasma ACTH and cortisol have been found to be elevated (Holsboer 2000). Also urinary free cortisol, saliva free cortisol, or cerebrospinal fluid (CSF) cortisol levels are increased. Escape from dexamethasone suppression was observed in a subgroup of depressed patients suggesting resistance to corticosteroid action. Hypercortisolism in depression is further supported by the enlarged adrenal glands of the patients. This indicates enhanced adrenal sensitivity to ACTH stimulation. The combined dexamethasone suppression–CRF stimulation test (Dex-CRF test) appears to be the most sensitive tool to detect depression related changes in HPA axis reactivity. Moreover, several studies reported that normalization of the HPA axis precedes or parallels the clinical response to antidepressant treatment (Binder et al. 2009).

Post Traumatic Stress Disorder

Core features of HPA axis changes in PTSD include low basal cortisol secretion and enhanced negative feedback control of the HPA axis (Yehuda 2002). The enhanced negative feedback was found using low-dose dexamethasone (0.25 mg) or metyrapone tests. Blunted ACTH responses to CRF stimulation are explained by downregulated CRFR1, possibly as a result of sustained, increased endogenous CRF levels. However, findings have not been consistent. Differences could involve disease stages, gender, genetic background, or type of trauma among others. Using the combined Dex–CRF test did not reveal HPA-axis abnormalities in PTSD patients when compared to trauma controls (also exposed to trauma but without PTSD). However, PTSD patients with a comorbid MDD showed an attenuated ACTH response compared to PTSD patients without comorbid MDD. This indicates the presence of PTSD subgroups with different HPA-axis regulation.

Psychoactive Drugs that Modulate HPA Axis Reactivity

First, almost all drugs that change central neuronal processes initially modulate basal and stress-induced HPA axis activity, because they acutely change homeostasis (Table 1). Here, drugs that affect parts of the regulatory mechanisms of the HPA axis and that are used in clinical practice are described.

Benzodiazepines. ▶ Benzodiazepines are a major first line of treatment in anxiety disorders. However, little is known of their effect on HPA axis reactivity in man. Administrations of 1 mg ▶ Alprazolam strongly inhibits psycho(social) stress-induced increases in ACTH and cortisol in males. Other ▶ GABA agonists such as Pivagabine (PVG), a hydrophobic 4-aminobutyric acid derivative (7 days treatment, 900 mg, twice a day), could inhibit ACTH and cortisol responses following a psychosocal stressor. Basal levels of cortisol are decreased following administration of Codeine (an opiate), ▶ diazepam, or ▶ oxazepam (benzodiazepines). Prolonged use of benzodiazepines results in profound suppression of the basal and stress-related HPA activity, and discontinuation of these drugs results in rebound activation. ▶ Flumazenil, which has been proposed to exert GABA R antagonistic properties, did show however a decrease in plasma ACTH and cortisol, following administration. ▶ Valproate used to treat bipolar disorders and epilepsy, has several modes of action including inhibition of GABA breakdown. Administration leads to enhanced HPA axis responsiveness. Taken together, drugs that stimulate GABAergic transmission decrease the activity of the HPA axis. ▶ Carbamazepine, acting on voltage dependent sodium channels, is used for mood stabilization in bipolar disorder and in epilepsy. This drug enhances both basal as well as ACTH and cortisol concentrations as outcomes of the Dex–CRF test following prolonged treatment. Also ▶ lithium did enhance Dex–CRF responses but also to increased morning cortisol levels in the DST (1.5 mg).

Cholinergic agents. These agents are mainly used to control blood pressure (hypertension Glaucoma), Myasthenia Gravis and are used during anesthesia. Furthermore, they are suggested to improve clinical signs of ▶ Alzheimer's disease. ▶ Physostigmine, an acetylcholine esterase inhibitor used in Myasthenia Gravis, did not change basal ACTH and cortisol secretion per se, excluding direct effects on basal HPA secretion under these conditions. However, eating-induced ACTH and cortisol responses were further increased. Also acute administration of physostigmine increased plasma cortisol lasting for several hours. Neostigmine (a parasympathomimetic, acetylcholine esterase inhibitor) given epidurally significantly reduced the plasma levels of cortisol in the early surgical period. Ectothiopate (parasympathomimetic, irreversible acetylcholine esterase inhibitor), used as eyedrops in glaucoma, has not been tested on HPA axis parameters. ▶ Scopolamine used to treat motion sickness or together with atropine in anesthesia, is a muscarinic antagonist but did not have an effect on the HPA axis. Pirenzepine, a muscarine 1 receptor antagonist used in peptic ulcers, enhanced the circadian differences of basal cortisol levels. ▶ Rivastigmine, ▶ tacrine, ▶ donepezil, and ▶ galantamine (all cholinesterase inhibitors) used in Alzheimer's diseases, have not been tested on HPA axis parameters and no clear data are available. ▶ Nicotine was

Neuroendocrine Markers for Drug Action. Table 1. Drug effects on HPA axis activity

Drugs				HPA axis			
System involved	Indication	Drugs	Action	Acute effects		Prolonged effects	
Biogenic monoamimes				Basal cortisol	Reactivity	Basal cortisol	Reactivity
NE 5-HT DA		Amphetamine	Reuptake inhibition	No effects			
	Antidepressant drugs	TCA	Reuptake inhibition	Increase		Decrease	Normalization
	Antidepressant drugs	TCA/SSRI	Reuptake inhibition	Increase		Decrease	Normalization
	Antidepressant drugs	Mirtazepine	NSSA, antagonist of 5-HT_2 and H_1	Decrease

found to be a strong activator of the hypothalamus pituitary adrenal (HPA) axis. In habitual smokers, a few cigarettes activate the HPA axis, but only small changes of basal HPA axis activity are observed, with an attenuated responsiveness of the HPA axis to psychological stress but not to injection of CRF. Etomidate, used in trauma settings to intubate patients, is short acting and activates GABA R and possibly also mACh receptors. It lowers plasma cortisol levels because of inhibition of the 11 β hydroxylase blocking the conversion of deoxycortisol to cortisol.

Biogenic monoamines and antidepressants. Monoamines clearly activate the HPA axis. Modulators of ▶ monoamines are used for the regulation of blood pressure and in psychiatric disorders. Oral administration of 5-HTP, the direct precursor of ▶ serotonin (5-HT) induces fast dose-dependent increases in circulating ACTH and cortisol. Also administration of the 5-HT releasing agent ▶ D-fenfluramine or the piperazine-based 5-HT receptor agonist mCPP increases acutely ACTH and cortisol responses. ▶ Buspirone, a 5-HT_{1A} agonist used to treat anxiety disorder, induces ACTH and cortisol responses following acute challenges. Gepirone, a partial 5-HT_{1A} agonist having ▶ anxiolytic properties, also resulted in large increases in plasma cortisol.

Noradrenaline (NE) or serotonin (5-HT) reuptake-inhibiting antidepressants such as ▶ reboxetine or ▶ citalopram acutely stimulate cortisol and ACTH release in healthy volunteers. ▶ Mirtazapine, a noradrenergic and specific serotonergic antidepressant (NaSSA), acutely inhibits the ACTH and cortisol release, probably due to its antagonism at central 5-HT_2 and/or H_1 receptors. The classic TCAs, such as desipramine, ▶ imipramine, and ▶ clomipramine, also induce an acute increase in ACTH and cortisol levels. Following longer treatment with most reuptake inhibitors, including SSRI's and noradrenergic specific reuptake inhibitors, a gradual normalization of the hyperactive HPA axis is found in depressed patients (Binder et al. 2009). These chronic effects probably depend, at least in part, on the increased expression of MR and GR, leading to a normalization of HPA axis reactivity. Nefazodone, a 5-HT_{2A} and alpha1 adrenergic antagonist also inhibiting NE and 5-HT reuptake, increased slightly cortisol levels following administration in healthy subjects. ▶ Moclobemide, a selective MAO-A inhibitor mostly used in refractory depression, slightly decreases cortisol levels upon acute administration.

▶ Methylphenidate is a norepinephrine and dopamine reuptake inhibitor with affinity for the serotonergic 5-HT_{1A} and 5-HT_{2B} is used in ADHD as a psychostimulant. Acute administration induces increases in cortisol while prolonged treatment with methylphenidate did not seem to affect basal cortisol or cortisol levels during exercise. ▶ Amphetamine increases levels of norepinephrine, serotonin, and dopamine in the brain by actions on the transporter and synaptic vesicles. However, acute amphetamine administration up to 20 mg did not activate the HPA axis. Cocaine is a dopamine, norepinephrine, and a serotonin reuptake inhibitor and acute administration induces an increase in plasma ACTH and cortisol.

Clonidine is an alpha2-adrenergic agonist used in hypertension and migraine, and its acute administration resulted in a strong decrease of the activity of the HPA axis, with low ACTH and cortisol levels. Methoxamine, an alpha1 agonist used for nasal congestion, enters the CNS following peripheral administration. ACTH and cortisol increased early during methoxamine infusion and ACTH returned to baseline promptly after the infusion ceased.

▶ Prazosin, an alpha1 antagonist used as an antihypertensive, lowers challenge induced activation of the HPA axis. ▶ Yohimbine is an alpha2-adrenergic antagonist acting on presynaptic terminals that inhibit (nor)adrenaline release. Acute administration of yohimbine results in increases in CSF noradrenaline levels leading to increases in plasma ACTH and cortisol. Following a serotonergic challenge, coadministration of yohimbine further increases cortisol values. Doxazosin, an alpha2 antagonist for treatment of severe hypertension, resulted in a short-lasting decrease of plasma cortisol. For ▶ propranolol, a beta receptor antagonist, mixed results have been reported ranging from no effects (psychosocial stress) to increased cortisol responses (exercise). Prolonged administration of Carvedilol, having alpha1 and beta receptor antagonistic properties, leads to a noticeable increase in serum cortisol levels. Nebivolol, a beta1 selective blocker with vasodilator properties, did not seem to affect basal cortisol or during exercise.

▶ Reserpine, which depletes stores of NE by inhibiting vesicular uptake, decreased basal excretion of urinary 17-OHCS significantly in Cushing patients and caused normalized suppression of plasma cortisol by 1 mg dexamethasone.

Glutamate. ▶ Ketamine is a clinical available NMDA receptor antagonist also used as an anesthetic, because of its effects on opioid receptors at higher dosages. Furthermore, ketamine is found to reduce the symptoms of opiate withdrawal, suggesting its potential role in the treatment of addiction. Acute administration of ketamine (e.g., 0.5 mg/kg) induces increases in plasma cortisol. The antiglutamatergic drug riluzole did not have any effects upon HPA system activity under baseline and cognitive-stress-induced conditions in elderly subjects.

Dopaminergic Drugs

Drugs activating the dopamine system are typically used to treat ▶ Parkinson's disease while antagonists of the dopamine system are used to treat psychotic symptoms, which often occur in ▶ schizophrenia and ▶ depression.

▶ Haloperidol, a dopamine antagonist used in schizophrenia, did not lower basal cortisol levels in control subjects. Among the atypical antipsychotic medication, olanzapine, an antagonist of several 5-HT receptors, the histamine H_1 receptor and the dopamine (D2) receptor, lowers basal cortisol levels at night in healthy male controls following a standard 8 days treatment. Similar effects on cortisol have been observed in patients with schizophrenia. Treatment of patients with ▶ olanzapine resulted in a blunted ACTH and cortisol responses following a mCPP challenge. Also ▶ quetiapine, showing dopaminergic, adrenergic and serotonergic receptor antagonism, lowers nocturnal cortisol output in healthy subjects. ▶ Clozapine, used for treatment resistant schizophrenia shows antagonist properties for different subtypes of dopaminergic, adrenergic, cholinergic, and histaminergic receptors. Basal cortisol levels decrease slightly during clozapine treatment. Clozapine might also inhibit mCPP-induced cortisol responses. ▶ Risperidone, acting at dopamine (D_2) and serotonergic ($5\text{-}HT_{2A}$) receptors, induced a modest decrease of cortisol levels following treatment. ▶ Sulpiride, a selective antagonist at postsynaptic D_2-receptors, suppresses increases in plasma cortisol levels induced by repetitive blood sampling at 180–240 min, compared with the response to placebo.

▶ Levodopa, first line treatment for Parkinson's disease, decreases plasma cortisol after acute administration. Also during physical exercise which increases cortisol, Levodopa resulted in a decrease of plasma cortisol in patients with Parkinson's disease. However, in children, administration of levodopa in combination with propranolol increased plasma cortisol. ▶ Pramipexole, a D_2 receptor agonist used in Parkinson's disease does not have a clear effect on cortisol levels. In conclusion, antagonists of dopaminergic transmission seem to inhibit HPA axis reactivity.

Anesthetic and Sedative Agents

This class of drugs generally inhibits excitatory channels (e.g., glutamate) and facilitates inhibitory channels (e.g., GABA). Ether induces a profound activation of the HPA axis with high levels of ACTH and cortisol. Halothane also induces an increase in plasma ACTH following administration without surgery in healthy volunteers. General anesthesia maintained with an isoflurane-nitrous oxide-oxygen mixture or sevoflurane is followed by a sharp increase in plasma cortisol. The combination of droperidol, a dopamine D_2 antagonist, with an opioid analgesic induced plasma cortisol elevations. In contrast, a mixture of propofol (acting at $GABA_A$ and maybe glycine and endocannabinoids) and remifentanyl (mu opiate receptor agonist) did not activate the HPA axis, and even blocked HPA axis responses during surgery. However, still under anesthesia with propofol, synthetic ACTH was still capable of inducing a profound cortisol plasma level elevation. Thiopental, a barbiturate acting on GABA receptors, also decreased plasma levels of cortisol during anesthesia and surgery. Other analgesic drugs such as aspirin did not affect basal or stress-induced HPA axis responses.

Opioids. ▶ Endogenous opioids, such as POMC-derived ▶ endorphins and the ▶ enkephalins, exert inhibitory influences on HPA axis activity; see remifentanyl (mu opiate receptor agonist) above. ▶ Naloxone, a mu opiate receptor antagonist, increases HPA axis activity by blocking the inhibitory tone of opiates on hypothalamic CRF secretion. However, the acute administration of ▶ methadone, an opioid agonist results in a profound short-lasting activation of the HPA axis.

Cannabinoids. Smoking of marijuana or acute administration of tetrahydrocannabinol (THC) induces release of ACTH and cortisol. However, ▶ endocannabinoids limit activation of the HPA axis. This difference in action probably results from context-dependent effects of endocannabinoids or a dose-dependency.

CRF antagonists. CRF is central in the activation of the HPA axis and increased expression is thought to play a role in several stress-related disorders. CRFR1 antagonists (e.g., NBI-34041) are currently explored as new antidepressants. CRFR1 antagonist decreased psychosocial stress-induced ACTH and cortisol responses, but not following CRF injection. This indicates that their effects are primarily in the brain to modulate behavioral appraisal rather than ACTH release from the pituitary and thus act not directly at the HPA axis.

Corticosteroids. Dexamethasone has been used to test negative feedback of the HPA axis. To test for Cushing's disease, dosages of 4 mg are used which in all healthy subjects results in suppression of morning ACTH and cortisol levels. Lower dosages such as 1.5, 1, 0.5, or 0.25 mg test for negative feedback at the level of the pituitary gland for more subtle changes, as observed in patients suffering from depression or PTSD. Also hydrocortisone (cortisol) has been used to test HPA axis negative feedback.

Mifepristone (RU 486) is a compound with progesterone as well as cortisol blocking activities. Within a day of treatment (e.g., 200 mg/day) increases in plasma ACTH and cortisol are observed, as a results of loss of the

feedback action of endogenous glucocorticoids. The compensatory increase in ACTH also resulted in increases in deoxycortisol, progesterone, and ► androgens. During prolonged treatment a resetting of the HPA axis at higher levels occurred showing an increase in the amplitude of circadian rhythmicity and an enhanced responsiveness to CRF administration, whereas sensitivity to dexamethasone decreased.

Fludrocortisone, a MR agonist, exerted a significant inhibition of ACTH and cortisol after acute administration (0.5 mg p.o.). Spironolactone, a MR antagonist, induces acute increases in plasma ACTH and cortisol, which supports a function of the MR in inhibiting the HPA axis under basal conditions.

Conclusions

Stress-induced HPA axis activation is blocked by corticosteroids as well as GABA and opioid agonists. HPA axis activity also is induced by glutaminergic, noradrenergic, and serotonergic agonists. The ► pharmacokinetic characteristics of the drugs need to be taken into account with respect to their penetration through the ► blood brain barrier and their site of action in the complex neural circuitry underlying HPA axis activation.

Prolonged use of drugs may result in adaptation of the HPA axis leading to *hypo* or *hyper*cortisolemic states. Alternatively, antidepressants such as SSRI's and TCA's and, to some extent, benzodiazepines, may normalize an overactive HPA axis. Hence, drugs may affect a wide range of peripheral and central functions through their action on the HPA axis.

These actions exerted by the drugs may be either directly targeted to the core of the HPA axis – the adrenal, pituitary, or PVN, or the drugs may act indirectly on circuits involved in processing of stressful information underlying emotional, motivational, and/or cognitive processes. Irrespective of the site and mode of action of the drugs it is often difficult to disentangle primary or secondary psychotropic effects proceeding through the HPA axis.

Neuroethics

Definition

Neuroethics is the study of the ethical, legal, and social questions that arise when scientific findings about the

brain are carried into medical practice, legal interpretations, and health and social policy. Neuroethics is a subfield within the broader domain of bioethics, which encompasses the ethical and moral implications of all biological and medical advances. Neuroethics was established to address the rapid developments within cognitive neuroscience and neuropsychiatry and addresses findings relating specifically to the sciences of the mind encompassing the central nervous system and the underlying brain mechanisms of human behavior.

In response to the advances in cognitive neuroscience and neuropsychiatry and their increasing potential for broader application in the "real world," and in part to the use of pharmacological cognitive enhancers in healthy individuals, the Neuroethics Society (www.neuroethicssociety.org) was established.

Synonyms

Adult neurogenesis; Postnatal neurogenesis

Definition

Neurogenesis refers to the production of new neurons in the brain; it is a complex process that begins with the division of a precursor cell and ends with the formation of a fully differentiated, functioning neuron.

Impact of Psychoactive Drugs

Neurogenesis

Postnatal cell proliferation in the brain of mammals has been occasionally reported during the first half of the twentieth century; however, this phenomenon only gained momentum in the 1960s (Altman 1962). By then, it was not clearly established if these newly born cells could develop into functional neurons and the potential importance of the original observations was not fully appreciated. In the 1990s, however, a clear-cut demonstration of neurogenesis in the adult brains of various species (from rodents to humans) was provided (Manganas et al. 2007); it was later shown that after maturation and differentiation, newly generated neurons are functionally integrated into preexisting neuronal circuits (most notably in the hippocampus). In the subventricular zone, neurogenesis gives rise to neurons that migrate through the rostral migratory stream and which are integrated as interneurons in the olfactory bulb.

How Is Neurogenesis Measured?

Early studies used [^{3}H]-thymidine, which incorporates into replicating DNA during the S-phase of the cell cycle, to label dividing cells by autoradiography. An important technical improvement was the introduction of the synthetic thymidine analog BrdU (5-bromo-3-deoxyuridine) that substitutes for thymidine in the newly synthesized DNA of proliferating cells. BrdU incorporated into DNA can then be easily visualized with immunocytochemical techniques using specific antibodies against BrdU. This technique allows quantitative analysis of proliferation, migration, differentiation, and survival of newborn cells by varying the time interval between the pulse administration of BrdU and the sacrifice of animals. Other specific antigenic or histochemical markers are usually combined with BrdU immunocytochemistry to reveal cell phenotypes, differentiation state, and survival. While BrdU labeling is the most commonly used method for studying adult neurogenesis, other markers, such as proliferating nuclear antigen (PCNA) and Ki-67, may substitute or complement analysis by BrdU labeling.

Neurogenesis, Depression and Antidepressant Treatments

Several thousand new cells are added to the adult rodent hippocampus each month, although the rate of constitutive neurogenesis declines with age. At the same time, however, there is a parallel loss of cells in this brain region through the process of apoptosis; therefore, neuronal turnover is likely to be of greater relevance than either neurogenesis or ► apoptosis alone.

While early studies in songbirds suggested a functional role for adult neurogenesis in seasonal song learning, the functional importance of this process in mammals remains unclear (Shors et al. 2002). However, it is a highly regulated process through the actions of hormones, growth factors, neurotransmitters, and environmental factors. In particular, glucocorticoids (e.g., cortisol) exert a strong negative influence on neurogenesis, an effect that may explain the marked reduction in hippocampal granule cell proliferation after exposure to ► stress; on the other hand, ► antidepressants stimulate hippocampal neurogenesis and can reverse the effects of stress. Since many depressed subjects display glucocorticoid hypersecretion (as a result of HPA axis dysregulation), a link between high levels of circulating adrenal steroids with reduced neurogenesis and depression is plausible. This view has been supported by observations of hippocampal atrophy in depressed patients (Sheline et al. 2003).

In contrast to adrenal steroids and stress, ► antidepressant drugs (including tricyclics and selective serotonin reuptake inhibitors ► SSRIs), as well as ► electroconvulsive therapy, lead to increased neurogenesis in the ► hippocampus in association with decreased depression-like behavior in animal models (Malberg et al. 2000). Altered monoaminergic transmission provides the best mechanistic explanation for these changes; two neurotransmitters of particular relevance are ► noradrenaline (NA) and ► serotonin (5-HT), the latter being a major regulator of adult neural cell proliferation. In adult rats, d,l-► fenfluramine, which releases 5-HT throughout the central nervous system, has a significant stimulatory effect on hippocampal dentate granule cell division, whereas reductions of 5-HT by lesioning 5-HT neurons with 5,7-dihydroxytryptamine (5,7-DHT) or the inhibition of 5-HT synthesis with parachlorophenylalanine (PCPA) result in long-term disruption of the proliferative capacity of the hippocampus. The neurogenic actions of 5-HT are mediated primarily by 5-HT_{1A} receptors but also by 5-HT_{2A} and 5-HT_{2C} receptors. Additionally, the recently introduced antidepressant, ► agomelatine, which is a mixed MT1/MT2 melatonin receptor agonist and 5-$HT_{2B/2C}$ receptor antagonist, also increases hippocampal neurogenesis and can reverse the anti-neuroproliferative effects of prenatal stress. Likewise, stress-induced reductions in neurogenesis can be reversed with ► corticotropin releasing factor type I receptor (CRF-R1) and ► arginine-vasopressin V1b receptor (AVP-1bR) antagonists, consistent with their ability to suppress adrenocortical secretion. However, the antidepressant clinical efficacy of these drugs remains to be established. Finally, the neurokinin type 1 receptor (NK1R) antagonists, which have been shown to increase neurogenesis in animal models, have failed to reveal significant antidepressant efficacy in clinical studies. Besides the antidepressants mentioned above, the atypical antidepressant tianeptine and the mood stabilizer ► lithium have also been found to increase proliferation and survival of new neurons in the dentate gyrus.

Together, the observations described, especially those derived from validated animal models of depression (► Depression: animal models) form the backbone of the notion that the therapeutic actions of antidepressants in patients depend on the generation of new hippocampal neurons. Irradiation of the hippocampus of naive ("non-depressed") mice abolishes the ability of antidepressants to relieve signs of anxiety behavior (Santarelli et al. 2003); anxiety is one behavioral element commonly seen in depressed patients but does not fully reflect the depressed state. However, other experiments in which hippocampal neurogenesis was blocked by chemical means clearly indicate that a wide range of antidepressants can improve depressive-like behavior in an appropriate model of the disease (rats exposed to a chronic mild stress paradigm) even in the absence of ongoing neurogenesis (Bessa et al. 2009). Accordingly, while the role of adult neurogenesis in the etiology of depression remains unclear, some researchers have focused on the potential importance of neurogenesis for other dimensions of recovery from depression, such as cognitive improvement (Perera et al. 2008).

If not Neurogenesis, then what?

Although the exact mechanisms by which stress and glucocorticoids on one hand, and antidepressants and serotonin on the other, affect neurogenesis have not been completely elucidated, there is evidence that implicates changes in the expression of cAMP response element binding (CREB) protein and, in turn, of ► brain-derived neurotrophic factor (BDNF). BDNF plays key roles in the survival and guidance of neurons during development, and is required for the survival and normal functioning of neurons in the adult brain. Stress triggers a decrease in brain levels of BDNF, thus potentially compromising neuroplasticity and neuronal development and survival. Since all current antidepressant treatments (drugs and electroconvulsive therapy) upregulate CREB and BDNF expression, it can be inferred that the cAMP-CREB cascade and BDNF are common targets of both stress (through elevated glucocorticoid secretion) and antidepressant treatments, with the opposing stimuli acting to influence neuroplasticity.

To gain an insight into how stress and antidepressants act, it is important to note that their effects are not

restricted to the regulation of adult neurogenesis. Exposure to chronic stress induces significant atrophy, debranching and synaptic reorganization of neurons in all divisions of the hippocampus, changes that negatively correlate with hippocampus-dependent cognitive functions such as learning and memory. Further, the changes in dendritic and ▶ synaptic plasticity correlate with decreased expression of neural cell adhesion molecule (NCAM) and synaptic related proteins such as synapsin 1 and are reversible with a variety of antidepressant drugs. Importantly, some of the stress-induced alterations in hippocampal plasticity propagate to other brain regions; for example, chronic stress interferes with dendritic and synaptic structure of pyramidal neurons in the prefrontal cortex in association with the onset of deficits in working memory and behavioral flexibility. In parallel, other brain regions show signs of hyperactivity, consistent with the consensual view that the cluster of depressive symptoms results from a "push-and pull" interplay between different brain regions. For example, anhedonia, a core symptom of depression that is characterized by decreased interest in pleasurable activities or the inability to experience pleasure, has been associated with a dysfunction of the brain reward pathway. ▶ Dopamine (DA) released from cell bodies in the ▶ ventral tegmental area (VTA) at terminals in the ▶ nucleus accumbens (NAc) plays a central role in this pathway and dysfunctional or suboptimal DA transmission has been implicated in the pathophysiology of depression. Altered dopaminergic neurotransmission in the VTA-NAc pathway modulates depressive-like behavior in animals and antidepressants influence dopaminergic activity in the VTA and its targets, including the NAc.

Neurogenesis, Schizophrenia and Antipsychotics

Psychopharmacological interest in neurogenesis extends beyond depression and the actions of antidepressant drugs to other psychiatric disorders, as recently evidenced by studies suggesting a role of disturbed neurogenesis in the pathogenesis of ▶ schizophrenia (Reif et al. 2006) and its modulation by ▶ antipsychotic drugs. Patients with schizophrenia show reduced volumes of the frontal lobes as well as of the medial temporal lobes, in particular of the hippocampus, with the dentate gyrus displaying a reduced number of cells with the potential to proliferate. Further, preclinical studies indicate that chronic antipsychotic treatment can stimulate neurogenesis in both the subgranular zone of the hippocampal dentate gyrus as well as in the subventricular zone. Neurogenesis in the subventricular zone is stimulated by the first-generation antipsychotic drug (▶ first-generation antipsychotics) ▶ haloperidol, a strong D_2 receptor antagonist. In contrast, the ▶ second-generation antipsychotics such as ▶ olanzapine, ▶ risperidone, ▶ clozapine, and ▶ quetiapine induce neurogenesis mainly in the hippocampus (Newton and Duman 2007), thus resembling the actions of antidepressants. Interestingly, the second-generation drugs are poorer D_2 receptor antagonists, as compared to haloperidol, but have affinity for 5-HTergic receptors. Since treatment with atypical antipsychotics improves neurocognitive function, it seems likely that hippocampal neurogenesis may play a role in the amelioration of the cognitive symptoms in schizophrenia.

Conclusions

Neurogenesis occurs during immediate postnatal life, right through adulthood, although at an ever-diminishing rate. However, the relevance of neurogenesis in the actions of psychoactive drugs and the etiopathophysiology of psychiatric illnesses remains uncertain. Evidence that neurogenesis occurs in parallel with the apoptotic loss of neurons suggests that neuronal turnover and accompanying changes in neuroplasticity may be more important than neurogenesis *per se*. Although hippocampal neurogenesis appears not to be essential for manifestation of the mood-improving actions of antidepressant drugs, the phenomenon might serve to rectify behaviors in associated behavioral domains such as anxiety and cognition.

Neuroimaging

Synonyms

Brain imaging; Brain mapping

Definition

Neuroimaging is a family of techniques used for obtaining images of the structure or the function of the human brain. Neuroimaging studies investigate structural and functional brain maturation in health or in diseases of the brain, such as schizophrenia, bipolar disorder, depression, ADHD, drug dependence, and autism. These studies often aim to find genetic and environmental markers of variance in brain structure and function over time. Through additions to diagnostic radiology, neuroimaging has broadened to become a distinct field in neuroscience. The neuroimaging techniques that are currently used in research include single-photon emission computerized tomography (SPECT), positron emission tomography (PET), distinct forms of magnetic resonance imaging (MRI) including structural and functional MRI, MR spectroscopy (MRS), and diffusion tensor imaging (DTI).

Neuroinformatics

Definition

Biophysical rules and mechanisms by which neuronal networks gather, represent, store, integrate, transform, and implement information for behavioral output. Understanding information representation and computational processing as a biophysical product of neural tissue is an emerging field of neuroscience that relies on a non-traditional integration of biological, mathematical, engineering, and computer science fields. Aims of this area of research are to define the information-processing and learning and memory capabilities and limits of biological neural networks and to characterize how physical mechanisms that integrate gene–environment interactions result in changes in neural information processing.

Neurokinin 1

▶ Substance P

Neurokinin 2

▶ Neurokinin A

Neurokinin 3

▶ Neurokinin B

Neurokinin-α

▶ Neurokinin A

Neurokinin A

Synonyms

Neurokinin 2; Neurokinin-α; Neuromedin L; NK2; NKA; Substance K

Definition

NKA is a neuropeptide from the tachykinin family similar in structure to SP and generated by alternative splicing

from the same preprotachykinin gene as SP. NKA is mostly expressed in smooth muscles and in discrete areas of the central nervous system implied in mood disorders. NKA binds and activates the NK2 receptor.

Neurokinin B

Synonyms
Neurokinin 3; Neuromedin K; NK3; NKB

Definition
NKB is a 10 amino acids neuropeptide from the tachykinin family generated by alternative splicing from the same preprotachykinin gene as substance P. It is present in smooth muscles and widely expressed in the central nervous system. NKB binds and activates the NK3 receptor.

Neuroleptic

Synonyms
Antipsychotic drug; Major tranquillizer

Definition
A term currently used to refer to antipsychotic drugs prescribed for schizophrenia and bipolar disorder. However it was also defined, notably in Janssen Pharmaceutica, as a centrally-active drug that specifically blocked dopamine receptors in a set of in vitro and in vivo laboratory preparations, a definition that formed the core of many searches for novel antipsychotic drugs.

Cross-References
► Antipsychotic Drugs
► First Generation Antipsychotics
► Second and Third Generation Antipsychotics

Neuroleptic Malignant Syndrome

Synonyms
NMS

Definition
A severe, potentially lethal adverse effect of antipsychotic treatment of unclear pathophysiology. Features include muscle rigidity, fever, altered consciousness, and autonomic symptoms such as dysregulations of blood pressure and respiration. Most patients also show elevations of creatine phosphokinase levels. NMS represents a psychiatric emergency. Treatment, next to intensive care measures, includes dopaminergic drugs such as ► bromocriptine as well as dantrolene.

Cross-References
► Antipsychotic Drugs

Neuromedin K

► Neurokinin B
► Tachykinins

Neuromedin L

► Neurokinin A
► Tachykinins

Neuronal Plasticity

► Synaptic Plasticity

Neuropeptide Y

Definition
► Orexigenic peptide produced primarily by cells in the hypothalamic arcuate nucleus. This peptide potently increases appetite and decreases energy expenditure via its actions in the hypothalamus. In the hippocampus and cortex, neuropeptide Y is associated with antiepileptic effects.

Neuropeptides

Definition
Neuropeptides are substances with a peptide structure that are synthetized in nervous tissue and used there as messenger molecules. Some neuropeptides fulfill all criteria for a neurotransmitter and may have additional roles as neuromodulators or growth factors.

Neuropeptidomics

Synonyms

Peptidomics of the brain

Definition

Neuropeptidomics is the technological approach for detailed analyses of endogenous peptides from the brain.

Neuroplasticity

Definition

A general term referring to changes in information content and processing within neural networks, instantiated by a large variety of biophysical changes of constituent neurons embracing molecular to cellular to higher scales of observation. Changes in neuronal gene-expression correspond to phenotypic changes, including, but not limited to, alterations in neuronal excitability, neurotransmitter release and receptor densities, location and number of axodendritic synaptic contacts, and branching morphology of axons and dendrites. Net up or down changes in neuron-to-neuron synaptic strength are characterized electrophysiologically by ▶ long-term potentiation (LTP) and ▶ long-term depression (LTD). These changes underlie an inherent structural and functional flexibility (i.e., plasticity) of neurons and neurocircuits brought on by a combination, and interaction, of developmentally timed patterns of gene expression and environmental stimuli. Incorporating all the physical processes and learning and memory capabilities of brain systems, neuroplasticity seeks to achieve the most adaptive mapping of behavioral programming on present and future conditions of the external world.

Neuroprotectant

- ▶ Neuroprotective Agent

Neuroprotectants: Novel Approaches for Dementias

Kenneth J. Rhodes
Discovery Neurobiology, Biogen Idec, Cambridge, MA, USA

Definition

Neuroprotection can be defined as a pharmacological activity that promotes the survival and function of neurons. Drugs that offer neuroprotection may be used to slow or prevent loss of brain function in a neurodegenerative disease.

Pharmacological Properties

▶ Dementia can be defined as a loss of memory function accompanied by impairments in other cognitive domains, including language, decision making, object recognition, spatial navigation, and other functions (American Psychiatric Association 2000). In order for a patient to be classified as demented, their impairments in memory and other cognitive abilities must be sufficient to affect routine aspects of daily life. Many types of dementia are caused by progressive, age-related neurochemical and neurodegenerative changes in areas of the brain required to support memory and other cognitive functions. As a result, efforts in drug discovery and development have focused on the identification of neuroprotective drugs as a means to reduce or prevent neurodegeneration and thereby slow or reverse ▶ cognitive impairment and dementia. Although many diseases of the central nervous system are accompanied by dementia, by far the most prevalent and devastating cause of dementia worldwide is ▶ Alzheimer's disease (AD). Because the incidence and prevalence of AD are increasing rapidly as the world's population ages, strategies for preventing or reversing the neurodegenerative changes of AD have become areas of intense focus for academic and industry research and will be the focus of this brief review.

The pathophysiology of AD has been the subject of intensive study for the past several decades. Tremendous progress in our understanding of disease mechanisms has been stimulated by the integration of genetics, histopathology, biochemistry, and animal models. As a comprehensive review of the scientific literature on AD pathophysiology is well beyond the scope of this encyclopedia, this review will focus on neuroprotective strategies centered on the role of ▶ amyloid-β (Aβ), a 38–43 amino acid peptide fragment derived from the amyloid

precursor protein (APP), and its contributions to the cognitive impairment and neurodegeneration of AD. Aβ is the core molecular component of the neuritic ► plaque, one of the hallmark neuropathological features of AD. The production and accumulation of Aβ is thought to contribute directly to defects in neuronal communication, amyloid plaque deposition, ► neurodegeneration, and cognitive impairment in AD.

The Aβ peptide is generated as a result of a two-step enzymatic cleavage of transmembrane APP. The first enzymatic cleavage, which generates the amino-terminus of Aβ and liberates a 99-amino acid C-terminal APP fragment (C-99), is termed β-site APP cleavage enzyme (β-secretase, BACE). The second enzymatic cleavage, which cuts within the C-99 fragment and generates the carboxyl-termini of Aβ, is mediated by a multi-subunit, integral membrane aspartyl protease termed γ-secretase (GS). In AD patients and normal healthy adults, there are two predominant forms of the Aβ peptide; Aβ40 and Aβ42. Aβ42 is less soluble than Aβ40, and rapidly and spontaneously assembles into soluble dimmers, fibrils, and insoluble higher molecular weight aggregates, which likely deposit in brain tissue as amyloid plaques. Mutations in APP that enhance cleavage by BACE are associated with increased Aβ production and early onset, familial AD. Mutations of GS or APP that enhance the production of Aβ, and specifically increase the production of Aβ42, are also associated with early onset, familial AD. Recently, dimers and higher molecular weight multimers of Aβ42, produced in vitro or isolated from AD brain tissue, have been shown to directly impair synaptic function and cause neuronal death in vitro (Shankar et al. 2008). These dimers and multimers isolated from human AD brain have also been shown to impair memory processes when infused directly into the brains of experimental animals. Together, there is now a wealth of preclinical data to indicate that the cascade of events, triggered by the formation of Aβ42, evokes detrimental changes in brain physiology leading to clinical symptoms of dementia as well as progressive neuropathology and neurodegeneration in AD.

The precise mechanisms whereby dimers and multimers (hereafter termed oligomers) of Aβ cause neurotoxicity are not well understood. Proposed mechanisms include the activation of specific cell surface receptors, including the direct or allosteric modulation of ion channels. These channels, when stimulated, are through to allow the entry of sodium and calcium ions into the neuron, thereby activating proteases, kinases, and other signaling molecules. The signaling events evoked by the binding of Aβ oligomers to the neuronal surface may lead to the removal of neurotransmitter receptors from synapses, thereby impairing neuronal communication, or may trigger processes that lead to neuronal injury or death (Kamenetz et al. 2003).

The primary goals of neuroprotective strategies in AD are to prevent the formation of Aβ peptides or increase their rate of removal from the brain. To this end, several companies are pursuing strategies to inhibit or modulate BACE or GS. Of these two strategies, GS inhibitors (GSIs) have progressed furthest into clinical development, with potent and selective GSIs (LY-450139, BMS-788163) currently in later stages of clinical development (see Harrison et al. 2004). GSIs potently and dramatically inhibit GS activity and thereby reduce the production of Aβ peptides by blocking the cleavage of the C-99 fragment of APP. GSIs have been shown to improve cognitive function in transgenic mice that over express mutant human APP. However, these compounds typically suffer from dose-limiting toxicities that may stem from inhibiting the cleavage of GS substrates other than APP, such as Notch. Notch is a cell surface receptor that, upon cleavage by GS, releases an intracellular C-terminal fragment that regulates a gene expression program critical for cell fate decisions in the gastrointestinal tract and in the immune system. A crucial component of GSI development is finding dose levels or a dose regimen that provides sufficient GS inhibition to reduce Aβ formation and AD pathology without causing intolerable digestive or immunological toxicity. Currently there is little evidence to indicate that GSIs reduce Aβ-mediated toxicity in vitro or in transgenic models of AD in vivo. Nevertheless, the hypothesis that GSIs, by their ability to halt Aβ production, will or prevent progressive neurodegeneration and preserve cognitive function in AD patients. This hypothesis is currently being evaluated in large, multinational clinical trials.

BACE inhibitors have also been the focus of intense drug discovery activity (see Ghosh et al. 2008). On the basis of data from BACE1 knock-out mice, a deletion of the BACE1 gene nearly completely suppresses Aβ production in vivo. Over the last several years, many pharmaceutical companies and academic laboratories have been pursuing BACE inhibitors as potential disease modifying therapies for AD. Although many potent and selective BACE inhibitors have been identified, these compounds typically suffer from poor oral absorption or are substrates for transport molecules that efficiently clear drugs out of the central nervous system, resulting in insufficient concentrations of drug in the brain to effectively inhibit BACE. The far, CTS-21166 has progressed into early phases of clinical development and has shown pharmacological activity by reducing plasma and CSF Aβ levels. Additional clinical testing is required to evaluate

the ability of this or other BACE inhibitors to ameliorate the cognitive decline and neurodegeneration in AD.

Another strategy to provide neuroprotection from toxicity mediated by Aβ is to neutralize or clear Aβ peptides once they are formed or deposited in amyloid plaques. This approach stems from the observation that transgenic animals expressing mutant human APP, which develop plaque-like Aβ deposits with increasing age, show a reduced accumulation of Aβ and a reduced plaque density following immunization with aggregates of Aβ or when they are treated systemically with antibodies that recognize Aβ peptides. This observation stimulated active and passive immunotherapy approaches targeting Aβ removal in AD patients. A clinical trial of active vaccination with aggregated Aβ42 (AN1792) was conducted by Elan and Wyeth (see Vellas et al. 2008). Although the trial was halted due to development of aseptic meningoencephalitis in some trial participants, long-term follow-up of trial subjects revealed several important findings. First, patients who developed strong antibody titers to Aβ42 aggregates, and specifically antibodies that recognized aggregated Aβ in plaques, showed a reduced rate of cognitive decline as compared to patients who did not develop such antibodies (Hock et al. 2003). Moreover, vaccine responders in the AN1792 study, followed up to 4 years, showed significantly reduced cognitive decline. Second, when their brains were examined after death, patients in the AN1792 study who developed sustained anti-Aβ titers showed unexpectedly low densities of Aβ plaques (Vellas et al. 2009). Together, these findings suggest that antibodies to Aβ can affect amyloid pathology in the AD brain and reduce the severity of the clinical course in AD. Whether this strategy reduced the overall rate of neurodegeneration, as evidenced by the preservation of brain gray matter volume, remains to be determined.

Although the AN1792 trial was halted, strong interest remains in exploring passive immunotherapy using monoclonal antibodies that target specific amino acid sequences within the Aβ peptide (see Nitsch and Hock 2005). In experimental animals, passive immunotherapy with anti-Aβ antibodies dramatically reduces amyloid pathology, improves behavioral performance, and seems to prevent neurodegeneration. Several humanized anti-Aβ antibodies, including Elan/Wyeth's bapineuzumab, and Eli Lilly and Company's solanezumab, are now in Phase III clinical trials as disease modifying therapies for AD. The outcome of these large, multinational trials will provide incredibly valuable information about the role of Aβ in neurodegenerative processes and cognitive impairment in AD.

Another approach to AD targeting Aβ involves the modulation of GS activity with the goal of selectively reducing the formation of Aβ42. Compounds that selectively reduce Aβ42 are called GS modulators (GSMs), because they reduce the generation of Aβ42 without affecting the total amount of Aβ that is produced. In contrast to GSIs, which reduce the production of all Aβ isoforms (and inhibit cleavage of all GS substrates), GSMs typically reduce the production of Aβ42, have no effect on Aβ40, and increase production of nonpathogenic Aβ38 roughly in proportion to the decrease in Aβ42. Although it is presumed that GSMs work by binding to an allosteric site on the GS enzyme complex, the binding site for GSMs and their mechanism of action have not been clearly elucidated. One potential advantage of GSMs over GSIs is that GSMs may avoid the toxicities associated with GS inhibition. GSMs alter the ratios of cleavage products that result from GS activity but do not inhibit GS activity completely. In the case of Notch, for example, although the site of Notch cleavage may be altered by a GSM, Notch C-terminal fragment is still generated and its ability to signal is not affected.

The first prototype GSM to enter large-scale clinical development was R-flurbiprofen (Flurizan). Although this molecule has very weak GSM activity in vitro ($IC_{50} > 150\,\mu M$) and penetrates the brain poorly, it was shown to reduce Aβ42 production in experimental animals and was advanced into clinical development (see Wilcock et al. 2008). Although a large Phase III clinical trial of R-flurbiprofen failed to demonstrate efficacy, considerable interest remains in developing more potent GSMs that achieve brain tissue concentrations sufficient for the effective and selective reduction of Aβ42. Several companies and academic laboratories are currently working to achieve this goal.

Other approaches to neuroprotection in dementia that are currently under active investigation in clinical trials are the disruption of Aβ fibrils (e.g., PBT2 – a chelator of divalent metal ions that seems to disrupt Aβ production and fibril formation), the inhibition of excitotoxicity by blocking excitatory amino acid receptors (e.g., ► memantine, Dimebon), preventing neuronal apoptosis by preserving mitochondrial function (e.g., Dimebon). There is generally a limited amount of published preclinical data from animal models to substantiate the activity of these novel agents as neuroprotective therapies in AD.

Future Directions

Exciting avenues for future research on neuroprotectants for dementia and AD center on the identification of a cell surface receptor or receptors for Aβ oligomers and an elucidation of the signaling events that link Aβ binding to neuronal membranes with altered activity and

morphology of synapses (Kamenetz et al. 2003; Shankar et al. 2008). A better understanding of these pathways may allow for the generation of therapies that specifically target the impaired synaptic function and early structural defects of AD. It seems likely that the modulation of these fundamental processes in synaptic transmission and memory may also provide novel therapeutic approaches to preserving cognitive function across many types of dementias.

Neuroprotection

A. Richard Green[1], Maria Isabel Colado[2]
[1]School of Biomedical Sciences, Institute of Neuroscience, Queen's Medical Centre, University of Nottingham, Nottingham, UK
[2]Departamento de Farmacologia, Facultad de Medicina Universidad Complutense, Madrid, Spain

Definition

The term neuroprotection is used to refer to either an endogenous mechanism within the central nervous system that protects neurons from cell death or, more commonly, the action of a drug to prevent cell death following the action of a neurotoxic drug or the consequences of brain injury.

Current Concepts and State of Knowledge

Mechanisms Involved in Cell Death

Neurons can die by one of two distinct mechanisms. One is programmed cell death or ▶ apoptosis, the other is ▶ necrosis. Both types of cell death have been reported to occur following a variety of insults to the brain (Chalmers-Redman et al. 1997). Insults to the integrity of the brain can be chemical, for example, ▶ neurotoxins, or traumatic, for example, ▶ stroke. Both chemical and traumatic insults result in neurodegeneration (▶ neurodegeneration and its prevention).

Neuroprotection Following Stroke and Traumatic Brain Injury

Stroke

Tissue damage following a stroke can be mitigated either by restoring blood flow with a thrombolytic ("clot busting") drug or by interfering with the biochemical changes which occur following the ischemic insult and thereby minimizing the damage. At present only the thrombolytic drug recombinant tissue plasminogen activator or rt-PA is in clinical use for the acute treatment of stroke (Green 2008).

Any compound that protects the brain from cell death following an acute ischemic stroke is known as a ▶ neuroprotective agent or neuroprotectant and its mechanism of action is generally based on trying to interfere with the biochemical changes which occur in the brain following an acute ischemic insult (Green and Cross 1997). The biochemical chain of events following ischemia is often referred to as the ischemic cascade. The initial change that occurs during ischemia is a pathological release of glutamate, an excitatory amino acid (▶ excitatory amino acids and their antagonists). This release produces further changes including depolarization of the cells, the production of ▶ free radicals, excitotoxicity, and cell death. It should also be noted that reperfusion, while mitigating neurodegeneration also results in the production of free radicals and is thus subject to studies examining whether additional treatment with a neuroprotective agent might be advantageous (Green and Shuaib 2006).

Neuroprotection can be determined in various ways in ► animal models of acute stroke. Primarily, neuroprotection is measured by histological evidence that the size of the damaged tissue (infarct area) is smaller. This can be achieved by staining tissue or counting intact cell populations. Such studies should be followed up by measuring the degree of motor impairment in living animals. Clinically, the use of scales which quantify the degree of motor impairment is the generally accepted outcome measure.

Since the initial event following the onset of cerebral ischemia is ► glutamate release, considerable efforts have been made to provide neuroprotection by producing drugs that are antagonists at the glutamate receptor. Antagonists of both the glutamate ► NMDA receptor and the ► AMPA receptor have been examined in animal models of acute stroke. Some of these have also been investigated in clinical trials with stroke patients. Glutamate antagonist compounds include the NMDA receptor antagonists, dizocilpine, aptiganel, and selfotel. Clinical studies have also been conducted with the NMDA glycine-site antagonist gavestinel, the NMDA polyamine-site antagonist eliprodil and the NMDA channel blocker magnesium. AMPA receptor antagonists such as NBQX have also been examined but less actively pursued, primarily because of safety concerns. All these compounds were effective in providing neuroprotection in animal models of stroke. However, all failed in clinical trials, either because the trial had to be terminated early because of safety issues or because the compound failed to demonstrate efficacy (Green 2008).

Another approach to providing neuroprotection in stroke has been to administer compounds which increased the function of GABA, an inhibitory amino acid neurotransmitter (► Inhibitory amino acids and their antagonists). Such approaches have included administration of the ► benzodiazepine diazepam or clomethiazole, a drug that increases GABA function at its receptor. Again, despite clear evidence for efficacy in animal models of acute stroke, both drugs failed to provide neuroprotection in patients as indicated by a decrease in stroke-induced disability.

Since a major consequence of both ischemia and reperfusion is excessive free radical production, attempts have been made to provide neuroprotection in stroke as well as other degenerative conditions such as Parkinson's disease (► Anti-Parkinson drugs) and Alzheimer's disease (► Dementias and other amnesic disorders) by the use of compounds that scavenge or trap free radicals. In stroke research, such compounds included ebselen, a selenium compound with glutathione peroxidase-like activity, the lazaroid compound tirilazad and edaravone, a hydroxyl radical scavenger. Only edaravone is claimed to be of clinical benefit but, at present, its use is restricted to Japan. One compound that showed considerable preclinical promise was the nitrone-derived compound NXY-059. However, despite the efficacy of this compound in a variety of animal models of stroke, it failed to demonstrate efficacy in late phase clinical trials. This failure, in particular, has resulted in considerable discussion in the scientific press as to the reasons for the failure of compounds to show translation from experimental to clinical efficacy, but an unequivocal answer has yet to be provided (O'Collins et al. 2006).

The failure of compounds acting on the ischemic cascade to provide neuroprotection in stroke patients has led to an increase in approaches that interfere with the role of ► cytokines in cerebral ischemia. Both tumor necrosis factor alpha (TNFα) and interleukin 1beta (IL-1β) are known to be involved in the inflammatory response to brain injury, and TNFα and IL-1β antibodies are neuroprotective in experimental stroke studies in animals. A recombinant IL -1 receptor antagonist is being examined clinically. Due to the possible problems in producing and administering protein-based compounds, research is also being undertaken to produce non-peptide compounds (Green 2008).

Traumatic Brain Injury

Traumatic brain injury (or TBI) is the term used to describe injury to the brain caused by mechanically induced damage such as that resulting from impact to the skull induced by a car accident or by a firearm. The pathological changes seen include those which occur following stroke, but also additional changes such as bleeding (hemorrhage) and mechanical damage to cerebral tissue due to impact. Several of the compounds developed to treat acute ischemic stroke are also being examined in TBI. Compounds such as aptiginal, the excitatory amino acid antagonist and IL-1β antibodies have shown to provide modest benefit in animal models of TBI but no compound has yet proved to have efficacy in human TBI.

Neuroprotection and Neurotoxic Amphetamines

3,4-Methylenedioxymethamphetamine (► MDMA or "ecstasy") is an ► amphetamine and a commonly used recreational drug, often ingested at warm and crowded dance clubs and raves. There is substantial evidence that the compound produces long-lasting neurotoxic changes in the brains of experimental animals. In the rat, MDMA, given either as a single high dose or several lower doses over a relatively short period of time, induces a long-term loss of 5-hydroxytryptamine (5-HT or ► serotonin) nerve

terminals in several regions of the brain. This effect is reflected in a substantial decrease in the activity of tryptophan hydroxylase, the first (and rate-limiting) enzyme responsible for the synthesis of 5-HT, and in the concentration of 5-HT and its metabolite, 5-hydroxyindole acetic acid (5-HIAA). There is also a reduction in the number of 5-HT transporters and a decrease in the immunoreactivity of 5-HT axons in several brain areas (Green et al. 2003).

In contrast to its effects in rats, MDMA is generally accepted to behave as a selective dopamine neurotoxin in mice, inducing a long-term decrease in the concentration of ► dopamine and its metabolites, a reduction in the number of dopamine transporters, and a decrease in the immunoreactivity of tyrosine hydroxylase in striatum and substantia nigra (Colado et al. 2004; Granado et al. 2008). Neurotoxicity in mice is evident following repeated and higher doses of MDMA than those administered to rats.

Another substituted amphetamine, ► methamphetamine (METH), is also known to induce neurotoxic loss of dopamine axon terminals in the striatum and cell body in the substantia nigra of mice. The fact that direct administration of MDMA and METH into the brain does not produce toxicity suggests that the parent compounds are not responsible for the toxicity and that toxicity probably results from the effects of metabolic products (Esteban et al. 2001).

The mechanisms producing this neurodegeneration are not totally understood at present, but evidence indicates that several factors play an essential role: acute hyperthermia, monoamine transporters, an oxidative stress process, strong microglia activation, and the release of pro-inflammatory cytokines such IL-1β and TNFα (Orio et al. 2004). Some of these potential mechanisms are also almost certainly involved in ischemia-induced neurodegeneration.

There have been a variety of compounds which, when given concurrently with MDMA or METH, have been shown to provide protection. However, recent studies have indicated that a significant number of such compounds, including several with clear efficacy as neuroprotective agents in animal models of acute ischemic stroke, only prevent amphetamine-induced damage because they either prevent the acute hyperthermia which follows amphetamine administration (for example, ► antipsychotics such as ► haloperidol) or because they induce hypothermia. Compounds in this latter class include ► barbiturates such as ► pentobarbitone, and NMDA antagonists such as dizocilpine and CGS 19755. Hyperthermia is one of the major features of acute MDMA toxicity in both rodents and humans and its presence is shown to markedly enhance the neurotoxic damage induced by MDMA administration (Green et al. 2003).

In contrast, there are some other compounds that are able to protect against MDMA-induced damage through some specific neurochemical mechanism and not merely by decreasing body temperature. The 5-HT uptake inhibitors (► SSRIs and related compounds) ► fluoxetine and ► fluvoxamine, coadministered with MDMA, completely prevent the long-term loss of 5-HT concentration without altering the hyperthermia following MDMA. Both compounds inhibit the 5-HT transporter and could be blocking the entry of a toxic metabolite of MDMA into the 5-HT nerve terminal. Monoamine transporters also appear to be involved in MDMA-induced neurotoxicity in mice since GBR 12909, a selective dopamine uptake inhibitor, also provided protection against long-term dopamine depletion induced by MDMA and METH without altering body temperature.

The role of free radicals in the damage induced by MDMA and METH has been demonstrated by several different approaches. α-Phenyl-N-tert-butyl nitrone (PBN) is a hydroxyl radical trapping agent that partially prevents the neuronal damage induced by MDMA on 5-HT nerve terminals as a result of its free radical scavenging activity. PBN, at a dose that did not modify hyperthermia, was shown to prevent MDMA-induced hydroxyl radical formation. Other free radical scavenging drugs (sodium ascorbate, L-cysteine) are also found to protect against MDMA-induced damage. Supporting the existence of an oxidative stress process is the fact that the antioxidant alpha-lipoic acid prevented the long-term loss of 5-HT in the striatum but did not alter the hyperthermia induced by MDMA. In addition to hydroxyl radicals, nitrogen reactive species are also shown to be involved in MDMA-induced neurotoxicity. In mice, there is also evidence for a key role of ► oxygen and nitrogen reactive species in the MDMA-induced neurotoxicity on dopamine neurons. Pre-treatment with nitric oxide synthase (NOS) inhibitors S-methylthiocitrulline (S-MTC), AR-R17477AR, or 3-bromo-7-nitroindazole provides significant neuroprotection against the long-lasting MDMA-induced dopamine depletion suggesting that MDMA leads to radicals that combine with nitric oxide to produce peroxynitrites. Peroxynitrites are also formed following neurotoxic doses of METH and NOS inhibitors attenuate the dopamine damage induced by METH (Colado et al. 2001; Sanchez et al. 2003).

Microglial activation is also emerging as an important element of the MDMA and METH neurotoxic cascade. Microglia are considered as the resident immune cells of the brain and are activated in response to brain injury

leading to the secretion of a variety of cytotoxic factors such as cytokines, prostaglandins, and reactive oxygen/nitrogen species, many of which have been involved in amphetamine-induced neurotoxicity. On the other hand, microglia may also initiate tissue repair and regeneration through secretion of growth and neurotrophic factors, thereby exerting a beneficial neuroprotective role. MDMA and METH cause a prompt and transient increase in microglial activation that seems not to be related to increased rectal temperature. There have been several attempts to implicate microgliosis in amphetamine-induced neurotoxicity but results have not always been successful. Thus, while dizocilpine and dextromethorphan prevent microgliosis following METH and provide neuroprotection against the loss of dopamine nerve terminals, some ► cannabinoid CB2 receptor agonists do not prevent MDMA-neurotoxicity. These data suggest that microglial activation occurs in response to amphetamine-induced neuronal damage but does not cause it. MDMA and METH also induces an increase in the brain levels of proinflammatory cytokines such as IL-1β and TNFα, respectively. Nevertheless, further studies are required in order to establish the specific role of these cytokines in amphetamine neurotoxicity, and, therefore, develop appropriate approaches for providing neuroprotection.

Hypothermia and Neuroprotection

There is a substantial body of evidence that hypothermia produces neuroprotection, not only in animal models of stroke, but also when neurodegeneration is produced by administration of neurotoxins such as methamphetamine and MDMA. This has meant that all experimental studies on neuroprotection must both monitor body temperature (and ideally also brain temperature) and must also ensure that body temperature is also adjusted where necessary to attenuate any body temperature changes. Only when this is done, can the experimenter be confident that the drug under investigation is producing neuroprotection by interfering with pathological processes involved in neurodegeneration rather than merely lowering body temperature. This is particularly important in rodent studies, as many administered compounds have been reported to lower body temperature though non-specific mechanisms.

Lowering body (or brain) temperature deliberately by the use of specific drugs or by cooling techniques such as exposing the head or body to low temperature using ice baths or cooling helmets is being investigated clinically. It is the only approved neuroprotective approach in persons who have suffered global cerebral ischemia due to cardiac arrest. Both the severity of the hypothermia and the speed of temperature decrease have to be controlled closely for benefit to occur.

The generally accepted explanation for the efficacy of hypothermia as a neuroprotectant is that free radical formation induced by either the ischemic insult or by the administration of the neurotoxin is markedly attenuated during hypothermia.

Neuroprotective Agent

Synonyms

Neuroprotectant; Neuroprotective drug

Definition

A drug or novel pharmacological agent that when administered after a cerebral trauma or neurotoxic compound attenuates the neuronal cell damage induced by the trauma or neurotoxin and thereby lessens the subsequent functional problems induced by the cerebral trauma.

Neuroprotective Drug

► Neuroprotective Agent

Neuropsychiatric Disorders

Synonyms

Mental disorders; Psychiatric disorder

Definition

Neuropsychiatric disorders are any illness with a psychological origin manifested either in symptoms of emotional distress or in abnormal behavior. Neuropsychiatric disorders (psychiatric disorders) have been classified according to criteria defined in the Diagnostic and Statistical Manual of Mental Disorders (APA – American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders – DSM-IV-TR, 2000) into major (clinical) depression, bipolar disorder, schizophrenia, anxiety disorders and attention-deficit hyperactivity, and subsequent subcategories. Due to the absence of sharp boundaries to and high occurrence as comorbidities in neurological disorders (i.e., stroke, Alzheimer's disease) an integrative view of psychiatric- and neurological disorders is currently discussed.

Definition

Neurotensin (NT) is a tridecapeptide that functions both as a hormone and a neurotransmitter. It regulates intestinal motility, feeding behavior, ► nociception, thermoregulation, and anterior pituitary hormone secretion. In the central nervous system (CNS), NT modulates classical monoamine neurotransmitter systems, most notably dopamine (DA). Because of its modulation of DA circuits, NT has been implicated in the pathophysiology of ► schizophrenia and ► drug abuse, and may represent a potential therapeutic target for treatment of these disorders.

Pharmacological Properties

Introduction

NT was first isolated from bovine hypothalamus by Carraway and Leeman in 1973. The NT gene is highly conserved between species and consists of a 10.2 kb segment containing four exons and three introns. The gene encodes an 170 amino acid precursor protein containing both tridecapeptide NT and a closely related hexapeptide, neuromedin N (NN). Post-translational processing yields both peptides. The amino acid sequence of NT is N-Glu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu-C. NT is stored in presynaptic vesicles and its release is Ca^{2+}-dependent. The half-life of NT in brain tissue is approximately 15 min with the primary mode of signal termination being cleavage of the peptide by a variety of peptidases. In addition, based on sequence homology, other structurally related

endogenous peptides that bind to NT receptors such as, NN, xenin, xenopsin, LANT-6, contulakin-G, and kinetensin, have been identified demonstrating the existence of a family of NT-related peptides (Boules et al. 2007; Kinkead and Nemeroff 2006).

NT is distributed throughout the central and peripheral nervous system with about 10% found in brain. In the CNS, high concentrations of NT are found in ▶ hypothalamus, ▶ amygdala, substantia nigra, ▶ ventral tegmental area (VTA), and olfactory tubercle (Binder et al. 2001b for anatomy review). There are intermediate concentrations in a variety of other areas, including the basal ganglia, brainstem, and dorsal horn of the spinal cord. Lower concentrations of NT are found in the thalamus and cortex. NT-positive cell bodies are located in the arcuate nucleus, extended amygdala, striatopallidum, basal forebrain, and numerous brainstem regions that give rise to cholinergic, DAergic, serotonergic, noradrenergic, orexinergic, and histaminergic ascending neuromodulatory projections. NT cell bodies also exist in the periaqueductal gray (PAG).

Mechanisms of Action

There are four known NT receptors (Kinkead and Nemeroff 2006 for review). The NT_1 and NT_2 receptors are ▶ G protein-coupled with the classic seven transmembrane-spanning regions. NT_2 is a receptor with low affinity for NT that also binds the histamine H_1 receptor antagonist levocabastine. The NT_1 receptor is a levocabastine-insensitive receptor with high affinity for NT. Two other identified receptors, NT_3 (sortilin) and NT_4 (SorLA/LR11) are members of the family of Vps10p domain receptors with high affinity for NT. In contrast to NT_1 and NT_2, the NT_3 and NT_4 receptors are type I amino acid receptors with a single transmembrane-spanning region. The majority of NT_3 and NT_4 receptors are found intracellularly and have been theorized to play a role in intracellular sorting processes. NT_3 has also been posited to play a role in cell death, and NT_4 may play a role in terminating NT function.

One of the most studied effects of NT is its modulation of DA neurotransmission. NT differentially modulates DAergic activity in the mesocortical, mesolimbic, and nigrostriatal pathways (Binder et al. 2001b). In general, the effect of NT is to decrease DA D_2 receptor-mediated effects with an overall effect on cell firing depending on the brain region. For example, within the midbrain where NT_1 receptors are found on DA cell bodies, NT functions to increase DAergic cell activity by attenuating D_2 receptor-mediated ▶ autoinhibition. The behavioral effects of increased NT neurotransmission in the midbrain resemble those of peripherally administered DAergic agonists. In contrast, in the ▶ nucleus accumbens (NAcc), receptor colocalization takes place primarily on postsynaptic GABAergic neurons. Allosteric receptor/receptor interactions between the activated NT receptor and DA D_2-type receptors lead to decreased D_2 receptor agonist binding affinity and to reduced DA agonist effects behaviorally.

Several small molecule NT receptor antagonists have been identified; SR 48692 and SR 142948A are the best characterized (Kinkead and Nemeroff 2006). Both these antagonists cross the ▶ blood–brain barrier and possess nanomolar ▶ affinity for the NT_1 receptor. Although SR 48692 has a lower affinity for NT_2 than NT_1 receptors, neither SR 48692 nor SR 142948A discriminate well between the NT_1 and NT_2 receptors, and there is some evidence that SR 48692 binds to the NT_3 receptor as well. SR 142948A and SR 48692 do not block all NT-mediated effects, indicating that there are pharmacological subtypes of NT receptors with which the available antagonists have low affinity. Whether these two NT receptor antagonists interact with the NT_4 receptor is yet to be determined.

NT is easily degraded by peptidases and must be injected directly into the brain in order to exert CNS effects. Thus, over the years, many groups targeting brain NT receptors for drug development have sought a compound that could be delivered peripherally (Boules et al. 2007). The last six amino acids on the NT C-terminus carry the full biological activity of NT, and several NT analogs that can be delivered systemically have been developed, including PD149163, NT66L, NT67L, NT69L, and NT77L. To date, all identified NT receptor agonists are modified peptide analogs of NT(8–13).

Effects in Disease States

NT has been implicated in the pathophysiology of ▶ schizophrenia, and it has been suggested that NT may function as an endogenous antipsychotic agent or neuroleptic (Nemeroff 1980). Decreased concentrations of NT are found in the cerebrospinal fluid (CSF) of a subset of schizophrenic patients, and NT levels normalize following effective treatment with ▶ antipsychotic drugs (Cáceda et al. 2006). Based on these findings as well as decades' worth of biochemical and behavioral preclinical data, it has been proposed that NT receptor agonists may represent a novel treatment for schizophrenia.

In addition to the possibility that NT receptor agonists may represent a novel class of antipsychotic drugs, evidence suggests that modulation of NT neurotransmission may be involved in the mechanism of action of the

existing antipsychotic drugs (Binder et al. 2001c). To date, all clinically effective antipsychotic drugs, none of which bind to NT receptors, have been shown to increase NT neurotransmission (mRNA expression, NT peptide concentrations, or NT release) in the NAcc. In addition, the viral vector overexpression of NT_1 receptors in the NAcc has many of the same behavioral effects as antipsychotic drugs (Cáceda et al. 2006). This has led to the hypothesis that increased NT release in the NAcc may mediate some of the therapeutic effects of antipsychotic drugs.

In fact, endogenous NT neurotransmission appears to be involved in the behavioral effects of some, but not all, antipsychotic drugs (Binder et al. 2001a; Kinkead and Nemeroff 2006; Cáceda et al. 2006). Pretreatment with an NT receptor antagonist blocks the behavioral effects of the typical antipsychotic drug haloperidol in two animal models of sensorimotor gating, ▶ prepulse inhibition (PPI) of the acoustic startle response, and ▶ latent inhibition. Likewise, mice lacking the NT gene exhibit deficits in PPI (similar to those seen in schizophrenia) that are restored by the antipsychotic drug ▶ clozapine, but not ▶ haloperidol, ▶ quetiapine, or ▶ olanzapine. These results suggest that increased endogenous NT is critically involved in the mechanism of action of a subset of antipsychotic drugs. In combination with the clinical data indicating that there is a subset of schizophrenic patients with deficits in NT neurotransmission, these findings raise the possibility of preselecting an effective antipsychotic drug for this subgroup of patients, thereby dramatically improving patient outcomes and reducing the risk of inadequate treatment.

NT has also been suggested to play a role in drug abuse. Drug abuse is characterized by a loss of control leading to compulsive drug use, despite obvious detrimental consequences. It has been theorized to be, in part, due to dysregulation of the mesocorticolimbic DA system, which mediates reward processing and learning. Because of its close association with the mesocorticolimbic DA system, NT is implicated in mechanisms underlying reward and addiction (Cáceda et al. 2006; Dobner 2005); and in particular, the development of ▶ sensitization to drugs. Although NT, as demonstrated by studies utilizing direct CNS injection of NT, does have rewarding properties in the VTA and does modulate the behavioral effects of ▶ psychomotor stimulants in the NAcc, this is not necessarily an indication of the role of endogenous NT in spontaneous locomotion or psychomotor stimulant-induced behavioral effects. In fact, though NT/NN mRNA expression and NT peptide concentrations are increased in the NAcc, striatum, and prefrontal cortex following acute ▶ cocaine or amphetamine administration, this acute release of endogenous NT does not appear to mediate the acute locomotor effects of these drugs. Indeed, peripherally administered NT receptor antagonists have no effect on the acute locomotor effects of psychomotor stimulants. In contrast, supra-activation of NT systems following intra-NAcc injection of NT, peripheral administration of NT receptor agonists, and NT_1 receptor overexpression in the NAcc significantly reduce amphetamine-induced hyperlocomotion. Therefore, while endogenous NT does not appear to modulate spontaneous locomotor activity or the acute locomotor effects of psychomotor stimulants, increased NTergic neurotransmission counteracts the acute locomotor effects of these drugs.

Much evidence implicates the endogenous NT system in psychomotor stimulant-induced behavioral sensitization. In humans, the repeated use of psychomotor stimulants can result in long-lasting alterations in the response to subsequent drug use, including the emergence of drug craving. In rats, this phenomenon, termed behavioral sensitization, is considered a useful animal model for drug craving. Repeated intra-VTA or ICV injection of NT leads to behavioral and chemical sensitization. Perhaps, most intriguing is the finding that pretreatment with an NT receptor antagonist (while not affecting acute stimulant-induced hyperlocomotion) prevents the development of locomotor sensitization. From these data, it can be inferred that NT neurotransmission is critically involved in the initiation of behavioral sensitization to psychomotor stimulants. There is some evidence that the role of NT in sensitization can be generalized to other drug classes including ▶ alcohol, ▶ nicotine, and NMDA receptor antagonists (Cáceda et al. 2006). Based on these findings, it is possible that genetic vulnerability within the NT system may contribute to drug addiction and provide a rationale for the development of compounds modifying NT neurotransmission in the treatment of drug addiction.

In addition, NT may also be involved in the pathophysiology of obesity. Within the CNS, the hypothalamus plays a key role in regulation of satiety and feeding behavior. As noted above, NT is found in high concentrations in the hypothalamus. In conjunction with other peptides (including ▶ leptin, galanin, ▶ neuropeptide Y, and others), NT modulates appetite and feeding behavior and is an important regulator of the central feeding circuit (Sahu et al. 2001). Activation of the NT system decreases feeding in rats, an effect which is downstream of ▶ leptin activation. Central injections of leptin increase hypothalamic NT mRNA expression as well as reduce food intake and decrease body weight in rats. In addition, NT receptor antagonists block leptin-associated ▶ appetite

suppression. Thus, the NT system may be a potential novel target for the development of anti-obesity drugs.

NT also plays an important role in modulating nociception (Dobner 2006). NT fibers and cell bodies are found in multiple brain regions involved in pain transmission and modulation, including the PAG, the rostroventral medulla (RVM), and the dorsal horn of the spinal cord. NT dose-dependently modulates nociception. When low doses of NT are injected into the RVM, the result is an enhanced nociceptive response and hyperalgesia. When higher doses of NT are injected into the RVM, the result is an antinociceptive response which is not mediated by endogenous ▶ opioids. Thus, NT modulates nociception via differences in intensity of signaling. Mice lacking the NT gene also exhibit deficits in ▶ antinociception. In addition, NT also plays a role in ▶ stress-induced antinociception, or decreased pain transmission in response to stressful stimuli, as blocking NT transmission in rats and mice causes hyperalgesia in response to stress (Dobner 2006). Because of NT's role in nociception, medications targeting NT transmission may be potential ▶ analgesics.

Definition

Neurotoxicity is the tendency of substances (also called neurotoxins), conditions, or states to alter the normal activity of the nervous system. This can eventually disrupt or even kill neurons; key cells that transfer and process signals in the brain and parts of the nervous system. Neurotoxicity can result from exposure to drug therapies and certain drug (ab-)use.

The "neurotoxicity theory" of ▶ schizophrenia states that an (untreated) psychosis is neurotoxic to the brain and that brain changes are an inherent feature of the neurobiological disease process in schizophrenia. Although the pathophysiology of this disorder is still unknown, we do know that antipsychotics; (dopamine receptor blockers), reduce symptoms of schizophrenia, but that party drugs like cocaine and amphetamine increase dopamine in the brain and may induce psychosis.

The term *neurotoxic* is used to describe a substance, condition, or state that damages the nervous system and/or brain, usually by killing neurons. The term is generally used to describe a condition or substance that has been shown to result in observable physical damage.

Current Concepts and State of Knowledge

Introduction

Although Kraepelin (1919) suggested that ▶ schizophrenia, dementia praecox, was a chronic, deteriorating psychotic disorder, evidence was lacking to prove this; in postmortem studies, no or little abnormalities in brains of patients with schizophrenia were found. In the 1960s and 1970s, schizophrenia was not thought to be a brain disease at all. Clinical investigators considered failing-family interactions instead as a cause. Especially, failing mother–child interaction was thought to cause or worsen schizophrenia.

This all changed when new in vivo ▶ neuroimaging techniques, such as Computer Tomography (CT) in 1976 revealed that patients with schizophrenia had enlarged ventricles when compared with a group of age-matched controls (Johnstone et al. 1976). In the early 1900s, the first evidence of brain ventricular enlargement was already provided by a pneumoencephalography (PEG) study in a small sample of schizophrenia patients (Jacobi and Winkler 1927).

Because of the lack of progression of cerebral ventricular enlargement of the earlier studies, the ▶ neurodevelopmental hypothesis began to emerge by which schizophrenia is suggested to result from abnormalities in neuronal connectivity, which arise during fetal life but are not expressed until the onset of illness. Despite the evidences in favor of the neurodevelopmental hypothesis, such as delayed milestones, there are some substantial symptoms of schizophrenia that cannot be explained with the neurodevelopmental hypothesis. The apparent progression of clinical aspects of the syndrome in some patients, including deterioration, dilapidation, and treatment resistance may suggest that schizophrenia is a progressive illness. Furthermore, recent longitudinal magnetic resonance imaging (MRI) studies in patients with schizophrenia have shown that through the course of the illness the brain volume reduces progressively. It remains unclear what the underlying neuropathological mechanisms are causing these progressive brain volume changes in schizophrenia, but it is thought that ▶ psychosis could be neurotoxic.

This essay will briefly describe the scientific evidence in favor of schizophrenia being a progressive brain disease. It will then discuss the neurotoxicity hypothesis of schizophrenia and the concept of neuroprotection.

Neuroimaging Studies

In 1976, a new in vivo neuroimaging technique, CT was first used in schizophrenia research by Johnstone et al. (1976). In this study, patients with schizophrenia showed enlarged ventricle volumes when compared with age-related healthy control subjects. In the last two decades, numerous studies were conducted using MRI techniques. In 2000, a cross-sectional meta-analysis (Wright et al. 2000) convincingly showed that brain volume changes are present in schizophrenia. Lateral ventricle volume was found to be increased (16%) while cerebral volume

was reduced (2%). The latter was primarily attributed to a decrease in gray matter volume (2%). Nevertheless, a small but significant reduction was found in white matter volume (1%). Furthermore, the improved quality of the MRI scans made it also possible to manually delineate brain areas of interest. Regional pathology indicates larger reductions in temporal and frontal lobe and more specifically in medial temporal structures (► hippocampus and ► amygdala). The finding of reduction in frontal and (medial) temporal areas of the brain in patients with schizophrenia has been corroborated by using a voxel-based morphometry approach.

It has long been argued that the brain volume changes found in schizophrenia are (partly) caused by the antipsychotic medication. Indeed, in the early stages of schizophrenia progressive decreases in gray matter (Cahn et al. 2002) and frontal lobe volume (Gur et al. 1998; Madsen et al. 1999) have been found associated with the amount of antipsychotic medication taken. Those patients who were prescribed the highest doses of ► antipsychotic medication also had the greatest progressive decreases in brain volumes. Nevertheless, this brain volume decrease might not be a direct effect of the medication as those who are prescribed the highest doses of antipsychotic medication are generally the most severely ill patients. Increases and decreases in brain volumes depend on the type of antipsychotic medication. Basal ganglia volumes decrease on typical antipsychotic medication and increase (or normalize) on atypical medication or ► clozapine (Hakos et al. 1994; Scheepers et al. 2001). Recent longitudinal MRI studies have shown that ► olanzapine and ► clozapine actually attenuates brain tissue loss in schizophrenia, whereas typical antipsychotic medication do not (DeLisi 2008; Lieberman et al. 2005; van Haren et al. 2008).

In the last decade, many studies have focused their attention on investigating the effects of first psychotic episode on the brain. Studying the early phase of the illness is useful since the confounding effects of chronicity and long-term medication can be excluded. MRI studies in antipsychotic naïve patients appear to show a relative paucity of ► brain abnormalities which stands in marked contrast with findings in more chronic schizophrenia patients. Several explanations can be contemplated to elucidate the discrepancy in brain abnormalities between those patients who are chronically ill and those who are in the early phase of the illness. Medication might increase brain abnormalities and could contribute to these brain volume changes. Finding few brain abnormalities in antipsychotic naïve patients with schizophrenia could also be the result of a selection bias favoring the inclusion of patients who have a less severe form of schizophrenia; and last but not least, progression of the illness may lead to an increase of brain abnormalities.

Indeed, there is a growing body of evidence that brain abnormalities become greater in schizophrenia over the course of the illness. Various reviews of (longitudinal) MRI studies in patients with (first-episode) schizophrenia conclude that there is accelerated loss of gray matter particularly in the frontotemporal cortical areas, as well as sulcal and ventricular expansion over time. In schizophrenia, a 3% gray-matter decrease is found with a 0.5% decrease per year, which is consistent with the result of postmortem studies in schizophrenia (Hulshoff Pol and Kahn, 2008). Although changes in brain volume over time are reported in both first-episode patients and chronic patients with schizophrenia, the magnitude in first-episode patients (e.g., −1.2% in 1 year for whole brain volume) suggest that these brain volume reductions are particularly prominent during the first years of illness (Cahn et al. 2002).

Nevertheless (progressive), brain-volume reductions are only relevant if they are associated to the clinical characteristics and outcome in schizophrenia. The most consistent finding of longitudinal MRI studies in first-episode and chronic schizophrenia is the relationship between reduced brain volume (gray matter decrements and ventricular increments) and poor outcome. Psychotic symptoms have also been examined in relation to brain-volume loss over time. A recent MRI study investigated the relationship between psychosis and brain-volume change in first-episode patients with schizophrenia over the first 5 years of illness. Associations between gray-matter volume loss, lateral and third ventricle volume increase, and longer duration of psychosis were found. Total duration of psychotic symptoms was further associated with greater decreases in total brain and cerebellar volume (Cahn et al. 2009). Other MRI studies, which examined smaller brain structures found reduced volumes of the medial temporal lobe, superior temporal gyrus, and hippocampal volumes in patients with psychotic symptoms. Furthermore, a long duration of untreated psychosis (DUP) is associated with poor clinical and social outcome. Various research groups have now found that patients with a longer DUP have more decreased gray matter volume than patients with a shorter DUP (Lappin et al. 2006). These findings suggest that brain-volume loss over time could be attributable to the "toxic" effects of the psychotic state.

Nevertheless, besides the (untreated) psychosis, there are other factors that could be neurotoxic in schizophrenia, such as cannabis use and stress. About 28–50% of patients with schizophrenia use cannabis. Clinically, patients who

use cannabis have more positive (but not negative) symptoms, an earlier disease onset and an increased number of psychotic episodes when compared with patients who do not use cannabis. Rais et al. (2008) found significantly more decrease in brain volume in patients using cannabis when compared with nonusing patients over a 5-year period.

Until now, there is only indirect evidence that life events might affect brain volumes in schizophrenia, as lower gray- and white-matter volumes in schizophrenia are associated with a dysregulated dopaminergic/noradrenergic-mediated stress response.

Neurotoxicity

The ▶ neurotoxicity theory of schizophrenia states that an (untreated) psychosis is neurotoxic to the brain and that brain changes are an inherent feature of the neurobiological disease process in schizophrenia. As mentioned previously, MRI studies show volume reductions over time, particularly of gray matter. Nevertheless, the brains of schizophrenia patients do not reveal characteristic histopathology like other neurodegenerative diseases do. Moreover, postmortem studies have not found evidence of neuronal injury or degeneration. A neurodegenerative process in the brain normally accompanies loss of neuronal cells and microglial cells (a type of glial cells that are the resident macrophages of the brain).

In schizophrenia, a lack of microglial cells has been found. Some researchers have postulated that neuronal cell death occurs in schizophrenia, but that this cell death is programmed (▶ apoptosis) instead of ▶ necrosis, where microglial cells "eat" the injured cells and leave scar tissue at the place where the necrotic cell used to be. Various intracellular and extracellular events, like increased ▶ glutamate stimulation, can induce a programmed apoptotic cascade which results in cell destruction. This apoptotic cascade could then produce synapse loss and synaptic remodeling, and would compromise cell function and alter brain morphology (Lieberman 1999).

Postmortem studies in schizophrenia have also reported reduced dendritic spines; a measure of the amount of synaptic contacts between neurons. Furthermore, they found smaller dendritic arbors on the pyramidal cells of the cortex, damage to myelinated fiber tracts, and increased neuronal density because of reduced neuropil; the synaptic syncytium between neurons where synaptic connections are formed between branches of axons and dendrites (Davis et al. 2003). This decreased interneuronal neuropil could cause functional and anatomic hypoconnectivity in a schizophrenic brain and would explain the decreased cortical volumes as seen on MRI (Davis et al. 2003).

Thus, a higher concentration of neurotransmitters in the brain can lead to excitotoxication and could induce cell death which in turn could result in brain-volume reduction. Although the pathophysiology of schizophrenia is still unknown, we do know that ▶ antipsychotics, dopamine receptor blockers, reduce symptoms of schizophrenia, and that party drugs like ▶ cocaine and ▶ amphetamine increase dopamine in the brain and may induce psychosis. So, it is thought that in schizophrenia there is an increase in dopamine in the mesolimbic system. This is the so-called ▶ dopamine hypothesis of schizophrenia. Nevertheless, this hypothesis only explains the positive symptoms and does not explain the negative and cognitive problems seen in schizophrenia (▶ aminergic hypotheses of schizophrenia). ▶ Phencyclidine (PCP), an *N*-methyl D-aspartate (NMDA)-receptor (a glutamate receptor) antagonist, which disinhibits excitatory glutamatergic pathways causing neuronal damage, induces symptoms more similar to those seen in schizophrenia. The ▶ glutamate hypothesis of schizophrenia postulates that there is a hypofunction of the ▶ NMDA receptor in the schizophrenic brain. The reduced activity of the NMDA-receptor affects the glutamate concentration, but influences other neurotransmitter systems, such as dopamine and GABA in the brain.

The NMDA receptor is an ionotropic excitatory receptor with glutamate as its ligand. Binding of glutamate causes an influx of Na^+ and $Ca2^+$ and thereby, postsynaptic membrane depolarization. When there is a reduced amount of NMDA receptors, the excess of glutamate stays in the synaptic cleft and increases stimulation of other ionotropic receptors like those for α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (▶ AMPA) and kainite receptors. This overstimulation, also called excitotoxication, leads to dysregulation of the $Ca2^+$ homeostasis and causes oxidative stress and thereby, apoptosis (Deutsch et al. 2001).

Antagonism, or reduced activity, of the NMDA receptor and thus a hypofunctioning of glutamate signaling may also result in changed dopamine concentration. Prefrontal D_1 receptors are hypostimulated, which may lead to negative and cognitive symptoms of schizophrenia. A later developed episodic hyperactivity of the mesolimbic dopamine system may lead to positive symptoms of schizophrenia (Jarskog et al. 2007).

The NMDA receptors are also present at the GABAergic inhibitory interneurons within the cortex. Glutamate activation normally leads to the release of GABA to inhibit glutamatergic neurons and the release of glutamate. With reduced NMDA-receptor activity, a decreased amount of GABA will inhibit glutamate activity and thereby

cause a heightened activity of glutamatergic neurons. GABAergic inhibition is of great importance in critical circuits of normal brain function and could be the cause of the cognitive symptoms in patients (Reynolds et al. 2004).

Neuroprotection

► Neuroprotection refers to treatment that helps to maintain the functional integrity of the brain in response to neurobiological stress, such as apoptosis and less synaptic activity due to neurotoxicity. Neuroprotection is already a rapidly advancing concept in the treatment of neurological disorders. Moreover, it is also seen as a therapeutic treatment for psychiatric disorders to improve loss of function or prevent neurodegeneration from occurring. The most common treatment for schizophrenia is ► antipsychotic medication. Almost all patients with schizophrenia receive antipsychotic medication during their illness; therefore, it is not clear whether the progressive brain changes occurring in the brains of the patients are due to the illness itself (untreated psychosis) or perhaps due to the use of antipsychotic medication. In other words: Are antipsychotics neurotoxic or neuroprotective to the brain (Hulshoff Pol and Kahn 2008)?

Increases and decreases in brain volumes appear to depend on the type of antipsychotic medication. Basal-ganglia volumes decrease on typical antipsychotic medication and increase (or normalize) on atypical medication or clozapine. Recent longitudinal MRI studies have shown that olanzapine and clozapine actually attenuates brain-tissue loss in schizophrenia, whereas typical antipsychotic medication does not. It has been suggested that antipsychotic drugs, specifically the atypicals, have an effect on synaptic remodeling and neurogenesis, and thereby ameliorate the pathophysiology of schizophrenia (Lieberman et al. 2008). The progressive brain loss seen in patients who are treated with ► haloperidol and other typical antipsychotics could be due to the fact that typical antipsychotics are not neuroprotective, and thus, the progressive brain loss continues to increase despite the treatment.

Furthermore, it has been suggested that physical exercise, psychoeducation, and cognitive therapy in schizophrenia are neuroprotective, but very limited research has been done so far. Future studies need to be conducted to examine the neuroprotective effects of medication and (psychosocial) treatments in schizophrenia.

Synonyms

Catecholamine toxins; Excitotoxins; Immunotoxins; Metabolic toxins; Plant toxins

Definition

Neurotoxins are poisons that disable or kill neurons.

Current Concepts and State of Knowledge

Some neurotoxins have been discovered as synthetic chemicals, whether intended for neuronal targeting (e.g., ▶ 6-hydroxydopamine, MPTP) or as side effects of other applications (e.g., paraquat and other pesticides). Others are signaling molecules of normal cells but delivered in excess (e.g., nitric oxide, ▶ glutamate). Nevertheless, the most powerful neurotoxins come from the natural world, having evolved for use by animals and plants both for predation and for defense, such as snake, insect, and spider venoms or plant toxins. Neurotoxicology is a wide field in its own right, seeking to understand the pharmacology and mechanisms of neuronal action of toxins in order to promote safety, whether in the testing of manufactured products or protection of the environment, in humans and animals alike. Neurotoxins have also, however, emerged over the last four decades as a powerful tool in experimental neuroscience and this is the focus of the present chapter. In particular, I briefly consider the development of a range of molecules that allow selective targeting, disruption, and death of specific populations of neuronal cells in the CNS. These tools can then be used to make lesions for experimental analysis of the normal function of the targeted neurons; to generate effective and efficient animal models of human diseases; to study mechanisms of neurodegeneration; and to develop novel therapeutics.

The utility of particular toxins relates to multiple factors, including *specificity* for the particular target population alone; *validity* to reproduce the specific neuropathology, and ideally the pathogenic process, involved in the target disease; *reliability* to yield consistent toxicity from one application to the next; and *practicality* for safe, simple, efficient, and cost effective handling and use within the laboratory environment.

Monoamine Neurotoxins

6-Hydroxydopamine (6-OHDA)

6-OHDA is structurally related to dopamine (DA) and is selectively incorporated via active uptake channels into catecholamine (DA and noradrenaline, NA) neurons, where it is metabolized to produce toxic products that cause cell death. When injected systemically, 6-OHDA will induce ▶ sympathectomy, but will not cross the ▶ blood–brain barrier; so, direct administration into the brain is required to induce lesions in the central neurons. The precise stereotaxic placement of the injection will determine which population of central catecholamine neurons are targeted. Thus, injection into the nigrostriatal pathway is effective in producing an effective lesion of central DA neurons of the ventral mesencephalon (substantia nigra and ▶ ventral tegmental area) resulting in widespread DA denervation of the neostriatum, ventral striatum, and associated cortical and limbic projections, and provides a widely used animal model of ▶ Parkinson's disease (PD). In adult animals, bilateral 6-OHDA lesions, whether made by intraventricular or nigrostriatal injection, are associated with a profound akinetic syndrome and failure to engage in any voluntary behaviors results in ▶ catalepsy, aphagia, and adipsia, making these animals

extremely difficult to maintain in good health and suitable for experimental analysis. By contrast, unilateral lesions produce a marked motor asymmetry involving neglect of contralateral space, postural and response bias to the ipsilateral side, and marked head-to-tail turning response ("rotation") when activated by an arousing stimulus or stimulant drug. Rotation in unilateral lesioned animals has been very widely used as a simple, reliable, quantitative functional test of experimental therapeutics – including neuroprotective agents, trophic factors, cell therapies, and novel pharmaceutics – targeted at DA system function, in particular with respect to PD, and also covering applications in schizophrenia, ADHD, and addiction.

Centrally administered 6-OHDA will affect all catecholamine neurons and their projections within the vicinity of the spread of the injection. To some extent, the lesions can be made selective to an individual population of neurons by the judicious placement of the injection, but for example, nigrostriatal placement will inevitably also affect collateral NA projections in the medial forebrain bundle. If selective targeting of DA neurons is required, NA neurons can be protected by pretreatment i.p. with the selective uptake inhibitor desipramine. Conversely, selective NA depletion can be achieved by use of a selective NA toxin, such as DSP-4 (see below), or by 6-OHDA injection caudal to the ventral mesencephalon where the ascending DA neurons are located. Moreover, the forebrain projections of brainstem NA cell groups to hypothalamic, limbic, and cortical targets separate in dorsal and ventral bundles that can again be selectively disrupted by differential placement. Such manipulations were important in the pioneering studies that first distinguished the specific substrates for reward and motivational systems in the brain.

Dihydroxytryptamines (DHTs)

5,6-DHT and 5,7-DHT are structurally related to ▶ serotonin (5-hydroxytryptamine, 5-HT) and cause death of these neurons by a similar process of active uptake and intraneuronal cytotoxicity. Thus, injection into the cerebral ventricles or into the ascending fiber pathways in the medial forebrain bundle can produce relatively extensive depletion of forebrain serotonin. This has proved useful in studies of the role of 5-HT systems in the ▶ hippocampus, and in particular in the interdependence and interaction of serotoninergic and cholinergic afferents in regulating hippocampal function, both physiologically (such as in maintenance of the theta rhythm) and in studies of the central substrates of learning and memory. However, the DHTs do not have the same degree of potency and selectivity as 6-OHDA. Both 5,6-DHT and 5,7-DHT cross-react with catecholamine neurons, and greater attention needs to be paid to selective blockade of uptake into both DA and NA neurons, and to selective placement into the target terminal areas such as the hippocampus.

DSP-4

An alternative catecholamine neurotoxin is DSP-4 (N-2-chloroethyl-N-ethyl-2-bromobenzylamine) which, following peripheral administration, appears to have a relatively selective toxicity against NA neurons and nerve terminals, in particular the cortical and hippocampal projections of the locus coeruleus. In spite of the ease of administration and the relative selectivity for NA neurons within the brain, the toxin has been reported to also produce collateral damage in DA and 5-HT systems and lasting changes within the periphery as well as center, which may be overcome by direct central injection into circumscribed brain regions. Moreover, the precise mechanisms of DSP-4 toxicity remain ambiguous. This neurotoxin may nevertheless prove useful in combination with other toxins, such as 5,7-DHT, in comparing the interaction of NA and complementary 5-HT projections in the forebrain on the profiles of anatomical compensation, behavioral and electrophysiological changes within the target nuclei, in particular in the hippocampus or neocortex.

Other Models of Parkinson's Disease (PD)

1-Methyl-4-Phenyl-Tetrahydropiridine (MPTP)

MPTP was discovered as a by-product of a failed illegal synthesis of meperidine analogs, when it caused a profound parkinsonian syndrome in drug addicts who self-administered the substance. The peripheral administration of the drug in monkeys and mice induces major mesencephalic DA cell loss and a similarly marked PD-like motor syndrome. As in the idiopathic disease, MPTP-induced PD is responsive to L-DOPA.

MPTP is not itself the toxic agent. Rather it is metabolized by monoamine oxidase (MAO-B) to the active form, MPP+, which is taken up into cells via active DA uptake channels, and acts on mitochondria to cause cell death via mechanisms believed to involve reduced oxidative phosphorylation, lipid peroxidation, and disturbance of calcium homeostasis. MAO inhibitors such as deprenyl inhibit toxicity. Interestingly, the drug has little effect in rats which is believed to be due to the fact that the dominant isoform of MAO in this species, MAO-A, does not provide an equivalent substrate for MPTP conversion to MPP+, whereas if MPP+ itself if injected into the rat brain, it is as toxic in rats as it is in mice and monkeys.

MPTP continues to be widely used to model PD in mice and monkeys. Animals exhibit an acute parkinsonian

syndrome that recovers rapidly after a single injection, and they need to be treated chronically to achieve stable bilateral cell loss, associated with profound parkinsonian debility, including ► akinesia, aphagia, and adipsia. As a consequence, unilateral lesions that retain the animals in better health are more suitable for long term studies of reparative and neuroprotective therapeutics, and can be achieved in monkeys by unilateral infusion of the toxin into the ascending carotid artery, thereby restricting drug distribution to just the ipsilateral hemisphere.

Industrial and Agricultural Chemicals

A variety of other toxins – including paraquat, rotenone, other industrial pyridines and agricultural fertilizers – have been identified that appear to induce preferential toxicity against DA neurons after peripheral administration. This may relate to these neurons being particularly sensitive to oxidative stress and associated sensitivity of nigral neurons to iron toxicity. Indeed DA agonists such as ► methamphetamine and DA itself can be toxic to DA neurons both in vitro and in vivo when administered in high concentration. Although heavily investigated in terms of seeking to understand mechanisms of pathogenesis in PD, none of these toxins have been found to be sufficiently reliable, consistent, and specific to provide a practical alternative to 6-OHDA and MPTP.

A variety of other pharmaceutical agents are associated with extensive disruption of dopamine metabolism, such as ► reserpine and α-methyl-para-tyrosine. These drugs offer reversible tools to study acute dopamine depletion and were widely used in particular in early studies of experimental Parkinsonism. Repeated high doses of ► amphetamines (in particular methamphetamine) can also induce partial cell loss in substantia nigra.

► Ubiquitin–Proteasome System (UPS) Inhibitors

The UPS is the major system of the cell for tagging and digesting damaged, misfolded, and aberrant proteins. PD has been associated with impairment in proteolytic activity of the 20/26S proteasomes in the substantia nigra, leading to the investigation of UPS blockade as a model of PD. Thus, the injections of UPS inhibitors such as lactastatin, epoxomicin, or synthetic inhibitor peptides into the substantia nigra have been reported to produce not just selective DA depletion, but also protein aggregation in nigral neurons and formation of ► Lewy body-like protein inclusions in the cells, characteristic of the major neuropathological hallmark of the human disease. Although this remains a plausible and attractive model of PD, there continues considerable debate about the reproducibility of the model, which seems to depend on quite precise lesion parameters to reproduce the specific pathology.

Excitotoxins

Excitatory Amino Acids (EAAs)

The excitotoxins are a class of neurotoxins with the common feature of being glutamate receptor (GluR) agonists. The first discovered EAAs with neurotoxic potential in the brain were monosodium glutamate (active after peripheral administration) and kainic acid (requiring central injection). Their common action as GluR agonists led to the "excitotoxicity hypothesis," *viz.* that at a sufficient dose such EAAs induce a prolonged depolarization of glutamate receptive neurons, resulting in their cell death through some process of overactivation or overstimulation. Subsequent studies have identified a cascade of changes following GluR depolarization producing a "cycle of toxicity," which includes sodium influx, osmotic imbalance and cell lysis, calcium influx, activation of the mitochondrial energy chain and oxidative stress, inflammatory response, induction of specific cell death gene expression pathways, and other metabolic changes that combine to cause neuronal death via both necrotic and apoptotic mechanisms.

Kainic Acid (KA)

EAAs such as kainic acid offered a distinct advantage over older lesion methods such (as aspiration, electrolytic and radiofrequency lesions) in permitting localized induction of cell loss while sparing axons of passage. This allowed for the first time making selective lesions in areas traversed by *en passant* fiber bundles, such as in the hypothalamus and neostriatum in rodents, and permitted important studies for the first time of the relative role of discrete hypothalamic nuclei vs. ascending brainstem regulatory systems in the central control of essential motivational and reward related processes; and early studies of behavioral anatomical and neurochemical changes in the striatum to produce the first usable animal models of ► Huntington's disease (HD).

Nevertheless, the excitatory potential of kainic acid was also associated with a marked potential for inducing sustained neuronal firing originating from the lesion focus, but inducing epileptogenic activity throughout the brain, overt seizures, and cell loss in susceptible neuronal populations in remote areas of the brain, in particular in the ► hippocampus and piriform lobe.

Receptor Subclass Selectivity

The profile of EAA-induced hyperactivity and cell toxicity depends on the match between the profile of glutamate

receptor distribution on the different populations of neurons in the target area and the GluR selectivity of the agonist. EAAs with excitotoxic properties have been identified binding to all major classes of GluR, notably the kainate, ► AMPA, and ► NMDA selective subclasses of ionotropic receptors, and ► metabotropic receptors sensitive to quisqualate. Some EAAs are relatively selective for a single receptor subclass, such as kainate, AMPA, and NMDA themselves, whereas others have mixed receptor targets, such as ibotenic acid.

With different cell populations in a nucleus or brain area expressing different receptors, judicious selection of toxin can provide different profiles of cell death. Thus, a comparison of alternative toxins following injection into the nucleus basalis magnocellularis (NBM) identified quisqualic acid and AMPA as the toxins of choice for the (relatively) selectively targeting of the cholinergic neurons of the basal forebrain-cortical projection system in comparison to the damage in non-cholinergic neurons produced by ibotenic acid, NMDA, and kainate.

Targeting NMDA receptors using NMDA itself has emerged as the neurotoxin of choice in ► hippocampus and cortex, and NMDA has provided a potent toxin for demonstrating the effects of hippocampal lesions on a range of learning phenomena. Moreover, the NMDA receptor antagonist AP-5 has been particularly influential in mapping parallel effects of hippocampal NA denervation disrupting behavioral and electrophysiological function, supporting the hypothesis that hippocampal LTP both in vivo and in slice preparations provides a valid cellular substrate of the neural processes underlying learning and memory within hippocampal circuits.

More recently, quinolinic acid has emerged as the EAA of choice within the striatum. After intrastriatal injection, quinolinic acid is relatively selective for the median spiny (► DARPP-32 positive) projection neurons of the striatum with relative sparing of the large ACh and medium NADPH-diaphorase-positive and other aspiny interneurons. It has proved of additional interest as an animal model of HD because this molecule is found in the normal brain as an endogenous product in one of the two main pathways of tryptophan metabolism, and the lesion has been widely used to explore the development of novel cellular, neurotrophic, and neuroprotective therapeutics for the human disease.

Nevertheless, receptor distribution is not the sole determinant of selectivity. Alternative excitotoxins also differ in (1) epileptogenic potential, as a consequence of which kainic acid is seldom used today for in vivo lesion studies; (2) lipophilicity, as a consequence of which ibotenic acid shows much greater diffusion through myelinated fiber tracts causing e.g., more damage in deep layers of the cortex after striatal injection than does, say, quinolinic acid; and (3) inflammatory activity that can cause the demyelination of passing axons and reduce the fiber sparing benefits originally claimed for the EAAs. Thus, the selection of an appropriate excitotoxin may be suggested by theoretical considerations, but will require systematic empirical validation before use within any new model application.

Metabolic Toxins

3-Nitropropionic Acid (3-NP)

3-NP is a plant and fungal toxin associated with a toxic dystonic syndrome in man, and has its action as an inhibitor of succinate dehydrogenase, a component of ► mitochondrial complex II energy metabolism. In the 1990s, 3NP was optimistically adopted as a particularly efficient metabolic toxin since it appeared to provide selective striatal lesions even after peripheral administration. For reasons that remain poorly understood i.p. injections produce selective destruction of the medium spiny projection neurons of the neostriatum, with relative sparing of the striatal interneurons. This seemed to reproduce the profile of cell loss in HD and was adopted in several labs as a simple and efficient method to reproduce the human pathology. However, the toxin has a number of practical difficulties for experimental application. Standardized dosing can produce very great variability of toxicity with some animals exhibiting very extensive nonspecific lesions and large necrotic holes in the striatum, whereas other identically treated animals have no detectable pathology at all. In order to achieve consistent and relatively selective striatal lesions, it is necessary to administer very many small injections over a regular and extended time period, typically daily over weeks or even months, combined with daily testing with a functional readout that will allow setting a criterion for the cessation of dosing each animal at a comparable stage. The only effective protocols for achieving reliable and reproducible lesions that can be used to then test experimental therapeutics involve a major investment in time and resources that largely offsets the original promise of efficiency offered by the peripheral route of administration.

Other Mitochondrial Toxins

Although 3-NP may be relatively unreliable in its toxicity and specificity, a variety of other toxins similarly affect the mitochondrial energy chain, including malonic acid (MA, malonate), which inhibits the same mitochondrial complex II enzymes as 3-NP, and aminooxyacetic acid (AOAA). Unlike 3-NP, these toxins do not cross the

► blood–brain barrier and so require central injection. Thus, when injected into the striatum, both MA and AOAA induce effective striatal lesions. These toxins have been described as inducing secondary or "indirect" excitotoxicity to neurons in the area of injection, since the profile of lesion toxicity is similar to that induced by GluR agonists, they potentiate the effects of low doses of the latter EAAs, and their toxicity is partially blocked by the NMDA antagonist MK-801. These metabolic toxins have again been of particular interest as another model of HD since they are associated with a similar cellular impairment in metabolic function as seen in the human disease, and have been argued to model a final common pathway in cell death. Moreover, toxicity is age dependent and selective for medium spiny neurons with relative sparing of striatal interneurons. However, in contrast to the human disease, malonate appears to have a toxic effect also on DA afferents to the striatum, and can be more variable in its effects than the consistent results obtained with the classic EAA excitotoxins.

Immunotoxins

Cholinergic Neurotoxins

The selective targeting of cholinergic neurons for a long time relied on the selective placement of excitotoxins into the circumscribed cell body nuclei in the medial septum and the NBM. This achieved effective lesions of the target neurons and extensive cholinergic deafferentation of the targets of cholinergic projections in the cortex and hippocampus, respectively, but could never be demonstrated to be specific; co-localized non-cholinergic neurons and parallel projections were typically equally affected (e.g., damage to the parvalbumin-positive ► GABA neurons of the medial septum projecting in parallel to the hippocampus). A claim was made for cholinergic selectivity for the ethylcholine mustard axiridinium ion, AF-64A, but this has not been well supported. In the hands of most people, AF-64A produces cavitation at the site of injection and extensive nonspecific lesions. Greater specificity has subsequently been demonstrated for the immunotoxin, 192-IgG ► saporin.

Immunotoxins

Following a similar logic to the familiar neuroanatomical use of antibodies to label specific target molecules on cells in a range of sensitive immunohistochemistry techniques, immunotoxins involve conjugating an immunoglobulin antibody (or immunoglobulin fragment) to target cell surface receptors or channels with a cytotoxin that will then induce death of the target cell. The trick is to select targets such as neurotrophic factor receptors, which will internalize the ligand, thereby allowing the toxin to be transported into the cell for intracellular concentration, often with active transport back to the cell body where its primary toxic action takes effect. A range of antibody fragments and cytotoxins have now been developed for a range of application, the first of which to receive major attention was 192-IgG saporin.

192-IgG Saporin

192-IgG saporin was the first used and most extensively explored of the burgeoning range of immunotoxins. The 192-IgG immunoglobulin recognizes the p^{75} low affinity NGF receptor which is widely expressed on cholinergic neurons in the forebrain. After central injection, 192-IgG saporin binds to the NGF receptor, achieving selective internalization preferentially in cholinergic neurons, retrograde transport of the cytotoxin saporin to the cell body and consequent death of the cell. Although the preparation and stability of the toxin and precise parameters of injection are important, 192-IgG saporin has proved the most successful technique for selective lesion of septal and basal forebrain neurons sparing co-localized cells, and has been widely used to confirm that many of the electrophysiological and behavioral changes in learning and memory function associated with excitotoxic lesions of the medial septum and NBM are indeed attributable to the selective depletion of the cholinergic innervations of the hippocampus and cortex respectively.

Other Immunotoxins

More recently, other immunotoxins have been developed using a similar conjugate strategy to develop tools for simple and effective lesion of NA neurons by targeting the synthetic enzyme dopamine-ß-hydroxylase; DA neurons by targeting the ► DA transporter; striatal neurons by targeting the substance P receptor; and selective lesions of basal forebrain neurons receiving glutamatergic projections by conjugating saporin to the NMDA receptor. Indeed, the selectivity provided by immunotoxins allows a variety of previously intractable experimental issues to be addressed, such as the relative contributions of striosome and matrix compartments of the striatum by targeting the striosome projection neurons with a saporin-antibody complex recognizing the ► μ-opiate receptor.

Conclusions

The last three decades has provided a wide range of novel neurotoxins that allow selective disruption and death of targeted populations of neurons within the brain. Targets may be selected by anatomical location, morphological

cell type, specific neurotransmitter (via selective uptake channel), pharmacological and immunological targeting of identified receptors, or disruption of subcellular metabolic cell processes. These then provide powerful tools for making selective manipulations as the independent variable in physiological, pharmacological, and behavioral analyzes of normal and abnormal brain function in health and disease. Nevertheless, while most available toxins are effective in reproducing particular profiles of cell loss and features of cellular and subcellular pathology of the corresponding human disease, they frequently do not reproduce the neuropathogenic process accurately, and the lesions are typically acute rather than slowly progressive as is characteristic of most human neurodegenerative diseases. Consequently, neurotoxin-based lesions can provide effective models to study functional organization in the nervous system and have value for evaluating symptomatic and reparative approaches to treatment. However, such lesions are less suitable for the experimental analysis of neuroprotective processes and for the development of therapeutic strategies to alter or reverse the progressive course of disease. For such applications, alternative genetic models are increasingly considered preferable.

Acknowledgments

I thank Dr Simon Brooks and Dr Emma Lane for their helpful comments on the manuscript. I acknowledge the ongoing support for our own studies from the UK Medical Research Council, the Parkinson's Disease Society, the High Q Foundation, and the FP6 and FP7 research programs of the European Union.

Neurotransmitter

Definition

Neurotransmitters are chemical substances that relay, amplify, and modulate signals between one neuron and another, or between a neuron and another cell. Typically, neurotransmitters are packaged into vesicles that cluster beneath the membrane on the presynaptic side of a synapse, and are released into the synaptic cleft, where they bind to receptors in the membrane on the postsynaptic cell. Release of neurotransmitters usually follows arrival of an action potential at the synapse, but may follow graded electrical potentials. Low level "baseline" release may also occur without electrical stimulation.

Neurotransmitter Transporters

Definition

Proteins that function to take up neurotransmitters from the extracellular milieu into cells such as neurons and glia. These transporters are targets for many psychotherapeutic drugs (e.g., ► Fluoxetine, Prozac©) and sites of action of abused (e.g., ► cocaine) drugs.

Neurotrophic Factors

Definition

A neurotrophic factor is a neuropeptide that regulates the growth, differentiation, and survival of certain neurons in the peripheral and central nervous systems.

- ► Brain-Derived Neurotrophic Factor

Neurovascular Unit

Definition
In addition to the capillary endothelial cells, the site of anatomical blood–brain barrier, neurons, and nonneuronal cells such as pericytes, astrocytes, microglia together constitute a functional unit, often referred to as a neurovascular unit.

Cross-References
► Blood–Brain Barrier

Neutral Antagonists

Definition
A ligand that binds to a receptor, does not increase or decrease cellular activity, but can block the actions of both agonists and inverse agonists.

Newer Anticonvulsants

► Second-Generation Anticonvulsants

Nicotinamide Adenine Dinucleotide

Synonyms
NAD

Definition
Coenzyme utilized during alcohol breakdown; rate-limiting factor of ADH-related metabolic tolerance.

Nicotine

Paul B. S. Clarke
Department of Pharmacology and Therapeutics, McGill University, Montréal, QC, Canada

Synonyms
(−)-1-Methyl-2-(3-pyridyl)pyrrolidine

Definition
Nicotine is by far the most extensively studied chemical in tobacco smoke. This chapter summarizes its pharmacokinetics, mechanisms of action, and behavioral effects in humans and animals. Particular attention is paid to the role of nicotine in tobacco addiction, as currently understood from the perspective of animal and human studies. Finally, the possibility that tobacco addiction is facilitated by additional chemical components of tobacco smoke or by nonchemical reinforcers interacting with nicotine is discussed.

Pharmacological Properties

Pharmacokinetics
Nicotine is a tertiary amine and weak base, such that it is more than 50% ionized at physiological pH. In its nonionized form, nicotine tends to pass rapidly through membranes. For example, when nicotine reaches the brain via the carotid arteries, it is swiftly taken up and then released slowly into the bloodstream. Animal studies have shown that the brain can maintain a three-fold higher nicotine concentration than plasma, although how much of the drug is free to act on brain receptors is unclear. Nicotine is metabolized by a number of hepatic CYP450 enzymes, and its plasma ►elimination half-life in humans is around 2 h (1 h in rats), with notable interindividual differences resulting from genetic variation. Peripherally formed nicotine metabolites appear to have only minor pharmacological effects. However, in animals and potentially in humans, nicotine is also metabolized within the brain. One metabolite formed locally within the rat brain, nornicotine, is a weak nicotinic agonist (► Nicotinic Agonists and Antagonists) but may accumulate with repeated nicotine dosing.

It was long believed that cigarette smoking extracts nicotine rapidly from the lungs, such that each puff would promptly deliver a highly concentrated bolus to the brain. However, empirical evidence now suggests that arterial levels of nicotine rise quite gradually, peaking only after 20–25 s. This finding potentially has major implications for our understanding of nicotine reinforcement (see below).

Mechanisms of Action
Nicotine exerts almost all of its known actions via nicotinic acetylcholine receptors (nAChRs). Each nicotinic receptor comprises five protein subunits, arranged around a water-filled channel. The receptor is normally closed, but opens upon the binding of the agonist. Channel opening allows the passage of ions, notably Na^+ and/or Ca^{++}. These

positively charged species rapidly enter the cell, causing depolarization. This depolarization in turn stimulates the opening of voltage-gated ion channels, with a consequent cascade of intracellular signaling events. Hence, at the cellular level, the stimulation of nAChRs can trigger contraction (skeletal muscle), action potential generation, and modulation of transmitter or hormone release.

Nicotinic receptors are widely expressed by neurons in brain, spinal cord, autonomic ganglia, and by primary sensory neurons. Indeed, there is scarcely a nucleus in the brain that does not express nicotinic receptors. Although most CNS nAChRs are located in or on neurons, some appear associated with glial cells. Nicotinic AChRs also occur on other nonneuronal cells, for example in skeletal muscle, lung, skin, immune cells, and vascular endothelium.

Neuronally expressed nicotinic receptors are highly heterogeneous (Gotti et al. 2006; see also Nicotinic Agonists and Antagonists). This diversity partly reflects the diversity of protein subunits which can combine to form a receptor. Each type of nAChR subunit is encoded by a different gene, and neuronal nAChRs are formed from combinations of α2–α7 and β2–β4 subunits. Theoretically, then, a vast number of nAChR subtypes might exist, but the real number appears far smaller, with perhaps one dozen accounting for most pharmacological actions of nicotine (Gotti et al. 2006). Subtypes of nAChR are named according to their constituent subunits, with the stoichiometry indicated if known (e.g., α4β2 or $\alpha4_2\beta2_3$). By convention, an asterisk indicates the possible presence of additional subunits (e.g., α4β2*). Most nAChR subtypes comprise combinations of both α and β subunits, but α7 subunits can additionally form homo-oligomeric receptors (i.e., $\alpha7_5$). Individual neurons are capable of expressing more than one nAChR subtype, each of which may contain several different types of subunit.

Nicotinic AChR subtypes differ in several important respects. First, each subtype possesses a unique anatomical pattern of expression. Second, nAChR subtypes differ in their channel properties. For example, α7-containing receptors are unusually permeable to Ca^{++} relative to Na^{+}ions, and this property has important implications for transmitter release and other intracellular functions mediated by Ca^{++}. Third, nAChR subtypes differ in their sensitivity to nicotinic agonists and antagonists, and in their propensity to desensitize and resensitize. Fourth, some receptor subtypes proliferate in response to chronic agonist administration, although the functional consequences of such upregulation are not well understood.

Nicotinic receptors transition through three main functional states: resting, activated, and desensitized. In the absence of agonist, the receptor-associated channel is predominantly closed. The binding of agonist leads to channel opening, an extremely rapid transition typically occurring within milliseconds. The activated receptor may subsequently enter a desensitized state in which the channel is again closed. With time, the desensitized receptor assumes the resting, activatable state. Certain nAChR subtypes desensitize rapidly (e.g., α7 in less than 1 s), whereas others desensitize slowly if at all. Although desensitization was once thought to require high agonist concentrations, it is now known that even very low (nanomolar) concentrations of nicotine can desensitize some nAChR subtypes, without significant receptor activation. This is potentially significant, since in habitual smokers, plasma nicotine levels remain in this range even after a night of abstinence. With prolonged agonist exposure, nicotinic receptors can enter a more persistent desensitized state, termed inactivation (Gentry and Lukas 2002). Here, functional recovery may require several days or more.

It is not at all clear to what extent cigarette smoking stimulates versus desensitizes neuronal nAChRs. The answer will surely depend on the nAChR subtype, previous nicotine exposure, and the temporal pattern and amount of nicotine intake. Most animal models related to tobacco smoking employ relatively brief nicotine exposures, which are unlikely to mimic the complexity of tobacco smoking.

Behavioral Effects of Nicotine in Humans and Animals

Nicotine exerts a plethora of acute behavioral effects, which is unsurprising given that nAChRs are very widely expressed in the brain and elsewhere. Certain behavioral effects depend not only on the dose administered, but also on recent or remote drug history; some effects undergo transient or persistent ▶ tolerance, whereas others show ▶ sensitization or else remain largely stable across repeated tests.

Comparison of behavioral effects in humans versus animals is hindered by several factors. First, behavioral procedures are usually quite different. Second, most human studies are conducted with tobacco smokers; these individuals often have many years of drug experience. Third, very few animal studies have attempted to mimic the complex ▶ pharmacokinetics associated with tobacco smoking. Instead, nicotine is typically administered as an acute subcutaneous or intraperitoneal "depot" injection, in doses providing plasma levels higher than those found in most habitual smokers (Matta et al. 2007). The use of relatively high doses in animals leads to numerous behavioral effects, not all relevant to tobacco

smoking. Behavioral responses to nicotine that are most related to reinforcement are described in a later section.

In drug-naïve rats, nicotine can produce marked behavioral disruption, associated with prostration and ▶ ataxia. However, upon repeated dosing, persistent tolerance develops, such that a generalized stimulant effect emerges in tests of locomotor stimulation and ▶ operant responding. This transition is often viewed in terms of behavioral sensitization (▶ Sensitization to drugs), although it is at least partly due to tolerance to the initial depressant effect. The behavioral activating effect of nicotine appears quite general, since operant responding is also increased during time-out periods when reinforcers are unavailable and also in tasks where low rates of responding are preferentially reinforced.

Nicotine's status as a mild ▶ psychostimulant drug is supported by several other findings. For example, like ▶ amphetamine and similar drugs, nicotine improves sustained attention and produces an amphetamine-like discriminative stimulus (▶ Drug Discrimination) (i.e., drug cue) in nicotine-experienced rats (Smith and Stolerman 2009). Pharmacological and lesion studies that have been conducted in animals further suggest that like psychostimulants, nicotine can increase locomotor activity and serve as a ▶ reinforcer via a mechanism dependent on mesolimbic dopaminergic transmission (see below).

Many other behavioral effects of systemic nicotine administration have been reported in rodents or human subjects, or both. These include antinociception (▶ Analgesics), improved cognition (▶ Cognitive enhancers), reduced or increased anxiety (▶ Anxiety: animal models), attenuated ▶ aggression, reduced food intake (▶ Appetite suppressants), and ▶ conditioned taste aversion.

Antinociceptive effects of nicotine have been observed in several animal pain models (▶ Antinociception Test Methods). Neuronal and receptor mechanisms have been partially elucidated. Pain-suppressing effects of tobacco smoking have also been demonstrated in human subjects; limited evidence suggests that nicotine is at least partly responsible.

Sustained ▶ attention is improved by nicotine in both animals and humans (Levin et al. 2006) (▶ Rodent Tests of Cognition). Improvements have been documented using several procedures in rats, including the ▶ five-choice serial reaction time task. In the latter procedure, major differences between rat strains were observed. Interestingly, attentional enhancement by nicotine was not fully mimicked by amphetamine, suggesting divergent mechanisms. Attentional processing is also increased in human subjects receiving nicotine via skin patches. Enhancement has been found not only in abstinent smokers, but also in nonsmokers. Patients suffering from ▶ schizophrenia or ▶ attentional deficit hyperactivity disorder have also shown improvements in attention.

Learning and/or memory is improved by nicotine in a wide variety of vertebrate species and procedures (Levin et al. 2006). In rodents, nicotine tends to enhance these cognitive aspects more strongly than attention, whereas the reverse has been found in humans. It is unclear whether this divergence represents a species difference or reflects the particular behavioral tests used in rodents versus humans. In rats, nicotine-associated improvements in working memory have been extensively studied using the eight-arm ▶ radial maze (▶ Short-term and Working Memory in Animals). Here, several nicotinic agonists have proven effective, and nicotine is also effective when given chronically. Mechanisms of memory improvement have been partially elucidated in terms of nAChR subtypes, transmitter systems, and brain structures (Levin et al. 2006).

Although in most animal and human studies, subjects are exposed to nicotine during acquisition and test sessions, a few reports employing post-trial administration suggest that nicotine can also improve memory consolidation (Levin et al. 2006) (▶ Reference Memory and Consolidation). Nicotine has had beneficial effects in rodents with impaired learning or memory due to brain lesions. However, nicotine does not appear to improve memory in Alzheimer's disease (▶ Dementias and Other Amnesic Disorders) or schizophrenic patients, despite improvements in attentional processing.

Tests of anxiety in rodents have provided clear evidence of both ▶ anxiolytic and ▶ anxiogenic effects, with dose and baseline anxiety acting as modulating variables (▶ Anxiety: animal models). Genetic deletion of different nAChR subunits suggests that multiple nAChR subtypes modulate anxiety levels in complex ways. Rodents undergoing nicotine withdrawal show signs of anxiety, and in smokers, tobacco withdrawal-related anxiety is alleviated by nicotine replacement. Although smokers commonly expect that smoking or nicotine will reduce stress-induced negative affect, published evidence is equivocal.

Aggressive behavior, elicited in various ways, is reduced by acute systemic administration of nicotine in several species, including rats and human subjects (▶ Aggression). In some studies, the effect is demonstrably not due to motor impairment. Irritability and aggressiveness commonly occur during smoking cessation, and are alleviated by nicotine replacement therapy especially in subjects with high trait hostility. Mechanisms underlying these effects of nicotine remain unexplored.

Tobacco smoking reduces the body weight setpoint, and weight gain is a common consequence of cessation. Many smokers, especially young women, regard body weight gain as a deterrent to quitting. However, smokers tend to eat as much as nonsmokers, and an acute administration of nicotine appears not to reduce hunger or caloric intake in hungry smokers, suggesting that metabolic factors may be critical instead. Nicotine deprivation does not appear to contribute much to post-cessation weight gain, since the latter is only mildly inhibited by nicotine replacement therapy. In rodents, nicotine not only exerts complex effects on peripheral energy metabolism but also suppresses appetite. The ► anorexigenic effect of nicotine likely arises from peripheral and central actions, especially within the lateral hypothalamus.

► Conditioned taste aversion is readily produced by nicotine in some strains of mice and in adult, but not in periadolescent, rats. The effect is due to a central action of nicotine, and it appears dependent on dopaminergic transmission in the ► nucleus accumbens.

Nicotine provides a recognizable and reliable ► discriminative stimulus (cue), in humans, monkeys, and rodents (Drug Discrimination). Typically, nicotine has been administered by nasal spray (humans) or by systemic injection (animals). In rats, the nicotine cue has been identified as central in origin, likely involving multiple nicotinic receptor subtypes, transmitter pathways, and brain regions (Smith and Stolerman 2009). The multiplex nature of the nicotine cue, together with the potential for redundancy across different neural pathways, has hindered mechanistic dissection. As mentioned, the nicotine cue has psychomotor stimulants-like properties in rodents, with contributions from ascending dopaminergic projections as well as α4β2 nAChRs. However, the nicotine cue is not critically dependent upon mesolimbic dopamine transmission in rats, unlike the drug's reinforcing and locomotor stimulant effects (Smith and Stolerman 2009). Candidate trigger sites have been identified in medial ► prefrontal cortex and ► hippocampus.

Subjective Effects of Nicotine in Human Subjects

Nicotine acutely elicits multiple and complex subjective effects, including changes in mood, alertness, and anxiety (Kalman and Smith 2005). These effects depend on a host of factors, such as personality, smoking status, degree of abstinence, situational context (e.g., stress), passive versus self-adminstration, other drug use, and dose. Nicotine has been administered intravenously or via nasal spray in most studies. Stronger subjective responses have been seen in nonsmokers than in smokers. Generally, low to moderate doses tend to improve mood in smokers, especially during abstinence. However, dysphoria is commonly encountered as well, particularly at higher doses. Nicotine increases subjective arousal in smokers but reduces it in subjects who have never smoked; it can also make both types of individual feel less relaxed. A number of studies have suggested that nicotine can exert euphoric, "head-rush" effects resembling ► cocaine. However, such findings have little relevance to tobacco smoking, since they were obtained in known substance abusers given rapid (10-s) intravenous infusions of nicotine in doses equivalent to one or two cigarettes (i.e., 0.01–0.04 mg/kg). Puff-size doses of nicotine (e.g., 0.1 mg/infusion IV), in contrast, have only mild subjective effects.

Nicotine as a Contributor to Tobacco Addiction

In many individuals, cigarette smoking represents an addiction: it is a compulsive behavior, unaided quitting is rare, and relapse is common. Nicotine has been accorded a leading role in tobacco addiction, mostly notably in the 1988 US Surgeon General's Report. This document concluded that "nicotine is the drug in tobacco that causes addiction" (► Nicotine Dependence and its Treatment). The main arguments that have been forwarded in support of this conclusion are as follows. Nicotine is consumed in ways that avoid the many pyrolysis products found in tobacco smoke (e.g., snuff, chewing tobacco). The tobacco ► withdrawal syndrome can largely be attributed to nicotine withdrawal, since most symptoms are countered by nicotine replacement therapy, and a nicotine withdrawal syndrome can be produced reliably in animals. Nicotine replacement therapy doubles the chance of quitting. In the absence of tobacco, nicotine can serve as a positive reinforcer in human and animal self-administration studies. Nicotine shares important characteristics with other drugs of abuse such as amphetamine (e.g., cue properties, sensitization, release of mesolimbic dopamine, facilitation of brain stimulation reward). However, as discussed below, several of these statements are subject to important qualifications, and consequently a more nuanced view of nicotine's role in tobacco addiction is beginning to emerge.

Animal Models Related to Nicotine Reward

"Reward" is a multifaceted concept, and the rewarding effects of nicotine are commonly operationalized as intravenous self-administration, conditioned place preference, or facilitation of ► intracranial-self-stimulation. Most animal studies have been performed using rats.

Intravenous self-administration (► Self-administration of Drugs). It is well-established that intravenous infusions of nicotine can serve as a primary reinforcer in several mammalian species including humans (Le Foll

and Goldberg 2008). However, the great majority of studies have employed rates of drug delivery and doses outside the range experienced by smokers. In particular, nicotine has been virtually always given as a rapid (e.g., 1-s) bolus, whereas after a cigarette puff, the drug is released only slowly into the circulation, with arterial levels peaking after some 20–25 s. In addition, most animal and human studies have used doses of 15–30 μg/kg per infusion, whereas smokers receive only 1–2 μg/kg per puff (Matta et al. 2007). In contrast, recent evidence suggests that doses as low as 3 μg/kg can support self-administration behavior in monkeys and rats; indeed, rats worked for this dose even when it was delivered in a slow infusion. To date, studies of brain mechanisms related to nicotine self-administration have relied on the conventional fast infusion-high dose procedure. This work has established a critical role for ▶ mesolimbic dopamine transmission. However, it should be recalled that in human subjects, high doses of nicotine have also been reported to produce psychostimulant-like subjective effects, whereas smoking-relevant doses have not.

Conditioned place preference (▶ Conditioned place preference and aversion) has been observed after acute nicotine administration in rats and mice (Le Foll and Goldberg 2008). Many positive reports have relied on the use of "biased" procedures, which are methodologically questionable, and conditioned place aversion has also been reported. Nicotine place preference, where observed, is neither as reliable nor as large as with drugs such as ▶ morphine and psychostimulants. Recent evidence suggests that the rewarding and aversive effects of nicotine in this procedure can be dissociated by brain lesions and pharmacological manipulations.

▶ Intracranial self-stimulation is facilitated by acute nicotine administration in rodents. In particular, nicotine reduces reinforcing thresholds of electrical brain stimulation. This action, which is shared by psychostimulants and opiates, is thought to reflect the sensitization of a neural substrate of reward. A persistent lowering of self-stimulation thresholds has also been observed more than 1 month after a period of intravenous nicotine self-administration. Whether this reflects a general increase in sensitivity to reinforcers remains to be established.

Nicotine Withdrawal in Humans and Animals

Many of the signs and symptoms of tobacco withdrawal (▶ Withdrawal syndromes) can be alleviated by nicotine replacement therapy, giving rise to the notion that tobacco withdrawal is principally due to *nicotine* abstinence. However, several caveats are in order (Hughes 2007). For example, even in placebo-controlled trials, nicotine patch and nicotine gum can produce detectable cues, suggesting that some nicotine-treated subjects may expect to obtain withdrawal relief. It has also been argued that some tobacco withdrawal symptoms are nonspecific to nicotine but would also be seen upon loss of other reinforcers. Another puzzling feature of tobacco withdrawal is that it is not readily precipitated by the administration of the centrally active nicotinic antagonist ▶ mecamylamine. Just as it is unclear to what extent tobacco withdrawal reflects nicotine abstinence, opinions differ as to the importance of positive versus negative reinforcement in the maintenance of cigarette smoking (Hughes 2007).

Rodents readily express signs of nicotine withdrawal following a period of chronic exposure (Malin and Goyarzu 2009). Withdrawal signs can be induced spontaneously after a period of intravenous nicotine self-administration. In most studies, however, nicotine is delivered via subcutaneous osmotic minipumps, providing constant 24 h exposure. The standard minipump infusion dose used in adult rats (3 mg/kg/day) would be expected to provide nicotine plasma levels of 50 ng/mL or higher, beyond the range of most smokers.

Both spontaneous and nAChR antagonist-precipitated types of withdrawal are manifested by "somatic" and "affective" signs. Somatic signs include behaviors (e.g., ptosis, writhing, and grasping) and pharmacological features reminiscent of opiate withdrawal, although there is little evidence of opioid involvement in tobacco withdrawal signs in humans. "Affective" signs are manifested by elevations in brain simulation reward thresholds and conditioned place aversion. Somatic signs derive at least partly from the inhibition of central nAChRs, hence they are also termed "somatically expressed signs" (Malin and Goyarzu 2009). Affective signs, in contrast, exclusively reflect central nAChR function. Somatic and affective signs are also distinguishable in terms of nAChR subtype mediation.

Nicotine in Relation to Nicotinic Cholinergic Transmission

Nicotinic AChRs represent an important target for the neurotransmitter acetylcholine (ACh). Although nAChRs and ACh are both widely expressed in the brain, evidence for nicotinic cholinergic transmission in the brain has only emerged in the past two decades. For several reasons, it is not known how many nAChRs actually participate in cholinergic transmission. First, many published attempts to localize nAChRs using immunocytochemistry are now considered unreliable because of doubts about antibody specificity. Second, some evidence suggests that ACh may be capable of acting not only as a synaptic transmitter, but also via volume (extrasynaptic) transmission. Third, α7-containing nAChRs may also be activated by endogenous

levels of *choline*. To date, there has been little attempt to integrate knowledge about nicotinic cholinergic transmission with the known behavioral effects of nicotine.

Nicotine or Nicotine-plus?

Nicotine is only mildly rewarding in standard animal models (intravenous self-administration and conditioned place preference), although it does reliably increase the reinforcing strength of electrical brain stimulation. How, then, might it be critical to tobacco addiction? Several explanations have been proposed. First, standard behavioral procedures may not capture the full reinforcing potential of this drug. For example, animal studies tend to be of short duration, lasting at most a few weeks. This limitation may be important because it is known that in the case of cocaine, rats become much more motivated to seek the drug after they have had several months of drug exposure. Equally, if cigarette smokers use nicotine as a cognitive tool or for emotional support, these aspects would not be modeled in standard self-administration and place preference animal tests. A second possibility is that nicotine simply serves as a stronger reinforcer in humans, or perhaps primates in general, than in rodents. Thirdly, extensive evidence from rodent studies suggests that nicotine's ability to support self-administration behavior is critically dependent on its capacity to make drug-associated reinforcers more powerful (Caggiula et al. 2009). Translated into the human arena, nicotine would enhance the intrinsic or conditioned reinforcing effects of stimuli that are associated with smoking.

An additional explanation for why nicotine may be particularly reinforcing in cigarette smokers relates to the enzyme monoamine oxidase (MAO). It is known that smokers possess reduced levels of MAO-A and MAO-B isoforms, both in the CNS and periphery. This reduction is at least partly due to the presence of identified MAO-inhibiting chemicals in tobacco smoke. Monoamine neurotransmitters, and dopamine in particular, are metabolized by MAO, giving rise to the suggestion that MAO inhibition enhances neurochemical actions of nicotine that reinforce tobacco smoking. Research to date suggests that several MAO-inhibiting drugs (►Monoamine Oxidase Inhibitors) do indeed make rats more motivated to self-administer intravenous nicotine. However, in all studies published to date, the degree of MAO inhibition far exceeded that reported to occur in smokers.

Tobacco addiction and smoking cessation

Definition

Dependence is part of a diagnostic system (► DSM-IV) designed to classify the nature and extent of problems that people have in controlling their use of chemical substances. The concept of ► dependence can apply to any drug that people use on a regular basis, including tobacco, alcohol, marijuana, opiates, and stimulants. Since ► nicotine is thought to be the main chemical that makes tobacco use addictive, nicotine and tobacco dependence are often used synonymously. Features of dependence include excessive time spent acquiring, using, and recovering from the use of drugs; using larger amounts of them and for longer periods of time than intended; having difficulty in stopping them(repeated unsuccessful quit attempts); developing tolerance to drug effects; having withdrawal symptoms when the use of the drug is stopped; interference in social, recreational, or work activities; and continued use despite knowledge of adverse consequences. Not all these criteria apply to cigarette smoking, but many of the key criteria (e.g., continued use despite knowledge of adverse consequences; withdrawal symptoms, and difficulty quitting with repeated attempts) do apply.

Role of Pharmacotherapy

It is not difficult for people to start smoking, since tobacco cigarettes worldwide are a legal, readily available, and often heavily promoted product. Smoking prevalence may still be rising in many countries, but in the USA, rates have steadily declined over the past 50 years with growing recognition of the health risks associated with smoking, as well as increasingly stringent environmental restrictions and rising cost of cigarettes. Today, the smoking rate in the US general population stands at 21%. With much lower than historical rates of smoking, this is still a remarkably high prevalence rate for something that is known to be a very serious behavioral risk factor for premature morbidity and mortality.

Interestingly, at least among US smokers, about 70% at any given time claim that they want to quit smoking. Furthermore, many of these smokers, perhaps 25–30%, do attempt to quit each year. The problem is that the quit attempt for many is short-lived with a return to smoking being the ultimate outcome. This return to smoking following a quit attempt is called relapse. Scientists have been trying to understand when, why, and how people relapse during a quit attempt to get clues to help smokers succeed in quitting permanently.

Relapse Circumstances

Smokers have been asked to report on the circumstances of their return to smoking both in retrospective and real-time surveys, and the factors surrounding relapse have been well documented (Shiffman et al. 1996). Withdrawal symptoms are a clinical reality when smokers try to quit and are a factor contributing to relapse. These symptoms include irritability, anxiety, restlessness, and cravings for cigarettes, and they last for about 2–3 weeks after quitting. Interestingly, withdrawal symptom intensity has not been clearly linked to smoking cessation outcomes, but craving levels do appear to be important. Specifically, higher ► craving levels at any given point of time are associated with poorer outcomes at later points of time, whether the timeframe examined is early or later in the quit attempt. Intensity of post-quit craving may reflect the smoker's level of dependence on cigarettes. Alleviation of withdrawal symptoms can make people feel less irritable and more comfortable after quitting; at the same time, a reduction in craving may be especially important for improving quit success.

A second important factor associated with relapse is negative affect. While relapse can occur in positive mood states, people frequently report going back to smoking when they feel negative emotions including anger, frustration, stress, and even boredom. Emotions may serve as a strong cue for smoking, particularly if people have previously used smoking to enhance positive emotions and/or to feel better in the presence of negative mood states. Thus, any intervention that can help people avoid or improve postquit negative mood states may be beneficial.

Drinking alcohol increases the likelihood of a relapse. Not only is ► alcohol a cue for smoking, it may directly enhance the pleasant effects of smoking and promote continued smoking through behavioral disinhibition. Due to this interaction between alcohol and cigarettes, smokers are often advised to avoid alcohol during their quit attempt. Finally, self-confidence in being able to stay away from cigarettes is often associated with better outcomes in a quit attempt. Self-confidence may be influenced by many factors, but encouragement and support

from people in the social network of a smoker who is trying to quit may be helpful for boosting self-confidence.

All relapses must by definition begin with the first inhalation of tobacco smoke following the start of a quit attempt. This initial re-exposure, whether it happens within the first 24 h after the quit attempt or after several weeks or months, is called a slip or lapse. Theoretically, the smoker who slips by taking several puffs or even smoking a whole cigarette could just stop and return to abstinence. However, research shows that slips indicate a poor prognosis and are associated with long-term failure in the quit attempt. People who have an initial slip or lapse within the first 2 weeks after they quit would have only a 10% chance of succeeding in their quit attempt (vs. a 90% chance of failing), whereas those who do not smoke at all in the first 2 weeks have a much better chance (about 50%) of long-term success (Kenford et al. 1994). Thus, it would be beneficial if treatments could prevent or reduce the negative impact of smoking slips during a quit attempt.

Successful treatments must simultaneously address all the factors that contribute to relapse, which include withdrawal symptoms and cravings, response to environmental and internal emotional cues, and the negative impact of smoking slips. There are currently two things that smokers can do to improve their chances of quitting. One is to use an approved medication and the other is to use behavioral counseling support for smoking cessation. Many smokers quit on their own with no help from medicines or therapy. It is estimated that the success rate for unaided quit attempts is about 5% on a given try. In contrast, when modern treatments for smoking cessation are tested, long-term (e.g., 6–12 months) success rates may be as high as 30% (Fiore et al. 2008).

Medications: Nicotine Replacement Products

There are several places to find reviews of medications for smoking cessation (Fiore et al. 2008; Foulds et al. 2006; Le Foll and George 2007; Nides 2008). The first medications approved for smoking cessation were the nicotine replacement products (NRT). These products come in five different forms: patch, gum, lozenge, inhaler, and nasal spray. All the products deliver pure nicotine to the body to provide a short-term substitute for cigarettes when the smoker is trying to quit, and these can lower the intensity of withdrawal symptoms and cravings. Further, all the NRT improve smoking cessation outcomes, approximately doubling the chances of a successful quit when compared with placebo medication. The NRT products differ primarily in the route and speed at which nicotine is absorbed, as well as in their convenience and ease of use (see Table 1). Nicotine delivered in medications is much safer than nicotine delivered by smoking tobacco. This is because all the toxins and carcinogens delivered in smoked tobacco are eliminated, while nicotine itself is not cancer-causing. Nicotine does stimulate heart rate and blood pressure, but it can be used safely even by people with heart disease, because it is safer than smoking cigarettes (Benowitz and Gourlay 1997).

Nicotine can be absorbed from any surface of the body; this includes any part of the skin, mouth, and nasal membranes as well as the surface of the lung, as in smoking. (Nicotine is not well absorbed by the stomach owing to the acid content of that organ.) The various NRT formulations have taken advantage of this absorption versatility to deliver nicotine by different routes.

Nicotine patches are perhaps the most widely used method of nicotine delivery. They are very convenient to use, being applied and changed only once daily, and may be used for 16 or 24 h per day. Patches are the only formulation that delivers steady levels of nicotine throughout the day, and this is their advantage. Patches are meant to be used for 8–12 weeks after quitting to suppress withdrawal symptoms and cravings. Most patches deliver about 21 mg/day of nicotine. The dose content of patches can be tapered during the later weeks of use (e.g., to 14 then 7 mg/day), to gradually wean away from nicotine, or the patches can be stopped abruptly with no ill effects. Side effects are few and include skin irritation and disturbed sleep. Nicotine patches can be obtained either by prescription or over the counter (OTC).

With all the remaining nicotine replacement products, the number and timing of doses is controlled by the smoker. This is both the advantage and down-side of these products. The advantage is that the products can be used "as needed" when difficult situations arise, in which the individual may be tempted to smoke. The disadvantage is that people sometimes fail to use the medications in adequate amounts to gain the full benefits of nicotine replacement. Gum, for example, should be used at about nine pieces per day for full effect but many people use less. Gum and lozenge are very similar in that they both deliver nicotine through the mouth membranes; lozenge may be easier and more socially acceptable to use since it does not require chewing. Both are available OTC. Both gum and lozenge comes in 2 mg and 4 mg doses. The higher dose is recommended for heavier smokers (e.g., more than 1 pack per day).

The nicotine inhaler also delivers nicotine across mouth mucous membranes. This product requires a hand-to-mouth behavior that some smokers find comforting since it mimics smoking behavior. The disadvantage of the inhaler is that intensive puffing is

Nicotine Dependence and Its Treatment. Table 1. Pros and cons of smoking cessation therapies.

Treatment	Pros	Cons
Medications		
Nicotine patch	Easy to use (applied once daily); available OTC; provides steady nicotine levels	No smoker control
Nicotine gum	Smoker controls dose and timing; available OTC	Acceptability/effort of use; difficult to use with dentures
Nicotine lozenge	Smoker controls dose and timing; available OTC	Side-effects include nausea, hiccups, heartburn
Nicotine inhaler	Mimics hand-to-mouth behavior of smoking; smoker controls dose and timing	Needs prescription; intensive puffing required to get adequate dose
Nicotine nasal spray	Rapid onset effect; smoker controls dose and timing	Needs prescription; side effects include burning nose, runny eyes, sneezing
Bupropion (Zyban)	Twice per day pill	Needs prescription; Side effects include insomnia and dry mouth; Contraindicated with seizures, head trauma, eating disorders
Varenicline (Chantix)	Twice per day pill; few medical contraindications to use	Needs prescription; side effects include nausea and sleep disturbance; possible suicidal thoughts
Behavioral Support		
Group	Tips for successful quitting; social support from leader and group members	Effort required to find and use groups; location and scheduling barriers
Individual	Intense, tailored help	Hard to find
Telephone (quit lines)	Easy to use; provides guidance and social support	Therapy may be less intense and less structured than in-person methods
Internet	Easy to use; provides good information and suggestions	Less social support than in-person help; quality may vary across sites
Self-help booklets	Easy to use; provides good information and suggestions	Not shown to be efficacious in boosting quit rates

required to obtain adequate doses of nicotine, and there may be initial side effects including throat burning, watery eyes and nose, and coughing. The inhaler is only available by prescription. For all NRT taken by mouth, acidic drinks such as coffee and juice should be avoided for 15 min before product use, since these can reduce nicotine absorption.

Nicotine nasal spray delivers nicotine through nasal mucous membranes. This product delivers a relatively high dose with rapid absorption that most closely mimics nicotine delivery from cigarettes. Side effects include burning, runny nose and eyes, and sneezing but these effects subside with continued use. The spray is only available by prescription and is recommended for heavier smokers.

It is important to note that the use of NRT product combinations has recently been shown to further improve the chances of success beyond those obtained with the use of a single medication. In particular, combined use of patch plus a short-acting smoker-controlled medication such as gum or nasal spray can produce better cessation outcomes than either medication alone (Fiore et al. 2008). This may be because the advantages of steady nicotine replacement levels and smoker-controlled dosing are combined.

Medications: Non-Nicotine Products

In addition to all the NRT, there are also two non-nicotine medications that have been approved by the FDA for smoking cessation based on evidence of efficacy. ► Bupropion (Zyban) is an anti-depressant medication whose benefits for smoking cessation were discovered by chance during its use as an ► anti-depressant. Subsequent research has shown that bupropion doubles quit rates when compared with a ► placebo control and appears to

reduce both withdrawal symptoms and craving. Interestingly, the medication is equally effective for smokers with and without a history of depression, so it can be used by any smoker. Bupropion comes in 150 mg pills and is taken twice daily starting 1–2 weeks prior to the quit date; it needs to be obtained by prescription. There are some limitations on who can take it, related to medical conditions. For example, people with a history of head trauma, seizures, or eating disorders should not take this medicine (Fiore et al. 2008). Side effects are primarily insomnia and dry mouth. Even though this medication works in people with and without a history of depression, smokers who are concerned about negative affect may want to try this medication.

Varenicline (Chantix) is the most recent medication approved for smoking cessation. This drug, ► a partial agonist, was specifically developed as a smoking cessation aid. It attaches to the receptor responsible for nicotine effects in the brain, acting like a substitute to reduce withdrawal symptoms and cravings. However, there is also some evidence that ► varenicline can reduce the reinforcing effects (e.g., satisfaction) of nicotine when smokers have a post-quit slip or lapse, thus potentially addressing this important relapse risk factor (West et al. 2008). The research on which FDA approval of this drug is based showed that varenicline efficacy is better than that of both placebo and of bupropion, and that the medication can triple the chances of a successful quit attempt when compared with placebo (Gonzales et al. 2006; Jorenby et al. 2006). Varenicline must be obtained by prescription; the only medical contraindication is severe kidney impairment. Side effects are mainly nausea and disturbed sleep, but concerns have also been raised about increased suicidal thoughts in people taking this medication.

Table 1 summarizes the available smoking cessation medications and highlights their pros and cons. Smokers generally choose a smoking cessation product based on convenience and availability, the advice of their doctor, and their own personal experience with the use of these products. Because smokers generally require several attempts before they can quit for good, there is an opportunity to try different medications and see which ones work best for each individual.

The medications listed earlier are broadly recommended for use by all types of smokers, but there are two specific groups for whom the medications may not be recommended (Fiore et al. 2008). Research with adolescent smokers (under 18 years of age) has shown that counseling therapy is beneficial but has not shown that medications (NRT or bupropion) improve the chances of successful quitting. Therefore, medications are not currently recommended for adolescent smokers. Pregnant women are the second group where recommendations must be qualified. In this case, there has been only limited research conducted with medications because of safety concerns. Nicotine most likely does have adverse effects on the fetus, which is why it is important for pregnant women to stop smoking. However, they should try to stop with behavior therapy alone, if possible. If this does not work, pregnant smokers should consult with their doctor about the use of smoking cessation medications.

Behavior Therapies

Smokers trying to quit will benefit from using a behavior therapy program in addition to medications. Behavior therapy is frequently available through hospitals or community agencies and should consist of individual or group counseling sessions offered both before and after the target quit day. In these programs, smokers are taught how to prepare for a quit attempt and what to expect when they quit. Relapse prevention skills are also stressed with interactive discussion of how to handle difficult situations, in which the newly abstinent smoker may be tempted to light up a cigarette. Research has shown that behavior therapy can improve the chances of successful quitting through problem solving and social support, and that in general, the more therapy people get, the better their outcome is likely to be. Specifically, 4–8 or more in-person therapy sessions have been shown in research to be optimal for improving outcomes (Fiore et al. 2008).

More recently, there is evidence that therapy delivered over the telephone via quit lines is efficacious (Fiore et al. 2008). This is an encouraging finding, since some people find it difficult or inconvenient to go to an in-person therapy program and some may be reluctant to engage in face-to-face therapy. Ideally, quitlines should offer a structured series of calls following the initial contact, with calls initiated by the therapist who provides guidance and support during the quit attempt comparable with what would be found in an individual or group therapy program. There are also internet programs now available that can help smokers quit. The quality of these programs may vary. An ideal program would include personalized help with specific issues and problems, monitoring and feedback on personal progress, and a chance to interact with others who are trying to quit.

In summary, there are several ways that smokers can improve their chances of success in smoking cessation but the most important principle is that a combination of medication and behavior therapy has been shown in research to be the optimal approach for best outcomes. There are seven FDA approved medications available either by prescription or OTC, and behavior therapy is

more available than ever with the advent of telephone and internet-based counseling. Smokers attempting to quit are advised to take full advantage of these resources.

Definition

The wide range of pharmacologic effects of ► nicotine and other nicotinic natural products, such as epibatidine, anabasine, lobeline, and cytisine, together with increasing knowledge of the role and function of nicotinic acetylcholine receptors (nAChRs; ► nicotinic receptor), has led to great interest in the potential of ► antagonists, ► agonists, and ► partial agonists of nAChRs, as treatments for central nervous system (CNS) disorders. Focused efforts to design selective nAChR ligands as new therapeutic agents have been going on for more than two decades, but to date, few synthetic nAChR ligands have been approved for clinical use – nAChR antagonists such as mecamylamine for hypertension in 1950 and the nAChR partial agonist varenicline for smoking cessation in 2006. Evidence is accumulating for the involvement of nAChRs in several CNS disorders in addition to nicotine dependence, including alcoholism, ► depression, ► schizophrenia, pain, ► attention-deficit/hyperactivity disorder (ADHD), and neurodegenerative diseases. Advances have been made in the design and development of selective compounds targeting these disorders.

Current Concepts and State of Knowledge

Pharmacologic Properties of Neuronal Nicotinic Acetylcholine Receptors

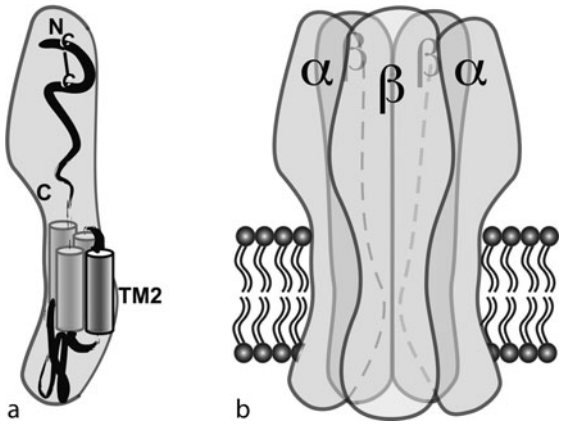
When the French doctor Jean Nicot brought tobacco plant powder to cure the headache of his queen in the sixteenth century, it would have been impossible to predict that Nicot would leave his name in the history of pharmacology. The natural alkaloid in the tobacco plant was termed nicotine; however, it is only centuries later, with the discovery of receptors that are specifically activated by nicotine, nicotinic acetylcholine receptors (nAChRs), that we are beginning to

understand nicotine's effects on the CNS and peripheral nervous system.

nAChRs belong to a superfamiliy of ligand-gated ion channels characterized by a conserved sequence in the N-terminal domain flanked by linked cysteines that also includes 5-HT_3, GABA and glycine receptors. These highly conserved, integral membrane proteins are pentameric structures, composed of α and β subunits. To date, nine α (2–7, 9–10) and three β (2, 3, and 4) subunits have been identified in the CNS. nAChRs may consist of five identical subunits (homomeric) or two or more different subunits (heteromeric). The α7 subunit forms homomeric receptors, a major component of the nAChRs in the CNS. Heteromeric receptors formed by the α4 and β2 subtypes are the principal receptor types in the mammalian brain. Some subunit combinations are more widely expressed in the CNS than others, while some are restricted to well-defined neuronal pathways. For example, the α6-containing receptor, which predominantly results from coassembly with α4 and β2 subunits, is preferentially expressed in the mesolimbic system (Albuquerque et al. 2009; Dani and Bertrand 2007). Since receptors can contain multiple α and β subunit types and the subunit composition varies in different species, insight into receptor composition and localization, especially in the human brain, is critically important. However, our knowledge remains limited due to a lack of sufficiently specific antibodies/ligands to detect the receptors.

To understand the relevance of receptor composition for signal transduction during receptor activation, key properties of the ligand-binding site should be examined. nAChR subunits are arranged in a doughnut-like manner, forming an ionic pore in their center. They have an extracellular ligand-binding site, N- and C-termini, and four membrane-spanning domains. Figure 1 is a schematic representation of the receptor. Three loops in the N-terminal of the α subunit form the major component of the ligand-binding site and appose three loops of the adjacent subunit that form the complementary binding site. In this specific arrangement, both subunits interact with the ligand and, therefore, determine the binding properties.

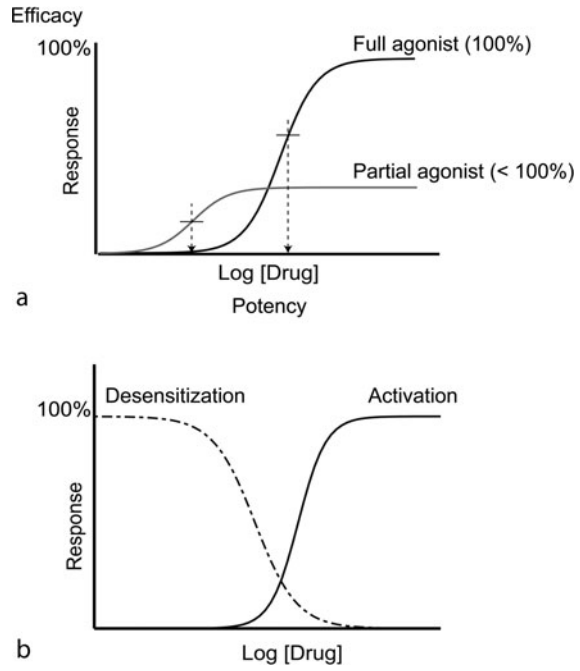
The simplest representation of nAChR ligand binding is a bimolecular reaction, in which the ligand binds and is released with a single association and dissociation constant. Accordingly, ligand affinity is characterized by a binding constant, that is, the equilibrium between the ON and OFF rates. However, such data provide little or no information on the conformational states that are stabilized by ligand binding, so that agonists, which stabilize the open active state, are indistinguishable from antagonists, which



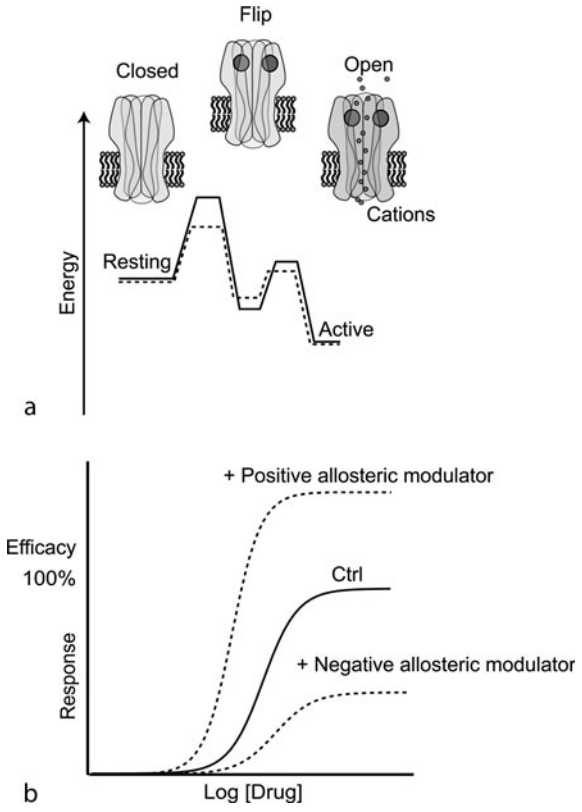
Nicotinic Agonists and Antagonists. Fig. 1. Schematic representation of the nAChR and the ACh binding site. (**a**) Representation of a single subunit formed of α-helices (cylinders), spanning the membrane four times with the N- and C-termini facing the extracellular domain. Note the position of the second transmembrane domain (TM2) that is facing the ionic pore. (**b**) Schematic drawing of the nAChR inserted into the cell membrane lipid bilayer represented to scale. The ligand-binding site lies at the interface between two adjacent subunits.

stabilize a closed conformation. Additionally, radioligand binding affinities provide no insight into the functional efficacy needed to classify ligands according to their pharmacologic effects. Typically, ligands are subdivided according to their physiologic effects – full agonists are as efficacious as ▶ acetylcholine (ACh) in activating the receptor; partial agonists are less efficacious than ACh; and antagonists inhibit ACh receptor activation. Importantly, functional efficacy (the amount of receptor activation at maximal concentration) is not correlated with potency (the concentration of ligand required to cause half activation of the receptor; Fig. 2a). It should be noted that the continuous presence of a partial agonist in the vicinity of the receptor will alter its response to a full agonist (Hogg and Bertrand 2007). Such a condition is typically encountered when a compound is given systemically and interacts with the endogenous release of the neurotransmitter.

A further complexity, common to all ligand-gated channels, is that sustained presence of an agonist progressively stabilizes the receptor in a desensitized and nonconducting state. Thus, exposure to an agonist is expected to cause transient activation, followed by sustained inhibition due to desensitization, which typically occurs at concentrations one or two orders of magnitude lesser than those required for activation. This indicates



Nicotinic Agonists and Antagonists. Fig. 2. Concentration activation profiles for nAChR activation and desensitization. (**a**) Typical concentration activation curves for a full agonist (100% efficacy) and a partial agonist (<100% efficacy) with different EC_{50} values (dotted arrows). Note that the potency of the compound (EC_{50}) does not correlate with its efficacy (relative activation vs. ACh). (**b**) Concentration relationships for activation and desensitization are represented on the same graph. Note that desensitization occurs at lower concentrations when compared with that of activation, indicating that sustained exposure to an agonist will mainly cause receptor desensitization.



Nicotinic Agonists and Antagonists. Fig. 3. Activation and modulation of the nAChRs. (**a**) Schematic representation of the energy barriers between the closed (resting) and the active (open) state. The intermediate state, also referred to as the "flip state," has been recently shown to play an important role for partial agonists. (**b**) Effects of positive (+) or negative (−) allosteric modulators on the concentration activation profiles. Note that positive allosteric modulators cause an enhancement of the evoked response, the agonist potency, and increase in the apparent cooperativity (slope of the curve).

that ligands display a higher affinity for receptors in the desensitized state than in the active state, which is easily seen when plotting activation and desensitization profiles in one graph (Fig. 2b). Since radioligand binding data are acquired during prolonged incubation (>0.5 h) with the ligand to reach equilibrium, agonist binding affinities correlate best with receptor desensitization potencies.

Transition from the resting (closed) to the active (open) state reflects changes in the three-dimensional structure of the receptor. The probability of conversion from the resting to the active state in the absence of a ligand is very low, as shown by the low frequency and brief duration of channel opening. Though the simplest model involves only one transition between the resting and active states, evidence points toward the existence of an intermediate state, thought to be closed and termed as the "flip state" (Fig. 3) (Lape et al. 2008; Mukhtasimova et al. 2009).

The complex receptor structure allows high-affinity binding at sites other than the ligand-binding (► orthosteric) site. Molecules that bind at these so-called ► allosteric sites can either increase (positive ► allosteric modulators) or decrease (negative allosteric modulators) the evoked current and thereby affect nAChR function (Changeux and Edelstein 2005).

nAChR Antagonists and Partial Agonists as Pharmacotherapies

Given the diversity of physiologic roles of specific nAChR subtypes and their relationship with disease states, the

possibility of subtly modulating the function of these receptors with agonists, partial agonists, antagonists, and allosteric modulators has fueled interest in developing selective ligands as potential pharmacotherapeutic agents for a number of CNS disorders (Table 1).

nAChR subtypes are widely distributed throughout the human body and it is beyond the scope of this chapter to give a complete overview of all known nAChRs and locations. However, Fig. 4 shows a schematic representation of the major nAChRs subtypes that are most relevant as CNS targets for therapeutic intervention, as well as peripheral nAChR subtypes that could mediate adverse events.

Addiction

Nicotine Dependence Nicotine dependence (► Nicotine Dependence and Its Treatment) is a chronic, relapsing condition that makes smoking cessation extremely difficult because of pronounced withdrawal symptoms (► Nicotine). The current thinking is that the addictive effects are mediated following the interaction of inhaled nicotine with high-affinity nAChRs, such as α4β2 or α4α6β2 receptors, which results in rapid, pulsatile increases in the mesolimbic ► dopamine release (Benowitz 2009). Pharmacotherapy for nicotine dependence is highly cost effective and improves long-term abstinence, although quit rates for the first two approved treatments, nicotine replacement therapy (NRT) and ► bupropion, are modest, with odds ratios $\leq$2. NRT provides a constant delivery of nicotine to the brain, where it interacts with nAChRs to reduce craving and withdrawal symptoms when quitting. Bupropion (Fig. 5), a dopamine–norepinephrine reuptake inhibitor initially approved as an ► antidepressant, has moderate ► efficacy in nicotine dependence, and it was recently shown that bupropion and especially a hydroxy metabolite (Fig. 5) have weak nAChR antagonist properties.

To improve efficacy, pharmacotherapy should not only provide nicotine-like reinforcement to relieve craving during abstinence, but also attenuate the rewarding effects of nicotine when smoking, by blocking access to the receptor. In 1992, Rose and Levin proposed that this could be achieved via concurrent agonist–antagonist administration by combining the agonist nicotine (as NRT) with a nonselective nAChR antagonist, ► mecamylamine (Fig. 5). This suggested that the use of a partial agonist with specificity for the nicotine high-affinity nAChRs could exert such a dual effect. A partial agonist will exert a mild nicotine effect to relieve craving during abstinence, and prevent nicotine binding when smoking, thereby attenuating nicotine's reinforcing effects (Rollema et al. 2007). This dual action, predicted to improve quit rates, was borne out by the efficacy of a potent and highly selective α4β2 nAChR partial agonist, varenicline (Fig. 5). Since most (partial) agonists are more potent in desensitizing than activating the nAChRs (see section "Pharmacologic properties of neuronal nicotinic acetylcholine receptors"), an antagonist effect will significantly contribute to the clinical activity of a partial agonist. However, at least some degree of receptor activation is required for efficacy, since the nAChR antagonist mecamylamine lacks efficacy in nicotine dependence.

Two natural alkaloids with α4β2 nAChR antagonist and partial agonist properties, lobeline and cytisine (Fig. 5), have been examined as smoking cessation aids. There is no clinical evidence that lobeline has an effect on smoking behavior, whereas the partial agonist cytisine, used as a smoking cessation aid in Eastern Europe, was found to have moderate efficacy. Additionally, abstinence rates achieved by a synthetic α4β2 nAChR partial agonist, dianicline (SSR591813; Fig. 5), were insufficient and its development was halted. The lower efficacy of cytisine and dianicline compared with that of varenicline is likely due to the poor brain penetration of cytisine and the weak binding affinity and functional potency of dianicline at α4β2 nAChRs. Further progress in this area may arise from refining the selectivity of nAChR ligands for subtypes that have recently been shown to play an important role in modulating mesolimbic dopamine release, such as α4α6β2-containing nAChRs.

Alcohol Dependence There is a great need for new alcohol dependence treatments with improved efficacies and side-effect profiles over those currently available (► disulfiram, ► acamprosate, and ► naltrexone). Common mechanisms may be involved in alcohol and nicotine dependence, since ethanol also activates the brain's reward system through nAChRs, most likely α4β2, α3β2, and/or α7 subtypes, but nAChRs have not received much attention as potential therapeutic targets for alcohol dependence. However, the demonstrated efficacy and safety of varenicline for smoking cessation and preliminary data indicating that mecamylamine reduces the stimulant and euphoric effects of ► alcohol, combined with the high comorbidity of nicotine and alcohol dependence, prompted studies on varenicline's potential as a treatment method for alcohol dependence. In preclinical studies carried out in a rodent model of alcohol dependence, varenicline selectively reduces alcohol seeking and consumption, without a rebound increase in intake when treatment ends.

Clinical data support these findings, with varenicline treatment decreasing alcohol self-administration in

Nicotinic Agonists and Antagonists. Table 1. Overview of nAChR ligands in preclinical or clinical development or used as pharmacological tools that are discussed in this chapter.

Compound	Application	Testing stage
Nonselective agonists

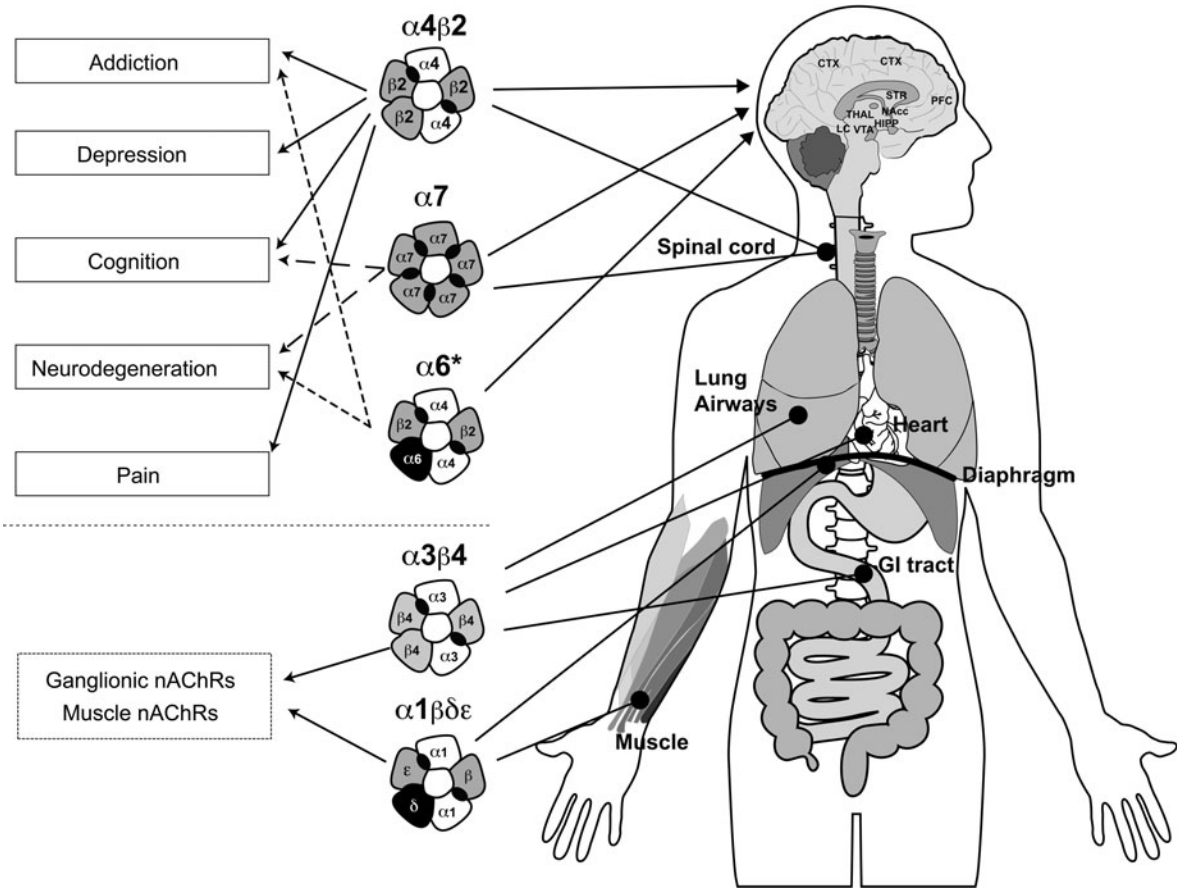
NRT nicotine replacement therapy; *ADHD* attention-deficit/hyperactivity disorder; *AD* Alzheimer's disease

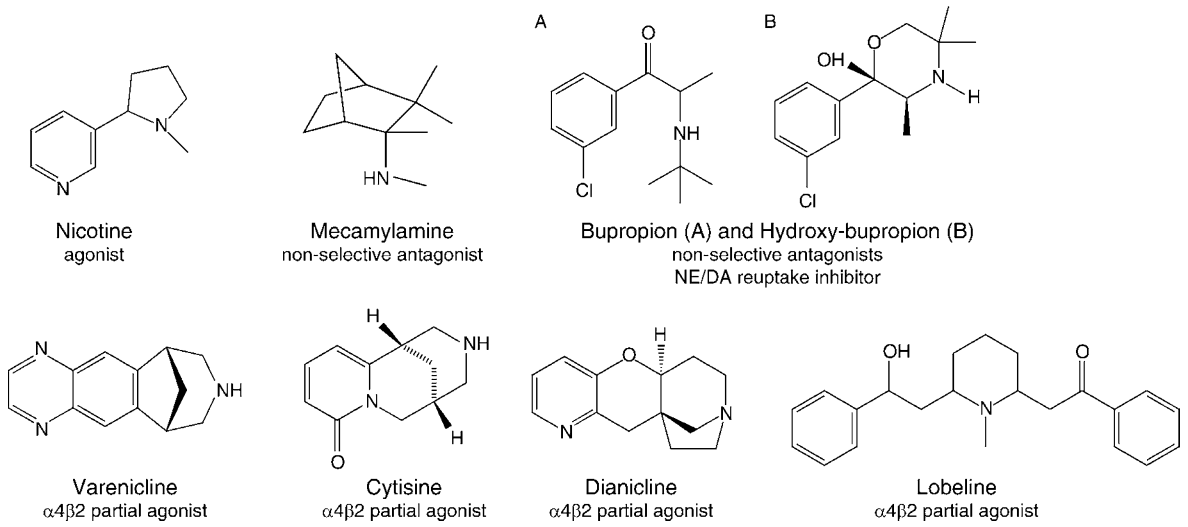


Nicotinic Agonists and Antagonists. Fig. 4. Schematic overview of the predominant central nAChR subtypes that are targets for the treatment of the central nervous system (CNS) disorders discussed in this chapter. Examples of CNS areas that are modulated by nAChRs are cortex (CTX), prefrontal cortex (PFC), hippocampus (HIPP), thalamus (THAL), locus coeruleus (LC), ventral tegmental area (VTA), nucleus accumbens (NAcc), striatum (STR), and spinal cord. Medicinal chemistry efforts targeting CNS disorders attempt to minimize activity at peripheral nAChR subtypes such as α1βδε (muscle) and α3β4 (ganglionic) that control a variety of critical physiological functions. Note that the figure is not inclusive of all nAChR subtypes expressed in the body; additional receptor subtypes not shown could represent therapeutic targets or mediate adverse events.

nonalcohol-dependent, heavy-drinking smokers. Additionally, one week of varenicline pretreatment significantly reduced alcohol consumption, attenuated alcohol craving, and increased the likelihood of remaining completely abstinent during an ad libitum self-administration period. Although these data came from a small study of short duration, they provide support for further clinical trials on the effects of α4β2 nAChR partial agonists on drinking behavior. Given the uncertainty over which nAChR subtypes mediate the effects of alcohol, studies on compounds with different nAChR subtype selectivity might provide clues for the potential of other nAChRs as targets for alcohol dependence treatments.

Depression

The cholinergic–adrenergic theory of ► depression states that overactivation of nAChRs by ACh contributes to the development and exacerbation of depressive symptoms. This hypothesis is supported by the well-established association between depression and nicotine and quitting smoking, the weak nAChR antagonist properties of most antidepressants, and the preclinical antidepressant-like activity of compounds that reduce nAChR activity. Clinical observations that the nonselective nAChR antagonist mecamylamine improves the antidepressant response in treatment-resistant depressed patients further strengthen the idea that reducing nAChR activity results in antidepressant effects (Shytle et al. 2002).



Nicotinic Agonists and Antagonists. Fig. 5. Structures of nicotine and nAChR ligands discussed for nicotine and alcohol dependence.

While nonselective nAChR antagonists block all central nAChR subtypes, selectively reducing the activity of nAChRs thought to contribute to depressive symptoms could result in better antidepressant efficacy and/or improved side-effect profiles. Decreasing α4β2 and/or α7 nAChR signaling can be achieved via receptor blockade using selective antagonists, via receptor desensitization using selective partial agonists, or by the action of negative allosteric modulators. As discussed earlier, partial agonists can potently desensitize nAChRs and could thus have antidepressant activity at low concentrations associated with desensitization (Picciotto et al. 2008).

Results from preclinical studies in animal behavioral models have demonstrated antidepressant-like activity for the antagonists mecamylamine (nonselective), methyllycaconitine (MLA, α7 selective), and dihydro-β-erythroidine (DHβE, α4β2), and the α4β2 selective partial agonists varenicline, cytisine, and ispronicline (TC-1734, AZD-2389) (Fig. 6). In contrast, the full agonists nicotine (Fig. 5), RJR-2403 (α4β2 selective; Fig. 6), and PNU-282987 (α7 selective; Fig. 6), were devoid of antidepressant-like activity.

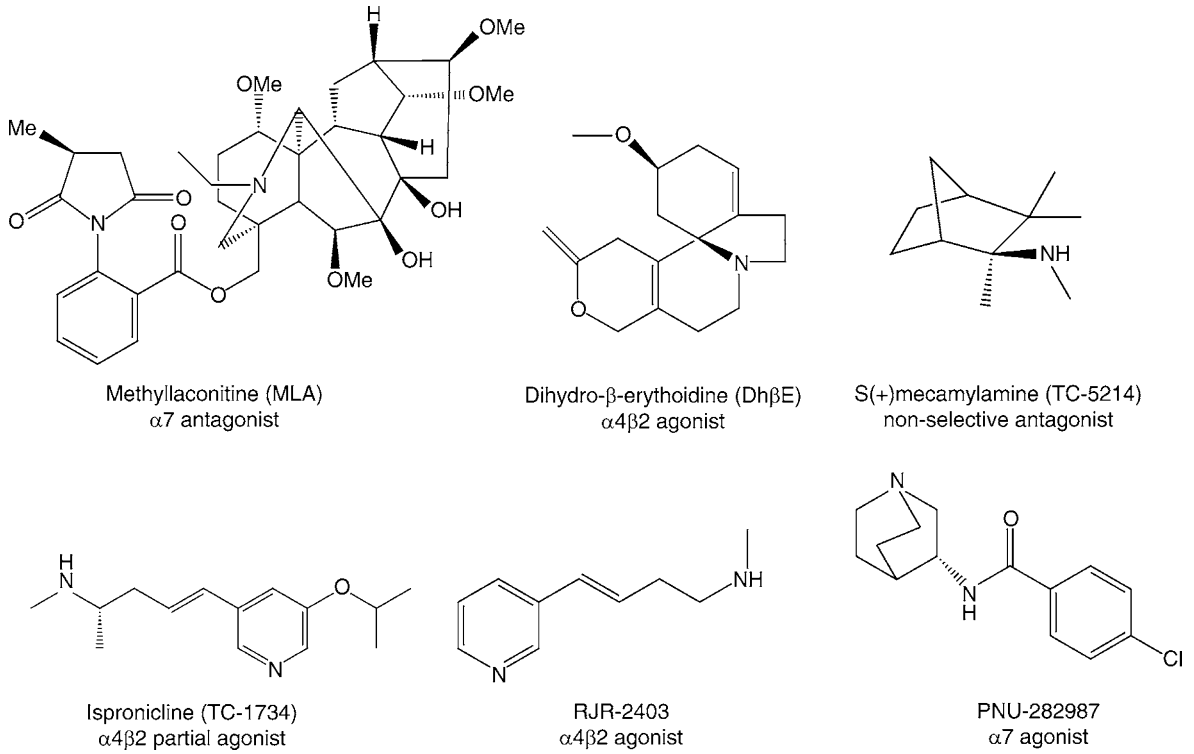
Combined with antidepressants, nAChR antagonists and partial agonists show synergistic effects in animal depression models. Mecamylamine potentiates the activity of both ▶ tricyclic antidepressants and selective serotonin reuptake inhibitors (▶ SSRI), co-administration of nicotine also enhances the effects of antidepressants, consistent with the potent desensitization activity of nicotine. Additionally, co-administration of a low dose of varenicline significantly enhances the effect of the SSRI ▶ sertraline.

The potential of nAChR antagonists and partial agonists as an antidepressant-augmentation strategy is supported by clinical data in treatment-resistant patients with major depressive disorders. Results from a small pilot study suggested that adding mecamylamine to antidepressants significantly decreases depressive symptoms, while a larger study found that co-administration of ▶ citalopram and mecamylamine improves depressed mood and irritability. Further clinical studies are now being conducted with the (+) enantiomer of mecamylamine, TC-5214, which showed robust effects as an augmentation therapy in treatment resistant patients in a large phase 2a study. Finally, in a small open label study, administration of the partial agonist varenicline to smokers on a stable antidepressant regimen significantly improved depression scores over eight weeks starting at week 2 of treatment.

While the available preclinical and clinical data support the notion that selective nAChR ligands may have antidepressant effects via antagonism or desensitization of α4β2 and possibly α7 nAChRs, large blinded studies with selective nAChR ligands are needed to demonstrate the validity of this approach.

Cognitive Deficits

Nicotine improves aspects of attention and memory in both laboratory animals and humans. The high prevalence of smoking in individuals with mental disorders has led to the speculation that nicotine use may be a form



Nicotinic Agonists and Antagonists. Fig. 6. Structures of nAChR ligands discussed for depression.

of self-medication to ameliorate some of the cognitive symptoms (► Cognitive Enhancers, ► Cognitive Enhancers: Novel Approaches) associated with disorders such as schizophrenia and ADHD. Beyond the adverse health effects of tobacco use, nicotine is not well suited as a therapeutic agent owing to its ► pharmacokinetic properties and poor toleration, especially among nonsmokers. Therefore, a number of selective nAChR ligands are being investigated as potential therapies for psychiatric and neurodegenerative disorders (Cincotta et al. 2008; Rusted et al. 2000).

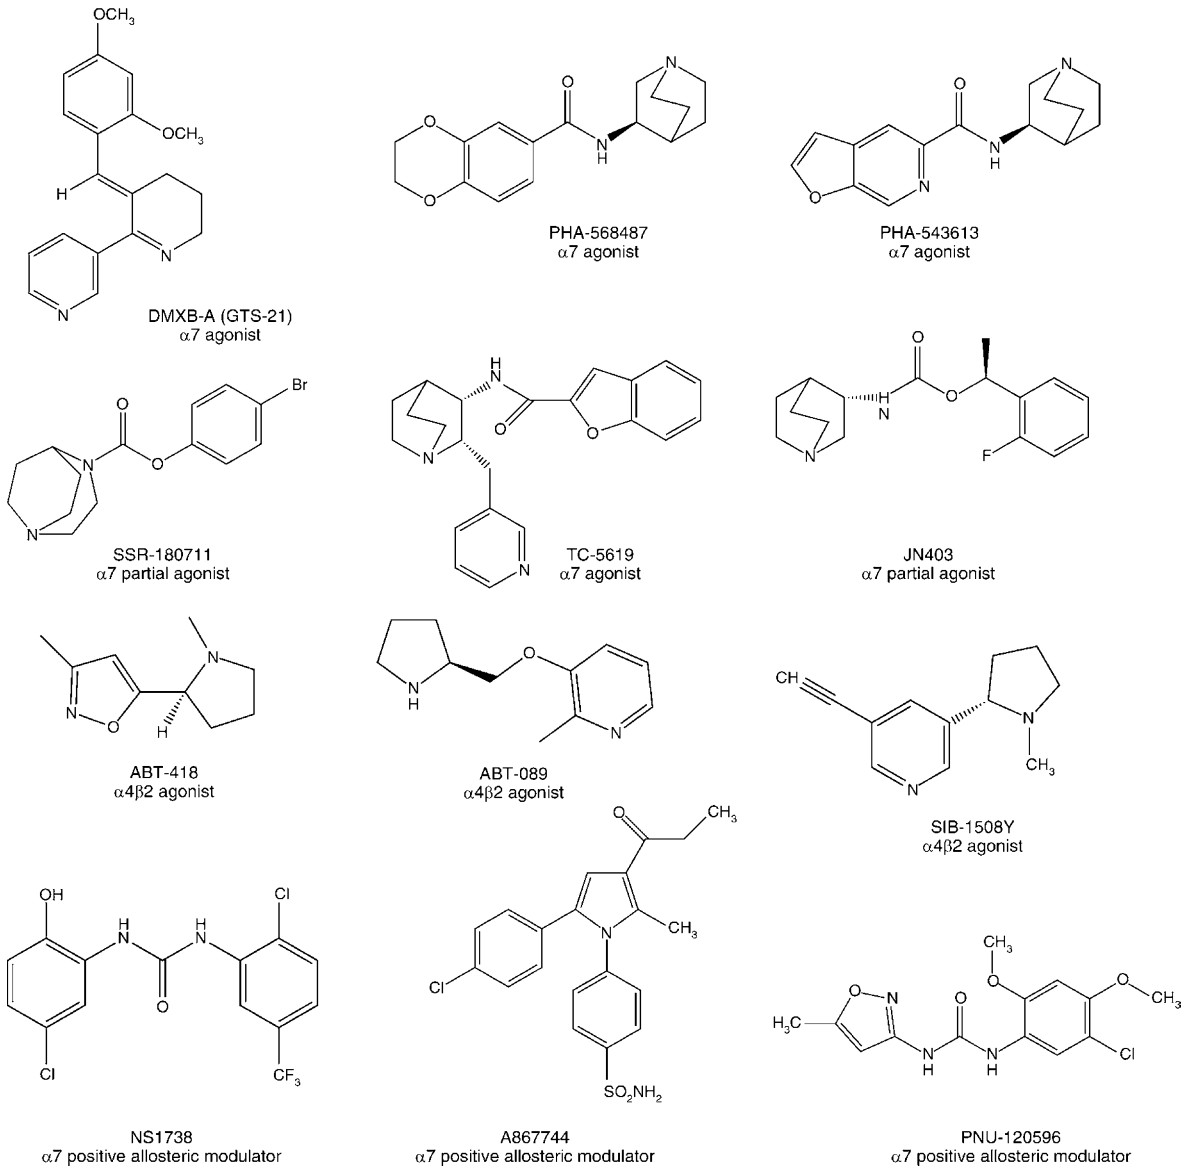
The largest effort has centered on the α4β2 and α7 nAChRs. These subtypes are the most prevalent among brain nAChRs; they influence cognitive function in preclinical models (► Rodent Tests of Cognition) and have been associated with both psychiatric and neurodegenerative disorders. However, recent data suggest that ligands targeting α6* nAChRs may be useful pharmacotherapies for diseases involving dopamine dysfunction.

The following sections address the major psychiatric and neurodegenerative disease areas, where nicotinic ligands have been proposed and/or tested for clinical benefit. It should be noted that the physiologic roles of individual nAChR subtypes is highly complex and far from being comprehensively understood. In addition, disease state and ligand exposure can substantially alter the number and type of nicotinic receptors expressed in various brain regions. Given these complexities, it is likely that ligands targeting an individual nAChR subtype may be beneficial for more than one disease.

Alzheimer's Disease ► Alzheimer's disease (AD) is characterized by the accumulation of neuritic ► plaques, ► neurofibrillary tangles, neuronal loss, and progressive deterioration of memory and cognitive function. Decreased levels of α4β2 nAChRs have been correlated with disease progression. This relationship, coupled with the importance of α4β2 nAChRs in cognitive function, has made this receptor subtype an attractive therapeutic target for AD, and several selective compounds have advanced to clinical trials. As the other major nAChR in the mammalian brain, the α7 receptor has also been the focus of extensive preclinical research. Activation of α7 nAChRs has been linked to cognitive enhancement, and disruption of α7 nAChR gene expression or function impairs cognitive performance and attention. Substantial drug discovery and development efforts with α7 nAChR agonists as potential treatment methods for impaired cognition in neurodegenerative diseases are ongoing.

Ispronicline (TC-1734 or AZD-3480; Fig. 6), an α4β2-selective partial agonist, significantly improved several cognitive measures for ► attention and ► episodic memory after 10 days of treatment in healthy volunteers, and induced ► Electroencephalography patterns associated with increased attention and vigilance. Similarly, ispronicline improves cognitive function in elderly subjects with age-associated memory impairment. Initial reports on the efficacy of ispronicline in patients with AD have been mixed, but improvements in some endpoints, such as the "Mini-Mental State Examination," have been reported.

The selective α4β2 nAChR agonist ABT-418 (Fig. 7) demonstrates positive effects in attention and in a ► delayed matching-to-sample task performance in aged monkeys. Transdermal application in patients with AD results in dose-dependent improved ► verbal learning, ► memory, and reaction time, some of which are qualitatively and quantitatively similar to those seen in acute



Nicotinic Agonists and Antagonists. Fig. 7. Structures of nAChR ligands discussed for cognitive defects (Alzheimer's disease (AD), schizophrenia, and attention-deficit/hyperactivity disorder (ADHD)) and neuroprotection for neurodegenerative diseases (Parkinson's disease (PD)).

trials with ACh-esterase inhibitors. Interestingly, consistent with animal studies, AD patients also show dose-related decreases in anxiety and fear, suggesting that this agent may also have ► anxiolytic effects.

DMXB-A (3-(2,4-dimethoxy)benzylidene-anabaseine, GTS-21; Fig. 7) was the first α7 nAChR agonist to undergo clinical testing for AD. Initial studies in healthy volunteers indicated positive effects on reaction time, correct detection during digit vigilance, word and picture recognition, memory, immediate and delayed word recall, and performance speed in numeric and spatial working memory tasks. However, DMXB-A is a very weak agonist at α7 nAChRs, and potent antagonist at α4β2 nAChRs. These characteristics, combined with suboptimal pharmacokinetic properties, have given rise to the search for new α7 nAChR agonists. Several pharmaceutical companies are advancing α7 nAChR partial and full agonists to clinical trials, e.g., TC-5619, SSR-180711, JN403 (Fig. 7), ABT-107, EVP-6124, AZD-0328, and R3487 (MEM3454; structures not disclosed). On the basis of publicly available information, the α7 nAChR partial agonist R3487 (MEM3454) appears to be currently ahead, with ongoing Phase 2a trials in AD and schizophrenia showing promising results. Significant progress has been made with the design of α7 nAChR allosteric modulators that are active in preclinical models, such as PNU-120596, NS-1738, A867744, (Fig. 7), and other compounds with undisclosed structures, and initial clinical evaluation is anticipated in the near future.

Schizophrenia Interest in specifically targeting α7 nAChRs to treat cognitive deficits in ► Schizophrenia was stimulated by evidence linking this receptor to deficits in auditory gating, a common ► Endophenotype associated with schizophrenia. Auditory gating is a form of sensory filtering whereby the amplitude of an auditory evoked potential is reduced if immediately preceded by a similar auditory tone ("prepulse"). Impairments in this filtering process are thought to lead to excessive sensory input, and result in poor performance in measures of attention. ► Single nucleotide polymorphisms (SNPs) in the gene encoding the α7 nAChR subunit (CHRNA7), and reduced levels of the encoded protein in patients with schizophrenia, further implicates α7 nAChR dysfunction as a contributing factor to this disease.

Although the clinical testing is still in the early phases, initial reports on the efficacy of α7 nAChR agonists for treating cognitive symptoms in schizophrenia are encouraging. For example, the α7 nAChR agonist DMXB-A (Fig. 7; see section "► Alzheimer's disease"), tested in a small ► double-blind study in patients with schizophrenia, normalized auditory gating and improved performance on a Neuropsychological Status (RBANS) scale and an attention subscale, with larger effect sizes than seen for nicotine or atypical antipsychotics in previous studies (Freedman et al. 2008). The effect of several doses of the α7 partial agonist MEM 3454 (also under investigation for cognitive improvement in AD; see section "► Alzheimer's disease") is currently being evaluated in a Phase 2 clinical study for cognitive impairment associated with schizophrenia. However, the development of some α7 nAChR agonists, e.g., PHA-568487 and PHA-543613 (Fig. 7), was halted in Phase 1 owing to safety concerns.

► Attention-deficit Hyperactivity Disorder Stimulant medications were introduced more than 60 years ago to treat the motor overactivity, impulsivity, and inattentiveness associated with ADHD, and remain one of the main treatment options. Though highly effective against these core symptoms, stimulants often do not fully address the cognitive impairments associated with ADHD that are increasingly recognized as key factors in long-term outcomes, including academic and occupational success. Therefore, there is growing interest in developing nonstimulant medications with reduced abuse liability that can also address the cognitive aspects of ADHD. The development of nAChR ligands as potential treatments has been largely driven by the cognition-enhancing properties of nicotine and other nicotinic ligands (Wilens and Decker 2007). As with other cognitive disorders, ADHD patients use tobacco products at a higher rate than the general population, suggesting that nicotine may alleviate symptoms of ADHD. Indeed, when tested in clinical settings, nicotine has consistently demonstrated beneficial effects on disease symptom rating scales as well as on the measures of cognitive function. However, the ► Adverse Effect of nicotine, predominantly gastrointestinal and cardiovascular effects, preclude the broad use of nicotine to treat ADHD.

Three nicotinic compounds with selectivity for α4β2* nAChR subtypes have been evaluated in clinical efficacy and safety studies in ADHD patient populations. ABT-418 (Fig. 7) is a high-affinity ligand that displays full agonist activity at α4β2* nAChRs in vitro and specificity versus α3-containing ganglionic nAChRs. In a three-week study, transdermal ABT-418 was associated with a significantly higher proportion of subjects demonstrating moderately to significantly improved scores on the Clinical Global Impression scales versus placebo. ABT-418 was generally well tolerated with nicotine-like side effects (adverse effects), including dizziness and nausea.

A related nicotine analog ABT-089 (pozanicline; Fig. 7) also has high binding affinity and selectivity for

the α4β2* receptor subtype, but very low efficacy at heterologously expressed α4β2* nAChRs. Interestingly, ABT-089 stimulates [^{3}H]-DA release in brain slices and synaptosomal preparations with full efficacy when compared with nicotine. This difference between heterologous and native nAChR affinities suggests that ABT-089 may interact with additional nAChR subtypes, e.g., receptors containing α4, α6, β2, or β3 subunits (Yang et al. 2009). In a placebo-controlled clinical trial, ABT-089 significantly improved spatial ▶ working memory, attention, hyperactivity, and ▶ impulsivity on an adult ADHD Rating Scale, and was well tolerated with no observed dose-limiting adverse events. Finally, it was recently reported that the selective α4β2 nAChR partial agonist ABT-894 (structure not disclosed) that is also in development for pain, showed positive results in a Phase 2 study in adult ADHD patients with comparable efficacy to ▶ atomoxetine.

Neuroprotection for Neurodegenerative Diseases

Selective nAChR agonists potentially represent a promising novel class of agents to treat neurodegenerative diseases (Rusted et al. 2000). AD is characterized by the presence of plaques containing ▶ amyloid-beta (Aβ) in the brain, which presumably contribute to neurodegeneration. Though there are conflicting reports in the literature, evidence suggests that Aβ can interact directly with α4β2- and α7-containing nAChRs, resulting in a functional blockade of these receptors. However, other reports suggest that some forms of Aβ can actually activate both α7 and non-α7 nAChRs. Although it appears that modulation of α7-containing nAChRs offers protection to neurons against Aβ-induced toxicity, the nature of these interactions and their relevance to AD need to be further investigated.

There is, however, substantial preclinical evidence that nAChR activation is neuroprotective against non-Aβ toxicity induced by a variety of insults in AD. Although multiple nAChR receptor subtypes are likely involved, neuroprotection seems to be mediated mainly via α7 nAChRs. Activation of α7 nAChRs protects in vitro cell and slice preparations against ethanol toxicity and cell death; cultured neurons against glutamate-induced ▶ excitotoxicity; and hippocampal slices against oxygen and glucose deprivation. To date, there are no clinical study reports on the potential neuroprotective effects of selective nAChR ligands in AD.

Compelling epidemiologic evidence exists for an inverse relationship between tobacco use and incidence of ▶ Parkinson's Disease (PD), with smokers of the longest duration and highest daily consumption at the lowest risk of developing the disease. Though many interpretations for this relationship have been made, it seems unlikely to result from genetic factors for either PD or smoking. Indeed, the preponderance of data suggests that a component of tobacco, likely nicotine, offers a biological protection against neurodegeneration of dopaminergic neurons (Quik et al. 2008).

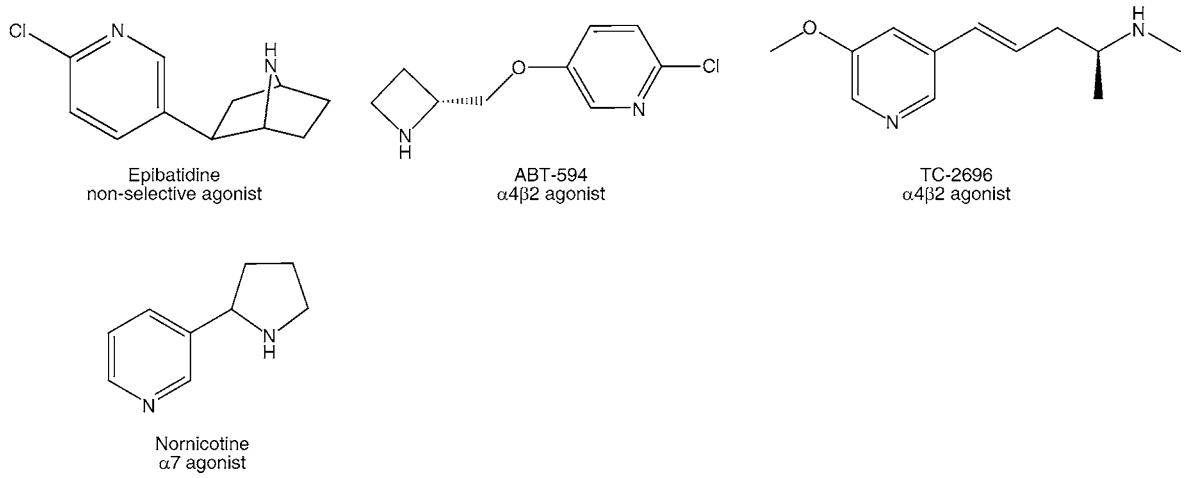
A hallmark feature of PD is loss of nigrostriatal dopamine function. Two nAChR populations are largely responsible for nicotine-evoked dopamine release in striatum: α4β2- and α6*-containing nAChRs. Though both populations appear to regulate dopamine release from the dopaminergic terminals, α6* nAChRs are more sensitive to nigrostriatal damage induced in animal models, generally paralleling other indices of nigrostrial degeneration. Declines in α4β2 nAChRs are also observed with disease progression, but this receptor population appears to be less sensitive than α6* nAChRs. Thus, targeting nAChRs appears to be a promising approach to protect against further nigrostriatal damage and to offer symptomatic relief by enhancing dopamine outflow.

Several small clinical studies have evaluated the effect of nicotine administered via smoking and/or NRT gum on the motor symptoms of PD (▶ Anti-Parkinson Drugs). However, evidence for the improvement of patients' status in these trials was at best modest and, in most cases, absent. Similarly, at least one clinical study has reported that the α4β2 agonist SIB-1508Y (Fig. 7) did not improve PD symptoms.

Although it is tempting to speculate that selective activation of α6* nAChRs may provide a greater opportunity for symptomatic relief, it is unclear if the progressive loss of the dopaminergic neurons that express this nAChR subtype would limit the therapeutic benefit for PD, especially in the later stages of the disease.

Pain

Preclinical pharmacologic studies have established that nicotine and several natural nicotinic compounds have analgesic effects that are attenuated by mecamylamine pretreatment. One example is the frog alkaloid epibatidine (Fig. 8), which has received much attention as an extremely potent analgesic that binds with high affinity to several nAChR subtypes (Arneric et al. 2007). Involvement of α4β2-containing nAChRs in nociception is suggested by their presence in regions that modulate pain perception, and increased inhibitory GABAergic tone in the spinal cord (an analgesic mechanism) following α4β2 activation. Other nAChR subtypes may also be involved in the pain response, but have not yet been investigated in the same detail. In this respect, it is interesting to know that the nicotine metabolite nornicotine (Fig. 8), which is



Nicotinic Agonists and Antagonists. Fig. 8. Structures of nAChR ligands discussed for pain.

reported to have analgesic activity, has an affinity for α7 nAChRs.

Since neither nicotine nor epibatidine can be used clinically owing to safety concerns at analgesic doses, synthetic nAChR agonists are being pursued as analgesics and most research has focused on selective α4β2 agonists. The α4β2 nAChR agonist ABT-594 (Fig. 8) is structurally related to epibatidine with similar analgesic potency, but its development was not pursued owing to limited tolerability. Similarly, the development of two other selective α4β2 nAChR agonists, TC-2696 (Fig. 8) and TC-6499 (structure not disclosed), which had shown analgesic efficacy in preclinical pain models, was halted because of lack of efficacy and an insufficient therapeutic index. More promising is a second-generation α4β2 full agonist, ABT-894 (structure not disclosed), which is currently under development for neuropathic pain.

While the clinical evidence for analgesic efficacy of selective α4β2 nAChR ligands is still limited, the possibility remains that the activity at other nAChR subtypes contributes to analgesic efficacy.

Conclusion

Our increased understanding of nAChR pharmacology and how agonists, partial agonists, and antagonists modulate the function of these receptors has led to the discovery of a large number of selective ligands that are being used either as tools for exploring the role(s) of nAChR subtypes or are in the preclinical or clinical stage of development as potential new pharmacotherapies. Several compounds represent promising new treatments for disorders in which nAChRs are thought to participate. However, the fact that to date very few nAChR ligands have been approved for clinical use illustrates the tremendous challenge of developing selective nicotinic compounds as novel medications without major side effects. The high degree of homology between the different receptor subtypes calls for a better knowledge of their function and distribution throughout the body and for the finding of subtype-selective compounds. In addition, high selectivity is essential for an acceptable side-effect profile to avoid interactions with peripheral muscle and ganglionic nAChR subtypes associated with cardiovascular, gastrointestinal, and respiratory adverse events. Clearly, progress in the development of novel drugs that target nAChR subtypes is dependent on the design and discovery of highly selective ligands with sufficient potency and adequate pharmacokinetic properties to have efficacy at doses at which selectivity is maintained.

Nicotinic Receptor

Synonyms

nAChR

Definition

A subtype of acetylcholine receptors that respond to the alkaloid nicotine. They consist of ligand-gated ion channels. The two main groups are the muscle-type nicotinic receptors that are located in smooth and skeletal muscle cell membranes and the neuronal nicotinic receptors located in the plasma membranes on neurons of the CNS.

Nimetazepam

Definition

Nimetazepam is a benzodiazepine that has anxiolytic, sedative, and anticonvulsant properties. It has a moderately long duration of action due to an elimination half-life of 14–30 h and conversion to the active benzodiazepine metabolite ► nitrazepam. Like most

similar compounds, nimetazepam is subject to tolerance, dependence, and abuse.

Cross-References
► Anxiolytics
► Benzodiazepines

Nitrazepam

Synonyms
1,3-Dihydro-7-nitro-5-phenyl-2H-1,4-benzodiazepin-2-one; Mogadon

Definition
Nitrazepam is an ► anxiolytic drug of the benzodiazepine class. It is a nitrobenzodiazepine and like other benzodiazepines, in addition to its anxiolytic properties, it is a hypnotic drug with sedative, amnestic, anticonvulsant, and muscle-relaxant effects. It is long-acting, lipophilic, and is metabolized in the liver by oxidation. It acts as a full agonist at benzodiazepine receptors in the brain, enhancing binding of ligands for $GABA_A$ receptors. It has ► abuse potential and is associated with a typical benzodiazepine ► withdrawal syndrome.

Nitrites

Synonyms
Volatile nitrites

Definition
Nitrites are volatile compounds that are subject to abuse by inhalation. The first of these to see widespread use was amyl nitrite, an antianginal medication sold in ampules. The ampules were "popped" open and the contents inhaled, hence they were often referred to by illicit users as "poppers." Because they were available without a prescription in many areas in drug stores, supplies were easy to obtain. In many areas, restrictions were placed on amyl nitrite ampule sales that limited their availability. Almost immediately, commercial products containing other volatile nitrites such as butyl nitrite and cylohexyl nitrite were sold in sexual paraphernalia and video stores as room "odorizers." Nitrite vapors have a distinct smell not unlike the odor of one of the first products of this type named *Locker Room*. Other commercial nitrites adopted names associated with their use in sexual activity, such as Thrust, Ram, and Hardware. "Odorizers" and "aromas" are still widely available on the Internet and claim to contain nitrites, but their actual contents are not clear.

► Inhalant Abuse

Nitrous Oxide

Definition
Nitrous oxide is a widely abused inhalant than is used in medicine and dentistry for anesthesia. It is a gas at room temperatures and is sold under compression in cylinders. Soon after the discovery of nitrous oxide, its euphorigenic effects were noted and it became known as "laughing gas" and was used in minstrel shows where local dignitaries would agree to become intoxicated and behave abnormally for the delight of the audience. Another source of nitrous oxide is as a propellant in certain aerosols such as those for whipping crème. Nitrous oxide canisters for whipped crème dispersers became known as whippets and are subject to abuse. Nitrous oxide is usually directly inhaled from balloons or plastic bags that have been filled with the gas. The effects are almost instantaneous with the result that users can fall over and harm themselves or others.

NMDA Receptors

Synonyms
N-Methyl-D-aspartate receptor

Definition
NMDA (N-methyl-D-aspartate) receptors are a class of receptors for the excitatory neurotransmitter ► glutamate. They are composed of four subunit proteins (two NR1 plus two NR2 subunits) that assemble together to generate a channel permeable to sodium, potassium, and calcium ions. The receptors are important for normal cognitive function and targets of some neuroactive steroids.

Nociception

Definition
The neural process of signaling tissue damage or chemical irritation that is perceived as pain or itch. Nociceptors (receptors responding to noxious stimuli) initiate the process by responding to mechanical, thermal, or chemical stimuli. Nociceptors then send afferent impulses to the spinal cord and brain, leading to the perception of pain.

Non-Benzodiazepine Agonists

Jaime M. Monti[1], Daniel Monti[2]
[1]Department of Pharmacology and Therapeutics, School of Medicine, Clinics Hospital, Montevideo, Uruguay
[2]Department of Pharmacology and Therapeutics, School of Medicine, Pittsburgh, PA, USA

Synonyms
Z-drugs

Definition
The non-benzodiazepine hypnotics that work by selectively affecting γ-aminobutyric acid-A ($GABA_A$) receptors include a structurally dissimilar group of

substances, such as the cyclopyrrolone agents zopiclone and eszopiclone, the imidazopyridine derivative zolpidem, and the pyrazolopyrimidine compounds zaleplon and indiplon (Monti 2004).

Pharmacological Properties

Zolpidem was synthesized by Synthélabo Recherche in the early 1980s, and its therapeutic potential for the treatment of sleep disorders was recognized soon after.

Preclinical studies have shown ▶ zolpidem to exhibit sedative, anticonvulsant, and myorelaxant activities. However, zolpidem is more potent in suppressing locomotor activity (sedative effect) than pentylenetetrazol convulsions (anticonvulsant activity), and rotarod performance (muscle relaxation) in rats. In contrast to zolpidem, the ▶ benzodiazepine hypnotics produce a sedative effect with doses that are similar or greater than those producing anticonvulsant or myorelaxant effects.

In relation to the effects of zolpidem on sleep, a spectral analysis of sleep ▶ electroencephalograms in curarized rats has revealed that its power density in nonrapid eye-movement (NREM) sleep (▶ NREM sleep) is predominantly increased in the low frequency band (1.0–4.0 Hz). Moreover, in freely moving animals, zolpidem has been found to augment the duration of NREM sleep and to reduce ▶ wakefulness. The effect endured during subchronic administration with no rebound occurring after abrupt withdrawal. On the other hand, variable results have been reported in regard to rapid-eye-movement (REM) sleep (▶ REM sleep). In this respect, an increase and a reduction of REM sleep has been described in rats recorded during the light period (Monti et al. 2008).

Zopiclone was synthesized by Rhône-Poulenc Recherches in the early 1970s. Eszopiclone, the dextrorotatory enantiomer of racemic zopiclone, has a single chiral center with an S(+)-configuration.

Preclinical studies have shown ▶ zopiclone to exhibit sedative–hypnotic, anticonvulsant, myorelaxant, antiaggressive, and anticonflict activities. With regard to the sedative–hypnotic activity, zopiclone decreases locomotor activity, reduces waking, and increases slow wave sleep in the rat. Spectral analysis of the electrocorticogram after zopiclone administration has shown an increase of power density in the 2.0–4.0 Hz (delta), and the 12.0–16.0 Hz (beta) bands in the rat. Eszopiclone shares the sedative–hypnotic properties of zopiclone, whereas the (R)-enantiomer has no hypnotic activity (Carlson et al. 2001; Monti and Pandi-Perumal 2007).

▶ Zaleplon was synthesized by American Cyanamid Laboratories in the 1980s, and has been evaluated for its potential sedative, muscle relaxing, and anticonvulsant activity in mice and rats. Zaleplon has been shown to reduce locomotor activity and to produce motor deficits in the rotarod and grid tests. In addition, the pyrazolopyrimidine derivative blocked electroshock-, pentylenetetrazole-, and isoniazid-induced convulsions. In a ▶ drug discrimination procedure using rats trained to discriminate the benzodiazepine agonist ▶ chlordiazepoxide, zaleplon produced partial substitution for chlordiazepoxide at doses that significantly reduced response rates.

Both sedative and discriminative stimulus effects of zaleplon were antagonized by the benzodiazepine antagonist ▶ flumazenil (Sanger et al. 1996).

Zaleplon increased slow wave sleep and the relative electroencephalographic power density in the delta frequency band of rats prepared for chronic sleep recordings. REM sleep values showed no significant changes.

Indiplon originated in the 1980s at American Cyanamid's Laboratories. Indiplon inhibits locomotor activity, rotarod latency, and vigilance measures in the rat over a dose range consistent with its sedative activity. Indiplon is active in the Vogel test of anxiety in rat and, in addition, produces deficits in the passive avoidance and the ▶ delayed nonmatch to sample paradigms in rodents, both currently used as measures of learning and memory (Foster et al. 2004).

Mechanism of Action

▶ GABA is the most important inhibitory neurotransmitter in the mammalian brain and localizes to approximately 30% of central nervous system synapses.

The ▶ $GABA_A$ receptor is the site of action of cyclopyrrolone, imidazopyridine, and pyrazolopyrimidine derivatives. These different classes of ▶ hypnotic drugs modulate GABAergic function through different GABA receptor subtypes, defined by the subunits that participate in the receptor assembly. Most $GABA_A$ receptors consist of α, β, and γ subunits which contain multiple isoforms or variants: α_1–α_6, β_1–β_3, and γ_1–γ_3. Zolpidem, zaleplon, and indiplon preferentially bind α_1-containing subtypes (Ator and McCann 2005). Similar to the benzodiazepine hypnotics, zopiclone and eszopiclone bind at all $GABA_A$ subtypes. Notwithstanding this, the cyclopyrrolones might have more selectivity for certain subunits of the $GABA_A$ receptor (Sanger 2004).

$GABA_A$ receptors have been analyzed by gene knockout strategies. The sedative/hypnotic activity of benzodiazepines (including flunitrazepam and diazepam) has been shown to be dependent on the integrity of the α_1 subunit. On the other hand, the anxiolytic, anticonvulsant, myorelaxant, ataxic, and withdrawal effects depend upon their predominant affinity for the α_2- and α_3-containing

receptors. The finding that zolpidem, zaleplon, and indiplon have more selectivity for the α_1 subtype could tentatively explain the difference in effects on sleep architecture and the lower incidence of adverse events such as rebound insomnia, tolerance, dependence, and abuse.

Pharmacokinetics

The ► pharmacokinetics of zolpidem has been investigated in healthy adults and in elderly patients. Zolpidem is rapidly absorbed and extensively distributed to body tissues, including the brain. It has a bioavailability of approximately 70%, and is extensively bound to plasma protein. Peak plasma concentrations are attained 30–60 min after a single therapeutic dose of 10 mg, and the terminal-phase elimination half-life amounts to 2.6 h in healthy adults. Zolpidem is metabolized in the liver by a number of ► cytochrome P450 isoenzymes, but predominantly CYP 3A4, to inactive metabolites. The major routes of metabolism are oxidation and hydroxylation. After oral administration, zolpidem metabolites are largely excreted in the urine.

The metabolic clearance of zolpidem is reduced in elderly patients, resulting in increases in maximum plasma concentration, area under the concentration curve, and terminal-phase elimination half-life, the latter amounting to 2.9 h (Monti and Monti 2006).

Administration of zopiclone 7.5 mg orally at night is rapidly absorbed. It has a bioavailability of 75% and a time of occurrence of maximum plasma concentration of 1.6 h. The compound undergoes oxidation to the *N*-oxide metabolite, which is pharmacologically less active, and demethylation to the inactive *N*-demethyl-zopiclone. The ► elimination half-life for zopiclone and its *N*-oxide metabolite ranges from 3.5 to 6.0 h (Monti and Monti 2006).

Eszopiclone is rapidly absorbed and extensively distributed to body tissues. It is weakly bound to plasma protein. Peak plasma concentrations are attained 1.0–1.6 h after a single therapeutic dose of 3 mg, and the terminal elimination half-life amounts to 6.0 h. Eszopiclone is also extensively transformed in the liver to the *N*-oxide (less active) and the *N*-desmethyl (inactive) derivative. After oral administration, eszopiclone is predominantly excreted in the urine, primarily as metabolites. Less than 10% of the compound is excreted in the urine as parent drug.

The metabolic clearance of zopiclone and eszopiclone is reduced in elderly patients, resulting in increases in maximum plasma concentration and terminal elimination half-life. The latter is approximately 9.0 h in elderly patients who are being treated with eszopiclone (Monti and Pandi-Perumal 2007).

Zaleplon is rapidly and almost completely absorbed following oral administration of a 10 mg dose. The compound undergoes significant first-pass hepatic metabolism after absorption. As a result, its bioavailability amounts to only 30%. It attains maximum plasma concentration in approximately 1 h and has a terminal elimination half-life of 1.0 h. Zaleplon is primarily metabolized by aldehyde oxidase, and all of its metabolites are pharmacologically inactive (Hurst and Noble 1999).

Indiplon is rapidly absorbed following oral administration of a 15 mg dose. The derivative reaches a maximum plasma concentration at <1 h and has a terminal elimination half-like of 1.5 h. Indiplon undergoes demethylation and deacetylation to the inactive *N*--desmethylindiplon and *N*-deacetylindiplon metabolites (Madan et al. 2007).

Clinical Uses

Various populations have been included in the studies that assessed the efficacy and safety of the non-benzodiazepine hypnotics: subjects with transient ► insomnia, non-elderly and elderly patients with chronic primary insomnia, and patients with secondary or ► comorbid insomnia.

Zolpidem has been shown to be effective in improving sleep induction (reduction of sleep latency) at the recommended dose of 10 and 5 mg in non-elderly and elderly patients, respectively. In addition, subjective assessments and ► polysomnographic measures have shown that zolpidem improves sleep maintenance (reduction of wake time after sleep onset and the number of awakenings, and increase of total sleep time). However, the improvement of sleep maintenance was restricted in several studies to the first part of the night. This has led to the development of a modified-release formulation that provides extended plasma concentrations beyond four hours after administration. The available evidence tends to indicate that modified-release zolpidem is effective for the treatment of chronic primary insomnia characterized by difficulties with sleep onset and sleep maintenance at the recommended dose of 12.5 and 6.25 mg in adult and elderly patients, respectively Monti and Monti (2006).

Zopiclone has been studied in adult insomniac patients in clinical trials and sleep laboratory studies using objective measurements of sleep variables. In all these studies zopiclone 7.5 mg reduced the time to onset of sleep, the number of nocturnal awakenings, and increased total sleep time. The hypnotic drug also improved the quality of sleep. In controlled studies, elderly insomniac patients slept significantly better during treatment with zopiclone 3.75–7.5 mg than with placebo.

The subjective perception of improved sleep following eszopiclone 2 or 3 mg treatment has been demonstrated in

studies of up to 6 months' duration. In these studies, the drug significantly reduced sleep onset latency, the number of awakenings, and wake time after sleep onset, whereas total sleep time and quality of sleep were increased in non-elderly and elderly patients. Sleep laboratory studies of the effects of eszopiclone have confirmed the drug's clinical efficacy in subjects with chronic primary insomnia. Eszopiclone, unlike benzodiazepine hypnotics, does not significantly alter values corresponding to slow wave sleep and REM sleep (Monti and Pandi- Perumal 2007).

Zaleplon 10 mg was superior to placebo in decreasing latency to persistent sleep in normal adults experiencing transient insomnia.

Zaleplon 10–20 mg and 5–10 mg significantly reduced time to sleep onset in adult and elderly outpatients with chronic insomnia, respectively. Generally, a significant difference from placebo on total sleep duration was not demonstrated.

The efficacy of immediate-release indiplon (10 or 20 mg) was determined in adult patients with chronic primary insomnia. Compared with placebo, indiplon significantly reduced the latency to persistent sleep. Similar findings were obtained after administration of immediate-release indiplon (5 or 10 mg) to elderly patients with chronic primary insomnia. Modified-release indiplon administered to adult (20 and 40 mg) and elderly (15 mg) patients with chronic primary insomnia reduced sleep-onset latency, the number of awakenings and wake time after sleep onset, and increased total sleep time (Neubauer 2005).

Nonorganic Insomnia

Synonyms

ICD-10

Definition

Nonorganic insomnia (ICD-10) is a condition of unsatisfactory quantity and/or quality of sleep, which persists for a considerable period of time, including difficulty falling asleep, difficulty staying asleep, or early final wakening.

Cross-References

- ► Insomnia
- ► Sleep

Non-Rapid Eye Movement Sleep

Synonyms

NREM sleep

Definition

NREM sleep is characterized by EEG brain waves that are slow with high voltage. Blood pressure is low, breathing and heart rate are regular and slow. NREM sleep is

subdivided into stages of increasing depth of sleep leading to REM sleep (NREM 1, 2, and 3/4). About 80% of sleep is NREM sleep. In the rat, it is identified by the presence of high-voltage slow cortical waves interrupted by low-voltage fast electroencephalographic activity, whereas slow-wave sleep distinguishes as continuous high-amplitude slow frontal and occipital waves combined with a reduced electromyogram.

Norepinephrine

Synonyms
Noradrenaline

Definition
Norepinephrine is a ► catecholamine neurotransmitter that is synthesized from tyrosine via dopamine. In the brain, it arises almost exclusively from a single circumscribed region in the brain stem, referred to as the *locus coeruleus*. It is involved in arousal and sleep, emotion-related processes, the processing of sensory and spatial information, and other higher cognitive functions dependent on the ► prefrontal cortex. Outside the brain, norepinephrine is produced in postganglionic sympathetic neurons, and is released into the blood from the adrenal glands and contributed to the "fight-or-flight reaction"; its main physiologic actions include constriction of small blood vessels (leading to increased blood pressure),

increased heart rate, relaxation of smooth muscle, and release of glucose from energy stores.

Cross-References
► Beta-Adrenoceptor Antagonists

Norepinephrine Transporter

Synonyms
NET

Definition
This is the plasma membrane-bound protein that is responsible for removing norepinephrine from the synaptic cleft, transporting it back into the noradrenergic neurons from which it originated, thereby terminating its signaling activity on postsynaptic neurons. This is a target for classes of medications (including ► psychostimulants) used in the treatment of depression and attention-deficit/hyperactivity disorder.

Nortriptyline

Definition
Nortriptyline is a ► tricyclic antidepressant with a tertiary amine chemical structure. One of the earlier tricyclics to be developed, it acts by inhibiting the reuptake of norepinephrine. It is a metabolite of amitriptyline. While its primary use is in the treatment of depression, it is also used in lower doses to treat migraine headache and as an aid for smoking cessation, for which it is considered as a second-line treatment. Side effects are typical for tricyclic antidepressants and include sedation, cardiovascular, and anticholinergic effects.

Novel Object Recognition

Synonyms
Novelty preference test

Definition
A recognition test that is often used for psychopharmacological studies in rodents. In a typical test, animals are first allowed to explore two objects within an environment for a specified period of time. After a delay, a second session is carried out in which one of the original objects has been replaced by a new one. During the second session, the animals are reintroduced into the environment and allowed to explore the objects that are present. Animals that spend more time exploring the novel object, relative to the old object, are said to recognize the old one.

Number Needed to Treat

Synonyms
NNT

Definition
The number of patients that need to be treated in order for one to obtain a benefit that is attributable to active treatment and not placebo. It is a measure used in evidence-based medicine and epidemiology measure to assess the efficacy of interventions. The lower the number needed to treat, the more effective the intervention. Maximum efficacy is achieved when NNT = 1.

Cross-References
► Randomized Controlled Trials

Numbers-Needed-to-Harm

Synonyms
NNH

Definition
Number-needed-to-harm (NNH) is a clinically useful measure for the difference between treatment groups regarding a negative outcome, such as all-cause discontinuation, relapse, or number of patients with significant weight gain. It denotes the number of patients that need to be exposed to a treatment until one additional negative event of interest occurs in excess of the rate in the comparator group. The NNH is calculated by subtracting the percent rate of the comparator group from the percent rate of the active treatment group and dividing the difference by 1. An NNH of below 10 is generally considered clinically meaningful.

Obsessions

Synonyms

Obsessive ruminations; Repetitive thoughts

Definition

Obsessions are persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate and that cause marked anxiety or distress. They are not simply excessive worries about real-life problems. The person usually attempts to ignore or suppress them with some other thought or action. The person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind. At some point during the course of the disorder, the person has recognized that the obsessions are excessive or unreasonable (**Note:** this does not necessarily apply to children (► Obsessive–Compulsive Anxiety Disorder in Childhood). The obsessions cause marked distress, are time consuming (>1 h/day), or significantly interfere with the person's normal routine, occupational or academic functioning, or usual social activities or relationships.

Definition

► Obsessive-compulsive disorder (OCD) is a common, debilitating illness that was considered untreatable until the 1960s. Since then, a relatively narrow range of pharmacotherapies has been found to be effective: clomipramine in the 1960s, selective serotonin re-uptake inhibitors SSRIs (► SSRIs and related compounds) in the 1980s, and adjunctive ► antipsychotic drugs in the 1990s (Fineberg and Gale 2005). The current standard of care is to offer either ► cognitive behavior therapy (CBT) or medication first line (NICE 2006). The form of CBT that has been most effective in OCD is *exposure and response prevention* (Drummond and Fineberg 2007). Whereas recognizing the importance of all aspects of management, we focus here on pharmacological approaches to treatment.

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

Role of Pharmacotherapy

OCD and the Serotonin Hypothesis

Reports that ▶ clomipramine, the 3-chloro analog of the tricyclic imipramine, but not other ▶ tricyclic antidepressants (including desipramine, ▶ imipramine, ▶ nortriptyline, and ▶ amitriptyline), relieved obsessive-compulsive symptoms directed early OCD pharmacotherapy research. Clomipramine differs from other tricyclic antidepressants by its marked potency for blocking ▶ serotonin reuptake, generating a hypothesis that serotonin might be involved in OCD pathophysiology. Although clomipramine is a powerful serotonin reuptake inhibitor (SRI), its active metabolite has noradrenergic properties. However, additional studies favorably compared the more serotonin-selective SSRIs (▶ SSRI and related compounds) with the noradrenergic tricyclic desipramine as well as ▶ monoamine oxidase inhibitors (MAOIs) such as ▶ phenelzine. Despite this apparently selective pharmacological response, we understand little about the role of serotonin in the etiology of OCD or the mechanisms by which SSRIs (SSRI and related compounds) exert anti-obsessional effects (Fineberg and Craig 2008). Indeed, although SRIs are usually essential for OCD pharmacotherapy, because clinical response is not always satisfactory, we devote the latter portion of this essay to pharmacological approaches to SRI nonresponders.

Evaluating ▶ Treatment Response and ▶ Remission (Fineberg et al. 2007) in OCD

The pivotal rating instruments for measuring OCD severity and treatment response or remission in OCD include the ▶ Yale-Brown Obsessive-Compulsive Scale (Goodman et al. 1989) (Y-BOCS) and the ▶ Clinical Global Impression Scales (CGI) (Guy and editor. ECDEU Assessment Manual for Psychopharmacology 1976). Treatment response and remission rates in acute-phase OCD trials (lasting around 12 weeks) of SSRIs (SSRI and related compounds) rarely exceeded 60% and 45%, respectively, emphasizing the incomplete effect of these treatments over the short term in OCD.

Clomipramine in Acute Phase Treatment Trials

Several positive ▶ double-blind placebo-controlled trials conclusively established clomipramine as an effective treatment for OCD. Efficacy was demonstrated using as few as 14 patients, emphasizing the potency of the effect. The introduction of large-scale multi-center controlled studies enabled drug interventions to be assessed in reasonably heterogeneous groups of patients with OCD (Fineberg and Gale 2005). Two such trials, involving 238 and 263 subjects, specifically excluded comorbid depression to prevent it from confounding the outcome. Significant advantages for the clomipramine ($\leq$300 mg) group emerged by the first or second week and benefits accrued up to the 10 week endpoint. Under clomipramine, Y-BOCS scores decreased by roughly 40% (compared with 5% under placebo) and correlated with similar improvements in social and emotional well-being. It is important to investigate OCD *with* comorbid depression as up to 2 out of 3 individuals with OCD are depressed when they seek treatment. Depression in OCD is profoundly impairing (Heyman et al. 2006). Of the few studies that looked at this comorbidity, most used clomipramine, which was found to significantly reduce obsessional symptoms, though the effect on depression was often not reported.

SSRIs in Acute Phase Treatment Trials

▶ Fluvoxamine (including slow-release formulation), ▶ fluoxetine, ▶ sertraline, ▶ paroxetine, ▶ citalopram, and ▶ escitalopram have demonstrated efficacy against placebo in large-scale studies. Small-scale SSRI (SSRI and related compounds) studies, including only around 20 patients, were also positive, again suggesting a potential effect. Fluvoxamine was effective both in the presence and absence of depression. Moreover, in depressed cases of OCD, superiority for fluvoxamine over desipramine was reported for both Y-BOCS and Hamilton Depression Scale scores, highlighting the importance of treating co-morbid OCD with an SSRI (SSRI and related compounds). ▶ Venlafaxine, despite acting as an SRI at lower-dose levels, has not been found effective versus placebo.

SRIs in OCD – Which Dose?

Clomipramine has not been subjected to multiple-dose comparator trials, though fixed doses as low as 75 mg were found to be effective. Higher doses are associated with greater frequency of unwanted effects (described here). Two multicenter trials found that clomipramine dosed up to 300 mg was clinically effective. In the UK, the maximal SPC dose is 250 mg. ECG and plasma level monitoring is recommended if doses above this level are prescribed. Combined plasma levels of clomipramine plus desmethylclomipramine 12 h after the dose should be kept below 500 ng/mL to minimize the risk of seizures and cardiac conduction delay.

Apart from fluvoxamine, the SSRIs (SSRI and related compounds) have been subjected to placebo-controlled fixed-dose analysis in OCD trials. Fluoxetine – 60 mg, paroxetine – 60 mg, and escitalopram – 20 mg appeared the most effective when compared with the lower fixed doses of active drug in acute-phase studies, but the

superiority for 60 mg citalopram appeared only on secondary analyses, at the same time the sertraline study was unable to distinguish a dose–response relationship, possibly owing to design problems related to that study. An extended placebo-controlled study of escitalopram demonstrated enduring superiority for the 20 mg over the 10 mg dose lasting for 16 weeks. In a 12-month fixed-dose placebo-controlled fluoxetine trial in SSRI-responders, only the 60 mg dose protected against relapse. Thus, higher SRI doses appear the most effective for OCD. Though fast upward titration may produce earlier responses, long-term benefits of this approach are not established and may lead to a greater burden of side effects. Expert consensus currently favors moderated doses in the first instance, with upward titrations to maximum should symptoms persist (NICE 2006). Table 1 illustrates target doses recommended by the American Psychiatric Association for OCD.

Patients should be advised at the outset of treatment that the response to SSRI (SSRI and related compounds) or clomipramine is slow and gradual and the anti-obsessional effect takes several weeks to develop. A trial of at least 12 weeks at the maximum tolerated dose with careful assessment is advisable before judging its effectiveness.

Adverse Effects: SSRIs Versus Clomipramine

SSRIs (SSRI and related compounds) appear safe and well tolerated to the maximal SPC dose limits, according to the placebo-referenced OCD trials, which reported adverse-event-related withdrawal rates of around 5–15%. SSRIs (SSRI and related compounds) may be associated with initially increased nausea, nervousness, insomnia, somnolence, dizziness, and diarrhea. Sexual dysfunction, including reduced libido and delayed orgasm, affects up to 30% individuals. Three controlled studies compared the clinical effectiveness of different SSRIs (SSRI and related compounds), and the results were not strong enough to support the superior efficacy of any compound.

► Pharmacokinetic variation may be relevant for deciding which SSRI (SSRI and related compounds) needs to be prescribed. Fluoxetine, paroxetine, and to a lesser extent sertraline inhibit the P450 isoenzyme CYP 2D6, which metabolizes tricyclic antidepressants, antipsychotics, anti-arrythmics, and beta-blockers. Fluvoxamine inhibits both CYP 1A2 and CYP 3A4, which metabolize warfarin, tricyclics, ► benzodiazepines, and some antiarrhythmics. Citalopram and escitalopram are relatively free from hepatic interactions, and may therefore have an advantage in the elderly and physically unwell. Fluoxetine has a long ► half-life, and fewer discontinuation effects, which can be advantageous if treatment-adherence is poor. It has also been extensively used in pregnancy and generally shown to be safe.

In contrast, clomipramine is commonly associated with typical "tricyclic" effects such as dry mouth and constipation, produced by anticholinergic blockade, sedation, and weight gain, resulting from antihistaminic (H_1) binding (► histaminic agonists and antagonists) and orthostatic hypotension, caused by alpha-adrenergic blockade. Nausea, tremor, impotence, and anorgasmia also occur with clomipramine (as with other SRIs) and are probably mediated by serotonin. Sexual performance is impaired in up to 80% of patients. Compared with the SSRIs (SSRI and related compounds), clomipramine is

Obsessive-Compulsive Anxiety Disorders. Table 1. SRIs in OCD; usually prescribed dosages (From Koran 2007).

	Starting dose (mg/day)[a]	Usual maintenance dose (mg/day)	Occasional maximum dose prescribed (mg/day)[b]
SRIs[c]			
Citalopram	20	40–60	80–120
Escitalopram	10	20	40–60
Fluoxetine	20	40–60	80–120
Paroxetine	20	40–60	80–100
Sertraline	50	100–200	200–400
Fluvoxamine	50	100–300	300–450
Clomipramine	25	100–250	–

[a]In the elderly and in some individuals there may be a need to initiate the medication at half this dose to minimize side effects
[b]In cases of treatment resistance with no or mild side effects and in rapid metabolizers
[c]SRIs appear equally efficacious in treating OCD. SSRIs are safer and better tolerated than clomipramine and therefore should usually be chosen first line (NICE 2006)

also associated with a greater risk of potentially dangerous side effects including seizures (up to 2%) and prolongation of the cardiac ► Q-T interval. These risks increase at dosages exceeding 250 mg/day. Intentional overdose with clomipramine can thus be lethal and needs to be borne in mind when prescribing for OCD, in view of the increased suicide risk associated with the illness (Guy 1976). Comorbidity between ► bipolar disorder and OCD has been reported in up to 30% cases. SSRIs (SSRI and related compounds) are less likely than clomipramine to precipitate mania, but mood stabilizing medication is still advised to mitigate the risk (Koran 2007).

Which SRI First-Line?

Clinical effectiveness depends on a balance between efficacy, safety, and tolerability. Several studies, including placebo-controlled, head-to-head comparator studies and a meta-analytic review (NICE 2006), have demonstrated this, whereas the SRIs appear equally efficacious in treating OCD. SSRIs (SSRI and related compounds) are safer and better tolerated than clomipramine, and therefore should usually be chosen first-line.

Long-Term Effectiveness

OCD is a chronic illness and so treatment needs to remain effective over the longer term. Studies have shown that placebo-referenced gains accrue for at least 6 months and according to open-label follow-up data, for at least 2 years. The SRI-response is characteristically partial, particularly in the first few weeks. An uncontrolled study followed-up fluvoxamine-treated patients with severe OCD for 6–8 years. By the end of the study, responder rates of 60% were reported and 27% of patients had entered remission. However, the majority of patients had required further treatment (either medication or CBT) in the intervening years, suggesting that long-term treatments may be required to maintain efficacy. Results from an extended double-blind placebo-controlled escitalopram study showed that the responder rate has increased to 70% after 24 weeks of continuous SSRI, and 40% of these individuals achieved remission, suggesting a more favorable outcome with sustained treatment. Consistent findings were reported from an open-label trial where 320/468 (78%) cases achieved clinical response status and 45% cases achieved remission after 16 weeks escitalopram.

Thus, first-line treatments can lead to remission or clinically meaningful improvement in around 45 or 75% of cases, respectively, in clinical trial populations. Benefits increase gradually with ongoing treatment and treatment continues to be effective over the longer term. It is important to give some time for the treatment effect to develop and also not to discontinue, reduce dose levels, or change the drug prematurely. Indeed, studies looking at the effects of discontinuing SRIs under double- blind, placebo-controlled conditions showed a rapid and incremental worsening of symptoms in most people who switched to placebo. Therefore, treatment probably needs to be continued for patients to remain well.

Relapse Prevention

The question as to whether continued SRI treatment protects against relapse may be investigated using a ► relapse prevention study design. Table 2 systematically records the peer-reviewed relapse-prevention studies in OCD. Studies of fluoxetine and sertraline found that ongoing SSRI was associated with continued improvement in Y-BOCS scores and quality of life measures up to 12 months of open-label treatment. In the fluoxetine study, only patients remaining on the highest dose (60 mg) showed significantly lower relapse rates, implying an ongoing advantage for staying at the higher dose levels. Large-scale studies of paroxetine and escitalopram clearly demonstrated a significantly better relapse outcome for those remaining on the active drug over the 6-months double-blind

Obsessive-Compulsive Anxiety Disorders. Table 2. Double-blind studies of relapse prevention in adults with OCD.

Drug	Duration of treatment prior to randomization (weeks)	Number in randomization phase	Duration of follow-up after randomization (weeks)	Relapse rates
Fluoxetine	20	71	52	PBO=pooled FLUOX, PBO > 60 mg FLUOX
Sertraline	52	223	28	PBO=SERT (Acute worsening of OCD symptoms: PBO >SERT) (Dropout due to relapse: PBO > SERT)
Paroxetine	12	105	24	PBO > PAR
Escitalopram	16	320	24	PBO > ESC

discontinuation phase: 59% and 52% relapsed on placebo compared with 38% on paroxetine (20–60 mg) and 24% on escitalopram (10–20 mg), respectively. The risk of relapsing on placebo was more than double than that on SSRI.

Taken together, these data emphasize the importance of maintaining SSRI (SSRI and related compounds) at an effective dose level (NICE 2006), and argue against discontinuation even after one year. Protection is not complete, however, with roughly one quarter of cases becoming unwell despite adherence to treatment, highlighting the need for better long-term therapies.

Treatment of SRI-Resistant OCD

It is advisable to delay changing medication until an adequate trial of 12 weeks at the maximally tolerated dose has been attempted. There is a shortage of evidence to support drug-switching when compared with extending treatment with the same drug for a longer time. In one review, 11–33% of patients not responding to the first SRI were reported to show clinically meaningful response to a second drug, with decreasing likelihoods for subsequent changes (Fineberg et al. 2006). According to meta-analyses, factors linked with ▶ SRI-resistance include early onset, longer duration, more severe illness, and poor response to previous therapy. Few studies have investigated pharmacological treatments for SRI-resistant OCD using adequately controlled trial conditions.

Increase SRI Bioavailability

One strategy has been to increase the dose of SSRI (SSRI and related compounds) beyond SPC limits (Table 1). Citalopram (160 mg) and sertraline (400 mg) were helpful in small, open-label case studies of resistant OCD. Another study randomly assigned patients to sertraline (250–400 mg) and reported an improved Y-BOCS response when compared with those who remained within SPC dose limits, and high-dose sertraline was well tolerated. Risks are greater for increasing doses of clomipramine owing to its inherent toxicity; ECG and plasma monitoring is advisable above doses of 250 mg/day and other strategies are usually preferable.

Altering the mode of drug delivery may be another way to gain control of severe intractable OCD. A double- blind study showed intravenous clomipramine to be effective. Six out of 29 patients with refractory OCD were classed as responders after 14 daily infusions when compared with none in the placebo group. The superiority of intravenous citalopram observed during an open-label trial requires substantiation under double-blind conditions.

Change to ▶ SNRI

There are few rational alternatives to SRIs for first-line treatment. Two small open-label studies suggested that patients not responding to one or more SRIs might benefit from a change to venlafaxine. However, a double-blind, prospective study was negative.

Add ▶ Antipsychotic Drugs to SRI

There have been no positive trials using antipsychotics as monotherapy, though growing evidence supports their use as adjunctive treatment with SRIs. Placebo-controlled studies of adjunctive antipsychotic drugs have been limited by methodological shortfalls including small size, focus on acute treatment, and lack of consensus on definitions of treatment-resistance or response. ▶ Haloperidol, ▶ risperidone, ▶ olanzapine, and ▶ quetiapine have been found beneficial and between 18% and 64% of individuals responded. So far, there have been no long-term studies or fixed-dose trials in OCD, though treatment is usually started at low doses and increased cautiously subject to tolerability (e.g., 0.25–0.5 mg haloperidol, titrated slowly to 2–4 mg). One study reported a high level of relapse following open-label discontinuation, hinting that the antipsychotic may need to be continued to remain effective. This finding needs further confirmation. A meta-analysis suggested that patients with comorbid tic disorders were particularly responsive to adjunctive antipsychotic drugs (Bloch et al. 2006). Efficacy in OCD supports a theoretical link between OCD and ▶ Tourette's syndrome, for which antipsychotic drugs constitute the first-line treatments. Second-generation antipsychotics (▶ second- and third-generation antipsychotics) affect a broader range of neurotransmitters and may be preferred because of their more benign side-effect profile. Interestingly, emergent obsessions have been reported during the treatment of ▶ schizophrenia with second- generation antipsychotics (▶ second- and third- generation antipsychotics). It is unclear why dopamine antagonists work when added to SRIs but do not seem to have anti-obsessional properties when used alone or in OCD associated with schizophrenia.

Novel Pharmacotherapies

Novel treatments have been tested in resistant OCD, but few show promise (reviewed in (Fineberg and Craig 2008)). There is no convincing evidence that augmentation with ▶ lithium, ▶ buspirone, pindolol, ▶ clonazepam, desipramine, or St. John's Wort are beneficial. Monotherapy with oxytocin and ▶ naloxone have also failed to produce benefit. A small study suggested oral ▶ morphine augmentation was shown to be effective

when compared with placebo. A number of lines of research, from neuroimaging to genetics are converging to suggest that abnormal glutamatergic transmission may be important in OCD. These findings have led to a number of trials involving drugs that modulate ► glutamate such as riluzole, ► memantine, ► topiramate, and D-cycloserine. To date, these are mainly at the stage of case reports and open-label series. Other compounds with initial positive results warranting further study include inositol and D-► amphetamine.

Conclusion

SRIs have a rapid onset of effect and a broad spectrum of actions. SSRIs (SSRI and related compounds) offer advantages over clomipramine in terms of safety and tolerability and usually constitute first-line treatments. Higher doses usually offer greater benefits and gains continue to accrue for weeks and months. Ongoing treatment protects against relapse for most patients. For SRI-resistant cases, the strongest evidence supports adjunctive antipsychotic drugs. Their long-term effects remain unclear. Increasing the dose of SSRI (SSRI and related compounds) or switching SRIs are rational alternatives.

Definition

Obsessive-Compulsive Disorder (OCD) is currently classified as an anxiety disorder (► Anxiety Disorders) in ► DSM-IV. OCD is typically characterized by both ► obsessions and ► compulsions. Obsessions are repetitive, unwanted, intrusive thoughts, images, or impulses.

Compulsions are repetitive physical or mental acts an individual feels driven to perform in a characteristic, stereotyped way, usually to relieve the anxiety or discomfort associated with depression. Typical symptoms of OCD include contamination obsessions and cleaning compulsions (i.e., fear of germs and compulsive hand washing), forbidden thoughts (i.e., obsessions about harm coming to self or others, sexual, or religious obsessions), hoarding, and symmetry (i.e., the need to have things symmetrical, ordered, arranged) (Bloch et al. 2008). These obsessions and/or compulsions must be severe enough to cause significant distress or impairment or be time-consuming (take up more than 1 h a day). Typically, patients with OCD have insight that their obsessions and compulsions are excessive and unreasonable, but feel driven to perform them by intolerable anxiety and discomfort caused by the obsessions.

OCD is generally considered to have a bimodal distribution in terms of age of onset, with a presence of 1–3% throughout the lifespan. The first incidence peak occurs around puberty and the second occurs in early adulthood. Across the life cycle, symptoms of OCD are similarly expressed; however, there are several important differences between pediatric and adult-onset OCD. Pediatric-onset cases of OCD have a male predominance (unlike adult-onset OCD cases, which are female predominant), have a stronger family history of OCD, and have higher rates of comorbid ►Attention-Deficit Hyperactivity Disorder and ►tic disorders. They are also more likely to experience a remission of their OC symptoms compared with adult-onset OCD. The specific content of obsessions and compulsions also differ across age ranges. Children with OCD have much higher rates of aggression obsessions (such as fear of a catastrophic event, and fear of harm coming to self or others) and tend to have poor insight (being unable to recognize their obsessions and compulsions as excessive and unreasonable). Adolescents with OCD have a higher proportion of obsessions with sexual and religious themes, whereas cleaning and contamination OCD symptoms are quite prevalent across all age ranges. Patients with OCD and comorbid tics have a significantly higher rate of intrusive, violent, or aggressive thoughts and images, sexual and religious preoccupations, concerns with symmetry and exactness, hoarding and counting rituals, and touching and tapping compulsions. Also common in patients with OCD and comorbid tics, are compulsions designed to eliminate a perceptually tinged mental feeling of unease, coined in the literature as "Just Right" perceptions.

The age threshold that differentiates pediatric-onset OCD from adult-onset OCD is not clearly defined in the scientific literature, as investigators differentiate the two groups with puberty or at age 16 or 18. The pharmacological and behavioral treatments for OCD are remarkably similar across the lifespan. The combination of pharmacotherapy with selective-serotonin reuptake inhibitors (►SSRI's and Related Compounds) (SSRIs) and cognitive-behavioral therapy (CBT) (POTS 2004) are most common. There are slight differences in pharmacological management and behavioral techniques to treat pediatric-onset OCD that appear more important when the child is younger.

Role of Pharmacology

SSRIs are the pharmacological treatment of choice for obsessive-compulsive disorder. The number needed to treat (►Number needed to treat) (NNT) with SSRIs to induce a clinical treatment response, as defined by a 25–35% reduction in CY-BOCS scores, has ranged from 4 to 6 in double-blind, placebo-controlled studies (Compton et al. 2007). Based on cumulative studies, SSRI pharmacotherapy will lead to an average of a 6.5–9 point decline in CY-BOCS ratings and an average 30–38% reduction in symptom severity. In OCD, improvement with SSRI pharmacotherapy commonly continues to occur up to 2–3 months after initiation of treatment. In adulthood OCD, a recent meta-analysis has demonstrated that higher doses of SSRI pharmacotherapy are more effective than lower dose treatments (Bloch et al. 2009). No fixed-dose SSRI trials exist in pediatric-onset OCD to demonstrate if this phenomenon is similar in children. OCD patients with comorbid tics appear less likely to respond to SSRI pharmacotherapy than those without comorbid tics (March et al. 2007). Table 1 depicts the typical starting and target doses of SSRI pharmacotherapy in children and adults with OCD.

Compared to other medications used to treat child psychiatric conditions, SSRIs are generally well tolerated in children. Children, however, appear slightly more sensitive to initial treatment and dose increases than adults. Gastrointestinal disturbance, headache, fatigue, and insomnia are common side effects of SSRI medications. These side effects are ephemeral and commonly occur at the initiation of treatment or at an increase in dose. Often, with continued treatment with the same dose, these side effects can disappear. Sexual side effects, including decreased sexual desire, pleasure, or performance, are all common dose-dependent side effects of SSRIs. Sexual side effects are a common, often unmentioned cause of medication noncompliance in adolescents and adults. It is, therefore, important to outline these possible sexual side effects to adults and adolescents and inform them

Obsessive-Compulsive Anxiety Disorders in Childhood. Table 1. Recommended dosing for serotonin reuptake inhibitors in OCD.

Medication	Starting dose (in mg)		Target dose (in mg)	
	Children	Adults	Children	Adults
SSRIs				
Fluoxetine	5–10	20	10–80	40–80
Fluvoxamine	12.5–25	50	50–300	100–300
Sertraline	12.5–25	50	50–200	150–250
Paroxetine	5–10	10–20	10–60	20–60
Citalopram	5–10	20	10–60	20–60
Escitalopram	2.5–5	10	5–30	20–40
TCAs				
Clomipramine	12.5–25	25	50–200	100–250

that they are not permanent. The sexual side effects disappear with SSRI discontinuation and often simply with a dose reduction.

Behavioral activation and suicidal ideation are less common but more severe side effects of SSRI pharmacotherapy. The Food and Drug Administration issued a "► black-box warning," stating that these medications were associated with an increased risk of suicidality when utilized in pediatric populations. This warning was based on a meta-analysis of 24 placebo-controlled trials in children with depression, anxiety disorders, and ADHD (Bridge et al. 2007). The ► meta-analysis found a 2% increase in the risk of suicidal ideation with treatment of SSRIs, which is equivalent to a relative risk of 2. There were no completed suicides that occurred in any of these trials. Subsequent meta-analyzes have suggested that this increased risk of suicidal ideation appears restricted to only pediatric patients with depression and that the risk/benefit profile of SSRIs appears better in pediatric anxiety disorders (Bridge et al. 2007). Based on this warning, the FDA currently advises clinicians to see a child weekly for 4 weeks after starting SSRIs, and monthly thereafter.

Behavioral activation is a syndrome associated with SSRI use that is characterized by hyperactivity, giddiness, insomnia, and agitation. These symptoms can sometimes involve mania, irritability, and aggression. Behavioral activation appears to be more associated with ► tricyclic antidepressant use and pharmacological treatment at a younger age (Martin et al. 2004).

Clomipramine, a tricyclic antidepressant with primarily serotonergic properties, was the first antidepressant the FDA approved for the treatment of pediatric OCD. A meta-analysis of pharmacotherapy trials for pediatric OCD found, using meta-regression techniques, that ► clomipramine was superior to the selective-serotonin reuptake inhibitors in the treatment of pediatric OCD, and the different selective-serotonin reuptake inhibitors currently used to treat OCD were roughly equivalent (Geller et al. 2003). These meta-regression results, however, should be interpreted with caution, considering that no studies have directly compared the efficacy of clomipramine to other selective-serotonin reuptake inhibitors in children with OCD. Studies comparing these agents in adults have found no significant differences. Clomipramine, due to its worse side effect profile compared to SSRIs, is no longer used as an initial pharmacological treatment for OCD. Clomipramine has higher rates of somnolence, gastrointestinal upset, and weight gain than SSRIs. Clomipramine also has anticholinergic effects, reduced seizure threshold, and arrhythmogenic side effects. Due to the potential arrhythmogenic properties of clomipramine, a baseline electrocardiogram and a detailed screening for a personal and family history should be undertaken in all patients before the initiation of pharmacotherapy. Guidelines for unacceptable EKG indices for use of clomipramine have been issued by the FDA, and are as follows: (1) PR interval >200 ms; (2) QRS interval >30% increased over baseline or >120 ms; (3) blood pressure greater than 140/90; (4) heart rate >130 bpm or (5) QTc >450 ms. Despite these concerns, clomipramine remains a valuable treatment option for children who do not respond to initial pharmacotherapy with one or more selective-serotonin reuptake inhibitors. Clomipramine is now utilized mainly as monotherapy for OCD patients who have not responded to two SSRI trials of adequate dose and duration, or as an augmentation agent to SSRIs in low doses. When using clomipramine as an augmentation agent, clinicians need to be vigilant for the onset of the ► serotonin syndrome.

Approximately half of the children placed on SSRI pharmacotherapy will fail to respond despite optimum pharmacologic treatment. If CBT has not been offered and conducted, it should be done so at this point. In adults with OCD, as many as 25% of initial nonresponders may respond if treated with another SSRI or clomipramine. Other options for augmentation include antipsychotic augmentation or augmentation with ► glutamate modulating agents.

No controlled trials of antipsychotic augmentation exist for children with OCD. A meta-analysis of placebo-controlled trials of adults with treatment-refractory OCD, has demonstrated that these agents are effective (Bloch et al. 2006). The NNT to induce a clinically significant treatment response (35% reduction in Y-BOCS ratings) in adults with OCD was 4.5 (95% CI: 3.2–7.1). ► Neuroleptic augmentation appears particularly effective in OCD patients suffering from comorbid tics (NNT = 2.3). This result is not surprising since antipsychotics are the most effective medications in treating tic disorders. The doses of neuroleptic medications used to augment SSRIs are traditionally much lower than those used to treat psychosis and aggression in children. Lower doses are preferred due to the increased sensitivity of children with TS and OCD to these medications and the CYP2D6-based pharmacologic interactions these medications have with many SSRIs. Children with OCD appear particularly prone to the metabolic side effects associated with ► antipsychotics. The restriction of antipsychotic augmentation is, therefore, advisable only for children with comorbid tics or severe functional impairment despite adequate treatment with SSRIs and behavioral therapy.

Riluzole is a glutamate modulating agent that is approved by the Food and Drug Administration for neuroprotection in the treatment of amyotrophic lateral sclerosis, also known as Lou Gehrig's disease. Riluzole is postulated to affect glutamate neurotransmission by reducing presynaptic glutamate release and by increasing glial cell reuptake of glutamate. Uncontrolled studies of both adults and children have provided encouraging data of efficacy. A case series of six children with treatment-refractory OCD at NIMH found four treatment responders (Grant et al. 2007). Case series of treatment-refractory adults demonstrated a 57% response rate and treatment gains that maintained for at least 2 years of follow-up (Pittenger et al. 2006). Riluzole's potential efficacy is yet to be demonstrated in any blinded or placebo-controlled trials. Although quite well-tolerated by most patients, riluzole's widespread use is limited by its potential hepatotoxicity. Riluzole use requires monitoring of liver function tests every 3 weeks for the first 3 months of treatment.

Role of Nonpharmacological Therapies

Cognitive behavioral therapy is a first-line treatment for pediatric-onset OCD. The NNT for CBT in pediatric-onset OCD is 2.6 (95% CI: 1.7–4.2) to induce a treatment-response (POTS 2004). CBT for children with OCD is based on exposure and response prevention. In CBT for OCD, the therapist must first examine and take a detailed history of a child's specific OCD symptoms. Symptom checklists, such as those that accompany the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS), Children's Y-BOCS, and Dimensional Y-BOCS are useful in these efforts. Then the therapist, working with the child and his/her parents, develops a hierarchy of exposures, both direct and imaginary, to trigger the anxiety associated with obsessions of OCD (i.e., touching a toilet seat for a child with contamination concerns, or imagining a parent in a car accident for a child with fears of harm coming to others). The therapist then enters into a contract with the child and parent to work on completing these exposures over a set time frame, usually a period of a couple of months. Next, the therapist engages in the specific exposures with the child (and sometimes the parents) over the next few treatment sessions, asking the child to agree not to engage in his/her compulsions in response to the anxiety produced. During exposures, the child reports his/her level of anxiety using subjective units of distress (SUDS), an anxiety thermometer. The child and parent are given similar exposure assignments to complete after each session. With increased duration of exposure and subsequent exposure, the child's anxiety lessens (without performing the compulsions), helping him/her to overcome the OCD. Most CBT treatment manuals for children with OCD are freely available, and additionally include techniques such as relaxation therapy, to help children deal with stress and anxiety. The manuals may also include exercises to illustrate other tenets of CBT. For example, they may help the child to recognize cognitive distortions common in OCD, such as overestimation of risk, all-or-nothing thinking, overcoming the need for certainty, and recognizing excessive feelings of responsibility or guilt. CBT is as effective as any pharmacological intervention for OCD, and should be utilized before pursuing less evidence-based augmentation strategies for OCD.

Conclusion

SSRIs and CBT are effective treatments for pediatric-onset OCD. The combination treatment of both SSRIs and CBT is more effective than either treatment alone. Although many children with OCD respond to submaximal doses of SSRI pharmacotherapy, it is important to pursue an SSRI trial of adequate dose, (maximal tolerated dose), and

duration (2–3 months) before progressing to augmentation therapies. Antipsychotic augmentation appears to be a particularly effective strategy for OCD patients with comorbid tics. Riluzole augmentation is an emerging treatment for OCD that may be effective for some patients. While there are several effective treatment options for OCD, there is still a great need for treatments that work better and faster.

Obsessive–Compulsive Disorder

Synonyms

Obsessive–compulsive neurosis; OCD

Definition

Obsessive–compulsive disorder (OCD) is a disabling psychiatric disorder that usually pursues a chronic course and is characterized by recurrent unwanted thoughts obsessions and/or physical acts compulsions that are severe enough to be time consuming, cause marked distress or significant impairment. At some point during the disorder, the obsessions or compulsions are recognized to be excessive or unreasonable (DSM1V). If another DSM-IV Axis I disorder is present, the content of the obsessions or compulsions is not restricted to it. Nor is the disturbance due to the direct physiological effects of a substance or a general medical condition.

Occasion Setting with Drugs

Rick A. Bevins[1], Matthew I. Palmatier[2]
[1]Department of Psychology, University of Nebraska-Lincoln, Lincoln, NE, USA
[2]Department of Psychology, Kansas State University, Manhattan, KS, USA

Synonyms

Drug as cues; Drug discriminative stimulus; Drug facilitator; Drug modulator; Drug occasion setter

Definition

Occasion setting is a form of hierarchical learning involving associative and nonassociative processes. Occasion setters are discrete stimuli or contexts that disambiguate

Pavlovian and/or operant relations. In cases where stimuli or responses are "sometimes" associated with biologically relevant events, occasion setters can provide discriminant information that resolves the ambiguity of the antecedent. Drug states are internal contexts that can predict positive relationships between stimuli/responses and outcomes (feature-positive occasion setters) or negative relationships between stimuli/responses and outcomes (feature-negative occasion setters). Traditionally, occasion setters are considered nonassociative because their ability to influence behavior does not depend on a direct association with the antecedent or biologically relevant events, but can "transfer" to novel responses and situations.

Impact of Psychoactive Drugs

Introduction

In a standard ► Pavlovian (classical) conditioning experiment, the investigator establishes a relation between two stimuli. In a typical study involving rodents, one stimulus might be a tone or a light (termed ► conditioned stimulus [CS]) that is repeatedly paired with a more motivationally relevant stimulus such as food, water, drug, etc. (termed ► unconditioned stimulus [US]). Sometimes, the CS–US pairing occurs only in a particular situation or when some other stimulus is present. The stimulus that disambiguates when the CS will be reinforced is often referred to as a feature-positive occasion setter. Under these conditions, the CS evokes a ► conditioned response (CR) only when the feature is present. Alternatively, the feature might indicate when the CS will *not* be reinforced. In this case, the stimulus is referred to as a feature-negative occasion setter, and conditioned responding during the CS is withheld or inhibited. Many drugs have interoceptive (subjective) properties that function as stimuli capable of guiding learned behaviors. These interoceptive properties can be conceptualized as polymodal contextual (situational) cues in which the stimulus elements reflect the complex neurobiological action of that drug. As such, a drug state can function either as a feature-positive or as a feature-negative occasion setter disambiguating when a CS–US relation will or will not be in force, respectively. Drugs such as ► bupropion, ► caffeine, ► chlordiazepoxide (CDP), ► cocaine, D-► amphetamine, ► ethanol, ► flumazenil, indorenate, ► nicotine, ► methamphetamine, ► morphine, ► pentobarbital, ► rimonabant, ► sertraline, and Δ-9 tetrahydrocannabinol (THC) appear to function as feature-negative and/or feature-positive occasion setters.

Example Tasks

The occasion-setting function of drug states has been described in a variety of paradigms using a range of CS types, as well as appetitive and aversive USs. For the sake of brevity, we will focus the present discussion on two variants: discriminated ► conditioned taste aversions (DTA; Jarbe and Lamb 1999) and discriminated ► goal tracking (DGT; Palmatier and Bevins 2008). In DTA studies, the drug state sets the occasion in which a taste CS would or would not be followed by a noxious or aversive event, often lithium chloride-induced illness. Subjects are provided repeated access to a novel taste CS. During half of these conditioning trials, the taste CS is accessed in the drug state; during the remaining trials, the taste CS is accessed after a ► placebo injection (nondrug state). Following access to the CS, the illness-inducing US or placebo (no US) is administered. The CR is typically defined as avoidance of the taste CS. In DTA studies, drug states are most often trained as positive features – the taste CS is followed by illness when it is accessed in the drug state, and the same tastant is followed by a placebo injection when it is accessed in the nondrug state. Subjects learn to avoid the taste CS when it is presented in the drug state, but readily consume the CS in the nondrug state. Because the feature-positive drug state occasions taste-illness pairings in this task, it is sometimes referred to as a "danger cue." In this paradigm, drug states can also serve as negative features, which set the occasion in which the taste will not be followed by illness and are sometimes referred to as "safety cues" (see Skinner et al. (1995) and Hallmarks of Occasion Setters for more information).

In DGT studies, the drug feature sets the occasion on which a CS will or will not be followed by a rewarding US, typically food or sucrose solution. In this task, a brief auditory or visual stimulus (CS) is presented both in the drug state and the nondrug state (placebo). If the drug state is a positive feature, then the CS presentations that occur in the drug state are followed by access to the US; the same CS is presented in the nondrug state, but the US is withheld (Palmatier and Bevins 2008). Conversely, when the drug state serves as a negative feature, the US follows the CS after placebo injection and the US is withheld after drug injections (Bevins et al. 2006). In these studies, the CR is goal tracking, which reflects anticipatory approach to a location where the appetitive US has occurred previously (e.g., head entries into the receptacle where sucrose is delivered).

The concept that the internal milieu can provide a context with discriminant properties is not limited to drug states. Davidson and his colleagues (Davidson 1998) have

argued that internal contexts of hunger and satiety might function as occasion setters. In one notable study, hunger and satiety contexts were used to set the occasion for when a rat would receive a shock (US) in a particular chamber (CS). Rats were able to use an internal state to determine when a shock would occur, and the occasion-setting function of the hunger/satiety state transferred to other chambers that were associated with shock, but not to chamber CSs that were never associated with shock. Based on these and other findings, Davidson (1998) has argued that the occasion-setting function of the internal milieu could explain why more appetitive behaviors are exerted when food stimuli are presented in "hunger" states relative to "sated" states.

Hallmarks of Occasion Setters

An important aspect of occasion setting is ascertaining whether the feature's influence on behavior depends on a direct relationship with the US. Occasion-setting features typically have a perfect positive or negative correlation with the US, meaning that they may function only as simple conditioned excitors (feature-positive) or ► conditioned inhibitors (feature-negative) rather than occasion setters. Determining whether a feature is an occasion setter or a simple excitor/inhibitor often demands manipulating its relationship to the US and then a test to examine whether the manipulation has altered the feature's ability to increase or decrease responding evoked by the CS. If the feature functions only as a conditioned excitor or inhibitor, then this manipulation is expected to abolish its ability to modulate CS-evoked responding.

In the DGT task, the drug states (amphetamine, nicotine, and CDP) trained as positive features increased responding to a CS paired with sucrose (Palmatier and Bevins 2007). In the nondrug state, the CS evoked very little conditioned responding. To investigate whether these drug states increased responding because they served as simple CSs (i.e., direct association with US), we changed the relation between the drug state and the US. Each feature underwent an ► extinction treatment – rats were repeatedly exposed to the drug in the absence of the US. The discrete exteroceptive CS was never presented on these extinction trials. In subsequent tests, all three drug states still increased responding evoked by the CS. This finding suggests that the drug states functioned as occasion setters (nonassociative) rather than simple conditioned excitors (associative).

A second hallmark of occasion setters is their transitive nature; a feature that sets the occasion for one CS–US association can often transfer its discriminant function to another CS. Transfer of occasion setting normally involves a novel combination of features and CSs after the subjects have been trained on multiple discriminations. For example, we recently trained two drug states (nicotine and CDP) as positive features for two different CSs in the DGT task. A noise CS was followed by sucrose after nicotine injections, and a light CS was followed by sucrose after CDP injections. After placebo injections, the light and noise were presented but were never followed by sucrose. Following training on both discriminations, rats were tested on different combinations of drug features and CSs. As expected, nicotine and CDP facilitated responding to the CSs which typically occurred in those drug states. However, each drug also facilitated responding to the CS which had occurred in the *other* drug state. Neither CS evoked conditioned responding when presented after injection of a novel drug (i.e., amphetamine), and neither feature facilitated responding to a novel CS (Palmatier and Bevins 2008). In DTA procedures, positive drug features ("danger cues") typically transfer their facilitative function in a less specific manner. Skinner et al. (1998) have demonstrated that these danger cues will inhibit consumption of the taste CS as well as novel and familiar tastants that have never participated in an occasion-setting discrimination. They have argued convincingly that positive drug features in the DTA paradigm may set the occasion for associations between consummatory responses and the illness-inducing US (Skinner et al. 1998).

Recall that in the case of feature-negative training, conditioned responding evoked by the target CS in the drug state is significantly attenuated relative to the nondrug state. To our knowledge, transfer of negative occasion setting with drug features has not been investigated. This may be because researchers in this area suspect that negative drug features are functioning as simple conditioned inhibitors (Bevins et al. 2006; Skinner et al. 1995). The theoretical and, hence, the therapeutic implications could be significant if a drug state could acquire inhibitory properties. To gather convincing evidence for inhibitory conditioning to the interoceptive effects of a drug, one must show that a drug trained as a negative feature passes the summation and retardation tests of conditioned inhibition. In the ► summation test, the putative-conditioned inhibitor will also inhibit conditioned responding to an excitatory CS that has been trained independent of any occasion-setting function. For the ► retardation test, subsequent acquisition of an excitatory conditioned response to the negative feature will be impaired (retarded) relative to controls. Morphine trained as a negative feature in the DTA task ("safety signal") passes the summation test. That is, avoidance of a separately trained saccharin CS was diminished across repeated

extinction sessions in the presence of morphine that was previously trained as a negative feature indicating that vinegar solution would not be paired with illness (Skinner et al. 1995). A retardation test has not been conducted using the DTA procedures, nor has either the retardation or summation test been used within the DGT task. Thus, the field awaits a definitive demonstration as to whether a feature-negative drug state inhibits conditioned responding through direct inhibitory properties.

Significance and Application

Training the interoceptive effects of a drug as an occasion setter requires a discrimination to be made at least between the drug and nondrug state. Of course, as indicated earlier the discrimination is more specific than a mere presence vs. absence of an altered internal state. Given this pharmacological specificity in control of conditioned responding, these Pavlovian drug discrimination tasks have been used as a complement to the operant-drug discrimination task that uses drug ► discriminative stimuli to help elucidate the neuropharmacological processes underlying the subjective effects of a drug (Kreiss and Lucki 1994; Reichel et al. 2007).

Although clear advances have been made in understanding drug states as occasion setters, the role of such factors in addiction and other health-related behaviors and their therapeutic implications have yet to be fully realized. Regardless, we expect their importance to be high given the demonstrations that learning can alter the functional impact of the drug state. A salient example described earlier is the transfer (substitution) of occasion-setting function to a pharmacologically unrelated drug, only when the drugs share a common learning history – that is, trained as feature-positive occasion setters with different target CSs. Another example is the alteration of the psychomotor effects of stimulant drugs depending on whether there has been a training history with a positive or negative drug feature (Reichel et al. 2007). Briefly, rats were trained with ► methamphetamine as the occasion setter. For one set of rats, methamphetamine served a feature-positive occasion setter indicating when a brief light was paired with sucrose. The other set of rats had methamphetamine indicate when the light was not reinforced (i.e., feature-negative occasion setter). Following acquisition of the discrimination were intermixed substitution tests in which the cocaine and bupropion were tested. Substitution tests indicated that bupropion and cocaine had methamphetamine-like stimulus effect. More interestingly, from the current discussion's perspective is that the typical stimulant effects of these two drugs were significantly blunted if rats had methamphetamine trained as a negative feature. Much more research is needed to know the generality, extent, and mechanism(s) of this effect. Regardless, a well-documented behavioral effect of cocaine and bupropion was affected by training methamphetamine as a negative feature.

The significance of occasion setting by drug states is critical to the study of drug addiction. The widespread acceptance of associative learning processes in addictions is reflected by their inclusion as a critical component in bio-behavioral models of drug dependence (e.g., Koob and Le Moal 2008). However, the role ascribed to associative learning in most models is best described as simple and elemental. One cannot assume that for drug-dependent individuals all "drug-cues" are followed by rewarding drug effects each time they are experienced. For example, a smoker may be exposed to stimuli (i.e., cigarette packaging) that have a history of pairing with the reinforcing effects of nicotine. However, in many circumstances (i.e., in public buildings, offices, hospitals, filling stations) the effects of nicotine may be unattainable. In these cases, the contextual stimuli probably modulate the meaning of the CS (cigarette packaging). Given the frequently observed comorbidity between the drug dependence disorders (e.g., alcoholism and smoking), it is critical that we expand the role of learning processes in addictions and further examine the role of occasion setting by drug states and other contexts. These principles undoubtedly extend to other forms of addiction (e.g., gambling), other impulsive and compulsive behaviors (e.g., eating; see Davidson 1998), as well as pain management and cancer treatment.

Octreotide

Synonyms
Sandostatin; SMS201-995

Definition
Octreotide is an octapeptide, the first somatotropin release-inhibiting factor (SRIF) receptor agonist in the clinic. Octreotide is used to treat acromegaly, some GIT disorders, and primarily a number of tumors in the gastroenteropancreatic tract. Octreotide has high affinity for sst2 and sst5 receptors.

Off-Label Use of Drugs

Definition
The label is a document about a drug, which is approved by governmental "regulatory" agencies, such as the Food and Drug Administration (FDA) in the US and the European Medicines Agency (EMEA) in the EU. The label is the source for the package insert. The label includes the drug's approved indications, that is, the conditions, diseases, disorders, that can be treated with the drug. Off-label use refers to the practice of using a drug for the treatment of a disease or condition that is not listed on its label, or used in such a way that is not described in the label (e.g., in higher doses). Synonyms of off-label are extra-label use, nonapproved use or unapproved use. Off-label prescription raises legal and ethical issues. Some countries ban or restrict off-label use of drugs. Insurance companies may reject the reimbursement claims for off-label prescriptions. In case of unexpected side effects/adverse events of the drug treatment (unexpected adverse events are those, which are not described in the label), the manufacturer holds no responsibility as it is the case with prescriptions based on the label. Regulations may mandate that even evidence-based scientific speech violated the law if manufacturers were involved and the information concerned off-label uses.

Describes the origin and the developmental history of an organism from the embryo to its mature form (adult). The term is opposed to "phylogeny" which denotes the evolutionary history of a species.

Open-Field Test

Catherine Belzung
INSERM U930, Université François Rabelais Sciences et Techniques, Tours, France

Definition

Test consisting of scoring the behavior of a rodent that has been forced into a novel arena. Enables detection of effects of drugs on anxiety behavior, activity, and memory.

Principles and Role in Psychopharmacology

History

In 1934, Hall (1934) designed the open-field test to assess "emotionality" in rats. The procedure consists in introducing an animal into a new arena from which escape is prevented by walls (Walsh and Cummins 1976). Hall's apparatus consisted of a brightly lit circular environment (thereafter termed as "open field") of about 1.2 m diameter closed by a wall of 0.45 m high. Rats were placed individually in the open field and their behavior was recorded for 2 min, during daily repeated trials. In some cases, rats were tested after 24 or 48 h of food deprivation. Hall observed that rats exhibited increased locomotion when food was deprived, and also, surprisingly, some rats did not eat, in spite of the high alimentary motivation related to the food deprivation: these animals were termed "emotional." When compared with non-emotional rats, they displayed increased thigmotaxis (i.e., they walked in the outer ring of the apparatus, always maintaining a tactile contact with the walls via their vibrissae); these emotional rats also exhibited higher levels of defecation and micturation (Fig. 1).

Procedure

The procedure is generally based on the forced confrontation of the rodent with the open field, but in some cases

Open-Field Test. Fig. 1. A mouse in a circular open field – Dimensions of the arena: 40 cm diameter and 30 cm high.

animals have also been allowed free access to the arena from their familiar nest.

In this free confrontation situation, rodents will generally show avoidance for the brightly lit environment: before entering the arena, the animal will show risk assessment postures directed toward the open field. This is a first argument indicating that the open field may be a stressful situation. In case of forced confrontation, the animal is placed in the apparatus and the following behavioral items are recorded, usually during five min: locomotion, frequency of rearing or leaning (sometimes termed vertical activity), and grooming. Increase of time spent in the central part, higher ratio of central/total locomotion, or decrease of the latency to enter the central part are indications of reduced anxiety-like behavior. Therefore, experimenters are not measuring the effects of the factors they are interested in on exploration, as is sometimes claimed, but the effects on the reaction of the subjects to a stressful event. Additionally, other parameters may be measured, including physiological, neural, or endocrinological ones. For example, using telemetry, it has been shown that the forced confrontation to the open field induces increased heart rate, further indicating that the animal is in a stressful situation. Immunohistological experiments, allowing measuring of the activation of various brain areas via c-fos, have shown that exposure to the arena induces activation of several structures belonging to the limbic system, such as the ► hippocampus, the ► amygdala, or the bed nucleus of stria terminalis, further suggesting that the rodent is stressed. This is accompanied by an activation of some hypothalamic nuclei, including the paraventricular nucleus. Finally, open-field exposure also induces a rise of plasma corticosterone, which is the main stress hormone. Taken together, this indicates that forced exposure to the open field induces a complex response, characterized by a specific behavior associated with physiological, endocrine, and neural modifications all suggesting that the animal has been stressed.

Utilization

The open-field test is now one of the most popular procedure in behavioral neuroscience (see Belzung 1999; Prut and Belzung 2003), and is used to assess the effects of different factors on anxiety-like behavior, including the action of ► anxiolytic drugs, brain lesions, or genetic invalidation. In fact, it has become a convenient procedure to measure not only anxiety-like behaviors but also activity, enabling to detect sedation (decrease of activity) or hyperactivity. It can also be used to assess learning and memory. Several versions of the apparatus have been designed, differing in shape of the environment (circular, square, or rectangular), lighting, presence of objects within the arena, and so on. Utilization of this apparatus has been extended to a great number of species including not only farm animals such as calves, pigs, lambs, rabbits, but also other species including invertebrates such as honeybees and lobsters. In fact, stressful experience in the open field is triggered by two factors: individual testing (the animal is separated from its social group) and forced novelty (the animal is subjected to an unknown environment, with no ability to turn back to its home cage or to predict the outcome of this confrontation; further, the arena is very large relative to the animal's home cage or natural environment consisting in small galleries). These two factors may respectively be interpreted as stressful only in gregarious species and/or in species that show fear of open spaces into which they are forced. This is precisely the case with rodents that live in groups and in small underground tunnels. This is of course not the case in species such as lambs or cows that live in large fields.

Interpretation Bias

Behavior of rodents in the open field depends on several sensorial modalities, with a main involvement of tactile factors. Indeed, mice without vibrissae no longer display thigmotaxis, as they lose tactile contact with the walls. One must thus emphasize the possibility of misinterpretation of data related to effects of some treatments on the sensorial characteristics of the animals. As already indicated, exploration can be increased by some factors including food or water deprivation: it is therefore very important to verify that a given treatment does not act on such variables, before concluding the possible anti-stress effects. Finally, open-field behavior also depends on lighting conditions and upon the light–dark cycle (because exploration and food patrolling is increased during the animal's high-activity period, i.e., at the beginning of the dark phase) so that it may be relevant to ensure that a treatment does not modify internal clock-related behaviors and test the treatment under different lighting conditions.

Assessment of Drug's Effects on Anxiety Behavior

Using this device, the effects of different treatments have been investigated, mainly in the field of behavioral genetics (18% of the studies investigating the effects of targeted mutation of a given gene on anxiety-like behavior have been conducted using this device, a percent rising to 26%

for mutants of the serotoninergic system) and in the one of psychopharmacology. Concerning this last aspect, one may notice that many different drugs have been investigated in this situation, including compounds not only with effective or potential anxiolytic-like effects (► benzodiazepines, ► serotonin ligands, ► neuropeptides) but also compounds with psychostimulant (► amphetamine, ► cocaine), sedative (► neuroleptic), preictal (the state characterizing the prostration state induced by some epileptogenic drugs) activity or amnesic effects. An increased locomotion or time spent in the central part of the device without any modification of total locomotion has been interpreted as an anxiolytic-like effect while the contrary, which is a decrease of these variables, is associated with ► anxiogenic-like effects. Increased total locomotion (i.e., an increase of central and peripheral locomotion, in the same proportions) can be interpreted as hyperactivity while decreased rearing and locomotion are related to sedation or to postictal prostration. Concerning anxiety-like activity, the effects of three categories of drugs have been investigated, including compounds acting on the ► $GABA_A$ pentamer (not only benzodiazepine receptor ligands but also $GABA_A$ receptor agonists, ► barbiturate and ► neurosteroid ligands), serotoninergic-acting drugs such as ligands of the different 5-HT receptors or inhibitors of the serotonin transporter, and the effects of neuropeptidergic ligands (CRF, corticotropin-releasing factor; CCK, ► cholecystokinin; NK, neurokinin; neuropeptide Y). Interestingly, the open field is able to detect the anxiolytic-like effects produced by compounds effective in normal anxiety behavior, such as classical benzodiazepines and 5-HT_{1A} receptor agonists, while it lacks sensibility for the anxiolytic action of atypical benzodiazepines such as ► alprazolam or for the anxiolytic action of chronic antidepressants such as ► Selective Serotonin Reuptake Inhibitors, that display efficacy in some anxiety disorders such as panic, obsessional–compulsive disorder, social phobias, and post-traumatic stress disorder. It is to be emphasized here that benzodiazepines and 5-HT_{1A} receptor agonists do not increase exploration as it is sometimes claimed; they act by reducing the stress-induced inhibition of exploration. Further, this device detects the effects of these compounds on anxiety-like behavior, and not on anxiety. Indeed, anxiety-like behavior is only one component of the anxiety-like response, which also includes expressive reactions (e.g., the vocal expression such as ► ultrasonic distress calls), physiological alterations (modifications in body temperature, heart rate, arterial pressure), as well as cognitive/subjective aspects.

Assessment of Drug's Action on Locomotion (Sedation and Hyperactivity)

Concerning the ability to detect sedation, for example, after administration with high doses of benzodiazepines, ethanol, or neuroleptics, an important point to consider is that the free exploration situation is much more sensitive to the sedative effects of a treatment when compared with the forced situation. Indeed, in order to detect sedative effects, two-fold higher doses should be used in the forced situation. This can be explained by the fact that the forced confrontation imposes the experimenter to take the animal out of its home cage, which may induce awaking of an animal that would have been sleeping in its home cage. One may also mention the fact that the effects of a sedative treatment on rearing appear at lower doses than the ones on locomotion, indicating that this parameter is more sensitive. Sedative-like effects have to be distinguished from the preictal prostration that can be observed after administration of some proconvulsive treatments. The phenomenological features of these two behaviors may seem identical, as animals exhibit a reduced exploration in both cases. Therefore, when reduced exploration is seen, the experimenter has always to be very prudent in the interpretation of data. Further, reduced exploration can also be observed if the rodent is freezing; but in this case, the experimenter will observe a very different posture, the rodent showing a tonic immobility, while when sedated displays a nontonic immobility.

Hyperactivity can also be detected using this device. ► Hyperactivity never corresponds to increased exploration. Indeed, after treatment with ► psychostimulants, the animal will show elevated locomotion, sometimes close to stereotypy (as it may repeat the same locomotion pattern several times) with reduced exploratory items (no sniffing, few rearing).

Assessment of Drug's Effects on Learning and Memory

The open field has also been used to detect the effects of some treatments on learning and memory. Three different processes can be assessed in this case: ► habituation, object recognition, and ► spatial memory. To test habituation, one can compare the behavior of the rodent during the first 5 min with the ones of the last 5 min of a 15-min session, enabling to detect the effect of a treatment on short-term habituation. Alternatively, one can confront a rodent to several 5-min sessions, separated by inter-trial intervals of some hours or several days. In this case, one can distinguish the effects of a given treatment on encoding from its effects on consolidation or restitution, depending upon the injection schedule. When testing

object recognition using an open field, the subject is usually first introduced in the arena during a 5-min session. After an inter-session delay, the animal is further subjected to the open field, which now contains two identical objects. During a third session, the rodent is again introduced in the device, which contains one object identical to the one it has been confronted before and another one that is different. Higher exploration of the new object indicates that the animal has been able to remember the object it had seen before and is therefore considered an index of recognition memory. Pharmacological treatments can be tested either to detect promnesic/amnesic effects, or to counteract the stress-induced decline in learning and memory (e.g., ► antidepressants are able to restore a stress-induced decline in object recognition). Finally, this situation can also be used to detect the effects of drugs on spatial memory. In this case, the rodent is confronted to the arena containing three identical objects, placed in a precise spatial configuration; (e.g., a line) and after a delay, it will again be introduced in the device, with the same objects, placed, for example, in a triangular configuration. In this case, exploration of all objects that had been declining after habituation will start again. This process can be altered with pharmacological treatments such as, for example, anticholinergic drugs.

Conclusion

In conclusion, the open field is a very popular and useful device, not only enabling detection of effects of drugs on anxiety behavior, but also action of pharmacological compounds on sedation, hyperactivity, learning, and memory.

Operant

Definition

A class of activities, all of which produce a common effect on the environment. A typical example is pressing a lever. The different forms of behavior that result in lever depression are members of the operant class.

Operant Behavior in Animals

Marc N. Branch
Psychology Department, University of Florida, Gainesville, FL, USA

Synonyms

Instrumental behavior; Instrumental performance; Purposive behavior

Definition

Operant behavior in animals encompasses activities that are influenced by their consequences. More precisely, the future likelihood of such behavior is a function of the history of consequences for that behavior. Particular classes of activities that are influenced by their consequences are called ► operants. For instance, any form of behavior that successfully results in the depression of a lever by a rat would be considered as part of the operant "lever pressing." Effective consequences are divided into two categories, those that make the behavior more likely in the future and those that make it less likely. The former are called ► reinforcers or reinforcing stimuli (akin to the everyday word "rewards") and the latter are called punishers or punishing stimuli. Reinforcers and punishers are further subdivided into two subcategories, positive and

negative. Positive reinforcers increase the subsequent probability of behavior if they are presented as a consequence, for example, presenting food to a hungry rat after it presses a lever, whereas negative reinforcers make behavior more likely when they are removed as a consequence, for example, when pressing a lever turns off an irritating loud noise. Positive and negative punishers therefore exert their effects upon presentation and removal, respectively. Behavior that is increased by experience with consequences is said to be reinforced and the process is called ► reinforcement. Conversely, decreasing behavior by means of consequences is called ► punishment. The effective consequences are functionally defined. For example, reinforcers are defined by three features. One, an operant has a consequence. Two, the operant subsequently becomes more probable. Three, the increase is due to the consequential relationship, not to the mere presentation of the consequence (e.g., consider trying to reinforce crying in a baby by pinching it when it cries). Punishment is analogously defined, the only difference being that the operant becomes less likely. Operant behavior in animals is used to model willful, voluntary behavior in humans. When consequences occur regularly (see next), either naturally (as when a door moves when pushed) or as a result of deliberate planning (as when an experimenter arranges that a lever press results in food presentation) and the behavior is affected by that relationship, it is often said that a ► contingency of reinforcement is evident.

Impact of Psychoactive Drugs

Principles and Use in Psychopharmacology

The basic techniques for establishing and studying operant behavior in animals were developed in large part by B. F. Skinner and his colleagues in the 1940s through the 1960s (see Skinner 1938). They have become a signature part of the armamentarium of psychopharmacology. Operant techniques play a prominent role in ► drug discrimination, drug ► self-administration, and ► behavioral economics. They are also used to study drug effects on sensory processes and on cognitive processes such as choice, timing, learning, and memory, as well as emotional responses such as anxiety and stress (Mazur 2006). Most of these applications of the techniques involve two important processes that characterize operant behavior. Those are (1) ► stimulus control, or discrimination (Nevin 1973), and (2) *intermittent reinforcement* via ► schedules of reinforcement (Ferster and Skinner 1957; Zeiler 1977). Before discussing these two processes, however, it is necessary to describe the conditions required to establish operant behavior.

There are two main methods for establishing operant behavior. The first is called free-operant acquisition, and the second is called shaping. In both, animals are generally studied, one at a time, in relatively barren environments. Usually, the animal is placed in a comparatively small space (sometimes called a Skinner box) outfitted with a device that the animal can move, such as a lever for a rodent or nonhuman primate or a lighted disk that can be depressed by a rodent or avian. Also available is an apparatus that permits delivery of a consequence, for example, a bit of food. In free-operant acquisition of lever pressing, for instance, the animal is initially habituated to the enclosure and it learns where the food is delivered. The experimenter then arranges the apparatus so that when the lever is initially pressed, for whatever reason, the food is immediately delivered. Under appropriately controlled conditions, the lever press is soon followed by many others and the behavior has been established for further study. The second method, shaping, can be used to establish behavior such as lever pressing, but also can be used to engender behavior that is extremely unlikely to occur if one simply waits. Shaping is also called the method of successive approximations, which provides a good description of how the procedure works. One reinforces successive approximations to the final activity. For example, suppose one wanted to train a rat to press a panel on the ceiling of its Skinner box. The first approximation might be providing a reinforcer when the rat walks to a place under the panel. Once that behavior has been established, reinforcement might then be made to depend on lifting a forepaw off the floor. The next approximation might be two paws off the floor, followed by requiring the paws to be progressively, at each step in the process, farther off the floor until the paws touch the panel.

Once operant behavior has been established it can be subjected to ► *extinction*, wherein the activity no longer results in the previously arranged consequence. Of course, the usual result of extinction is that the behavior becomes less probable over time.

Most often, operant behavior is studied under *free-operant* conditions. That is, the experiment is arranged such that after each instance of an operant, the animal is in position immediately to engage in the activity again, and the activity itself is generally of low effort and takes little time to execute. There are circumstances, however, in which the opportunity to perform the operant is limited, for example, by the use of a retractable lever. Such arrangements are usually used to study phenomena that are best examined with procedures in which independent trials can be arranged, and are called discrete-operant preparations. They are often used to study processes such as remembering and choice.

There are two characteristics of conditioned operant behavior that play a very large role in how such behavior is used in psychopharmacology. The first is that operant behavior can be brought under stimulus control, or in everyday parlance, it can be used to study discrimination among stimuli. The second is that operant behavior, once established, can be maintained with intermittent consequences. These two arrangements are often combined to produce relatively complex behavior to use when studying psychopharmacological agents.

To study discrimination using operant behavior, one needs to establish at least two different programs of reinforcing (or punishing) consequences, each associated with a distinctive circumstance. As a simple example, consider a monkey which has been trained to press a lever that results in intravenous injection of ► cocaine. To establish stimulus control one could arrange that a tone be on when pressing the lever is effective and that when the tone is off, pressing the lever results in presentation of nothing. If the monkey comes to press the lever when the tone is on and not when the tone is off, it indicates that the monkey can tell the difference between tone and no tone, that is, it can discriminate between the two stimulus circumstances. One could, by reducing the loudness of the tone, systematically determine how loud the tone needs to be for the monkey to be able to discriminate it. One could also test tones of other frequencies in order to test the degree to which the learning of the initial discrimination extends to other tones. All these, and many other processes, can be arranged so that the effects of psychoactive drugs on the behavior can be assessed.

Stimulus control can also be used to permit study of multiple activities. For example, one could in one stimulus circumstance (e.g., color of a light) study behavior that results in positive reinforcement, and when a different stimulus is present, study behavior that results in negative reinforcement. Simply by changing the stimulus, either kind of behavior can be "on call" for examination, and it can be accomplished in individual animals.

The "experiment" about discrimination summarized earlier would likely not be conducted exactly as described, but instead would probably involve intermittent reinforcement. That is, instead of reinforcing every lever press when the tone is on, only some presses would be reinforced. Two related experimental advantages accrue to the use of intermittent reinforcement. One, relatively large samples of behavior, often on the order of hundreds or even thousands of instances of an activity, can be generated in a single experimental observation period or session. Two, because of the large number of instances engendered it is possible to use frequency or rate of behavior as a measure, and that measure can vary over a very wide range of values, from near zero to hundreds per minute, yielding a potentially sensitive index.

Intermittent consequences can be arranged in myriad ways, with the various arrangements called ► *schedules of reinforcement*, which essentially are rules that describe which instances of behavior (usually called responses) will result in reinforcement. Schedules of reinforcement, interestingly, can have substantial influences on how a psychopharmacological agent acts. For example, in an influential experiment, Dews (1955) discovered that the schedule can influence whether a drug enhances or decreases a particular activity. In his study, pigeons pecked a lighted disk to earn access to food. In one condition, every 50th peck resulted in food presentation; in another, the first peck, after 15 min had elapsed, was followed by the opportunity to eat. Sodium ► pentobarbital was administered to birds under either condition. The surprising result was that a dose of the drug that greatly decreased pecking under the latter circumstance resulted in increases under the former. That is, depending on the reinforcement schedule, the drug acted as either a stimulant or depressant, for the same activity, key pecking, and for the same reason, to get food. Many other examples of interactions between reinforcement schedules and drug effects exist (e.g., Kelleher and Morse 1968). A final advantage of using intermittent reinforcement is that accumulated research indicates that under a wide variety of particular reinforcement schedules for free-operant behavior, reproducible temporal patterns and rates of behavior can be reliably established in individual animals (Ferster and Skinner 1957).

A final characteristic of operant behavior, especially as employed in the laboratory, is concerned with conditions that alter the effectiveness of consequences. Such factors are called motivational operations or ► establishing operations (Michael 1993). For example, to make food more effective as reinforcement, one often makes the animal hungry by not letting it eat for some time prior to the experimental test. Negative reinforcers, such as loud noises or irritating electric shock, are often made effective by their mere presentation, but how well they function depends also on their intensity and duration, both of which may be considered establishing operations.

Operant Chamber

Definition

Experimental apparatus to record the behavior of animals. The quintessential operant chamber is the "Skinner Box" designed by B.F. Skinner (1904–1990) to study instrumental behavior in animals, which typically has two response levers (for a rat) or pecking keys (for a pigeon), arranged side by side on one of the walls, and a method for delivering reinforcers (such as a dispenser of food or liquid). Modern chambers, which are controlled by computer, may have alternative operandi, such as poke holes or touch screens, and a variety of optional stimuli, including visual, auditory, and olfactory.

Operant Conditioning

Definition

Operant conditioning is the use of environmental consequences of reinforcement and punishment to modify the occurrence and form of behavior. The strength and frequency of a response can be controlled by the schedule of reinforcement and the contingent presentation of reinforcing or punishing stimuli. Hedonic properties such as pain and pleasure are often attributed to such stimuli but do not enter into their definitions, which are based upon observed changes in behavior such as the acquisition of new patterns of simple or complex behavior or the suppression of existing behaviors.

Operant Response

Definition

An operant response is a behavior that acts on the environment and is modifiable by its consequences. When behavior is modified by its consequences, the probability of that behavior occurring again may either increase (in the case of reinforcement) or decrease (in the case of punishment).

Opiate

Definition

This term is now mostly historical ("opioid" is now more commonly used) but strictly refers to drugs derived directly from opium. This includes morphine (the major

alkaloid in opium), codeine, and thebaine. Drugs derived by chemical modification of morphine and codeine are also sometimes referred to as opiates. These include heroin, oxymorphone, and oxycodeine.

► Opioids

Opioid

Definition
Any drug or endogenous substance that acts on classical opioid receptors (mu-, delta-, or kappa-receptors).

Opioid Addiction

► Opioid Dependence and Its Treatment

Opioid Analgesics

Synonyms
Narcotic analgesics; Narcotics

Definition
This is a group of natural and synthetic substances that have morphine-like pharmacological properties that are brought about through their actions on opioid receptors. Morphine is derived from the opium poppy (*Papaver somniferum*). Opiates are a group of naturally occurring compounds including ► morphine and related opium alkaloids; the name originally indicated their derivation from opium and they were also known as analgesics, because of their ability to relieve pain. The term "opioid" was later applied to synthetic substances with morphine-like effects but which were not from opium and had distinct chemical structures. The label opioid analgesic is now used to include all of these substances, regardless of whether they are of natural, synthetic, or semisynthetic origin.

Opioid Dependence and Its Treatment

Annemarie Unger, Gabriele Fischer
Department of Psychiatry and Psychotherapy, Medical University of Vienna, Vienna, Austria

Definition

Opioid Dependence
Opioid dependence is a medical condition characterized by an individual's preoccupation with and strong desire to take opioids coupled with persistent drug-seeking behavior. It involves a sense of compulsion to consume the psychoactive substance, an inability to stop using it or to control the mode of drug-taking behavior. Obtaining the drug takes on high priority and the condition is frequently accompanied by psychiatric comorbidity and multiple substance abuse, resulting in numerous social, psychological and biological problems. These include high risk behavior such as prostitution and drug-related crime, an increased risk of obtaining infectious diseases such as hepatitis and HIV through shared use of needles and sexual activity, leading to an increased mortality rate; accidental deaths by fatal overdose and suicides also contribute to these. According to the ► DSM-IV-TR (*Diagnostic and Statistical Manual of Mental Disorders*, 4th edn, text revision) clinical guidelines, three of the six following characteristics must be fulfilled for a definite diagnosis of dependency (American Psychiatric Association 2000).

1. The individual shows a sense of compulsion or strong desire to take the drug
2. The individual has difficulty in controlling drug-taking behavior in terms of its onset, termination, or levels of use

3. Stopping or reducing drug use results in a physiological withdrawal state with the characteristic ► withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms
4. Evidence of ► tolerance, such that increased doses of the drug are required to achieve the effects originally produced by lower doses
5. Progressive neglect of alternative pleasures or interests because of drug use, increased amount of time necessary to obtain or take the drug or to recover from its effects
6. Persisting with drug use despite clear evidence of overtly harmful consequences, such as harm to the liver, depressive mood states or impairment of cognitive functioning

Role of Pharmacotherapy

Opioids: Psychopharmacology and Receptors

Definition of Opioids

Opioid (meaning "similar to opium") is a collective term for a group of heterogeneous natural and synthetic substances displaying morphine-like properties that unfold their actions on opioid receptors located in the brain, the spinal marrow and peripheral organs such as the intestinal tract.

There are different subdivisions and groups of opioids: *Exogeneous opioids* may be divided into three groups:

1. *Natural opioids* referred to as "opiates" are substances that naturally occur in the opium poppy; examples are morphine, codeine and thebaine. In terms of their chemical property they are alkaloids and can be extracted from the milk of the opium poppy (*Papaver somniferum*). ► Morphine is considered the prototype opioid.
2. *Semisynthetic opioids* such as ► hydromorphone or heroin are derived from natural opioids through a chemical process.
3. Numerous *fully synthetic opioids* have been produced pharmaceutically to exploit their analgesic effects for medical purposes, at the same time trying to minimize side effects. ► Fentanyl, ► tramadol and ► methadone are examples of these.

► *Endogenous opioids* are opioid peptides (endorphins, endomorphines and enkephalins) that are naturally present in the human body and play a role in stress reactions and pain suppression.

Opioids can be consumed intravenously, orally, sublingually, nasally and by smoking.

Opioid agonist drugs have their main indication in the treatment of pain; other less prominent indications include suppression of coughing and sleep induction, hence the name "narcotic" drug. In the treatment of severe cases of diarrhea the constipation induced by opioids can be a therapeutic measure. In addition, opioid maintenance therapy is considered the standard therapy for opioid dependence.

Opioid Receptors

At present, three different ► G-protein-coupled receptors at which opioids unfold their action are known. They are referred to as the delta (δ), kappa (κ) and mu (μ) receptors. A fourth receptor, the nociceptin/orphanin FQ (N/OFQ) receptor, has been postulated and is subject to investigation. Most opioid drugs produce their effects by acting as agonists at the μ receptor, although some also act at the κ receptor, whereas the therapeutic potential of the δ receptor is still unclear. Located in the brain, the spinal marrow and in peripheral organs such as the intestinal tract, receptors are activated by opioid agonists that initiate central and peripheral effects through the production of G-proteins. The fact that different receptors mediate different profiles of responses may be explained by their differing distributions throughout the central nervous system (Brunton et al. 2007).

Central effects can include analgesia, euphoria, sedation, muscular rigidity, anxiolytic effects, cramps, hypothermia, miosis, respiratory depression, antitussive effects, antiemetic effects, lowering of blood pressure and bradycardia. Peripheral effects can be obstipation, delayed emptying of the stomach, disturbance of the bile flow, urinary retention and the inhibition of labor.

Development of Opioid Dependence

Biological Factors

Despite their original intended purpose as therapeutic agents, their highly addictive nature fostered by initial euphoria and strong physical withdrawal make opioids a candidate for abuse. An estimated total of eight million people worldwide abuse opioids and the use continues to increase. The illicit abuse of opioids and opioid dependence are a major public health problem worldwide. In recent years, an increased rate of abuse and dependence on opioids has been noted in Eastern European countries, whereas a decrease has been reported for the West, possibly due to more frequent drug trafficking across the European Balkan route.

Opioid-induced euphoria, described by opioid dependents, is mainly attributable to the effects of the neurotransmitter ▶ dopamine, which is released from dopaminergic neurons that exert their mechanism of action in the nucleus accumbens, located in the forebrain. Even a single exposure of morphine produces an effect on dopamine neuron activities and a desensitization of opiate receptors. Repeated exposure to morphine induces substantial adaptive changes in cellular and synaptic functions in the mesocorticolimbic system. These mechanisms are likely to be part of the neurobiological basis for the development of ▶ dependence.

Another biological determinant critical to addictive potential is the speed at which a drug crosses the ▶ blood-brain barrier. Heroin, for instance, penetrates the brain more rapidly than morphine because it is more lipid-soluble, accounting for subjective reports that following intravenous administration, the euphoric experience is particularly intense.

Opioids are among the most potent drugs with regard to ▶ physical dependence and withdrawal. When administration of the drug is discontinued or an antagonist is given, a withdrawal or abstinence syndrome is manifest, characterized by diarrhea, vomiting, fever, chills, cold sweats, muscle and bone aches, muscle cramps and spasms, restless legs, agitation, gooseflesh, insomnia, nausea, watery eyes, runny nose and nightmares.

Psychosocial Factors

There is a strong overlap between ▶ comorbid mental disorders such as borderline and antisocial personality disorder, ▶ attention deficit disorder (ADHD), ▶ post traumatic stress disorder (PTSD), affective disorders and the development of opioid dependence. Predictors for the development of opioid dependence include a history of sexual or physical abuse, cohabitation with an opioid dependent partner, and an upbringing in an environment permissive to substance abuse.

With regard to gender, men dominate in the prevalence of opioid dependence, though the gender gap is narrowing and women show a younger age of initial use and a faster progression to addiction. Further gender-specific differences are that opioid-dependent men are more likely to stay employed than women, while women tend to receive more social welfare and engage in prostitution. However, men are more prone to engage in general drug-related crime and drug dealing. Though women have a faster progression to treatment, they have a lower retention rate due to gender specific barriers such as higher stigmatization, intimate partner violence, fear of losing custody of their children and a higher rate of comorbid affective disorders. Treatment settings designed for a predominantly male population cannot adequately accommodate for gender specific social factors affecting women.

Consequences of Opioid Dependence

Somatic comorbidities generally result from poor standards of living and high- risk sex behavior and needle sharing; poor dental status, high rates of infectious disease such as HIV and hepatitis, endocarditis and abscesses are the consequence. Studies have shown that women have a higher risk for HIV infection than men because of higher impulsivity and exposure to health-compromising situations including homelessness, condom nonuse and exchange of sex for money and/or drugs (Gowing et al. 2008). Furthermore, suicide, accidental death and overdose contribute to a mortality rate 13–17 times higher than the general population, with slightly higher rates for men.

Treatment of Opioid Dependence

Though opioid dependence is a chronic reoccurring illness, individually tailored comprehensive treatment can allow patients to lead normal lives. There are three main branches of treatment: withdrawal/detoxification, opiate-antagonist maintenance and opioid agonistic maintenance treatment. Currently, the most effective treatment for opioid dependence is opioid agonist maintenance therapy (Amato et al. 2008).

Withdrawal/Detoxification – Drug-free

Medically assisted detoxification is successful only when it is seen as the first step in a series of behavioral interventions and counseling. Withdrawal alone will result in the same outcome with regard to relapse as having no treatment at all. Detoxification can be handled in different ways, for instance in an outpatient setting, where gradual ▶ buprenorphine taper is an option, whereas inpatient detoxification programs proceed faster and usually involve administration of ancillary medication such as clonidine, or its further development ▶ lofexidine. There is no conclusive evidence to show that either outpatient or inpatient treatment is more effective (Day et al. 2005).

Ultrarapid detoxification is a treatment in which ▶ naltrexone is administered to patients under deep sedation or anesthesia; because of a high risk of cardiopulmonary complications, this practice is not recommended.

Opiate-Antagonist Maintenance

Naltrexone is a long-acting pure opiate receptor antagonist that is used in rehabilitation programs to ensure abstinence from opioids and should be prescribed only

to addicts who have already been detoxified, to prevent relapse. Patients should be opioid free for at least 3 days before receiving naltrexone, as it can lead to unintentional rapid detoxification in heroin addicts, precipitating massive withdrawal symptoms.

Opioid Maintenance Therapy

Agonist maintenance therapy is considered first line treatment in opioid dependency and leads to statistically significant reductions in illicit opioid use, risk behavior related to drug use such as injecting and sharing injecting equipment, and an improvement in social and psychological quality of life (Amato et al. 2008; Gowing et al. 2008). The most widely used replacement, ▶ methadone, shows a statistically superior effect in reducing heroin use and retaining patients in treatment, compared to medication-free programs (Mattick et al. 2002).

Proper medication-assisted treatment of opioid dependence should ensure that patients do not experience any withdrawal symptoms, or feel drugged or high during a time period of 24 h; the medication used should be present in the blood in levels sufficient to maintain normalcy over a 24 h period.

With regard to dosage regimen, drug-to-drug interactions must be taken into consideration. Opioid drug-to-drug interactions can, for example, occur with CNS depressant drugs such as ▶ benzodiazepines or ▶ alcohol and are additionally frequently evoked by a combination with substances that inhibit or induce the activity of the cytochrome P450 enzyme system. Metabolism, poor absorption, changes in urinary pH, concomitant medications or drug abuse, diet, physical condition, pregnancy and vitamins may influence medication levels and the rate of elimination (Payte et al. 2003).

Special target populations may require additional planning in therapeutic dosing regimens. In the case of opioid-dependent pregnant women, changes in metabolism due to enzyme induction usually require a gradual dose increase or split-dosing around the third trimester. The benefits of methadone maintenance during pregnancy compared to detoxification have been well established. Detoxification is usually associated with relapse and marked fluctuations of serum methadone levels, both of which are unfavorable to fetal outcome.

Psychosocial Treatments in Addition to Pharmacological Therapy

In the treatment of opioid dependence, ideally, behavioral interventions and a comprehensive all-round approach with a multidisciplinary team including social workers, should accompany psychopharmacological treatment. Psychosocial interventions can include different psychotherapeutic methods such as cognitive behavioral therapy (CBT), interpersonal therapy, subliminal stimulation, supportive-expressive therapy and contingency management approaches such as voucher incentives. However, a review of the literature shows that adding psychosocial interventions such as counseling, social work and psychotherapy to maintenance therapy on a random basis has limited beneficial effect on retention rate, opiate use or psychiatric symptoms. The only overall benefit of psychosocial support pertains to an improvement of the number of participants still abstinent at follow-up (Amato et al. 2008).

An important aspect when evaluating the effectiveness of treatment, however, is that a chronic relapsing disease like opioid dependence should have outcome criteria that take its nature into account. For instance, effect measurement should be done during treatment and not after discharge, especially when acute relapse episodes remain untreated.

Substances Available for Maintenance Treatment

Examples of medications commonly used for maintenance treatment are methadone, buprenorphine, ▶ buprenorphine–naloxone and the comparatively less frequently used ▶ l-alpha-acetyl-methadol (▶ LAAM) and ▶ slow-release morphines (▶ SROMs).

Methadone

Methadone is a full μ receptor agonist and is the oldest, most common, and widely used substance for substitution treatment. It is a racemate available in tablet form, as an injection, or as oral solution.

Methadone has been used internationally since 1965 and is the best studied substance available for opioid maintenance in terms of clinical effectiveness (Clark et al. 2002). It has been comprehensively shown that methadone is an effective treatment in reducing illicit opioid consumption, reducing high risk behavior such as needle sharing and increasing rates of treatment retention (Mattick et al. 2002). It has been demonstrated that higher dosages of methadone maintenance medication lead to improved outcome in terms of treatment retention and decreases in illicit opioid use.

For methadone maintenance treatment (MMT) the medication is administered orally; concentrations in serum reach a peak level 3–5 h after administration; it has a ▶ half-life of 24–36 h (Brunton et al. 2007). Side effects can be increased sweating, mood swings, depression, lack of energy, weight gain, edema, loss of libido and prolonged QTc time in the ECG.

Combined use with other substances that can influence the QTc time in the ECG such as ► antipsychotics, antiarrhythmics, antibiotics, ► tricyclic antidepressants and antifungal medication should be avoided whenever possible. Cardiac safety recommendations include obtainment of cardiac histories, a pretreatment ECG and follow-up ECGs within 30 days and annually. Other interactions involve diuretics, antibiotics, antihypertensives, HIV medicines and other antiviral medicines, other narcotic medications and drugs against epilepsy; interactions may lead to increase in serum concentration and overdose.

Buprenorphine

Buprenorphine is a partial μ-opioid-receptor agonist and a κ-receptor antagonist that was first marketed in the 1980s as an analgesic. For opioid maintenance therapy, comprehensive treatment experience has been available in Europe and Australia since the mid-1990s and in the United States, the American Food and Drug Administration approved buprenorphine and a buprenorphine/naloxone combination product, in 2002. Because of its partial antagonism, buprenorphine counteracts the effects of concomitant opioids taken by the patient and, unlike other opioids, does not produce tolerance. It has less severe withdrawal effects than methadone, making discontinuation easier (Gowing et al. 2006).

In a systematic review, buprenorphine was found to be inferior to methadone in terms of suppressing heroin consumption and retention rates in treatment when both were administered at adequate dosages (Mattick et al. 2008). However, buprenorphine is safer than methadone, especially for patients with coexistent benzodiazepine dependence, as side effects such as respiratory depression develop only to an uncritical degree even after extreme overdosing and it has lower dependence-liability. The treatment of buprenorphine overdose with naloxone needs special medical observation because of the tight receptor binding of buprenorphine.

Buprenorphine is administered as a sublingual tablet. Resorption takes place through the oral mucosa. Peak serum levels are reached after 1–3 h, after which it remains effective in the body for up to 48 h. Because of this long duration of action, dosing intervals of two days are optional. Side effects can include nausea, vomiting, drowsiness, dizziness, headache, itch, dry mouth, meiosis, orthostatical hypotension, difficulty with ejaculation, decreased libido, urinary retention, and constipation.

When patients are induced on buprenorphine, caution should be taken because, due to its ► partial agonist/antagonist activity, it may precipitate significant withdrawal symptoms if the first dose is administered too soon after the intake of other opioids.

Buprenorphine–Naloxone Combination Tablet

The buprenorphine–naloxone combination tablet is a further development of buprenorphine invented with the intention of reducing intravenous misuse of the medication. Naloxone has low oral bioavailability and so does not influence the mechanisms of buprenorphine action when taken orally. However, when buprenorphine/naloxone combinations are dissolved and injected intravenously, opioid agonist actions are blocked by naloxone and can, depending on which drugs have been misused previously, precipitate unpleasant and dysphoric symptoms of opioid withdrawal. Buprenorphine–naloxone combination tablets contain buprenorphine with naloxone at a ratio of 4:1. The buprenorphine–naloxone combination tablet should not be administered to pregnant and nursing women, as naloxone exposure may alter fetal and maternal hormonal levels.

LAAM (L-alpha-acetyl-methadol)

LAAM is a derivative of and has a similar mode of action as methadone. It was first approved in the USA in 1993 and in several European countries in 1997. The most significant difference between the two substances is that LAAM has a longer duration of drug effect, lasting up to 72 h; therefore it can be administered every 2–3 days. The plasma half-life is only 14–37 h, but the substance is metabolized into two active metabolites, nor-LAAM and dinor-LAAM, which have a half-life of 24–38 h and 66–89 h respectively. All three substances exert their mechanisms of action on the μ-receptor; however, nor-LAAM is five times as potent as the others. It may be more effective at reducing heroin dependence than methadone, but it is associated with adverse effects such as cardiac arrhythmias and QTc prolongation, some of which may be life-threatening. Following ten cases of death caused by LAAM, it was withdrawn from the market in Europe on the recommendation of the European Agency for the Evaluation of Medicinal Products (EMEA). In the USA, the US FDA has recommended that LAAM should not be used as first line therapy.

Slow Release Oral Morphine – SROM

Morphine on its own is not recommendable for maintenance therapy as it has low oral bioavailability, a half-life of only 2–3 h, and a very short time of drug effect. SROMs are a group of pure opiate-agonists that are products of morphine (i.e., morphine sulfate and morphine hydrochloride) with retarded release characteristics. SROMs are

available as tablets (i.e., morphine hydrochloride) or capsules containing micro-granular compounds (i.e., morphine sulfate) and may be more tolerable than methadone in terms of side effects or as an option for patients with an inadequate suppression of withdrawal symptoms under methadone. SROMs hold the advantage of having a longer half-life and time of drug effect lasts up to 24 h. They can therefore normally be administered once daily, except to "fast metabolizers" who need at least twice daily administration. They hold the disadvantage that urine toxicology will not detect a concomitant consumption of heroin because morphine is a metabolite of heroin.

Intravenous misuse of SROMs can lead to an increased risk of pulmonary embolism, attributable to the wax particles that are briefly liquefied in the cooking process and then solidify again in the body. Patients maintained on SROM must be warned about misusing the substance and examined for signs of needle puncture. The use of SROMs for opioid maintenance treatment is registered only in some European countries but international interest is rising.

Conclusion

Internationally, opioid maintenance therapy has been proved doubtlessly and conclusively as the most effective treatment for opioid dependency. It reduces illicit opioid use, lowers mortality rate and criminal behavior, and leads to improved health and social conditions of chronic opioid-dependent individuals by increasing rates of retention in treatment. The nature of opioid dependence as a psychiatric disorder needs to be considered carefully and psychosocial interventions may accompany medical treatment if indicated.

After declining for several years, new demands for the treatment of opioid dependence are on the rise in Europe and, from a public health stand point, the availability of treatment needs to be improved further. Treatment coverage worldwide could change for the better in the light of the recent approval of office-based treatment in the USA, where, in contrast to Europe and Australia, both continents with a long-lasting tradition in office-based opioid maintenance treatment, only specialized addiction clinics could provide treatment until recently.
