Opioid Maintenance Treatment

Definition

Opioid maintenance treatment is an evidence-based treatment where patients with opioid dependence are provided with opioid agonistic replacement medication. Proper medication-assisted treatment of opioid dependence should effect that patients do not experience any withdrawal symptoms, or feel drugged or high during a time period of 24 h.

Opiates

Definition

The term opiate refers to drugs extracted from opium, i.e., morphine and codeine, whereas an ▶ opioid is any drug or endogenous agent that acts as an ▶ agonist or ▶ antagonist on one of the three major (classical) opioid receptors.

Pharmacological Properties

Opium that contains the principal ▶ opiate, morphine, has been used for its powerful pain relieving (analgesics), somnorific, and euphoric properties since antiquity (Brownstein 1993). Since the discovery of opioid receptors in 1972 and the first ▶ endogenous opioid peptides in 1975 much has been learned about the anatomy and function of opioid actions. However, much remains to be discovered about the function of endogenous opioids and opioid drugs in specific populations of neurons and neural systems. In addition to therapeutically valuable actions on the sensory and affective components of pain, opioids also produce profound effects on neural systems involved in respiration, reward and learning, and many other behavioral and physiological processes. Current knowledge of these systems is summarized in the following sections.

Endogenous Opioid Peptides

The general distribution of opioid peptides was reported soon after the discovery of ▶ enkephalins in 1975 (Khatchaturian et al. 1983). Genes encoding four endogenous opioids and opioid-related peptide precursors have since been identified in the mammalian genome, and the products of all but one act as agonists on the classical opioid receptors: ▶ mu (μ- or MOR, aka OP_3, MOP), delta (δ- or DOR, aka OP_1, DOP), and ▶ kappa (κ- or KOR, aka OP_2, KOP) ▶ receptors. As with other peptide hormones and neurotransmitters, the final active peptides are cleaved at dibasic amino acid sites from large polypeptide precursors by processing enzymes. The precursors such as pro-opiomelanocortin (POMC), preproenkephalin, and prodynorphin express the sequences for β-▶ endorphin, enkephalins, and ▶ dynorphins, respectively. POMC contains a single copy of β-endorphin (which can be lyzed to shorter, potentially active endorphin fragments) along with other biologically important hormones/neurotransmitters including the major ▶ stress hormone, adrenocorticotrophic hormone (ACTH). Preproenkephalin encodes multiple copies of two enkephalin pentapeptides, leucine-enkephalin and methionine enkephalin (longer active peptides can be found in some tissues). Prodynorphin contains the sequences of α-neoendorphin, dynorphin-A and dynorphin-B, as well as "big dynorphin," which is the uncleaved sequence of dynorphin-A and dynorphin-B (the dynorphin A and B peptides are separated by one pair of basic amino acids in prodynorphin).

All the endogenous opioid peptide families described above contain a canonical N-terminal amino acid sequence, N-Tyr-gly-gly-phe, followed by one to 26 other amino acids. The extended amino sequences, which vary in length in different cells, confer differential selectivity among the three major opioid receptors as well as potentially modifying susceptibility to degradation by peptidase enzymes such as "▶ enkephalinase" (EC 3.4.24.11). It should be noted that deletion (des-tyr) or chemical modification of the N-terminal tyr (N-acetylation occurs for a substantial proportion of the β-endorphin from the pituitary) renders all opioid peptides inactive at opioid receptors. These peptides subserve endocrine (e.g., β-endorphin from the pituitary; pro-enkephalin from the adrenal medulla) and paracrine (opioid peptides are expressed in the immune system;) functions in addition to their well known effects on the nervous system.

The most recently discovered opioid-related peptide family, orphanin-FQ or nociceptin (usually denoted N/OFQ), is distantly related to prodynorphin but contains an N-terminal Phe rather than Tyr. It is the endogenous ligand of the orphan opioid receptor Opioid-receptor-like-1 (ORL1, aka NOP, NOR). It has high affinity and selectivity for ORL1 but interacts very weakly with the KOR (see below). The N/OFQ-ORL1 system is not widely considered to represent an "opioid-system" because classical opioid drugs and endogenous opioids do not interact significantly with ORL1. It is therefore not considered in detail here.

Two additional endogenous opioids (endomorphin 1 and endomorphin 2) have been purified from mammalian tissue. Although these tetrapeptides are very selective for MOR and can be visualized in neurons immunohistochemically (which is not proof of presence), no genomic sequences encoding endomorphin 1 and

endomorphin 2 have been identified; so their physiological relevance will remain uncertain until a biological synthetic mechanism is identified.

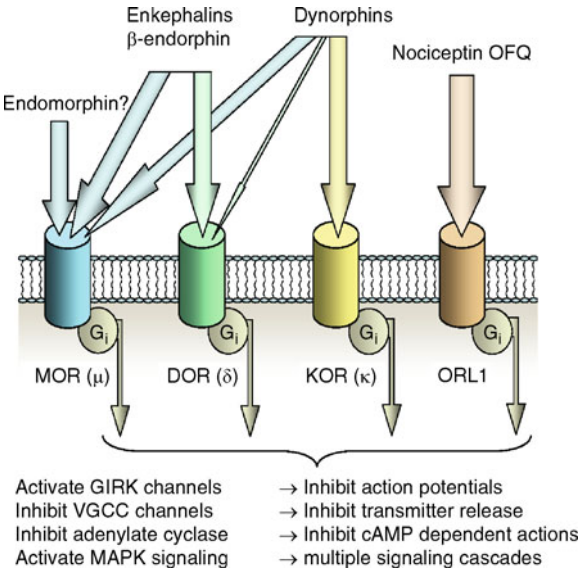
Opioid Receptors

MOR, DOR, and KOR opioid receptor types were first identified using pharmacological approaches. σ (sigma)-Opioid receptors also were proposed, but structural and pharmacological studies indicate that ► σ-receptors are not part of the opioid family. Three independent genes encoding MOR, DOR, and KOR have been identified, firmly establishing that these are the three principal opioid receptors. Soon after the isolation of these genes a fourth opioid-receptor like (ORL1) sequence was identified by homology screening of cDNA libraries for sequences resembling the other receptors. The biochemistry and regulation of opioid receptors are extensively reviewed elsewhere (e.g., Waldhoer et al. 2004). Briefly, the amino acid sequences of all opioid receptors (and ORL1) are about 60% identical with each other. They belong to a small subfamily of G-protein coupled receptors (► GPCR) that includes the ► somatostatin receptors. Multiple RNA ► splice variants have been identified, in particular MOR1A, B, and C (the biological relevance of other putative splice variants is uncertain). The B and C variants differ in the amino acid composition at the C-terminus and affect receptor regulatory events such as receptor distribution, ► internalization, and recycling rates but have little or no influence on drug selectivity. Opioid receptor subtypes, such as μ_1 and μ_2 receptors, also have been proposed, but they remain tentative. Splice variants of DOR or KOR may explain differential pharmacology of proposed receptor subtypes (e.g., putative δ1 and δ2 receptors), but these have not yet been established. Formation of ► hetero-oligomers between different opioid receptor types could also explain experimental results claiming existence of opioid receptor subtypes. As for other GPCRs, oligomer formation of opioid receptors appears to be obligatory for membrane expression and function (Milligan and Bouvier 2005). While homo-oligomers are probably the most commonly formed and appear to explain most opioid pharmacology in vivo, there is growing biochemical and pharmacological evidence that different subtypes of opioid receptors can form hetero-oligomers in isolated experimental systems and perhaps in vivo.

Interaction of Opioids with Opioid Receptors

Some authors have attempted to ascribe three distinct signaling systems to the three different opioid peptide families matching them respectively with the three receptor types. This is incorrect because each opioid peptide family can interact with more than one receptor type, as summarized in Fig. 1. Among the three peptide groups and receptors, the dynorphin-KOR pair is the best candidate to be defined as a distinct signaling system because dynorphin is the only endogenous opioid that interacts significantly with KOR. However, dynorphins are also potent MOR agonists and can potentially be metabolized to shorter and less selective dynorphin fragments (including leucine-enkephalin), which interact potently with both MOR and DOR. It should also be noted that early studies suggesting that enkephalins are the endogenous ligands for DOR were premature because they were subsequently shown to be nearly equi-effective agonists at both MOR and DOR.

A large number of small, organic molecule agonists for opioid receptors have been developed since the first isolation of morphine from opium in 1806 and synthesis of heroin in 1898 (Brownstein 1993). Nearly all of the small molecule agonists in clinical use are selective for MOR although experimental opioid agonists selective for DOR and KOR have been developed. A more limited



Opioids. Fig. 1. Selectivity profiles of the major endogenous opioids for the different opioid receptors are shown with thickness of the arrows indicating relative selectivities or potencies for MOR (blue), DOR (green), KOR (yellow) and ORL1 (orange). All endogenous opioids except nociceptin/OFQ (which is not generally considered an opioid) can act as agonists at more than one opioid receptor type. All opioid receptors couple to Gi proteins to modulate the major signaling mechanisms shown.

range of small molecule antagonists exists, although some of these commercially available antagonists display high receptor type selectivity. Most commercially available small molecule opioids have the advantage that they readily penetrate the central nervous system following systemic injection. However, some have been specifically developed to avoid crossing the ▶ blood-brain barrier (e.g., methylnaloxone). The optimal selection of an opioid for a given experimental purpose depends on a number of considerations, so recommendation of particular drugs for an opioid receptor type is beyond the current scope. The major pharmacological societies provide and regularly update comprehensive guides to the most appropriate selective agonists and antagonists for each receptor. These include The International Union of Basic and Clinical Pharmacology (IUPHAR) (http://www.iuphar-db.org/index.jsp) and the British Pharmacological Society (http://www3.interscience.wiley.com/journal/122206250/issue).

Opioid Receptor Signaling and Regulation

As shown in Fig. 1, all opioid receptors when activated by an agonist transduce intracellular signals via activation of inhibitory G-proteins. The major consequence of opioid receptor activation in neurons is inhibition in both cell bodies and nerve terminals. Downstream signaling includes modulation of many biochemical and gene regulatory cascades – a full description of which is beyond the current scope (see however, Williams et al. 2001; Waldhoer et al. 2004). Briefly, while subtle variations occur among the specific G-proteins activated by different receptor types (and perhaps hetero-oligomers), all opioid receptors activate Gi-proteins, which leads to the release of GTP bound active Giα subunits and Gβγ subunits from the receptor. The major immediate consequence (within ~50 ms of receptor activation) is inhibition of neuronal excitability via Gβγ subunit inhibition of ▶ voltage-gated calcium channels (VGCCs; particularly $Ca_V2.2$–2.3) and activation of ▶ G-protein coupled inwardly rectifying potassium channels (GIRKs) in the local membrane. Inhibition of VGCCs in nerve terminals can contribute to inhibition of neurotransmitter ▶ release probability upon invasion of action potentials. Other ionic channels and biochemical effects (e.g., inhibition of ▶ cAMP formation) also contribute to presynaptic inhibition. Free Gβγ subunits may also activate (more slowly) components of protein kinase cascades. Giα-subunits inhibit most isoforms of adenylate cyclase that are expressed in many types of neurons. Other cascades are modulated by the opioid receptor trafficking and internalization that occurs after activation in an agonist dependent manner (Waldhoer et al. 2004). It should also be noted that many of these mechanisms can contribute to the cellular and ▶ synaptic plasticity of signaling that are associated with ▶ tolerance, ▶ physical dependence, and ▶ addiction following chronic opioid treatment (Williams et al. 2001).

The complexity produced by multiple opioid receptor types and signaling mechanisms requires that opioid actions and adaptations in different neural systems be determined on a case by case basis. While the direct effects of opioids on cell bodies and synapses are almost invariably inhibitory, activation of neural systems can be the net outcome when the dominant opioid effect is localized to inhibitory interneurons and synapses. For example, MOR activation in the ▶ ventral tegmental area enhances ▶ dopamine release because MOR are located on inhibitory interneurons that synapse on dopaminergic neurons. This type of disinhibition is common to opioids. Thus, localization of opioid receptors to a particular structure provides little information about function without an understanding of the local cellular circuitry.

Opioid Receptor Distribution

Opioid receptors are found throughout the central and peripheral nervous systems. Some of the peripheral tissue locations such as the guinea pig ileum and mouse vas deferens are well known because of their use for many decades as assays for opioid receptor activity. Opioid receptor expression in the gut largely accounts for constipation, a major side effect of MOR agonists. Opioid receptors are also found on primary afferent nociceptors and immune cells (Stein et al. 2003).

MOR, DOR, and KOR can be found from the cerebral cortex to the spinal cord. The distribution of opioid receptors revealed by in situ hybridization, ligand binding, and immunohistochemsitry (Mansour et al. 1995) is so extensive that describing the many brain structures with receptors is more tedious than useful. This point is highlighted by a list of the structures in which opioid receptors have been reported (Table 1). High levels of MOR and KOR are found from the cerebral cortex to the dorsal horn of the spinal cord. DOR distribution also is extensive, but more limited than MOR and KOR. However, recent studies showing that DOR are mobilized by environmental stimuli (Cahill et al. 2007) indicate that DOR have a much broader distribution than previously thought. For example, chronic administration of morphine or prolonged stress stimulates the movement of DOR in the periaqueductal gray (PAG) from intracellular stores to the plasma membrane. Although previous studies did not report DOR in the PAG, functional membrane receptors can be found under these conditions. Thus, the

Endogenous Opioid Distribution

One would expect the distribution of ▶ endogenous opioids to match closely the distribution of opioid receptors. There is much overlap, but a clear one-to-one relationship between opioid terminals and receptors is not always evident. Of course, endogenously released opioids may also act by ▶ volume transmission and therefore have a greater spatial range of influence than a single point to point synapse (see Williams et al. 2001). Opioids derived from POMC are synthesized in just a few sites, but the terminal fields of these neurons are widely dispersed (Table 2). By contrast, neurons that produce opioids from proenkephalin and prodynorphin tend to be local interneurons (Khachaturian et al. 1993). These neurons are found throughout the central nervous system (Table 3).

Behavioral Effects of Opioids

Given the wide distribution of opioid peptides and receptors, it is not surprising that opioids influence many behaviors. These include the inhibition of pain (analgesia), reward and addiction, mood, eating and drinking, sexual activity, sedation, thermoregulation, cardiovascular function, respiration, gastrointestinal transit, and nausea (Bodnar 2008). Most of what is known about these behavioral effects is derived from studies in which opioid drugs are administered. Administration of opioid receptor antagonists have almost no effect on ongoing behavior indicating that tonic release of endogenous opioids has a negligible impact on behavior in most circumstances but more subtle effects have been determined from gene knockout studies (Kieffer and Gaveriaux-Ruff 2002). For example, administration of the opioid receptor antagonist naloxone does not enhance pain sensations except when used to reverse environmentally induced antinociception or to precipitate ► withdrawal from chronic opioid administration. A full description of the range of behaviors linked to opioids would require an entire book (Bodnar 2008). This section provides a brief description of a few key opioid receptor-mediated effects and identifies the brain structures contributing to these effects. Given that the primary medical use of opiates is the inhibition of pain, the role of opioids in pain inhibition will be highlighted. Opiates also are widely abused so the role of opioids in reward and addiction will be described briefly.

Analgesia

Administration of agonists for all three of the primary opioid receptors (MOR, DOR, and KOR) has been shown to produce analgesia, and this has been confirmed by extensive gene knockout studies (Kieffer and Gaveriaux-Ruff 2002). However, the best and most commonly used opiates for the treatment of pain act almost exclusively via the MOR receptor. Morphine, heroin, and other derivatives such as meperidine (Demerol), ► fentanyl, and ► codeine are common MOR receptor agonists with potent analgesic effects.

MOR agonists (and to some extent DOR and KOR agonists) produce analgesia via both inhibiting ascending pain transmission and activating descending pain modulatory pathways. MOR agonists produce profound analgesia when applied directly to the spinal cord (used clinically in humans) because MOR is expressed on both the nerve terminals of nociceptive afferent nerves and primary transmission neurons in the dorsal horn of the spinal cord. The principal descending pathway through which MOR agonists produce analgesia runs from the PAG to rostral ventromedial medulla (RVM) to dorsal horn of the spinal cord (Fields 2004). Direct application of a small concentration of morphine into any one of these sites in the rat inhibits nociception throughout the body. Opioids in these regions inhibit tonically active ► GABAergic neurons by activation of GIRK channels and direct inhibition of GABAergic synapses (Williams et al. 2001). The natural function of this system is to produce analgesia in response to ► fear or stress. Fear appears to activate the nociceptive modulatory system in the PAG via a projection from the ► amygdala. Although the source of PAG opioids for fear-induced antinociception is not known, both intrinsic enkephalin containing neurons

and β-endorphin terminals arising from the arcuate nucleus could contribute. With chronic treatment, repeated morphine inhibition of GABAergic neurons in the ventrolateral PAG, but not the RVM produces tolerance to the analgesic effects. Although tolerance is associated with a number of changes in MOR signaling, the specific mechanisms underlying tolerance to opioids are only partially known. In humans and other animals, the analgesic effects of morphine tend to be greater in males compared to females. Variations in the number of MOR, particularly in the PAG and the magnitude of morphine analgesia across the estrus cycle, suggest that estradiol influences the function of MOR.

Direct administration of morphine to many other brain regions also has been shown to inhibit pain in laboratory animals. For example, activation of MOR in the ► amygdala, nucleus submedius, or nucleus cunieformis produce ► antinocieption by activating the PAG. In addition to these central effects, MOR, DOR, and KOR receptor agonists attenuate pain by inhibition of primary afferents at the site of injury (Stein et al. 2003).

Reward and Addiction

Opioids, like other ► drugs of abuse (e.g., cocaine, amphetamine, ethanol) increase the release of dopamine in the ► nucleus accumbens (Le Moal and Koob 2007) and have been subject to animal models of addiction (► addictive disorders: animal models). The most commonly abused opiates, morphine and heroin, increase dopamine release in the nucleus accumbens by disinhibiting dopaminergic neurons in the ► ventral tegmental area. MOR and DOR agonists are thought to inhibit tonically active GABAergic neurons in the ventral tegmental area which activates dopamine neurons projecting to the nucleus accumbens. Direct opioid inhibition of ► nucleus accumbens neurons also contributes to the rewarding effects of opioids. Other brain structures that contribute to the reinforcing effects of opioids include the amygdala and bed nucleus of the stria terminalis.

Although the reinforcing effects of opioids are probably linked to many behaviors that are necessary for survival (e.g., food, sex, social interactions), this system also leads to opioid abuse and addiction. Addiction typically starts as a result of the euphoric effects of opioids, but is maintained by dysregulation of endogenous opioid signaling (Le Moal and Koob 2007). Removal of opioid administration results in intense ► craving and withdrawal, which leads to further abuse. The rewarding effects of opioids are specific to MOR and DOR. KOR agonists inhibit dopamine release in the nucleus accumbens and produce aversion.

The P300 refers to a positive EEG voltage deflection seen around 300 ms after the presentation of a novel stimulus. It can be recorded using stimuli of any sensory modality but most commonly in the auditory domain. The simplest paradigm used to elicit the P300 involves presenting repeated simple auditory tones of a given frequency every second or so. The P300 is generated when a tone of a different frequency is presented randomly at a rate of around 1 in 10 of the more common tones. It is observed by comparing the event-related potentials, time locked to the presentation of the tones, generated by the "frequent" versus the "rare" frequencies. It is seen most prominently over the parietal lobe. Unlike ► mismatch negativity, subjects need to be consciously attending to the stimuli. The presence, magnitude, topography, and time of this signal are often used as metrics of cognitive function in decision-making processes.

Palatability

Definition
A subjective measure of the acceptability and pleasantness of food. It implies a property of "being acceptable to the taste or mouth," with a sufficiently agreeable flavor for eating and pleasing to taste. It embraces the hedonic evaluation of a food resulting from its sensory properties, modified in relation to energy needs, past experience and learning, and the quantity of food consumed within a meal. Palatability may be inferred from the intensity and persistence of ingestion (palatability response). High-palatability foods tend to be energy dense, with high fat and carbohydrate content. It is an important determinant of caloric intake and can overwhelm processes of satiation;

Paliperidone

Synonyms

9-hydroxyrisperidone

Definition

Paliperidone is a second-generation antipsychotic medication indicated for the acute and maintenance treatment of schizophrenia. It acts as a dopamine D2 and serotonin 5-HT_{2A} antagonist. It is the 9-hydroxymetabolite of risperidone with which it shares many pharmacological properties. An extended release formulation of paliperidone allows for once-daily dosing, results in lower peak plasma levels and hence less side effects, and thereby limits the need for dose-titration that is otherwise required at the start of treatment with risperidone.

Definition

The aim of this entry is to describe the pharmacological treatment of one of the most common anxiety disorders: panic disorder. We have focused on antidepressants (ADs), especially on ▶ serotonin selective reuptake inhibitors (SSRIs), which have been found to be effective in treating panic disorder and are the first-line treatment with regard to their efficacy and safety. The other ADs are listed along with the other pharmaceutical classes with their indications, side effects, and implementation issues.

Role of Pharmacotherapy

Introduction

▶ Panic Disorder is one of the most common anxiety disorders in the general population with a lifetime prevalence of 4.7% (Kessler et al. 2005). It is often disabling, especially when complicated by agoraphobia, and is associated with functional morbidity and reduced quality of life. The disorder is also costly for individuals and society, with increased use of health care and absenteeism.

Role of Pharmacotheraphy

Medications have been known to be useful in the treatment of panic disorder for over 30 years, with the first description of efficacy of the ▶ tricyclic antidepressant imipramine for blocking ▶ Panic Attacks by Donald Klein in 1964. Many studies have recorded the efficacy of most ADs in panic disorder. ▶ Benzodiazepines are the other effective medication currently available. The aim of pharmacotherapy should be to eliminate panic attacks, if possible, because partial response often results in continued avoidance of frightening situations and impairment in social functioning. However, the goal of treatment should also be to reduce or eliminate associated anticipatory anxiety, phobic avoidance, and other symptoms due to co-morbid conditions such as major depression and to improve global functioning. Medications from several classes have been shown to be effective.

Treatments

Serotonin Selective Reuptake Inhibitors (SSRIs)

Efficacy The efficacy of SSRIs in the treatment of depression is now very well documented, and they have also been found to be effective in treating panic disorder. Their efficacy and safety render them the first-line treatment for this condition. Each of the six SSRIs (▶ fluoxetine, ▶ paroxetine, ▶ sertraline, ▶ fluvoxamine, ▶ citalopram, and ▶ escitalopram) has demonstrated its effectiveness in ▶ randomized clinical trials.

Meta-analyses and reviews focusing on several of these agents have reported medium to profound effects compared with placebo and have confirmed that this efficacy may be maintained for up to 1 year (Otto et al. 2001). Therapeutic response in panic disorder seems to be a class effect, which

is common to all the SSRIs, with no evidence of differential long-term efficacy within the class.

Side Effects The main side effects of SSRIs are headache, irritability, nausea and other gastrointestinal complaints, insomnia, sexual dysfunctions, increased anxiety, jitteriness, drowsiness, and tremor. They can be prescribed to patients with prostatic hypertrophy or narrow-angle glaucoma according to the absence of clinically significant anticholinergic effects.

► Discontinuation reactions have been associated with all the major classes of AD. They are reported to occur particularly with compounds having short ► elimination half-lives (for SSRIs, e.g., paroxetine) and can mimic the reappearance of the underlying disorder. These discontinuation symptoms may vary in nature and severity. They begin shortly after stopping the drug. Discontinuation reactions last between 1 day and 3 weeks with a rapid reversal on restarting the original drug. Tapering of antidepressant use is the most common preventive strategy.

Implementation Issues Patients suffering from panic disorder tend to be more sensitive to SSRIs side effects than depressed patients; hence, the treatment must be started at lower doses than those used in depression (half dose or less). After a few days, according to efficacy and tolerance, doses must be progressively increased to the same or greater levels than those used in depressive disorders. The onset of action is usually 2–8 weeks. There is no clear evidence about what should be the optimal length of treatment, but classically, treatment should be pursued until 6 months after the remission of symptoms (McIntosh et al. 2004).

Tricyclic Antidepressants

Efficacy ► Imipramine and ► clomipramine have been the most extensively studied of the tricyclic ADs and both have demonstrated efficacy in treating panic disorder. Other tricyclic ADs that have shown some evidence of efficacy include desipramine, ► doxepin, ► amitriptyline, and ► nortriptyline (for review see Cox et al. 1992). One meta-analysis concluded that there were no significant differences between SSRIs and tricyclic ADs in terms of efficacy or tolerability in short-term trials for panic disorder treatment (Otto et al. 2001). Another meta-analysis comparing paroxetine and imipramine concluded that paroxetine is better tolerated than imipramine and should be the first-line treatment (Wagstaff et al. 2002).

Side Effects All tricyclic ADs have common side effects such as anticholinergic effects (dry mouth, constipation, difficulty urinating, increased heart rate, and blurred vision), increased sweating, sleep disturbance, orthostatic hypotension, fatigue, cognitive disturbance, weight gain, and sexual dysfunction. Prostatic hypertrophy or narrow-angle glaucoma are contraindications for these molecules. Cardiac function should be carefully monitored.

Implementation Issues For the same reasons as with SSRIs, it is recommended that tricyclics be started at doses lower than those for patients with ► depression. For example, imipramine should be started at only 10 mg/day and gradually increased up to a minimal dose of 75 mg/day.

The duration of treatment should be the same as with SSRIs, and it is recommended that the dose be tapered before stopping.

Benzodiazepines

Efficacy ► Alprazolam and ► clonazepam (high-potency benzodiazepines) have been studied more extensively than low-potency benzodiazepines and have shown to be more effective for the specific treatment of panic disorder. The primary advantage of using benzodiazepines is rapid relief from anxiety and panic attacks. As already mentioned, ADs have a delayed therapeutic onset (Moroz 2004).

Side Effects The disadvantages of benzodiazepines include sedation, ataxia, slurred speech, cognitive clouding, interaction with alcohol, physiological dependence, and the potential for a ► withdrawal syndrome. The prescription of benzodiazepines in elderly patients must be carefully weighed against the risk of oversedation, falls, and cognitive impairment due to the decreased elimination of these compounds.

Implementation Issues Because of its short duration of action, alprazolam generally must be administered in three to five daily doses. Clonazepam, which has a longer duration of action than alprazolam, can generally be administered twice a day. Clonazepam is reported to have less abuse potential than alprazolam, and is found to be easier to taper during discontinuation owing to its longer half-life. Very few studies have empirically evaluated dose requirements. Thus, it is recommended to slowly increase the doses according to the efficacy/tolerability ratio. There are very few data indicating the optimum length of treatment with benzodiazepines, but short-term treatment is recommended to minimize the risk of ► tolerance and ► dependence.

Furthermore, benzodiazepines can be helpful when AD treatment is initiated and when a rapid onset of therapeutic effect is desired. They can also help to improve the short-term tolerability of SSRIs by blocking the jitteriness and exacerbation of panic sometimes observed when initiating treatment with an AD. Benzodiazepines can also be useful to "top up" the patient's treatment on an as-needed basis for sudden and unexpected decompensation or short-term psychosocial stressors. However, benzodiazepines are associated with a worse outcome in the long term than AD treatment (McIntosh et al. 2004).

Other Antidepressants

Venlafaxine ►Venlafaxine is a member of the dual serotonin–norepinephrine reuptake inhibitor (►SNRI) class of AD and received approval for panic disorder in the USA. A number of ►open-label and ►double-blind studies have demonstrated the effectiveness of venlafaxine immediate-release (IR) and extended-release (ER) formulations for the treatment of panic disorder. One study published in 2007 compared venlafaxine ER with paroxetine in the treatment of panic disorder with or without agoraphobia, demonstrating that both venlafaxine and paroxetine are more effective than placebo and are well tolerated. Both fixed doses of venlafaxine ER (75 and 150 mg/day) demonstrated efficacy and tolerability that were comparable with each other and with paroxetine at 40 mg/day. The most common side effects reported for venlafaxine were sweating, dry mouth, dizziness, anorexia, tremor, constipation, diarrhea, and somnolence (Pollack et al. 2007). Discontinuation reactions have been described for venlafaxine. These reactions are very similar to those with SSRIs. The same strategy of decreasing the doses very slowly should be used before stopping the treatment.

Nefazodone and Trazodone A retrospective analysis and two open-label trials reported that nefazodone may be effective in the treatment of panic disorder. Furthermore, nefazodone is reported to have a better side-effect profile than other ADs, with no weight gain or sexual dysfunction.

Two studies with ►trazodone found disparate results. One single-blind study reported that patients improved significantly compared with placebo, but a double-blind study comparing imipramine, alprazolam, and trazodone showed trazodone to be less effective than imipramine or alprazolam.

Mirtazapine A double-blind randomized controlled study with only 27 panic patients showed no statistical difference between ►mirtazapine and fluoxetine. Four open-label trials reported also the effectiveness of mirtazapine in panic disorder. The average dose is 30 mg/day and the most frequently reported side effects are weight gain, initial drowsiness, and constipation (Ribeiro et al. 2001).

Reboxetine ►Reboxetine is a selective norepinephrine reuptake inhibitor reported to be more effective than placebo in a double-blind randomized controlled trial. However, in a single-blind study, reboxetine appeared to be less effective than paroxétine in the treatment of panic disorder. The adverse events reported most frequently with reboxetine are insomnia, constipation, and dry mouth (Bertani et al. 2004).

Monoamine Oxidase Inhibitors

Efficacy In fact, there are no studies proving that the classical irreversible ►MAO inhibitors are effective in treating panic disorder specifically; however, six earlier pre-DSM III studies showed efficacy in the phobic anxiety of individuals with panic-like symptoms. Two studies with reversible inhibitors of MAO A (RIMAs), one a double-blind comparison of brofaromine with clomipramine and the other, an open study of brofaromine, showed antipanic and antiphobic efficacy. No medication in the RIMA class is currently approved for use in USA, but at least one drug, moclobemide, is widely used in Europe and Canada despite the lack of clear evidence of its efficacy (for review see Bandelow et al. 2008).

Side Effects The disadvantages of the MAO inhibitors make them second- or third-line treatments for panic disorder; these include orthostatic hypotension, weight gain, sexual dysfunction, and dietary restrictions (low tyramine diet), with the potential for a tyramine-induced hypertensive crisis. They should be prescribed by physicians with experience in monitoring MAOI treatment. The RIMAs appear safer, with lessened potential for side effects, and do not require adherence to a tyramine-free diet.

Other Agents

Anticonvulsants ►Anticonvulsants, such as ►valproate, ►carbamazepine, and levetiracetam, have demonstrated preliminary evidence of efficacy in the treatment of panic disorder, but with side effects such as gastrointestinal dysfunction, weight gain, dizziness, nausea, sedation, and alopecia (for review see Bandelow et al. 2008).

Levetiracetam is an anticonvulsant, currently approved by the US Food and Drug Administration for the adjunctive treatment of partial-onset seizures in patients with epilepsy. In an open-label, fixed-flexible dose study, 18 patients were treated with levetiracetam for 12 weeks. Of the 13 patients completing the study, 11 were rated "very much" or "much" improved on the CGI-I. For most patients, clinical benefits were apparent after only 1–2 weeks of treatment. The tolerance was good with minimum side effects.

Antipsychotic Medications There is no evidence that conventional antipsychotic medications are effective in the treatment of uncomplicated panic disorder. ► Second-generation antipsychotics such as ► aripiprazole and ► olanzapine appear to be effective as an augmentation strategy in the treatment of SSRI-resistant panic disorder, but in open–label studies or case reports only.

Recommendations and Conclusion

Unless otherwise indicated, an SSRI should be offered as a first-line treatment. When a medication is started, the efficacy and side effects should be reviewed within 2 weeks and again at 4, 6, and 12 weeks. At the end of 12 weeks, an assessment of the effectiveness of the treatment should be made and a decision taken to continue or consider an alternative intervention. If there is no improvement after a 12-week course of a first SSRI, another SSRI or an SNRI may be considered. SNRIs tend to be used as a second-line therapy after SSRIs fail to improve panic or in patients who cannot tolerate them. The tricyclics have the disadvantages that make them second- or third-line treatment now. If there is no improvement after another 12-week course, an AD from the alternative classes should be offered or a strategy adopted for augmenting SSRIs with benzodiazepines, other ADs, or atypical neuroleptics could be tried. There is no evidence that will allow the clinician to predict which of the three broad intervention groups (pharmacological, psychological, or self-help) will be effective for an individual patient, based on duration of illness, severity of illness, age, sex, gender, or ethnicity. In the same way, there is no evidence that will allow the clinician to predict which AD will be effective. Treatment choice depends on patients' characteristics (such as previous response or contraindication), the evidence-base supporting its use, and patient and physician preference. If the patient shows improvement on AD treatment, medication should be continued for at least 6 months after the optimal dose is reached, after which the dose can be tapered. There is no clear published evidence about what is the optimal length of treatment with medication (NICE 2004).

The response rate to pharmacotherapy approaches 70%, but many studies clearly show that discontinuation of medication results in relapse with rates of 25–50% recorded within 6 months, depending on various studies. The strategy for patients not responding to the first SSRI is not well documented with placebo-controlled studies; and the notion of resistance still needs to be clearly defined.

One of the first available analgesic formulas, papaveretum is now relatively uncommon due to the more widespread availability of simple and synthetic opioids. Papaveretum continues to be used primarily as a preoperative sedative, but also for moderate to severe pain. In comparison with morphine, papaveretum has fewer gastrointestinal side effects and little abuse potential as IV administration at low doses produces severe headaches in most individuals. An additional component, noscapine, was removed from the formula in 1993 due to potential genotoxic effects.

Definition
The class of sleep disorders known as Parasomnias (L. *Para*=next to; *Somnus*=sleep) includes some of the most unusual, challenging, fascinating, and potentially instructive of all behavioral disorders. These are clinical disorders characterized by abnormal behavioral or physiological events, usually unpleasant or undesirable, which accompany sleep-specific sleep stages or sleep/wake transitions (American Academy of Sleep Medicine 2005; American Psychiatric Association 2000; see Table 1). Parasomnias are associated with central nervous system (CNS) activation, increases in skeletal muscle activity, and autonomic nervous system (ANS) changes. The immediate consequences of parasomnias include the possibility of sleep disruption and physical harm to affected individuals. Parasomnias can also lead to poor health and psychosocial consequences. Because parasomnias tend to run in families, it has long been suspected that genetic factors are involved in their pathophysiology (Hublin and Kapiro 2003).

Clinical Diagnosis and Evaluation
Experienced sleep physicians can often diagnose parasomnias with a few simple questions. More detailed clinical diagnoses of parasomnias involve collecting a thorough

clinical history from the patients and family. Formal overnight ► polysomnography (PSG) is limited to those patients whose behaviors are violent or extremely bothersome to other individuals or which cause significant physical damage. Additionally, the final PSG assessment may include a more detailed montage to rule out other potential confounding factors (such as nocturnal seizures, obstructive sleep apnea (OSA), nocturnal panic attacks, or ► rapid eye movement (► REM) behavior disorder).

Parasomnias can be broadly and conveniently classified based on the state from which they arise – events that occur during *REM sleep*, nonrapid eye movement (NREM) sleep, or both sleep states.

Non-REM (NREM) Parasomnias

Disorders of arousal during ► NREM sleep include the following: sleepwalking, sleep terrors, and confusional arousals. Thought to occur because of the instability of slow-wave sleep (SWS), arousal disorders are not presumed to be an *all-or-none* phenomenon, but rather a continuum of behaviors involving reestablishment of full alertness, orientation, judgment, and self-control, and/or a rapid alternation between sleep and waking states (Mahowald and Schenck 2005a).

Confusional Arousals

Similar to sleepwalking and sleep terrors, confusional arousals are brief and incomplete arousals that typically begin during SWS. The aroused individual typically looks confused. A confusional arousal or behavior differs from sleepwalking in that the affected patient does not leave the bed. Inasmuch as the episodes generally follow arousals from SWS, they most commonly occur during the first one-third of the night. However, such arousals can also occur in other NREM sleep stages and/or during the later part of the night. Common examples include sitting up in bed and making simple vocalizations or picking at bedclothes. Confusional arousals are often seen in children not only from nocturnal sleep but also from diurnal naps. The term *sleep drunkenness* has also been used to describe such confusions inasmuch as the episodes, especially those following arousal upon arising in the morning, are often accompanied by disorientation, impaired cognition, and behavioral disturbance.

Approximately 10–20% of children and 2–5% of adults report a history of confusional arousals. In adults as well as children, ► anxiety, sleep deprivation, fever, and endocrine factors (e.g., pregnancy) can increase the frequency of episodes. Other precipitating factors include the consumption of ► alcohol and/or other hypnotics, antihistamines, ► lithium, and potentially other medications that tend to elevate the arousal threshold. In adults, primary sleep disorders (e.g., apnea or periodic leg movement syndrome) can also exacerbate such conditions.

Sleepwalking

Sleepwalking (somnambulism), which is initiated during SWS and generally occurs within the first one-third of the sleep period, consists of a series of complex, elaborate motor behaviors and results in walking during a state of altered consciousness. Sleepwalking occurs in 10–20% of children and 1–4% of adults. Most prevalent in children between 5 and 10 years of age and less so with advancing age, sleepwalking events range from subdued to elaborate. These events can include the unlocking of doors, dressing, and even driving. Typical episodes can last from 15 s to 30 min, with recall often being sketchy to absent the next day. During the somnambulistic state, there is an absence of dreaming. The affected individual's eyes are open and behavior may be clumsy. When awakened, the sleep walker typically responds with simple phrases and noninsightful mentation ("had to talk to John Doe"). Frequent sleepwalking in adults may be associated with violent or dangerous activity and warrants treatment. Sleepwalking patients are generally neurologically normal. The presence of other contributing sleep disorders should be investigated and ruled out prior to a final diagnosis.

Sleep Terrors (Night Terrors, Pavor Nocturnus)

Sleep terrors are also characterized by arousals from SWS. They are less common than sleepwalking, occurring in 5% of children and 1–2% of adults. A night terror starts with an incomplete arousal from SWS and is often associated with ANS activation and reports of frightening imagery. A typical event might terrify the patient, who often emits an abrupt piercing scream, accompanied by autonomic and behavioral manifestations of intense fear. The events are often associated with agitation, sweating, hyperpnea, and tachycardia. Episodes typically occur in the first one third of the night, with the patient having no or very little recall of the event the next morning. Witnesses tend to be more distressed by the events than patients. Children who present with sleep terrors often grow out of them. Events may be precipitated by such stressors as alcohol use, psychological strain, sleep deprivation, and shift work. Adults presenting with sleep terrors should be assessed for ► comorbid psychiatric disorders.

Treatment of Arousal Disorders

Once an arousal disorder is assessed and properly diagnosed, a treatment plan can be developed. The structure and sequencing of the plan should take into account the nature and severity of the symptoms. Management of arousal disorders, especially in children, should primarily

involve education. Patients and parents should understand that arousal disorders in children generally do not require intervention and that the symptoms will minimize with time. Although stress may be a factor in disorders of arousal, it should not be the clinician's first assumption.

Proper clinical management involves the recommendation of good sleep hygiene including refraining from alcohol and drugs. Further, the patient should keep a consistent sleep/wake schedule, and take steps to reduce bedroom light and noise. Sleep deprivation should be avoided. The environment should be kept safe (e.g., mattress on the floor, locks on doors, use of alarms) when necessary. Scheduled awakenings (on a regular basis awakening the patient 15 min before each usual arousal) have been shown to be effective. Table 2 lists common safety recommendations. Stress management skills, psychotherapy, and hypnosis have also been found useful. Pharmacological treatment becomes necessary when arousal events are frequent, put the family or patient at a risk of being harmed, or disturb the family life. ► Benzodiazepines (BDZs, used continuously or as needed) and ► tricyclic antidepressants have been successfully used in treatment, though controlled trials are lacking (Table 3).

In summary, because all the above episodes occur during NREM sleep, it is difficult to arouse the individuals from the episodes. When aroused, patients can be confused or even aggressive with subsequent amnesia for the episode. Dreaming is often absent in these episodes, although the patient may occasionally report vague and fragmented dreams. Further, all three arousal disorders can co-exist, making them difficult to distinguish from one another.

Parasomnias Usually Associated with REM Sleep

REM-Sleep Behavior Disorder

REM-sleep behavior disorder (RBD) is characterized by vigorous motor activity, which typically occurs during REM sleep and thus in the absence of muscle atonia. RBD often consists of injurious dream-enactment motor activity associated with vivid dreaming. REM sleep behavior disorder is symptomatically complex, often involving behaviors that are dangerous to the affected patient, or to his/her bed partner, and vivid dream imagery that is almost always unpleasant. REM behavior disorder is more frequent in males and usually occurs in the middle-aged or elderly. Although the exact prevalence of RBD in the general population is unknown, it is estimated to be 0.5% (Ohayon et al. 1997). Patients exhibiting such complaints should seek a thorough evaluation by a sleep specialist. RBD can be idiopathic or related to underlying neurological conditions (e.g., synucleinopathies). It is thus advisable that patients undergo a thorough physical examination for the purpose of identifying any comorbidities that might interrupt REM sleep (Ferini-Strambi et al. 2005). Acute RBD can be induced by medications (► monoamine oxidase inhibitors, serotonin reuptake inhibitors, and tricyclic antidepressants), alcohol, and BDZ withdrawal.

As was suggested for disorders of arousal, recommendations for therapy should emphasize the safety of the patient and his/her bed partner as paramount considerations. The patient and his/her bed partner should sleep in separate beds until events are controlled. Patients usually respond well to ► clonazepam (0.5–2.0 mg) or ► temazepam (15–45 mg). ► Melatonin, ► levodopa, and ► pramipexole have also been reported to be useful in some cases. See Table 4 for the minimum diagnostic criteria for RBD on a PSG.

Sleep Paralysis

Sleep paralysis occurs when there is a persistence of REM muscle atonia into wakefulness. Although eye movements and respiratory activity remain intact, somatic movements are not possible. Episodes of sleep paralysis may often accompany a residual dream-related fear or with anxiety when a patient realizes that movement is not possible. Although the episodes may last one to several minutes, they often can be terminated by an external stimulus (e.g., touch). Patients with infrequent episodes should refrain from sleep deprivation and alcohol, but further treatment (beyond reassurance) is generally not required. For recurrent episodes, evaluation for depression or other psychiatric conditions with the potential for producing sleep disturbance is warranted.

Nightmares

Nightmares are frightening dreams that can awaken the sleeper from REM sleep. Although they may occur at any part of the night, they predominantly occur during the final

Parasomnias. Table 4. Minimum diagnostic criteria of RBD based on polysomnographic (PSG) variables. (American Academy of Sleep Medicine 2005.)

The suggested criteria include:
1. PSG abnormality during REM sleep: REM sleep without atonia; elevated submental EMG tone or excessive phasic submental or limb EMG twitching
2. Documentation of abnormal REM sleep behaviors during PSG studies (prominent limb or truncal jerking; complex, vigorous, or violent behaviors) or history of injurious or disruptive sleep behaviors
3. Absence of EEG epileptiform activity during REM sleep

one-third of the night where REM sleep is more prominent. Recall of a nightmare is generally vivid and detail-oriented. Nightmares are often associated with predominant emotions such as fear or anxiety; however, feelings of anger, sadness, and embarrassment may also occur. Although more commonly seen in children, adults also report having nightmares, with stress and antidepressant or antihypertensive medications often being implicated as causal factors. Nightmare disorder, the experience of recurrent nightmares, can be idiopathic or related to an underlying condition such as psychological trauma or psychopathology (e.g., posttraumatic stress disorder, affective disorders). Frequent

nightmares can lead to disturbed sleep onset latency, awakenings, restless sleep, insomnia, and a lower overall quality of life. Imagery rehearsal therapy has shown promising results in the treatment of nightmares. Patients are taught to "change the dream any way (he) wishes" and imagine the new dream for 5–20 min daily. Though more commonly used to treat hypertension, prazosin has also been found effective as a routine treatment (Lancee et al. 2008).

Other Parasomnias

A host of other parasomnias, many of which are related to medical and/or psychiatric dysfunctions, have been described in the literature. Some require specific medical intervention, whereas others only require reassurance.

Sleep-Related Dissociative Disorders

Sleep-related dissociative disorders are commonly divided into three categories: dissociative identity disorder, dissociative fugue, and dissociative disorder not otherwise specified. During these states (which can vary in duration from minutes to hours), patients commonly have disturbances in consciousness, memory identity, and environmental awareness. Nocturnal re-enactments range in severity, and include episodes such as binging on high caloric sweets, acting out past physical and sexual abuse, driving an automobile, or eating uncooked foods. Patients generally lack memory of the event.

Patients often have histories of psychopathology or report past experiences of sexual, physical, and/or emotional abuse. A full psychological evaluation is recommended and no single treatment approach is accepted as the most effective in this population. A combined pharmacotherapy and psychotherapeutic approach is likely to be most effective. Treatment approaches most likely to succeed should focus on any underlying psychiatric disorders. Pharmacotherapy should similarly address the potential presence of depression and/or anxiety. Psychotherapy should be directed at tension management and reduction of stimuli that tend to provoke dissociative experience.

Sleep Enuresis

Sleep enuresis is characterized by recurrent involuntary voiding that occurs during sleep. Although bedwetting is considered normal for some ages, it becomes pathological when it occurs at least twice weekly during sleep in patients who are 5 years of age or older. Primary enuresis patients, those who have never been consistently dry during sleep, may have a neurological impairment or a deficient release of vasopressin. Secondary enuresis patients have had periods of remaining dry during sleep at least 6 months' duration. Enuresis has been linked to a number of factors including urinary tract infection, diabetes mellitus, epilepsy and other neurological disorders, and psychological stress. Treatment recommendations include reassurance and, especially in children, positive reinforcement for achieving goals. Patients should refrain from taking liquids late in the evening. Behavioral conditioning treatments such as bell and pad alarms have been found useful. Desmopressin has been used in some to reduce urine production. Tricyclic antidepressants (desipramine or imipramine) have also been found to be beneficial for short-term management.

Catathrenia (Sleep-Related Groaning)

Catathrenia is a rare form of parasomnia (Siddiqui et al. 2008). Often most disturbing to bed partners or family members, a typical episode is characterized by a prolonged groan, which is accompanied with an expiration of oronasal flow. Although catathrenia episodes predominantly occur during REM sleep, they can in some cases occur during NREM sleep (Siddiqui et al. 2008). Evaluation should include a PSG to rule out any comorbid sleep disorders (e.g., OSA). Catathrenia is not known to be associated with any apparent medical and/or psychiatric illnesses and it traditionally does not respond to pharmacotherapy. Reassurance is traditionally the treatment of choice.

Exploding Head Syndrome

Patients suffering from what has been termed as exploding head syndrome report being awakened by the sensation of a loud, explosion-like bursting sound in the head. Subjects may describe having a nonobjective auditory experience, with intensities ranging from a painless loud bang to more subtle loud sounds. Typically, these experiences occur just as they are falling asleep. Although the experience is usually painless, patients occasionally note a small jab of pain with the sound. The subjective explosions are often exacerbated by sleep deprivation or personal stress, and treatment recommendations emphasize reassuring the patient that these events are benign in nature.

Sleep-Related Eating Disorder (SRED)

Sleep-related eating disorder involves partial arousals from sleep where patients engage in involuntary eating and drinking. Patients have limited or no memory of events, and foods consumed can consist of peculiar combinations or even inedible/toxic substances such as coffee grounds, cake mixes, frozen or uncooked products, and eggshells or cleaning materials. Patients may have unexplained weight gain and morning anorexia. SRED has a higher prevalence in patients with a history of eating disorders or sleepwalking. Certain medications have also been reported to induce SRED (e.g., ▶ zolpidem, anticholinergics, and lithium). Patients should be evaluated for comorbid sleep disorders

such as periodic limb movements and obstructive sleep apnea. Topiramate and dopaminergic medications have been found effective for some patients.

Sleeptalking (Somniloquy)

Sleeptalking refers to the utterance of speech or sounds during sleep without simultaneous subjective detailed awareness of the event. Occurring during Stage 2, SWS or REM sleep, sleeptalking is the most common during the first half of the night. Episodes are exacerbated by stress, new medications, acute medical illness, or a comorbid sleep disorder. Simple sleeptalking generally does not require intervention unless another sleep disorder is suspected. If treatment is required, patients are counseled to follow proper sleep hygiene and reduce exacerbating factors such as alcohol and sedatives.

Sexsomnia

Sexsomnia (*somnambulistic sexual behavior*) is characterized by abnormal sexual behaviors during sleep, with patients having little to no memory of the event. The characteristic features of sexsomnia include sexual arousal accompanied by autonomic activation (e.g., nocturnal penile tumescence, vaginal lubrication, nocturnal emission, and dream orgasm). Many patients who have a history of sleepwalking and comorbid sleep disorders should be evaluated. Patients are advised to obtain adequate sleep on a regular basis.

Forensic Implications

Violent behaviors may occur during the sleep period and can occur without the conscious awareness by affected individuals. These sleep-related behaviors, which have been reported in 2% of the population, can occasionally have significant forensic implications (Mahowald and Schenck 2005b). Prominent legal cases involving murder, assault, or apparent suicide have occasionally been linked to disorders of arousal, RBD, psychogenic dissociative states, or sleep-related seizures. As an appreciation of such linkages is being increasingly acknowledged, sleep medicine clinicians are becoming more frequently involved in these cases as expert witnesses. It is thus in their professional interest to become informed of the medical and legal implications, where assumption of intentionality in aberrant behavior is involved. Further study is necessary to understand the true prevalence of these disorders, how to best diagnose and treat them, and how to protect others around the patient.

Conclusion

Parasomnias are often considered as the most fascinating category of sleep disorders. The associated phenomena, often distressing to those who experience them, have been well described behaviorally, but remain poorly understood in terms of their mechanisms. Parasomnias are common nocturnal events that can occur at any stage of sleep. Often a full or extended montage EEG set-up accompanied by video–audio PSG is necessary for proper diagnosis of this disorder. Genetic epidemiological studies reveal that the parasomnias often run in families. While genetic susceptibility of some parasomnias has been confirmed, not all variants of the disorder demonstrate a clear linkage. Further research into the interplay between gene–environment interactions and other potential environmental causes needs to be undertaken to understand the exact nature of such disorders. The clinician and patient should work together to tailor the treatment to each patient, and to reduce the risk of injury, increase the safety of family members, and to increase the patient's quality of life.

Pargyline

Synonyms
Methylbenzylpropynylamine; N-Methyl-N-2-propynylbenzylamine

Definition
Pargyline is an irreversible inhibitor of monoamine oxidase used for the treatment of depression with selectivity for MAO-B. It is less effective than ► tricyclic antidepressants and its interactions with dietary amines lead to serious toxicity. For example, foods such as cheeses that contain tyramine must not be consumed. It can also interact dangerously with other drugs including tricyclic antidepressants. Its use is now very limited, mainly to cases of depression that do not respond to newer antidepressants such as the inhibitors of the reuptake of serotonin and norepinephrine. Other side effects include hypotension, sedation, and weight gain.

Definition
Paroxetine is an antidepressant that inhibits potently and specifically serotonin reuptake (SSRI). It was introduced in 1992. It is mainly used in the treatment of ► major depression, ► social anxiety disorder or social phobia, ► generalized anxiety disorder, ► post-traumatic stress disorder, ► panic disorder, ► obsessive–compulsive disorder, and sometimes of migraine. It is claimed to be as effective as older tricyclic antidepressants, but with a more favorable side-effect profile. Its major side effects are nausea, sleep disturbances, decreased libido, and possible weight gain. The most serious concern with paroxetine treatment is the emerging risk for suicidal ideation and behavior in some adolescents and adults that led to the recommendation not to prescribe it for children. There continues debate about the seriousness of symptoms upon discontinuation of paroxetine.

Partial Agonist

Definition
Partial agonists bind to and activate a receptor, but are not able to elicit the maximum possible response that is produced by full *agonists*. The maximum response produced by a partial agonist is called its intrinsic activity and may be expressed on a percentage scale where a full agonist produced a 100% response. A key property of partial agonists is that they display both agonistic and antagonistic effects. In the presence of a full ► *agonist*, a *partial agonist* will act as an ► antagonist, competing with the full *agonist* for the same receptor and thereby reducing the ability of the full agonist to produce its maximum effect. The balance of activity between agonist and antagonist effects varies from one substance to another, according to their intrinsic activities, and is also influenced by the test system used to measure their effects. Weak partial agonists are those compounds, possessing low intrinsic activity, that are able to produce only a small percentage of the total response produced by an agonist and which act predominantly as antagonists. Strong partial agonists may come close to mimicking the maximum effects of a full agonist and may display only weak antagonistic ability. When the test system under study has a large receptor

reserve, weak partial agonists show greater agonist activity then when the system has a small receptor reserve.

Definition

Passive (or inhibitory) avoidance: An aversive (emotional) conditioning paradigm in which the subject learns to associate a particular context with the occurrence of an aversive event (e.g., an electrical shock, the unconditioned stimulus [US]). Passive avoidance behavior of rodents is defined as the suppression of the innate preference for the dark compartment of the test apparatus (or stepping down from an elevated platform) following exposure to an inescapable shock. Thereby, the passive avoidance task combines Pavlovian contextual ► fear conditioning with the expression of an instrumental response, the avoidance of entering a particular (punished) area of the training context.

Principles and Role in Psychopharmacology

Theoretical Background

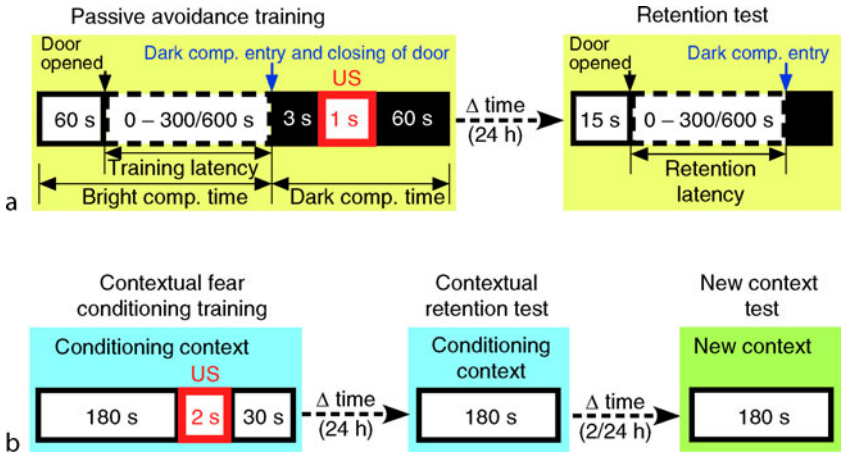
Analyses of learning experiments demonstrated very early that in conditioning certain relationships are established between particular external events, e.g., stimuli and/or responses. Psychological learning theory distinguishes between classical and instrumental aversive conditioning based on the different ways (contingencies) by which the aversive event (the ► unconditioned stimulus; US) is related to the ► conditioned stimulus (CS) and the unconditioned response (UCR). Instrumental (aversive) conditioning refers to contingencies in which the behavior of the subject determines whether or not the US will occur (Ögren 1985). In ► active avoidance paradigms, the rat has to perform a discrete response of a low probability, e.g., running from one side of a two-compartment box to the other when a discrete stimulus, e.g., the conditioned stimulus (CS) is presented in order to escape or avoid the US. In the passive avoidance task the animal learns to suppress a motor response to avoid exposure to the test area (context) associated with or predictive of the aversive event, such as a dark compartment of the passive avoidance apparatus that is normally preferred over the brightly illuminated compartment. Thereby a conflict situation is created.

Analyses of avoidance learning indicate that it involves different processes. Initially, presentation of the US results in a learned emotional state (e.g., ► conditioned fear), involving Pavlovian classical conditioning followed by the acquisition of the discrete, adaptive behavioral responses, the escape or avoidance response. The adaptive response requires for its association temporal contiguity between the US and the sensory stimulus or context used as the CS. Typical examples of the experimental sequence of passive avoidance and fear conditioning are presented in Fig. 1.

More recent theories on aversive learning have focused on the cognitive processes by which the animal acquires information about its experimental context. The cognitive interpretation of passive avoidance suggests that this paradigm is based on place learning involving the hippocampus (see below).

Passive Avoidance Tasks

Several varieties of passive avoidance tasks exist such as step-down or step-through avoidance. Passive avoidance is a learning task based on associative ► emotional learning (Ögren 1985), similar to contextual fear conditioning (Fendt and Fanselow 1999; LeDoux 2000). Unlike active avoidance tests, passive avoidance tests do not use an explicit CS. Instead, the training context serves as CS. Contextual stimuli are important for optimal ► retention performance. Changes in training context or internal stimuli, e.g., time of testing will impair retention performance.



Passive Avoidance. Fig. 1. Experimental sequences for passive avoidance experiments (**a**) and contextual fear conditioning (**b**) with training and retention tests with information on the duration of subintervals as used in previous studies. Blue arrows (**a**) indicate when the instrumental response occurs, i.e., the active choice of transferring from the bright into the dark compartment. In contrast, in fear conditioning the fear response is commonly quantified on the basis of visually observed or computer-derived freezing as index of active suppression of ongoing behavior. The test in the new context serves as control to determine the specificity of the fear response elicited by the distinct stimuli provided in the conditioning context. US = unconditioned stimulus (foot shock); comp. = compartment. (Modified from Ögren et al. 2008.)

Step-Through Passive Avoidance (Inhibitory Avoidance)

The step-through task is a one-trial emotional memory task combining fear conditioning with an instrumental response, e.g., the active choice of an animal to avoid entering the dark compartment associated with an aversive event (Ögren 1985). The passive avoidance task differs from the typical fear conditioning experiment in which training and testing occur in a one-compartment box. The rodent placed in the apparatus is exposed to one or several foot shocks (shock intensities 0.5–0.8 mA). Memory retention is measured as the degree of suppression of motor behavior quantified on the basis of ▶ freezing.

The typical step-through passive avoidance test is conducted in a two-compartment box with one bright and one dark compartment connected by a sliding door. The subject is placed in the bright compartment and will after a defined time interval gain access to the dark compartment. When entering the dark compartment (training latency), the door will be closed and the subject will be subjected to a brief aversive stimulus (US; foot shock intensities in mice around 0.2–0.4 mA) that will lead to the formation of an association of the dark compartment with the US. For the retention test (usually 24 h after training) the animal is returned in the bright compartment with the sliding door open. The animal has now the option to avoid or enter the dark compartment by discriminating the bright (safe) from the dark (unsafe) compartment. The rapid acquisition of not making a response indicates that the test involves learned inhibition rather than loss of an innate response tendency. Usually one trial, i.e., one exposure to the inescapable shock is sufficient to suppress the innate preference of the rodents for the dark chamber of the apparatus. The acquisition of passive avoidance is measured either as a significant increase of the step-through latency compared to training latencies or as the decrease of the time spent by the subjects inside the dark chamber. Thus, the passive avoidance procedure has the advantage of simplicity in that both the safe and the noxious compartment are clearly defined as well as the correct adaptive response that is to refrain from entering the dark compartment.

Step-Down Passive Avoidance

In the step-down passive avoidance task the subject is placed on an elevated platform from which it can step down onto the floor below, mainly a shock grid. When stepping onto the floor, the animal will be subjected to one or several ▶ aversive stimuli (US; foot shock) that will lead to the formation of an association between the shock and the context resulting in avoidance or delay to step down when returned to the platform in the retention test. Unlike the step-through passive avoidance procedure, the retention test is performed in the original (punished)

context similar to fear conditioning. This feature may lead to a substantial amount of contextual freezing, which is rarely observed in the step-through task. Another important issue relates to the compartment size, i.e., the space available for exploration in a one-compartment box. It is recommended to offer sufficient space for exploration instead of having systems with minimal compartment size from which animals instantly transfer when moving. Step-down passive avoidance tasks are more sensitive to changes in locomotor activity than step-through passive avoidance tasks particularly if the platform is small. Drug-induced or lesion-induced alterations in locomotor activity may confound the actual avoidance response.

Since the majority of passive avoidance investigations are based on the use of step-through avoidance paradigms, the following sections will focus on this task.

Procedural and Experimental Parameters

In the available literature there is quite a range of different procedures and experimental designs. Procedural differences have considerable consequences for passive avoidance performance and variability in results. Therefore, important aspects of different procedures are briefly summarized in Table 1. Different passive avoidance systems exist that are customized or available from different vendors. It is important that they fulfill certain hardware/software requirements for flexible use ideally with convenient software controls as indicated in Table 1.

Some pre-experimental procedures have considerable effects on the results. Handling by the experimenter has been shown to reduce variations between animals in the passive avoidance task probably by lowering the adverse effects of acute stress (Madjid et al. 2006). Another procedural modification, which reduces variations in results, is to allow the animal to explore both compartments for a short time (e.g., 1 min) 1 h before the actual passive avoidance training. However, this procedure may result in ▶ latent inhibition, e.g., reduced transfer latency, if the pre-exposure to the dark compartment is too long, if it occurs 24 h before training or if the strain of mice or rats is particularly sensitive to pre-exposure (Baarendse et al. 2008).

The most critical parameters in passive avoidance are the shock intensity and its duration. The avoidance response shows a very steep increase in the transfer latency with increasing shock intensity (Fig. 2). Thus, even small variations in intensity can change passive avoidance performance. Therefore, it is important to determine shock thresholds in all experiments, since large species and strain variations exist. To be able to study both enhancement and impairment of passive avoidance memory in the same experiment, different shock intensities can be used.

To enable demonstration of facilitatory effects on drugs on passive avoidance retention, a mildly aversive electrical current can be used while a strong current can be employed to explicitly study impairment of passive avoidance retention. This procedure provides a sufficiently wide for impairment and blockade of impairment when combining agonist and antagonist treatment (Fig. 3). An alternative approach is to use very long training latencies, e.g., up to 900 s, to have a sufficient dynamical range, or to combine it with pre-exposure (latent inhibition).

In addition, a wide range of retention measures is generally observed as a sign of large inter-individual variability. Therefore, larger group sizes (generally $n=12–16$/group) are required to achieve required statistical power unless profound drug effects are observed. Statistical analysis may have to be performed with nonparametric analysis of variance (ANOVA) using the Kruskal-Wallis test followed by the Mann-Whitney U test for pair-wise comparisons due to deviations from normal distribution of individual data and large group variances or responses exceeding maximum transfer latencies (cut-off latencies).

Handling of animals just after training can reduce the retention latency considerably. Particularly in mice, it is important that they can remain in the dark compartment of the passive avoidance apparatus for at least 30 s before being removed and transferred to their holding or home cage. Thus, the animal has to be given sufficient time to process the training context. In fear conditioning, exposure to the shock instantly after placement in the conditioning context leads to the "immediate shock deficit" in rats and mice, i.e., the absence of contextual conditioning. Thus, contextual information requires sufficient processing time to form an aversive association indicating the importance of the temporal relation of CS and US for associative learning. This is achieved by the initial confinement to the bright compartment. Another important rationale for the 30-s delay after US exposure is to avoid that mice form an aversive association of the US with the handling procedure (removal from the compartment after the US exposure).

Neural Systems

The nature of contextual stimuli which are critical for associative learning in the passive avoidance are not well characterized. It seems likely that passive avoidance, similar to contextual fear conditioning, depends on multisensory associations rather than unisensory associations. The relative role of sensory cues representing the CS is not known at present. Sensory afferents are required for the

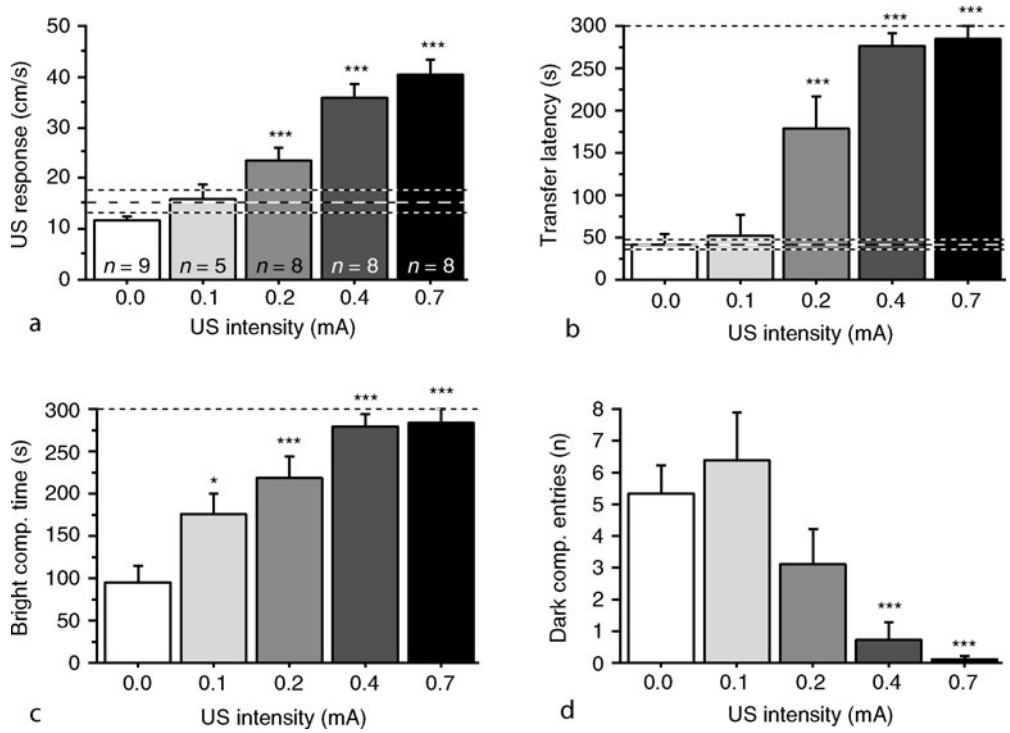
Passive Avoidance. Table 1. Important experimental features in passive avoidance experiments.

Apparatus:	Compartment sizes (larger compartments allow for movements irrespective of lack of transfer) Door size and visibility (larger doors promote faster transfer during training) Light intensity differences between compartments (should be profound, e.g., 10–100-fold difference) Door mechanism (a guillotine door falling on a mouse that is not yet completely in the dark compartment may act as US) Shocker with sufficient sensitivity (ideally >0.1 mA increments) and range (e.g., 0–1 mA)
Pre-experimental procedures:	Housing (single or group) and transfer (short vs. long) to the experimental room (arousal affecting the actual training and testing) Pre-exposure(s) before training, timing of pre-exposure (to reduce data variability), risk of latent inhibition Handling (to reduce variability in training latencies) Timing of drug treatment (pre- vs. post-training, pretest, state-dependent learning)
Experimental procedures:	Timing of retention testing (from short-term [1 h] to long-term memory [24-? h]; remote memory [>7 days] is hardly explored) Test duration (cut-off time: e.g., 300 s vs. 600 s) US intensity range used: low for facilitation vs. high for impairment Current: constant vs. scrambled shock (generally scrambled shocks are more effective) Extinction tests based on repetitive testing (with/without forced exposure to the dark compartment)* Waiting/delay time before access to the dark compartment is provided (e.g., 60 s during training, 15 s during testing)* Delay between dark compartment entry and US exposure to avoid escaping to the bright compartment*
Experimental parameters:	Transfer latencies detection (full transition when the animal is in the dark compartment with all four feet) Transitions between compartments (detection based on center of gravity may record transitions in mice during stretch-attend postures while exploring the door; this is not ideal for automated analysis) Total time spent per compartment US response assessment (important to avoid misinterpretations based on altered nociception) Activity measurements (some hypoactive and neophobic mouse strains such as A/J are unsuited for passive avoidance experiments despite implying to be good learners; therefore it is sometimes recommendable to include non-shocked controls) Time of testing (fluctuations in passive avoidance response throughout the circadian cycle have been reported in rats)
Statistical considerations:	Group sizes (normally n = 8/group is minimum, ideally n = 12–16/group) Parametric (ANOVA) and nonparametric data analyzes (Kruskal-Wallis and Mann-Whitney U test) (depending on the normal distribution of individual data [group variance] or skewed data because of maximum latency cut-off)

*These parameters have not been systematically investigated

detection of the different stimuli provided in the passive avoidance test environment from tactile to visual cues, nociceptive pain receptors for US detection and possibly also olfactory cues. Besides processing in the thalamus (except for olfactory information), higher brain centers are involved for ►encoding, ►consolidation, and ►extinction. The ►amygdala, the ►hippocampus, and the various cortical areas are part of the neural network that subserve passive avoidance learning (Baarendse et al. 2008; Burwell et al. 2004; McGaugh 2004; Ögren et al. 2008).

A number of studies have shown that passive avoidance depends on hippocampal function and its ►NMDA-receptors. Thus, infusion of the NMDA-receptor antagonists, AP5, into the dorsal hippocampus of mice profoundly impairs passive avoidance retention (Baarendse et al. 2008). Also neurotoxic lesions of the corticohippocampal circuitry (perirhinal, postrhinal, and entorhinal cortex) cause profound deficits in passive avoidance learning (Burwell et al. 2004). These results indicate that the passive avoidance task requires processing of spatial information about the test environment.



Passive Avoidance. Fig. 2. Passive avoidance performance in male C57BL/6J mice as a function of US intensity using multiple measures. US responses (activity) were measured during training and compared to baseline activity (**a**). In the retention test, transfer latencies (**b**), the total time spent in the bright compartment (**c**), and number of entries into the dark compartment (**d**) were analyzed as a function of US intensity (US duration: 2 s). The basal exploratory activity in the initial 180-s period of exploration in the light compartment is indicated as dashed horizontal line (dotted lines: ±SEM) in panel a. The dashed horizontal line (dotted lines: ±SEM) in panel b indicates the mean training latency. Dotted lines at 300 s in panels b and c denote the cut-off time in the retention test. Error bars indicate SEM. comp. = compartment; *$p < 0.05$ and ***$p < 0.001$ vs. 0.0 mA control group (based on Mann-Whitney *U* test for panel b).

The passive avoidance task differs from spatial tests such as the ► Morris water maze both with regard to sensitivity to parahippocampal lesions and modulation of cholinergic mechanisms, suggesting that these two spatial tasks differ in their dependence on processing of polymodal sensory information (Burwell et al. 2004; Ögren et al. 2008). Finally, it should be noted that mice with hippocampal dysfunction may acquire passive avoidance, although suboptimally, using a hippocampus-independent strategy (see Baarendse et al. 2008).

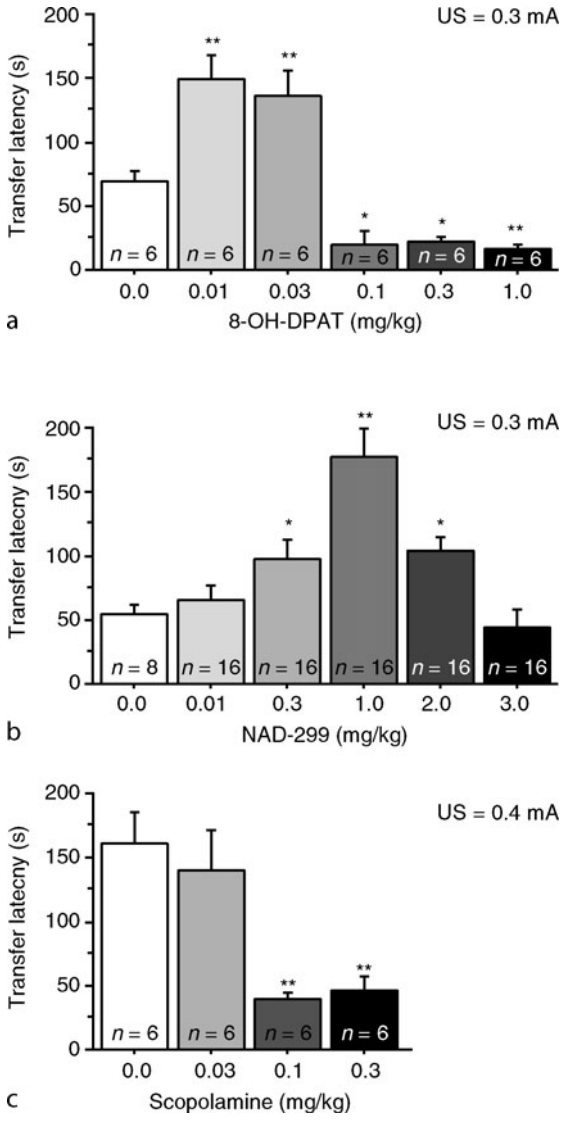
A large body of literature points at the crucial role of the amygdala, a heavily innervated assembly of many different subnuclei that are essential for aversive learning (LeDoux 2000; McGaugh 2004). Among these subnuclei, the basolateral nucleus plays a major role in the convergence of CS and US for associative learning. The basolateral nucleus of the amygdala is connected to the central nucleus of the amygdala. Outputs from the central nucleus of the amygdala are essentially responsible for the expression of fear responses. This network triggers behavioral adjustments indicative of learning and memory through motor control and concomitant autonomic and endocrine adjustments via efferent pathways. The efferent pathways are specific for certain response domains but subserve both learned and innate responses. These brain areas include hypothalamic and various brain stem areas that will not be discussed here.

Application of Passive Avoidance in Neuropsychopharmacology

Passive avoidance is one of the most frequently used animal tests for studying learning and memory mechanisms and to identify compounds modifying cognitive processes. This task is often a first-line test in

pharmaceutical companies. The task has also a prominent role in neuroscience research focusing on the role of neurotransmitters and molecular signals in learning and memory processes. An accumulated body of work has characterized the major multiple neurochemical systems and some of its molecular components which mediate or modulate this type of learning (Ögren et al. 2008). Research already in the 1970–1980s showed a significant role of cholinergic transmission in storage and retrieval of information. Thus, the nonselective muscarinic receptor antagonists such as ► scopolamine, when injected prior to passive avoidance training, were found to cause a dose-dependent impairment of passive avoidance retention (Bartus et al. 1982). Subsequent studies showed that administration of cholinomimetic drugs such as the acetylcholinesterase inhibitor ► physostigmine could partially antagonize the deficit caused by scopolamine. These findings formed part of the cholinergic hypothesis of geriatric memory dysfunction (Bartus et al. 1982) that provided the rationale for introducing ► cholinesterase inhibitors as anti-dementia drugs. A number of studies have also demonstrated a significant role for brain serotonin in passive avoidance learning. Both increases and decreases in brain 5-HT transmission have resulted in passive avoidance deficits (Ögren et al. 2008) probably reflecting the involvement of multiple 5-HT receptors in this task (Misane and Ögren 2000). However, through the use of 5-HT receptor subtype-specific ligands, such as selective 5-HT_{1A} receptor agonists and antagonists, the role of 5-HT in passive avoidance has been more thoroughly investigated (see Fig. 3). With passive avoidance as the major behavioral test it has been possible to distinguish the modulatory action of pre- and post-synaptic 5-HT_{1A} receptors in cognitive function (Ögren et al. 2008). Based on these findings, the 5-HT_{1A} receptors have emerged as an important target for drugs acting in psychopathologies characterized by mood disorders and disturbances in emotional memory (Ögren et al. 2008).

A major problem in the analysis of drug effects in passive avoidance is that drug-induced changes in emotionality, motivation, or brain chemistry may be part of the training context. ► State-dependent learning refers to the situations in which retention is poor for rodents when the drug state during learning and retention differs. This means that information acquired under the drug state can only be retrieved when the animal is in the same drug state. Analyses of state-dependent learning can be an important tool by which to assess nonspecific effects on performance from associative learning mechanisms. The research design in passive avoidance



Passive Avoidance. Fig. 3. Passive avoidance performance based on transfer latencies in the retention test in male NMRI mice as a function of drug treatment using different shock (US) intensities during training as indicated. The full 5-HT_{1A} agonist 8-OH-DPAT (**a**) facilitates at the low-dose range (0.01–0.03 mg/kg) and impairs at high-dose range (≥0.1 mg/kg). The selective 5-HT_{1A} antagonist NAD-299 (**b**) facilitates passive avoidance retention latencies in the dose range of 0.3–2 mg/kg. The muscarinic acetylcholine receptor antagonist scopolamine (**c**) impairs passive avoidance retention at 0.1 and 0.3 mg/kg. US duration was 1 s. Retention latency cut-off was 300 s. All drugs were injected either subcutaneously 15 min (a and b) or 40 min before training (**c**). Error bars indicate SEM; *$p < 0.05$ and **$p < 0.01$ vs. 0.0 mg/kg control group. (Modified from Madjid et al. 2006).

experiments should always include a test group receiving the same treatment at both training and test.

Advantages and Limitations of Passive Avoidance Experiments

The advantage with the passive avoidance procedure is that it is a single-trial task and it produces similar results in both mice and rats. Unlike multitrial tasks, single-trial tasks allow for a precise timing of drug injections either before or after training, or before the retention test. It is, therefore, possible to dissect out the possible contributions and effects of drug interventions on encoding, consolidation, and retention (memory retrieval and expression). Since the retention tests can be performed at variable time intervals after training, ▶ short-term (STM) and long-term memory (LTM) can be assessed separately. However, since subsequent tests are confounded by prior experiences, an animal can only be tested once. Post-training administration provides the opportunity for studying the endogenous modulation of memory consolidation.

There are also drawbacks with this one-trial task, including large inter-subject variability (discussed above) and different sensitivity to the shock exposures. The memory-strength (retention) is influenced by many factors including the mental state at the time of learning, emotional reactivity and responses to stress hormones (McGaugh 2004). Experimental manipulations that cause changes in locomotion, pain perception or anxiety states can also confound measures of memory. Information on these behavioral domains is important to rule out alternative explanations rather than altered cognitive function(s).

Attenuated pain perception by pharmacological or genetic manipulations with analgesic effects may render a low US ineffective as punisher, thereby preventing passive avoidance learning. Knowledge about the US responsiveness (see Baarendse et al. 2008) is crucial to rule out passive avoidance impairments because of lack of US salience/perception. Since the US is given in the dark compartment, quantification is hardly possible unless the passive avoidance system used can detect the activity of experimental animals in the dark compartment. It is useful to install photo beams that transmit through the black walls or using infrared cameras for video tracking. At least the US reactions (e.g., vocalization and jumping) of the animals should be visually observed and noted by the experimenter to exclude a potential lack of perception.

There is often a general assumption that enhanced anxiety-like behavior is associated with increased fear (avoidance) responses. Although this cannot be ruled out, there is at this moment no clear evidence that this assumption is valid (Madjid et al. 2006). On the contrary, studies using different strains of mice show that the DBA/2J strain which are more anxious than the C57BL/6J strain, show reduced passive avoidance learning compared to C57BL/6J mice (Baarendse et al. 2008). In conclusion, despite their limitations, passive avoidance paradigms have turned out to be very useful in analyzing the neurochemical and molecular basis of cognition.

Perspective

Passive avoidance tests have been used in research for more than 6 decades. The success of this behavioral test is probably based on the fact that it exploits adaptive behavioral mechanisms critical for survival and shaped through evolution. Moreover, the passive avoidance task is very flexible and allows for investigation of a large number of cognitive domains in neuropsychopharmacology and related disciplines. Yet, the full potential of this task in studying memory mechanisms is still not always well perceived in the research community. The advent of advanced passive avoidance systems will allow a much more penetrating analysis of domains of cognition with relevance for psychopathology such as latent inhibition and extinction of passive avoidance responses. In addition, the integration of additional measures such as neural responses and autonomic adjustments with passive avoidance will open up new avenues for an integrative analysis of avoidance behavior Therefore, it is suggested that the passive avoidance task has an important place in both current and future neuroscience research.

Passive Immunization

Definition

Administration of purified drug-specific antibodies produced in some other species (e.g., rabbits, mice) or in vitro. Primary advantages of this approach are the ability to achieve necessary serum concentrations of antibody virtually immediately and precise control of the antibody dose to allow study of dose–response relationships and the effects of high antibody concentrations that ca not be achieved via vaccination. Main disadvantages of passive immunization are that it requires relatively frequent injections to maintain antibody levels and is relatively expensive compared to vaccination.

Patch Clamp

Definition

Patch-clamp recording denotes a variety of electrophysiological recording modalities that exploit the property of a glass recording electrode to form an electrically tight seal (patch) against the cell membrane.

The patch-clamp technique can be used to study the opening and closing of single or multiple ion channels in mainly excitable cells. Measurements require a tight seal (gigaohm-seal) between a glass pipette, filled with an intracellular solution and a Ag/AgCl wire, and the membrane of a target cell. Various approaches can be used to yield differential data. For example, whole-cell patch clamping is used to measure the activity of ion channels across the entire surface of a cell whereas cell-attached, inside-out or outside-out patches can be used to monitor either single channel activity or massed activity of the section of membrane attached to the electrode. Inside-out patches are particularly useful for studying how cytosolic events affect ion channel activity.

Definition

Pathological gambling (PG) is classified as an ► impulse control disorder (► ICD) characterized by persistent and recurrent maladaptive ► gambling behavior and resulting in impaired social and/or occupational functioning (► DSM-IV-TR; American Psychiatric Association 2000). An essential feature of ICDs is the diminished ability to resist drives or urges to perform behaviors that may be harmful; consistently, individuals with PG frequently score high on measures of impulsivity. While classified as an ICD, PG shares many similarities with substance dependence. Of the ten diagnostic criteria that characterize PG, four resemble symptoms commonly observed in ► substance dependence including an intense preoccupation with gambling, repeated or unsuccessful attempts to stop or cut down, and aspects of tolerance and withdrawal (American Psychiatric Association 2000). Other similarities between PG and substance use disorders include clinical characteristics (e.g., higher prevalence rates in men compared to women) and courses (e.g., earlier age of onset in men, higher rates in adolescence, and lower rates in elderly adults), and an observed telescoping phenomenon in women (i.e., shorter duration between onset of gambling and the report of a gambling problem in women compared to men). Additionally, like substance dependence, individuals with pathological gambling experience cycles of ► abstinence and ► relapse.

In this sense, some have likened gambling to a nonchemical or "behavioral" addiction.

Role of Pharmacotherapy

Both psychotherapeutic and pharmacological treatments have been investigated in the treatment of PG. Effective psychotherapies have utilized behavioral (e.g., aversion therapy, in vivo and imaginal exposure, skills training) and/or cognitive (e.g., cognitive restructuring, problem solving) and motivational (e.g., motivational enhancement) techniques to address maladaptive gambling behaviors and thought patterns (Brewer et al. 2008). As with studies of psychotherapies, relatively few systematic, controlled, and adequately powered trials have investigated pharmacotherapies for PG.

Axis I and Axis II disorders often co-occur with PG (Ibanez et al. 2001); therefore, it is clinically relevant to consider treatment approaches based on types of co-occurring disorders (e.g., alcohol or drug use disorders, bipolar disorders, anxiety disorders, or major depression). Given the proposed mechanisms of action of specific psychotherapies and pharmacotherapies, it is also important to consider specific neurobiological aspects of PG (e.g., opioid system, serotonin system) when considering treatments. This chapter will focus on findings from placebo-controlled studies and cite references that review these and other studies. For additional information about specific studies, readers are encouraged to see the original sources cited in the review articles.

Opioid System

► Endogenous opioids and opioid receptors in the brain may mediate reward, urges, and hedonia. Controlled studies of opiate antagonists such as ► naltrexone and nalmefene have yielded particularly promising results. Opiate antagonists bind to opioid receptors, influencing the release of gamma-aminobutyric acid (► GABA) and subsequent dopaminergic neurotransmission from the ► ventral tegmental area (VTA) to the ► nucleus accumbens (NA) and the ventral pallidum. In this way, opioid antagonists are hypothesized to modulate the tension and/or pleasure that individuals with addictive and impulsive behaviors report feeling and are believed to help suppress urges that may lead to impulsive behaviors.

Naltrexone. Naltrexone, a long-acting opioid receptor antagonist, has been investigated in the treatment of disorders where urges are indicated as a predominant symptom including bulimia nervosa, ICDs, disorders with associated self-injurious behaviors, and various substance use disorders including alcohol and opioid dependence. Findings from such studies remain mixed, as naltrexone has not demonstrated consistent efficacy in reducing urges across all disorders. However, the success of naltrexone in treating addictive disorders (including FDA-approval for the treatments of opioid and alcohol dependence) has led to the investigations of PG (Brewer et al. 2008).

In a 12-week ► double-blind, ► placebo-controlled trial, 83 individuals with PG underwent a week-long, single-blind placebo lead-in and were randomly assigned to receive a flexible dose of either naltrexone (mean end-of-study dose of 188 mg/day) or placebo (Brewer et al. 2008). Thirty eight individuals were removed from the analyses for multiple factors (e.g., placebo responders, intolerable side effects, inability to keep study schedule) leaving 45 participants. Individuals who received naltrexone showed significant improvement on all three measures of gambling compared to those who received the placebo. By study end, 75% of individuals in the active naltrexone group, compared to 24% of those in the placebo group, reported significant improvement in gambling symptoms, although there was also a significant improvement from baseline within the placebo group. The findings from the study are limited by the frequency of placebo response, drop out related to elevations in liver enzymes, and the exclusion of individuals with co-occurring Axis I disorders.

A second, 18-week, double-blind, placebo-controlled trial of naltrexone was conducted to replicate and extend earlier findings (Grant and Potenza 2008). Following a weeklong placebo lead-in, 77 individuals with PG were randomly assigned to one of three doses of naltrexone (50, 100, or 150 mg/day) or a placebo. Based upon naltrexone's proposed mechanism of action and previous findings suggesting it reduces self-reported urges to gamble, only participants who reported significant gambling urges were included in the study. While there were no significant differences in response between doses of naltrexone, naltrexone treatment compared to placebo was associated with reduced self-reported gambling urges, longer abstinence, and improved psychosocial functioning. Placebo response was also observed, although response in this group was substantially lower than in the naltrexone group. The findings were limited by the study's short-term duration. That is, while the present study employed longer treatment duration of 18 weeks, it did not assess treatment effects past this point. Despite this limitation, the findings suggest naltrexone may be useful in treating acute PG, particularly among individuals who report significant urges to gamble. In addition, the findings suggest that a high dose of naltrexone targeted in earlier studies might not be essential to observe clinical response.

Thus far, naltrexone is the only medication having shown efficacy in two or more double-blind, controlled studies. The studies support the safety and tolerability of naltrexone in the short-term treatment of PG. However, clinicians should remain aware of its dose-dependent hepatotoxicity (Grant and Potenza 2008). Continued research via large-scale, multi-center, controlled clinical trials would help to better clarify the utility of naltrexone in the treatment of PG.

Nalmefene. Nalmefene is a long-acting opioid receptor antagonist that shares proposed mechanisms of action with naltrexone and, like naltrexone, has been investigated in the treatment of ► alcohol dependence. Unlike naltrexone, nalmefene has not shown dose-dependent hepatotoxicity. To date, one multi-center double-blind, placebo-controlled trial has examined the efficacy and tolerability of nalmefene in the treatment of PG (Brewer et al. 2008). Two hundred and seven PG subjects were randomly assigned to one of three doses of nalmefene (25, 50, or 100 mg/day) or placebo and followed for 16 weeks. Individuals who received nalmefene demonstrated improvement across a range of gambling measures, and this difference was greater than changes observed in individuals receiving placebo. The findings were limited by high frequencies of subject drop out and placebo response. Despite these limitations, the findings suggest nalmefene may be an effective pharmacologic option for the short-term treatment of PG. While its lack of hepatotoxicity makes it an appealing alternative to naltrexone, clinicians should remain aware of the reported adverse effects of nalmefene (e.g., nausea, insomnia, dizziness), particularly at higher doses, and its limited availability due to limited indications for which it is approved.

As individual differences have been associated with opioid-antagonist-treatment response in alcoholism, outcome data from nalmefene and naltrexone trials were analyzed (Grant and Potenza 2008). A positive family history of alcoholism and strong gambling urges were positively associated with response to opioid antagonists. Younger age was positively associated with placebo response. Taken together, these studies support a role for opioid antagonists in treating PG. However, more controlled studies are needed, particularly ones of longer duration and in conjunction with behavioral therapies.

Serotonin System

► Serotonin systems have been implicated in various impulse control and ► compulsive disorders (e.g., PG, kleptomania, compulsive shopping, compulsive skin picking) with studies suggesting deficits in serotonergic functioning being associated with increased impulsivity (Brewer and Potenza 2008; Williams and Potenza 2008). Thus, serotonergic medications have been examined in treating PG.

Clomipramine. ► Clomipramine is a serotonin reuptake inhibitor (SRI). In an early case study with a 31-year-old female gambler, treatment with clomipramine was associated with a reduction in gambling symptoms and gambling behavior (Kim and Grant 2001). To date, no further clinical investigations of clomipramine in the treatment of PG have been published. As such, precise conclusions about its efficacy in treating PG cannot be drawn.

Fluvoxamine. The efficacy and tolerability of ► fluvoxamine, a selective SRI (SSRI), was initially examined in the treatment of 16 individuals with PG (Brewer et al. 2008). Participants entered an 8-week placebo lead-in phase, followed by an 8-week single-blind trial of fluvoxamine. Of the original 16 participants, 10 completed the medication trial with 7 of these considered treatment responders. Treatment with fluvoxamine (mean end-of-study active dose 220 mg/day) was associated with reductions in gambling-related thoughts and behaviors. In two of the three nonresponders (both with histories of cycling mood disorders), treatment with fluvoxamine appeared to exacerbate gambling behavior. The findings are limited by a small sample size, an open-label design, and thus the possible placebo effects.

A subsequent study involving 15 patients with PG further investigated the efficacy and tolerability of fluvoxamine (Brewer et al. 2008; Kim and Grant 2001). Individuals entered a 1-week placebo lead-in followed by a 16-week crossover trial of fluvoxamine and placebo with ten participants completing the trial. Treatment with fluvoxamine (mean end-of-study active dose of 195 mg/day) yielded greater reductions in gambling-related thoughts and behaviors as compared to placebo. A significant drug-by-phase interaction was observed in which differences between fluvoxamine and placebo were observed in the second but not in the first phase of the crossover trial, consistent with a more robust placebo effect in the first phase. The study was limited by a small sample size, short treatment duration, and the placebo effects.

In a pilot study investigating the efficacy of fluvoxamine treatment, 32 individuals with PG were enrolled in a randomized, double-blind, placebo-controlled study of fluvoxamine for a duration of 6 months (Grant and Potenza 2007). There were no observed differences in treatment outcomes between the fluvoxamine-treated and placebo-treated groups. Similar to other trials of fluvoxamine, the findings were limited by placebo response and a small sample size, and the latter factor may have precluded the identification of between-group differences.

A comparison study investigated the effectiveness of fluvoxamine to ► topiramate (Iancu et al. 2008). Topiramate is a medication hypothesized to mediate its therapeutic actions via influencing the mesolimbic dopamine system via GABAergic mechanisms and has shown promise in treating disorders characterized by poor impulse control. Thirty-one men with PG were randomly assigned to receive 200 mg/day of either topiramate or fluvoxamine for 12 weeks. Results demonstrated treatment completers in both groups responded positively to treatment, with 9/12 individuals in the topiramate group and 6/8 individuals in the fluvoxamine group reporting full remission of symptoms at the end of treatment. Greater drop out was observed in the fluvoxamine group relative to the topiramate group. Additionally, improvement in scores on the Clinical Global Impression (CGI) scale reached significance for individuals who received topiramate, but not for those who received fluvoxamine. These findings were limited by a lack of a placebo-control group, raters unblinded to treatment conditions, and a small sample consisting solely of men. Nonetheless, the findings suggest that topiramate is well tolerated and may prove useful in the treatment of PG.

Paroxetine. ► Paroxetine, another SSRI, has been investigated as a possible treatment for PG. In a double-blind, placebo-controlled study examining the efficacy and tolerability of paroxetine treatment in PG (Brewer et al. 2008), subjects were entered into a week-long placebo lead-in and then assigned to receive paroxetine or placebo for 8 weeks. Results revealed a greater reduction in gambling symptoms in the paroxetine group as compared to the placebo group; however, the results are limited by a small sample size with unequal numbers of men and women and a relatively short treatment course of 8 weeks. Still, the findings provided preliminary evidence to suggest paroxetine may be effective in the treatment of PG.

A larger 16-week, double-blind, placebo-controlled study was conducted across several sites in two countries to further examine the efficacy of paroxetine (Brewer et al. 2008). Seventy-six individuals with PG were entered into a week-long placebo lead-in followed by randomization to paroxetine or placebo treatment. Although a numerically larger percentage of paroxetine-treated patients were clinical responders as compared to placebo-treated subjects (59% vs. 48%, respectively, at 16 weeks), the difference did not reach statistical significance. While the findings did not replicate those of the earlier study, perhaps related to the substantial placebo response, the results suggest paroxetine is well tolerated.

As with opioid antagonists, individual differences may be important to consider for SRIs. Specific subgroups of individuals (e.g., those with depression or anxiety disorders) might respond preferentially to SRIs, and this possibility warrants further investigation. A subsequent analysis of individuals involved in the earlier-mentioned paroxetine trial investigated the relationship between measures of impulsivity and compulsivity with respect to treatment outcome. Although both impulsivity and compulsivity measures were associated with gambling severity at treatment onset, changes in gambling symptomatology correlated with changes in impulsivity during the course of treatment. No relationship was observed with respect to paroxetine treatment. These findings suggest that treatments that target impulsivity may be worth pursuing further in the treatment of PG.

Sertraline. To date, only one controlled trial of ► sertraline, another SSRI, has been conducted (Brewer et al. 2008). Sixty individuals with PG were treated in a double-blind, flexible-dose, placebo-controlled study for 6 months. Improvement was observed in both the sertraline and the placebo groups, with no statistically significant differences in outcome measures between the two groups at trial end. These findings were limited by a high placebo response and a relatively small sample.

Escitalopram. ► Escitalopram, another SSRI, is FDA-approved for the treatment of major depression and anxiety disorders. As PG and anxiety disorders often co-occur, escitalopram has been investigated in the treatment of individuals with PG and co-occurring anxiety disorders. Thirteen individuals were enrolled in an open-label 12-week trial of escitalopram (Brewer et al. 2008; Grant and Potenza 2007, 2008). Approximately 62% of individuals who completed the study experienced a 30% or greater reduction in both gambling and anxiety symptoms and were considered treatment responders. These individuals were then enrolled in an 8-week double-blind discontinuation. While no statistically significant worsening of symptoms was reported for those who had received escitalopram, the individual randomized to placebo reported a return of gambling and anxiety symptoms within 4 weeks.

While a preliminary pilot, these data demonstrate an association between open-label escitalopram and improvements on reported gambling and anxiety symptoms and quality of life, and suggest both gambling and anxiety may be addressed simultaneously during a course of pharmacologic treatment. The study is limited by a small sample size, lack of a placebo control group in the initial phase, lack of blinding in the initial phase, and a small number of individuals participating in the double-blind discontinuation phase.

In a recent open-label trial, 19 individuals with PG were enrolled in a 10-week course of escitalopram

following a 2-week observation period (Black et al. 2007). Improvement in gambling symptom severity, urges, and behaviors and decreases in money wagered and time spent gambling were observed. The drug was well tolerated with no dropouts attributed to side effects. The limitations of the study include a small sample size, lack of a placebo group, lack of blinding, and short treatment trial duration.

Nefazodone. Nefazodone, primarily a serotonin receptor antagonist, exhibits characteristics of a mixed noradrenergic/serotonergic reuptake inhibitor (NSRI). Fourteen PG subjects were enrolled in an 8-week open-trial flexible-dose investigation of orally administered nefazodone (Grant and Potenza 2007). Of the 12 completers, 75% were considered responders with significant reductions in episodes of gambling and time and money spent gambling per week. Limitations include lack of both a placebo-control group and double blinding.

Overall, findings from studies investigating medications that target serotonin systems are mixed, generating a complex picture. While case studies and open-trial investigations have demonstrated support for the utility of SSRIs and serotonin receptor antagonists, larger controlled trials have been less consistent. The findings suggest that SSRIs and serotonin antagonists may be effective for specific groups of PG subjects. More extensive and targeted research with careful characterization of subject groups (e.g., defined by co-occurring disorders) or specific individual differences (e.g., readily measurable clinical information in self-report, behavioral and genetic domains) is necessary to better clarify the role of serotonergic drugs in the short- and long-term treatment of individuals with PG.

Mood Stabilizers

► Bipolar disorder and PG share characteristics including impulsive behavior, risk taking, fluctuations in mood, and poor judgment (Iancu et al. 2008). Additionally, PG often co-occurs with bipolar disorders. Should the impulsivity in ► mania and related disorders on a bipolar spectrum possess similar underlying neurobiological mechanisms as the urges in PG, then drugs effective in the treatment of bipolar disorder may be helpful for individuals with PG.

Lithium. A medication typically used to treat manic states and mood lability associated with bipolar disorder, ► lithium has been investigated in the treatment of PG. An early set of case studies investigated the effectiveness of lithium carbonate to treat three individuals with compulsive gambling and found lithium to be well tolerated (Brewer et al. 2008). Findings suggest lithium treatment may have blunted the reported thrill individuals experienced when gambling and decreased the frequency of gambling. The results are considerably limited by the nature of the case studies, providing only preliminary support for the continued investigation of lithium to treat PG.

To date, only one double-blind, placebo-controlled trial of lithium has been conducted (Brewer et al. 2008). Forty individuals with PG and bipolar-spectrum disorders (predominantly bipolar II) were randomly assigned to receive sustained-release lithium or placebo for 10 weeks. Although no significant between-treatment differences were observed between groups on several self-reported gambling behaviors (number of gambling episodes per week, time spent gambling per episode, or money lost gambling), greater improvement was observed for individuals receiving lithium on measures of gambling-related thoughts and urges compared to individuals receiving placebo. Decreases in measures of mania over time paralleled decreases in measures of gambling. The findings were limited by the relatively short treatment duration and a small sample size. Nonetheless, the study supports the tolerability and efficacy of lithium in the short-term treatment of PG and co-occurring bipolar-spectrum disorders. It also highlights the need for researchers to identify clinically relevant subgroups of individuals with PG.

Valproate. ► Valproate is an anticonvulsant and mood stabilizer that has been used in the treatments of bipolar disorder and epilepsy. Based upon the success of valproate and other mood stabilizers to treat disorders with impulsive features (e.g., aggressive behavior, kleptomania, ► trichotillomania, and borderline personality disorder), it has been explored in the treatment of PG.

In a single-blind trial, 42 individuals with PG were randomly assigned to receive lithium or valproate for 14 weeks (Brewer et al. 2008). Both treatment groups demonstrated improvement on gambling-related measures and no significant between-group differences by the end of treatment. While limited by a lack of a placebo-control group, a small sample size, and single-blind design, the findings suggest valproate may work as well as lithium in diminishing gambling-related symptoms in PG.

Olanzapine. Traditionally used as an antipsychotic, ► olanzapine demonstrates mood-stabilizing properties, possibly mediated through dopamine and serotonin receptor antagonism, and thus has been investigated as a possible treatment for PG. Support for its proposed use in PG stems from its efficacy in the treatment of other ICDs such as trichotillomania and skin picking. Two controlled trials of olanzapine to treat PG have been conducted.

In a 12-week double-blind, placebo-controlled trial, 42 individuals with PG was randomly assigned to receive

olanzapine or placebo (Grant and Potenza 2008). Treatment with olanzapine was similarly efficacious as placebo. Olanzapine treatment was associated with discontinuation. Limitations included a relatively small sample and short-term duration. A 7-week, double-blind, placebo-controlled trial of olanzapine was conducted with a group of 21 individuals with video-poker-based PG (Grant and Potenza 2008). As with the other investigations, no significant between-group differences in outcome were observed. The study was limited by a small sample, consistently, solely of video-poker gamblers and the exclusion of individuals with co-occurring psychiatric disorders. Findings suggest that olanzapine may not be any more effective than placebo in the treatment of PG.

Carbamazepine. ► Carbamazepine is a mood stabilizer that is used to treat bipolar disorder and has shown some efficacy in treating ICDs. Support for the investigation of carbamazepine to treat PG comes from two sources: the proposed relationship between PG and bipolar disorder, and the implication that carbamazepine may dampen the impulsivity proposed to underlie PG (Black et al. 2008). A 10-week open-label study examined extended-release carbamazepine in a sample of eight individuals with PG and found the majority to be treatment responders with a reduction in gambling severity; almost half reported abstaining from gambling during the final month of treatment. The findings suggest the possible efficacy of extended-release carbamazepine in the treatment of PG, but should be interpreted with caution based upon the small sample size, the lack of blinding and a placebo-control group, and considerable treatment drop out.

Overall, studies investigating the effectiveness of mood stabilizers in the treatment of PG suggest some medications may reduce preoccupations with gambling, frequency of gambling, and amount of money wagered on gambling; however, not all mood stabilizers have demonstrated consistent efficacy. Therefore, it is important for research to evaluate further the efficacies and tolerabilities of specific mood stabilizers in the treatment of well-defined groups of PG subjects such as those with co-occurring bipolar disorders.

Glutamatergic Agents

N-Acetyl cysteine. Studies have suggested that extracellular ► glutamate within the nucleus accumbens may mediate reward-seeking behaviors by decreasing cravings. ► N-acetyl cysteine (NAC), a glutamate-modulating agent, is proposed to influence extracellular levels of glutamate leading to a stimulation of the inhibitory glutamate receptors. NAC has been found to reduce reward seeking in studies of cocaine dependent rats and craving in a study of individuals with cocaine addiction.

To date, only one study has examined the potential of NAC in the treatment of PG (Grant and Potenza 2008). Twenty-seven individuals with pathological gambling were entered into an 8-week open-label trial of NAC with treatment responders completing a 6-week randomized, double-blind discontinuation phase. Gambling symptoms improved in the majority of treatment completers during the treatment phase, with a trend toward a significant difference between individuals in the active vs. the placebo group at the end of the discontinuation phase (response percentages of 83.3 and 28.6% for the active drug and placebo groups, respectively). These findings suggest that there may be an effect that is attributable to the administration of the active drug, although the lack of a placebo control group in the initial phase limits the interpretation of the results. Additionally, the study was limited by a small sample size. The results preliminarily suggest modulation of the glutamate system may play an important role in the reward-seeking behavior observed in PG and that NAC may be effective in the treatment of PG.

Other Agents

Bupropion. As a reuptake inhibitor of dopamine and noradrenaline, ► bupropion is approved for the treatment of major depression and nicotine dependence, and in the latter condition reduces both smoking-related urges and withdrawal. Based on data that bupropion may be helpful in the treatment of ► attention deficit hyperactivity disorder (ADHD), proposed similarities between ADHD and pathological gambling, and bupropion's proposed mechanism of action, bupropion was investigated to test the hypothesis that it would target impulsivity and attentional deficits in individuals with PG (Iancu et al. 2008).

In an initial open-label trial, ten individuals with PG were prescribed a flexible dose of bupropion for 8 weeks (Brewer et al. 2008). The drug was well tolerated and significant improvements in gambling symptoms were observed. Study imitations include the open-label, unblinded design, small sample, and short treatment duration. A subsequent study examined the efficacy of bupropion, comparing it to that of naltrexone, in the treatment of PG (Brewer et al. 2008). Thirty-six men with PG were randomly assigned to receive either sustained-release bupropion or naltrexone for 12 weeks. The majority of individuals in both treatment groups responded well to treatment with comparable percentages of responders. The findings suggest that bupropion may be as effective as naltrexone in reducing gambling severity,

the frequency of gambling, and the amount of money spent on gambling. Study limitations include the lack of a placebo-control group, short duration of treatment, and small sample.

A later placebo-controlled trial was conducted in which 39 individuals with PG were randomly assigned to a 12-week course of bupropion or placebo (Iancu et al. 2008). Individuals receiving bupropion and placebo showed comparable improvement on short-term measures of gambling severity and placebo response was frequently observed. Study limitations include significant treatment drop out. Together, findings suggest that future treatment trials target specific subgroups of individuals with PG, such as those with co-occurring depression or nicotine dependence, disorders representing current indications for bupropion.

Summary

Findings from pharmacologic studies emphasize the potential for pharmacotherapies, with arguably the strongest data supporting the use of opioid antagonists, particularly among individuals with strong gambling urges and familial propensities for addiction. Other medications (e.g., glutamatergic agents such as NAC) also appear promising, whereas other drugs (e.g., SRIs) have shown mixed results and might be particularly helpful for specific subgroups. The interpretation of open-label studies should be circumspect, given frequent placebo responses in controlled trials and apparent failures to replicate initially promising open-label findings in randomized placebo-controlled trials. Pharmacotherapy trials thus far have been relatively short and highlight the need for large-scale investigations with longer treatment courses in order to better understand the potential long-term benefits and risks of these medications. Medications that have been tested can be conceptualized and grouped based upon their proposed mechanisms of action (e.g., opioid antagonists, SRIs, mood stabilizers), and individual differences (e.g., with respect to co-occurring disorders) and may be particularly relevant in selecting the most appropriate drug treatments for specific patients. Investigating potential benefits and risks of specific pharmacotherapies in conjunction with specific empirically supported psychotherapies represents an important next step.

Patient-Controlled Analgesia

Definition

A method of pharmacological pain relief in which a patient initiates and controls delivery of the analgesic, typically by pressing a button on the PCA machine, which results in an infusion of a prescribed amount of the analgesic through an implanted intravenous catheter. There is a certain amount of time after each infusion during which no further infusions are possible.

Pavlovian Conditioning

Synonyms

Classical conditioning; Respondent conditioning

Definition

In its simplest form, Pavlovian conditioning typically involves the presentation of two stimuli; one is termed a conditioned stimulus (CS) and the other is termed an

unconditioned stimulus (US). The stimuli are often presented relatively close in time and independent of the subject's behavior. Conditioning is said to occur when one of the stimuli either comes to control a response it did not previously control or modify an ongoing behavior. In laboratory situations, the CS tends to be a relatively neutral stimulus such as an auditory, olfactory, tactile, or visual cue. The US tends to be a stimulus with motivational properties (food, water, sex, illness, drug, etc.). This setup tends to be for methodological convenience (i.e., easy to measure conditioning) rather than ecological relevance as stimuli with motivational effects readily function as CSs and occasion setters. Although most Pavlovian conditioning research involves repeated presentation of the CS and US, one trial conditioning is well documented.

Pavlovian Fear Conditioning

Classical fear conditioning; Conditioned emotional response; Conditioned freezing

Definition

Pavlovian fear conditioning is a behavioral paradigm in which an initially neutral cue (the ▶ conditioned stimulus, ▶ CS), usually a tone, is paired with an aversive stimulus (the ▶ unconditioned stimulus, ▶ US), usually a footshock, that elicits a fear ▶ unconditional response (▶ UR). As a result of this pairing, subjects form an associative memory between the CS and US. Following training, when presented with the CS alone, the subject will exhibit a fear-▶ conditioned response (▶ CR), which is a defensive behavior related, but not identical to the UR. Aside from fear of the tone (▶ cued fear), subjects also come to fear the environmental context associated with shock administration (▶ contextual fear). In the standard paradigm, rodents are trained in fear-conditioning chambers and receive 1–10 tone-shock pairings over the course of 5–10 min. The rodents are returned to the conditioning chambers days or weeks later for a brief contextual fear test, which consists of placing the animals in the chambers for 5–10 min and observing fear behaviors. On a third day, cued fear is assessed in a novel context by presenting the animals with the training tone 1–3 times after a 2-min baseline period (Anagnostaras et al. 1999, 2000; Fanselow 1984; Maren 2008). This overall experimental scheme is often modified depending on the needs of the experimenters. ▶ Fear is an inferred psychological state, which serves to organize and coordinate various species-specific defensive responses necessary for survival. Many defensive responses can be studied during the contextual and cued fear tests, including increases in heart rate, blood pressure, respiration, analgesia, ulcers, glucocorticoid activation, muscle tone, skin conductance, and potentiated startle (Davis 1992). However, the most commonly assessed fear response in mice and rats is ▶ freezing behavior, because of convenience and reliability. Freezing is defined as the absence of all movements other than that required for respiration, and can be scored by observers using time-sampling, a stopwatch, or a variety of automated methods (Anagnostaras et al. 2000; Fanselow 1984).

Impact of Psychoactive Drugs

Neurobiology

As the neurobiology and behavioral psychology of Pavlovian fear conditioning are well understood, Pavlovian fear conditioning has become a valuable rodent model of both memory and anxiety in humans. Pavlovian fear conditioning depends on the convergence of CS and US information in the basolateral/lateral complex of the ▶ amygdala. The CS–US association may occur in the amygdala via a synaptic process like ▶ long-term potentiation (Rogan et al. 1997). Production of the fear response, following presentation of the CS or US, depends on the central nucleus of the amygdala, which coordinates the output of defensive responses through downstream connections with response-specific brain centers (Davis 1992; Maren 2003). For example, freezing and conditioned analgesia are generated by the periaqueductal gray matter, while potentiated startle is mediated by the nucleus

reticularis pontis caudalis. Thus, discrete cued fear is a reductionist model of associative memory that can be studied in the basolateral/lateral complex of the amygdala. Aside from the amygdala, contextual fear is dependent on the ▶ hippocampus; and this rodent paradigm has become a leading model of human ▶ declarative memory (Anagnostaras et al. 2001; Maren 2008). As with human amnesia, lesions of the hippocampus made shortly after conditioning (recent memory) produce a severe and selective deficit of contextual fear, whereas those made 1 month or more after training (remote memory) have little or no effect on contextual fear, a phenomenon known as temporally graded retrograde amnesia. This occurs because over time, contextual memories come to depend on cortical areas. Therefore, contextual fear conditioning can be used as a model not only for acquisition of declarative memories, but also for consolidation of those memories from a hippocampus-dependent to cortical-dependent state. In contrast, the amygdala remains important for both contextual and tone-fear conditioning for the life of the animal (Gale et al. 2004). Therefore, it is believed that the role of the hippocampus in fear conditioning is specifically to acquire a spatial or configural representation of context, which is then conferred to the amgydala for association with the shock (Anagnostaras et al. 2001).

Role in Pharmacological Screening

As a Model of Higher Level Cognition

Fear conditioning is an efficient model of higher level cognition for many reasons (Anagnostaras et al. 2000). First and foremost, conditioned freezing is an extremely reliable behavioral measure, and the equipment used is fairly standardized, compact, and readily available. Second, the neurobiology is well understood and internally controlled; it can dissociate hippocampus-dependent and -independent memory within the same subject. For example, a deficit observed in contextual and tone fear can be interpreted as affecting fear in general, whereas a deficit selective to contextual fear can be interpreted as likely to affect declarative memory. Third, it is rapidly acquired (1–10 tone-shock pairings in a 5–10-min period are commonly used) and lasts the lifetime of the animal. Because training is punctate and brief, it is highly suitable for studies that require the examination of memory a few minutes or hours after acquisition, or those requiring administration of an agent during training. Most other hippocampus-dependent memory paradigms, in contrast, require many hours and days of training. Fourth, it is very amenable to high-throughput screening, because of reliability, quick acquisition, and compact equipment that can be concentrated in a small lab space. Fifth, the procedures for mice and rats are quite similar and fairly interchangeable. This means fear-conditioning researchers can take advantage of the large behavioral and pharmacological database for rats, as well as the more novel database for genetically modified mice. Finally, fear conditioning has already been used extensively in rodents to model cognitive function and a large experiential database exists on the various caveats and procedures one can use.

Some uses of fear conditioning in pharmacological screening include toxicological assessment for amnesia or specific assessment of drugs to enhance memory. For example, researchers may administer a given treatment drug during fear-conditioning training to ensure that overall cognitive functioning remains intact. Fear conditioning can be similarly useful in screening for agents that may enhance memory acquisition or expression. This can be done in normal mice or rats if screening for general cognitive enhancers or in genetic models of memory defects, such as ▶ Alzheimer's disease or mental retardation. Fear conditioning has already proven valuable in this sense, and its high efficiency and comparable performance in mice and rats have lent to this value (Maren 2008).

A variety of ancillary measures can be taken during the fear-conditioning session which can be useful in addressing confounds or other concerns the experimenter may have. For example, locomotor activity is frequently assessed prior to the tone-shock pairing on the training day, as an indicator of overall activity. If a drug or mutation produces a large drop or increase in activity during this time period, it is likely it would do so on the open-field paradigm as well. Second, activity during the shock can be used as a gross measure of pain. If shock reactivity is abnormal this could suggest that the animals are unable to feel pain. All of these measures may be taken using automated equipment (Anagnostaras et al. 2000). Finally, freezing during the training period (known as post-shock freezing) can be used as a measure of initial acquisition. This could be particularly important in situations where animals show deficits in contextual and tone fear during testing, in order to show that the animals are actually capable of exhibiting the freezing response. Thus, fear conditioning offers many opportunities for control over various confounds that may present themselves.

As a Model of Anxiety Disorders, Especially Phobia

Pavlovian fear conditioning is also a prominent model of pathological fear, such as in ▶ anxiety disorders. Fear conditioning is a model for both etiology as well as treatment of pathological fear, especially phobia. Most often phobia is treated through exposure (or extinction) therapy, whereby the subject is repeatedly exposed to the cues associated with fear. In animals, this is most often

modeled through repeated presentations of the tone without any reinforcement. ▶ Extinction is effective but weaker than initial conditioning, and is thus subject to loss due to changes in conditions of testing (such as a context shift, known as renewal), or simply passage of time (known as spontaneous recovery). Thus, considerable effort has been made to develop extinction-enhancing drugs, which would be given during extinction training to make it more stable and robust. Among agents that have been discovered this way are D-cycloserine and cannabinoid agonists (Quirk and Mueller 2008). Fear conditioning can also be used to screen for drugs which reduce fear specifically, though this is less common than using unlearned fear tasks, such as the ▶ elevated plus maze. This is likely to change as fear conditioning continues to be adopted in pharmacological work.

Conclusion

Pavlovian fear conditioning, especially conditioned freezing, has become a valuable tool for modeling general cognitive function, especially declarative memory or pathological fear. It is also a model of learning and memory, in general. The simple and reliable nature of the paradigm lends itself to high-throughput applications, which can be followed up in secondary evaluation by additional memory or anxiety tests. Thus, Pavlovian fear conditioning is a tool of growing utility in pharmacological assessment.

PDE3 Inhibitors

Definition

PDE3 inhibitors are drugs that inhibit phosphodiesterase3, which hydrolyzes cAMP. PDE3 is found in the heart and smooth muscles, but also throughout the brain.

There are two PDE3 inhibitors on the market; milrinone (Primacor) for the treatment of congestive heart failure and cilostazol (Pletal) for the treatment of intermittent claudication. Cilostazol is also in clinical development for the treatment of stroke.

PDE4 Inhibitors

Definition

PDE4 inhibitors are drugs that inhibit phosphodiesterase4, which hydrolyzes cAMP. PDE4 is found in a wide variety of tissues including lungs and smooth muscles. It is also present in brain structures such as the hippocampus, amygdala, and cortical areas. PDE4 inhibitors have clinical potential for the treatment of inflammatory disorders including asthma and chronic obstructive pulmonary disease. In addition, they could offer possible treatments for depression, Alzheimer's disease, or pain. However, up to now none of the developed PDE4 inhibitors has reached the market due to the emetic side effects including nausea and vomiting. One of the most explored PDE4 inhibitors is rolipram.

PDE5 Inhibitors

Definition

PDE5 inhibitors are drugs that inhibit phosphodiesterase5, which hydrolyzes cGMP. PDE5 is particularly present in smooth muscles of lungs and the corpus cavernosum. The PDE5 inhibitor sildenafil is on the market for the treatment of erectile dysfunction under the name of Viagra. In addition, sildenafil has been approved for the treatment of arterial pulmonary hypertension under the name of Revatio. Two other PDE5 inhibitors approved for the treatment of erectile dysfunction are vardenafil (Levitra) and tadalafil (Cialis).

Peak-Interval Procedure

Definition

Peak-interval (PI) procedure is a ▶ reproduction protocol that comprises two types of trials randomly intermixed: In fixed-interval trials, subject's responses are reinforced at the to-be-timed duration. In peak trials, subjects are required to respond at the appropriate time, but no reinforcement is available. The typical result is that the distribution of responses in peak trials is centered around the criterion duration, with a variance proportional to this criterion. In a variant of this procedure, the PI procedure with gaps, subjects are also presented with trials in which the to-be-timed duration is interrupted by a brief gap or retention interval in order to evaluate their short-term memory for time.

Definition

The onset of ▶ schizophrenia before age 18 years, i.e., during childhood and adolescence. Early onset schizophrenia refers to cases with onset between age 13 and 17 years whereas very early onset schizophrenia or childhood-onset schizophrenia refers to onset before age 13 years.

Role of Pharmacotherapy

Nosology, Epidemiology, Phenomenology

The diagnosis of pediatric schizophrenia is made using unmodified criteria for adulthood-onset schizophrenia (i.e., onset at age 18 or older). The subtypes of schizophrenia are also identical in both groups. While the prevalence of childhood-onset schizophrenia (onset of psychotic symptoms before 13 years of age) is very low (approximately 1/100 cases of schizophrenia), approximately 12%–33% of individuals with schizophrenia have their illness onset between age 13 and 17 (Kumra et al. 2008). Current phenomenological, cognitive, genetic, and neuroimaging data strongly support continuity between pediatric and adult onset schizophrenia, suggesting similar neurobiological correlates and clinical deficits (Kyriakopoulos and Frangou 2007). Although the (yet unknown) etiology and pathophysiology of pediatric and adulthood schizophrenia are believed to be very similar, patients with pediatric onset schizophrenia seem to have a worse illness course that generally is characterized by greater chronicity and functional impairment compared to the adulthood-onset counterpart (Kumra et al. 2008). Whether this is related to direct biological effects or to the fact that the psychotic illness occurs at a time of critical developmental tasks, which disrupts the achievement of educational and social milestones, is unclear. However, due to the difference in outcomes, schizophrenia with onset before 18 years has been used as a distinct phenotype for genetic research in order to achieve greater homogeneity. Of note, however, patients with adulthood-onset schizophrenia also commonly experience varying degrees of developmental delays, psychosocial and educational problems, and functional decline during childhood or adolescence. Moreover, patients with pediatric and adulthood-onset schizophrenia frequently report "prodromal" psychotic symptoms and signs in childhood or adolescence. The ▶ schizophrenia prodrome often consists of depressive and negative symptoms as well as, attenuated psychotic symptoms (i.e., subthreshold forms of unusual ideas, suspiciousness, grandiosity, abnormal perceptions, and disorganized thought, speech or behavior) (Correll et al. in press).

The Evidence Base

To date, 14 randomized controlled trials (RCTs) (n = 1,155) have been completed in patients with pediatric schizophrenia (Kumra et al. 2008; Sikich et al. 2008). Six trials had a placebo comparator and evaluated the efficacy and safety of ▶ haloperidol (N = 1, n = 12), haloperidol and loxapine (N = 1, n = 75), ▶ aripiprazole (N = 1, n = 301), quetiapine (N = 1, n = 220), ▶ risperidone (N = 1, n = 160), and ▶ olanzapine (N = 1, n = 107), and one trial (n = 279) used a very low dose of risperidone (0.15–0.6 mg/day) as a pseudo-placebo comparator (N denotes the number of trials with each drug, n denotes the number of patients).

In addition to the placebo-controlled, three-arm study comparing haloperidol and loxapine (N = 1, n = 75), another seven trials (n = 275) compared antipsychotics head-to-head in youth with schizophrenia. These included a comparison of ▶ thiothixene and ▶ thioridazine (N = 1, n = 21), haloperidol, olanzapine, and risperidone (N = 1, n = 50, 52% schizophrenia spectrum psychosis, 48% affective spectrum psychosis), ▶ molindone, olanzapine, and risperidone (N = 1, n = 119), haloperidol and ▶ clozapine (N = 1, n = 21), clozapine and olanzapine (N = 2, n = 64), and olanzapine and ▶ quetiapine (N = 1, n = 50, 64% schizophrenia spectrum psychosis, 36% affective spectrum psychosis).

Efficacy

While the two underpowered studies from 1976 and 1984 involving ▶ first-generation antipsychotics (FGAs) did not significantly separate from placebo, there was a trend for greater improvement on the Clinical Global Impressions-Severity (CGI-S) scale in favor of haloperidol and loxapine in the one study, and a significant baseline to endpoint change in the Brief Psychiatric Rating Scale (BPRS) for haloperidol, but not for placebo (Kumra et al. 2008). By contrast, all of the ▶ second-generation antipsychotic (SGA) trials completed since 2005 showed significantly greater improvements on the primary outcome measure, the Positive and Negative Syndrome Scale (PANSS) for all doses that were studied. Overall, the numbers-needed-to-treat (NNT) for study defined response for aripiprazole, olanzapine, quetiapine, and risperidone range from 4 to 10. Based on the results from these placebo-controlled trials in pediatric schizophrenia, risperidone, quetiapine, olanzapine and aripiprazole were approved by the Food and Drug Administration (FDA) in the USA for use in adolescents age 13–17 years old, and aripiprazole was approved for use in adolescents age 15–17 years in Europe by the European Medicines Agency (EMEA). Moreover, after an official FDA hearing in June 2009, olanzapine and

quetiapine are expected to receive FDA approval in the USA for use in adolescents age 13–17 years with schizophrenia. Despite inadequate trial data for first-generation antipsychotics, haloperidol and thioridazine were grandfathered in, being indicated for adolescents with schizophrenia in the USA, and the dosing and use of several first-generation antipsychotics, mainly haloperidol, for adolescents with schizophrenia is mentioned in regulatory documents in some European countries.

Across the seven studies, comparing two FGAs, one FGA with one or two SGAs, or two SGAs with each other, the only significant group differences were found in favor of clozapine compared to haloperidol, regular dose olanzapine (up to 20 mg/day) and to "high"-dose olanzapine (10–30 mg/day) (Kumra et al. 2008; Sikich 2008). Since in all active controlled studies, the numbers of patients in individual study arms were very small, ranging from 8 to 41, a type-2 error cannot be excluded; yet the results of relatively similar efficacy results parallel data in adult schizophrenia.

Tolerability and Side Effects

Children and adolescents seem to be more sensitive to most antipsychotic adverse effects, including sedation, ► Extrapyramidal motor side-effects (except for ► akathisia), withdrawal dyskinesia, prolactin abnormalities, weight gain, and metabolic abnormalities (Correll 2008a). On the other hand, adverse effects that require a longer time to develop (e.g., diabetes mellitus) and that are related to greater medication dose and lifetime exposure (e.g., ► tardive dyskinesia) are less prevalent in pediatric samples. However, there is concern that these later onset adverse events are not seen because of short follow-up periods and that they may emerge in vulnerable patients prematurely in adulthood the earlier antipsychotics are started in childhood.

► Extrapyramidal Side Effects (EPS)

In general, children and adolescents are more sensitive than adults to Parkinsonian side effects associated with FGAs and SGAs (Correll 2008a). An RCT of 40 youths with psychotic disorders comparing haloperidol (mean dose: 5 mg/d), risperidone (mean dose: 4 mg/d), and olanzapine (mean dose: 12 mg/d) found substantial EPS not only with haloperidol (67%), but also with olanzapine (56%) and risperidone (53%), although haloperidol-treated patients reported more severe EPS (Sikich et al. 2004). In the Treatment of Early-Onset Schizophrenia-Spectrum (TEOSS) study, patients randomized to molindone (mean dose: 59.9 mg/day) required more frequent coadministration of an anticholinergic (45%) than patients randomized to risperidone (mean dose: 2.9 mg/day, 34%) or olanzapine (mean dose: 11.8 mg/day, 14%), even though patients on molindone were given prophylactic, blinded benztropine 0.5 mg bid (Sikich et al. 2008). Clozapine and quetiapine appear to be associated with relatively low EPS rates in pediatric patients. For aripiprazole and ► ziprasidone, EPS rates appear to increase with increasing dose.

Akathisia

Incidence rates of ► akathisia from placebo-controlled RCTs in pediatric schizophrenia have been reported for aripiprazole (5% for placebo, 5% in the 10 mg/day group, and 11.8% in the 30 mg/day group), risperidone (6% on placebo, 7% in the 1–3 mg/day group, and 10% in the 4–6 mg/day group), corresponding to NNH of 15 to no risk for aripiprazole 30 mg/day and 10 mg/day, respectively, and 25 to 100 for risperidone 4–6 mg/day and 1–3 mg/day, respectively (Correll 2008b). The relatively high akathisia rates for placebo, especially in the pediatric schizophrenia trials, suggest the potential presence of a relevant carryover effect from prior antipsychotic treatment or the possibility of withdrawal phenomena after a brief washout from antipsychotics and/or medications that can mitigate akathisia. In the TEOSS study, molindone, but not olanzapine or risperidone, was associated with a significantly greater rate of self-reported akathisia compared to risperidone and olanzapine (Sikich et al. 2008).

Withdrawal Dyskinesia

During FGA treatment, youths are at risk of developing withdrawal dyskinesia, yet, unlike in adults, dyskinetic movements are frequently reversible. Withdrawal dyskinesia rates appear to be lower with SGAs compared to FGAs, although a switch from an antipsychotic with strong D2 affinity (risperidone or aripiprazole) to one with less potent affinity (quetiapine or clozapine) may predispose to withdrawal dyskinesia (Correll 2008a).

► Tardive Dyskinesia (TD)

Long-term TD data in patients with pediatric schizophrenia are lacking. A meta-analysis of 10 studies lasting at least 11 months reported on TD rates in 783 patients age 4–18 (weighted mean: 10) years old. Most patients were prepubertal (80%), male (82%), white (79%), and only 3% had a schizophrenia spectrum disorder (Correll and Kane 2007). Across these studies, only three cases of TD were reported, resulting in an annualized incidence rate of 0.4%, which was approximately half of the rate found in a prior meta-analysis of TD rates in adults. However, it is unclear how much these data can be extrapolated to pediatric patients

with schizophrenia, as antipsychotic doses were low, and lifetime exposure was relatively short.

Weight Gain

Although pediatric data are still limited, youth with severe psychiatric disorders seem to be at increased risk for being overweight or obese, especially when exposed to antipsychotics for longer periods of time. Age-inappropriate weight gain is of particular concern in pediatric patients, due to its association with glucose and lipid abnormalities and cardiovascular morbidity/mortality. Reasons for weight gain are complex, including psychiatric illness, unhealthy lifestyle, and treatment effects. A review of pediatric data suggests that the weight gain potential of FGAs and SGAs follows roughly the same ranking order as found in adults, but that the magnitude is greater (Correll 2008a). Exceptions may be a greater relative weight gain propensity of risperidone, and a greater likelihood of aripiprazole and ziprasidone to not be weight neutral in subgroups of pediatric patients (Correll et al. 2009). For example, in an 8-week study, Sikich et al (2004) found a higher weight gain in young patients age 5–17 years with psychotic disorders taking olanzapine for 8 weeks (7.1±4.1 kg) than in those taking either risperidone (4.9±3.6 kg) or haloperidol (3.5±3.7 kg); all weight gain was severe and disproportionate to that expected from normal growth. Results from four 6-week studies in adolescents with schizophrenia suggest that the olanzapine group had the greatest risk for significant weight, risperidone and quetiapine were associated with intermediate risk, and aripiprazole showed the lowest risk. The respective numbers-needed-to-harm (NNH) for ≥7% weight gain was 4 for olanzapine, 7–8 for quetiapine, 8 for risperidone, and 25–34 for aripiprazole (Correll 2008b). However, the interpretation of weight gain results across various studies and agents is complicated by the effects of baseline weight, developmental stage and growth, past antipsychotic exposure, treatment duration and setting, comedications, etc., that varied across trials.

Metabolic Adverse Effects

Whereas in adults the link between antipsychotics and adverse metabolic effects, such as dyslipidemia, hyperglycemia, diabetes, and metabolic syndrome, has been established, the few pediatric studies which reported data have produced mostly negative results. Interpretation of these findings is limited by the small sample size, varying treatment histories, and inclusion of non-fasting blood assessments. Case reports of new-onset diabetes in antipsychotic-treated youths and the known link between weight gain and metabolic abnormalities suggest that youths are at least as liable to develop metabolic abnormalities as adults. However, in pediatric RCTs, so far, only olanzapine has been associated with significant increases in glucose, insulin, and lipids (Correll 2008a,b). Nevertheless, the lack of significant metabolic abnormalities in the other short-term RCTs despite mostly significant weight gain needs to be interpreted with caution, as the negative findings could be due to the short-term trial duration, lack of strict fasting assessments, and to order effects in patients with more extensive past antipsychotic exposure. A recent cohort study in 272 antipsychotic-naive youth (30.1% with schizophrenia spectrum disorders) confirmed that during the first 12 weeks of treatment, olanzapine has the greatest adverse effect on body composition, which was associated with significant worsening of fasting glucose, insulin, insulin resistance and all lipid parameters, except for HDL-cholesterol (Correll et al. 2009). By contrast, despite similar adverse effects on body composition, the metabolic effects differed across quetiapine, risperidone and aripiprazole. At least during the first 3 months of treatment, quetiapine was associated with a significant increase in most lipid parameters, whereas with risperidone lead only to a significant increase in triglycerides, and changes with aripiprazole remained non-significant. This suggests that in addition to indirect, weight-related metabolic changes, direct, weight-independent effects on glucose and lipid metabolism exist, at least for some antipsychotics.

Prolactin-related Side Effects

FGAs and SGAs can elevate prolactin levels, and these elevations appear to be accentuated in children and adolescents. Similar to adults, albeit at higher levels during adolescence, the relative potency of antipsychotic drugs in increasing prolactin is, roughly: ▶ paliperidone≥ risperidone>haloperidol> olanzapine≥ziprasidone> quetiapine≥clozapine>aripiprazole. To date, adequate long-term data are lacking to determine if hyperprolactinemia at levels found during antipsychotic therapy alters bone density, sexual maturation, or the risk for benign prolactinomas (Correll 2008a). Since aripiprazole is a partial D2 dopamine agonist, prolactin levels can decrease below baseline. To date, no adverse effects of low prolactin have been described in youth. Complicating the interpretation of the relevance of prolactin elevations in youth is the fact that sexual and reproductive system side effects related to prolactin levels are rarely directly inquired about, and youth might either not express these symptoms due to sexual immaturity or because they do not know what their normal levels of functioning ought to be.

Summary and Conclusion

Although still understudied, schizophrenia with onset in childhood and, especially, with onset in adolescence seems to be biologically and phenomenologically continuous with adulthood-onset schizophrenia, albeit being more often associated with poorer illness course and outcomes. Moreover, children and adolescents appear to be more sensitive to antipsychotic adverse effects than adults, at least compared to more chronically ill samples. As in adults, antipsychotics are more effective than placebo, with meaningful clinical effects. Moreover, also like in adults, differences in efficacy between antipsychotics seem to be much smaller and less predictable than differences in side effects and, thus, in effectiveness, which takes the short- and long-term side effect burden and treatment discontinuation rates into account. Based on this risk-benefit evaluation, it appears that second-generation antipsychotics might be preferable to first-generation antipsychotics to reduce the risk for EPS, TD, secondary negative symptoms, early treatment discontinuations and, possibly, relapse rates. However, since a number of second-generation antipsychotics are associated with significantly greater risks for age-inappropriate weight gain and metabolic abnormalities than mid and high potency first-generation antipsychotics, the neuromotor side effect advantages and related benefits are likely offset by the risk of longer-term health problems for those higher metabolic risk second-generation antipsychotics. Therefore, it appears that second-generation antipsychotics with the least risk for developmentally inappropriate weight gain and related or, even, direct metabolic abnormalities are to be considered first-line treatment options. In case these fail, higher cardiometabolic risk antipsychotics should be tried. Given the significant efficacy advantage of clozapine over first- and second-generation antipsychotics in pediatric onset schizophrenia similar to adulthood schizophrenia, clozapine should be considered for severely ill and treatment resistant youth with schizophrenia to improve outcomes and functioning, balancing its problematic side effect profile against its superior efficacy.

Pemoline

Synonyms

Magnesium pemoline

Definition

Pemoline is a psychostimulant that was used for the treatment of attention deficit hyperactivity disorder. It was less effective than methylphenidate and was withdrawn from the U.S. market due to liver toxicity. In earlier studies, it was found to produce small enhancements in selective aspects of learning and memory in human and animal subjects.

Pentazocine

Definition

Pentazocine is a synthetic opioid with partial agonist–antagonist properties. It is used to treat mild to moderately severe pain. It can partially block effects of full opioid agonists such as ▶ morphine and heroin. It exists as one of two enantiomers: (−)-pentazocine is a ▶ κ-opioid receptor agonist while (+)-pentazocine is not but displays ten-fold greater affinity for sigma receptors. This action on sigma receptors may account for notable side effects that include hallucinations and other psychotomimetic effects. Apart from its analgesic effects, pentazocine has minimal clinical use. It is subject to abuse and dependence, although the severity is typically less than that for full opioid agonists. Some tablets are formulated to contain both pentazocine and naloxone to reduce abuse; the naloxone blocks opioid effects if the tablets are dissolved and injected, but allows analgesia to develop if they are taken orally.

Pentobarbital

Synonyms

Pentobarbitone; Sodium 5-ethyl-5-(1-methylbutyl) barbiturate

Definition

First synthesized in 1928, pentobarbital is a short-acting barbiturate used formerly in humans as a sedative/hypnotic and anxiolytic agent. Now it is used more commonly as an anesthetic in veterinary practice and as an anticonvulsant. Like other barbiturates, it acts at the $GABA_A$ receptor to enhance inhibitory neurotransmission but it also acts as an antagonist at glutamate receptors of the AMPA subtype, thereby reducing excitatory neurotransmission. It is now a regulated ▶ drug of abuse, partly because of its association with suicide and as an agent of euthanasia.

8 β[(methylthio)methyl]-6-propylergoline monomethanesulfonate; LY127809

Definition

Pergolide is a centrally and long-acting D1 and D2 dopamine receptor agonist. It is believed to stimulate dopamine receptors in the nigrostriatal system. The compound also inhibits the secretion of prolactin and thus is used to treat hyperprolactinemia. Pergolide is generally used as an adjunctive treatment with ▶ levodopa/carbidopa for signs and symptoms of Parkinson's disease. However, the compound was withdrawn from the US market due to stimulation of $5\text{-}HT_{2B}$ receptors and the resulting heart valve problems (valvulopathies). Perinatal Exposure to Drugs

Linda P. Spear
Department of Psychology and Center for Development and Behavioral Neuroscience, Binghamton University, Binghamton, NY, USA

Definition

Perinatal exposure to drugs involves exposure of the developing organism to substances of abuse or to psychotherapeutic compounds prior to birth and perhaps shortly thereafter. Such drug exposure typically occurs indirectly through maternal drug use, with the drug gaining access to the fetus via crossing the placenta to distribute in amniotic fluid and/or the fetal circulation, and to the infant via partitioning of the drug into milk during lactation.

Current Concepts and State of Knowledge

The prenatal and early ► postnatal period is often a sensitive period during which exposure to a variety of drugs may induce long-term alterations in brain function and behavior that are not evident with comparable exposures later in life. In recognition of this possibility, part of the testing process required for potential new therapeutic compounds in the United States involves assessment of each substance's developmental toxicity in pre-clinical studies (i.e., studies in laboratory animals) before the drug can be approved for initial (Phase 1) clinical trials (e.g., see Hodgson 2004). Initially spear-headed by studies of the ► fetal alcohol syndrome beginning in the mid-1970's, research examining the impact of maternal drug use during pregnancy and lactation has spread to encompass all major drugs of abuse. Through such studies, along with research examining the potential developmental neurotoxicity of environmental contaminants such as lead, consensus has been reached on a number of points. Some of these generalities will be briefly summarized here before highlighting consequences of perinatal exposure to several drugs of abuse.

Despite often necessary differences in assessment measures, generally comparable functional effects are often seen following perinatal drug/chemical exposure in humans and laboratory animals. During the first wave of research in ► developmental toxicology, there was appropriate concern as to whether findings obtained in laboratory animals would be comparable to those seen in human clinical studies. Careful examinations of across-species comparability of findings in animal models and clinical work, however, yielded notable across-species commonalities in the developmental toxicology of chemicals, ranging from ► alcohol, ► anticonvulsants, and ► methadone to environmental neurotoxicants such as lead and methylmercury, even though different measures were often necessary to assess particular functions (e.g., sensory or motor function, cognition, motivation, social behavior, etc.) in clinical studies versus research with laboratory animals (Stanton and Spear 1990). Additional evidence of general across-species comparability has continued to emerge with the escalation of research in this field over subsequent decades (e.g., Slikker et al. 2005; Slotkin 2008), despite challenges in attributing clinical findings to the focal drug per se versus other factors (stressful living environment, malnutrition, use of other drugs, etc.) that often co-occur with maternal drug use (see Fried 2002).

These findings lend credence to the use of animal models in studies of perinatal drug exposures. Such studies are important to confirm and extend clinical findings, anticipate other potential consequences of early drug exposure, determine the neural mechanisms underlying behavioral effects, and suggest potential therapeutic approaches. Yet, applicability of animal models is by no means assured. ► Pharmacokinetic differences are common across species, raising the importance of dose, route of administration and pattern of administration. Given the greater metabolic rate characteristic of small species such as rodents, higher doses may be necessary when using rodent models to produce drug levels in blood equivalent to those seen upon drug use in humans. Yet, too high a dose level may produce drug burdens that are out of the range associated with human exposures,

decreasing the potential relevance of findings obtained with the animal model. Other important considerations when developing animal models include controlling of possible drug-induced decreases in food intake and/or residual effects of drug exposure during pregnancy on subsequent maternal behavior – issues typically addressed via the use of ▶ pair-feeding and ▶ fostering procedures, respectively (e.g., see Spear and File 1996, for discussion and references for these and other control issues). Finally, although multiple offspring are commonly generated per litter when using rodent models of developmental toxicology, the evidence is clear that offspring from the same litter are not independent samples, and thus the assignment of more than one offspring/litter to a given experimental group markedly inflates the possibility of false positives.

Behavioral, hormonal, and neural alterations are typically induced at exposure levels well below those that induce major malformations or maternal toxicity (Adams et al. 2000). It is not surprising that at exposure levels high enough to induce maternal toxicity, chemical and other physiological consequences of that toxicity often exert multiple adverse effects on fetal development, including alterations in brain function and behavior. Yet, neurobehavioral effects are also evident in offspring at drug exposure levels lower than those necessary to induce maternal toxicity or signs of gross malformation in the offspring. The brain is unusually susceptible to disruption by drugs during its development, with drugs potentially affecting a variety of developmental processes, including neuronal migration and differentiation, glia proliferation, along with normal ontogenetic changes in cell adhesion, neural communication, energy utilization, and apoptosis (e.g., Goodlett and Horn 2001). Drug effects on ongoing developmental processes may extend well beyond the direct neural actions of that drug; for instance, perinatal exposure to ▶ nicotine alters not only cholinergic nicotine receptor function throughout life, but also influences the trajectory of development for a wide variety of neurotransmitter systems other than the cholinergic system (Slotkin 2008).

Observed consequences of perinatal exposures are not only drug- and dose-dependent, but also critically dependent on the timing of the exposure, and when and how functional consequences are assessed. Different portions of the brain develop at different times, and hence differ in the timing of their vulnerability to drug-induced disruption. Thus, consequences of developmental exposure to drugs are to some extent dependent on the timing of that exposure. Even as little as a one day difference in the timing of drug exposure can influence behavioral outcome, although generally speaking, the greatest vulnerability for structural damage occurs early in organogenesis, whereas functional impairments are most likely evident following drug exposure during mid- to late-organogenesis (See Spear and File 1996). When varying developmental stage during which drug exposure is given, it is important to note that ▶ altricial animals (such as laboratory rats and mice) are born at a less mature stage than humans. Hence, the ▶ prenatal period in rodents is approximately equivalent to the first and second trimesters of human pregnancy, with the first 10 days or so of postnatal life in rat approximating the third human trimester (see Spear and File 1996, for discussion and citations).

The timing during which functional consequences are assessed is also critical. Functional deficits often emerge well after termination of the drug exposure, and long after the drug and its metabolites have cleared the brain and body. Thus, developmental drug exposures are thought to alter the trajectory of normal brain development, changing future ontogenetic patterns in the emergence of brain neurocircuitry and function (see Slotkin 2008). Under some instances, deficits may be seen early in life and may recover thereafter, perhaps manifesting at some later developmental point (e.g., adolescence), during aging, or under stressful or challenging circumstances (Adams et al. 2000). In other cases, functional alterations may not be readily apparent until neural development is sufficiently mature to reveal underlying deficiencies. For instance, cognitive effects of prenatal exposure to marijuana are minimal during the infant and toddler stage, but do become progressively more evident as normally delayed ▶ executive function capacities emerge, with youth exposed prenatally to marijuana showing disruptions in certain aspects of executive function (e.g., attentional behavior; hypothesis testing) (Fried 2002).

The developmental toxicology of perinatal drug exposure is critically moderated by genetic background and the environment. The process of neural development is orchestrated by genes, with marked changes in the profile of genes expressed as development proceeds across different brain regions. Variants across individuals in the form of expression of particular genes (▶ gene polymorphisms) can increase vulnerability to adverse effects of perinatal drug exposures. Not all women who drink during pregnancy, for example, bear infants that meet the diagnostic criteria (i.e., growth deficiency, CNS disorders, and facial dysmorphic features) of fetal alcohol syndrome (FAS – e.g., see Mattson et al. 2001). Although timing and amount of alcohol use likely contribute to this variability,

the presence or absence of genetic variants that increase the vulnerability of the developing brain to developmental perturbations is also likely contribute. And, at the frontier of current research is the increasing recognition that perinatal drug exposure itself, like other environmental influences, may in turn alter developmental patterns of gene expression in specific brain regions through ▶ epigenetic regulation, exerting long-term effects on brain function through such "▶ developmental programming." Thus, exposure to drugs during the perinatal period provides an important component of the early environment of the developing organism that, along with other early experiences, may influence and be influenced by developmental patterns of ▶ gene expression (see Goodlett and Horn 2001). Consequences of perinatal drug exposure, like other adverse early experiences, may be moderated or exacerbated to some extent by environmental experiences as well. For instance, toddlers exposed to drugs prenatally have been found to be much more likely to exhibit secure attachment relationships if their mother had been abstinent since birth than if their mother continued to abuse drugs (Fried 2002).

Perinatal exposure to ▶ drugs of abuse often exerts lasting and drug-specific neurobehavioral effects. With some drugs of abuse, consequences for offspring may be immediate and obvious, and may resolve to some extent with time. The ▶ neonatal abstinence syndrome is a good example. That is, fetuses of drug-dependent mothers may themselves become addicted, and may undergo withdrawal following removal of their drug source (their mother) at birth. Such signs of withdrawal are most evident in neonates exposed prenatally to ▶ opiates such as heroin or methadone, and are characterized by transient hyperreactivity, irritability, feeding and sleep disturbances (see Spear 1997, for review and references). In contrast to these transitory effects, other consequences of perinatal exposure to drugs of abuse may be evident early in life and persist thereafter. Other consequences may not emerge until later, becoming manifest only when portions of the nervous system critical for expression of that function are sufficiently developed. To illustrate these effects of perinatal exposure to drugs of abuse, the focus will be on four drugs whose developmental effects have been particularly well studied: ▶ alcohol, ▶ nicotine, ▶ cocaine, and ▶ cannabinoids (including those in marijuana).

Cognitive effects. Cognitive deficits are a common sequela of perinatal drug exposure. Exposure to cocaine during development has been reported to impair performance of cognitive tasks in laboratory animals, and to lower IQ, impair language development, and disrupt cognitive function in children (e.g., Harvey 2004). Similarly, exposure to nicotine during development has been observed to induce deficits in cognitive function in both humans and laboratory animals (Slikker et al. 2005). Prenatal alcohol exposure has likewise been shown to disrupt learning and memory in animal studies, with FAS offspring also having difficulties learning both verbal and nonverbal problems, and showing deficits in certain aspects of memory performance (Mattson et al. 2001).

In studies of children exposed prenatally to marijuana, however, little sign of cognitive alterations were evident until the children approached school age. At this time, as non-exposed children began to exhibit increasing evidence of ability in various executive function domains, deficits in these functions began to emerge in children exposed prenatally to marijuana. Impaired ▶ executive functions persisted with age, and were particularly notable on measures of attentional capacity and abstract/visual reasoning. These alterations were not associated with alterations in global IQ scores (Fried 2002). Disruptions in attentional processes have also been reported following prenatal cocaine exposure in developmental studies of both laboratory animals and humans (Harvey 2004). Deficits in executive function also have been reported following heavy prenatal exposure to alcohol (Mattson et al. 2001).

Thus, although alterations in cognitive functions are a common outcome of perinatal drug exposure, the nature of those alterations seemingly differs with the drug of abuse. Indeed, from studies comparing cognitive function in offspring of mothers smoking cigarette versus marijuana during pregnancy, Fried (2002) concluded that in utero exposure to marijuana disrupts "top-down" executive functioning, whereas prenatal exposure to cigarette smoking was associated with alterations in certain basic perceptual abilities and fundamental cognitive skills – more consistent with dysfunction in "bottom-up" cognitive skills.

Increased later drug use/abuse. Human adolescents whose mothers used alcohol during pregnancy have been reported to exhibit early alcohol consumption and a greater propensity to abuse alcohol (Mattson et al. 2001). Indeed, there is some evidence that prenatal exposure to alcohol may exert a greater effect on later alcohol use/abuse than family history of alcohol abuse per se. Studies with laboratory animals have likewise generally observed that fetal or early postnatal exposure to ethanol enhances later intake of alcohol (Spear and Molina 2005). In laboratory animals, prenatal exposure to nicotine, as well as to cocaine, also has been reported to elevate levels of self-administration of the drug later in life beyond those

seen in non-exposed animals (see Harvey 2004; Slotkin 2008). Similarly, adolescents whose mothers smoked during pregnancy, regardless of whether their mothers continued to smoke during their childhood, were at increased risk for beginning to smoke and were more likely to relapse when they attempted to stop smoking (Slotkin 2008). Thus, there is considerable converging evidence across a number of drugs that perinatal exposure to a drug of abuse increases later risk for drug use and abuse.

Other behavioral alterations. Children exposed to alcohol prenatally (whether or not they meet the diagnostic criteria of FAS) are not only at risk for alcohol/drug abuse problems, but also are more likely than non-exposed children to exhibit other problem behaviors as well, including impulsivity, delinquency and hyperactivity, along with poor social and communication skills. Offspring exposed prenatally to marijuana smoke likewise have been reported to exhibit increased levels of delinquency, conduct disorder, hyperactivity and impulsivity (Fried 2002). ► Hyperactivity is also commonly reported following prenatal nicotine exposure in laboratory animals, as well as in children whose mothers smoked during pregnancy (Slikker et al. 2005). Such behavioral disorders are multifactorally determined, and hence could reflect alterations in a diversity of neural systems precipitated by perinatal exposure to these different drugs.

Neural alterations. Cognitive and behavioral alterations following perinatal drug exposures ultimately reflect drug-induced alterations in brain function. These effects are not global, but reflect alterations in specific brain regions that are typically drug-specific and are related to the timing of the exposure. For instance, fetal alcohol exposure was found in human imaging studies to exert particularly pronounced alterations in the corpus callosum, along with reductions in size of the caudate nucleus, cerebellum and hippocampus, findings reminiscent of those seen following prenatal ethanol exposures in laboratory animals (Mattson et al. 2001). The more invasive studies possible when working with animal models have revealed a rich variety of influences of perinatal drug exposure on the developing brain, including alterations in patterns of cell replication/differentiation, neural communication, signal transduction, cell death, gene regulation and so on (Goodlett and Horn 2001; Slikker et al., 2005). And, although observed neural alterations are sometimes highly selective to particular components of the neural systems normally targeted by action of that drug in adulthood, other neural systems are often impacted as well. For instance, in animal studies, prenatal cocaine exposure was found to uncouple D1 dopamine receptors, while leaving D2 receptor functioning largely unaffected. Long-lasting alterations in cortical cytoarchitecture were also evident in the cocaine-exposed offspring, and were suggested to reflect in part altered D1-receptor functioning and the resultant disruption in balance of D1 and D2 regulatory actions on neuronal development (Harvey 2004).

Conclusions

Perinatal exposure to drugs often exerts a long-term impact on brain function and behavior via alterations in the trajectory of neural development and its functional consequences. These effects are rarely global, but instead typically are drug-specific, dependent on the timing of exposure, and moderated by genetic background and early life experiences. Expression of drug-induced alterations also varies with assessment age and functions assessed. Among the consequences of perinatal exposure to drugs of abuse are increases in the propensity for later use/abuse of that drug, potentially contributing to a perpetuating and transgenerational cycle of drug use and abuse.

Peripheral Markers

Definition

Accessible markers mirroring physiopathologic processes of a disease. Usually, this term refers to markers of neuropsychiatric diseases, considering the difficulties involved in accessing directly into the CNS for studying the pathologic processes. Due to their availability, CSF and blood represent two major sources for identifying suitable peripheral markers of neuropsychiatric dysfunction.

Perospirone

Definition

Perospirone is a benzisothiazole derivative that belongs to the class of second-generation (atypical) antipsychotic drugs and is indicated for the treatment of schizophrenia. It has high-affinity antagonist activity at 5-HT_{2A} and D_2 receptors. It also displays partial 5-HT_{1A} agonist properties and some affinity for D_1, α_1-adrenergic and H_1 receptors, but has no appreciable affinity for muscarinic receptors. It has at least four active metabolites, but all of them have lower affinity for D_2 and 5-HT_{2A} receptors than the parent drug. It can induce extrapyramidal motor side effects and insomnia, but it displays low toxicity.

Perphenazine

Definition

Perphenazine is a first-generation antipsychotic medication that acts as a dopamine D2 receptor antagonist. It is a piperazine-phenothiazine derivative, also available as depot medication. Perphenazine is indicated for the treatment of schizophrenia and other psychoses, mania in bipolar disorder, and the short-term adjunctive treatment of severe anxiety, psychomotor agitation, excited or violent states. It can also be used as an anti-emetic drug. Extrapyramidal motor symptoms occur, especially dystonia especially at high doses.

Perseveration

Definition

The antithesis of flexibility, perseveration is the term used to refer to responses or behavior that persist even when it is no longer beneficial and may even have a cost. Whenever a task involves an uncued switch, shift, or reversal, the subject will make errors until the new contingencies are learned. If the previously rewarded response persists despite a lack of reinforcement, it is perseverative. There are examples in the literature of the classification of errors made after a rule change as "perseverative" when a respondent persistently returns to making a previously rewarded response even after there is evidence that a

new response has been learned (errors up until this point being classified as "learning errors"). In this, more specific, use of the term, a statistical criterion is applied to make the classification. The term is also used to refer to the continuous repetition of thoughts and statements.

Definition

Personality represents the structuring of human behavior into major traits that reflect the activity of (1) motivational–emotional systems and (2) their underlying neurobiological networks. There is consensus on the existence of four major traits: extraversion, neuroticism, social closeness or agreeableness, and constraint or conscientiousness. We describe the psychological features of these four traits, and how pharmacological protocols have aided in defining their underlying neurobiology. Discussion of the relation of dopamine (DA), serotonin (5-HT), corticotropin-releasing hormone (CRH), and mu-opiate functioning within specific brain regions to the four major traits is provided.

Current Concepts and State of Knowledge

The Nature of Personality. In the early 1970s, a significant development occurred in reconceptualizing the nature of personality. Employing an evolutionary biology perspective, Gray (1973) proposed a new structure of human-motivated behavior defined as systems that evolved to adapt to stimuli critical for survival and species preservation. Such behavioral systems are fundamentally emotional systems that incorporate both a motivational state and emotional experience that is concordant with, and engages us with or disengages us from, rewarding or aversive critical stimuli. Furthermore, Gray hypothesized that each of these motivational–emotional systems is associated with its own network of brain regions and with specific neurotransmitters and neuropeptides that modulate the functioning of those networks. Within this framework, the mean functional properties of the relevant neurotransmitters–neuropeptides, influenced by genetics and experience, may underlie stable individual differences in the behavioral reactivity of such systems. This theoretical framework led Gray to suggest further that stable neurobiological individual differences in motivational–emotional systems form the foundation of higher-order traits of personality. These notions raised the possibility that one means of testing the neurobiological tenets of this theory is the use of pharmacological protocols, where pharmacological agents that act as agonists or antagonists of neurotransmitters are used to assess whether drug-induced modulations of specific neurotransmitters are associated with particular personality traits.

The Structure of Personality. The structure of personality is hierarchical in nature, where behavioral features are assessed by inventory items which, by use of factor analysis, are clustered into lower-order primary or facet scales, which in turn are further clustered into higher-order traits. The higher-order traits represent theoretical constructs that attempt to account for the coalescence of the lower-order traits. From Gray's theoretical framework, the higher-order traits reflect the activity of a specific motivational–emotional system, and the lower-order traits represent different behavioral patterns that intercorrelate because they are influenced similarly by the motivational–emotional system represented by the higher-order trait. Although numerous classificatory systems of personality exist, all tend to agree on four higher-order traits: extraversion, neuroticism, social closeness or agreeableness, and constraint or conscientiousness. The first three traits are thought to reflect the activity of specific motivational–emotional systems, whereas the fourth may reflect not a specific emotional system, but rather a general property of the central nervous system that affects the threshold for eliciting all types of emotional behavior.

Extraversion. Depue and Collins (1999) provided a comprehensive analysis of the trait of extraversion as reflecting the activity of one of Gray's motivational–emotional systems – behavioral approach based on in centive motivation. Both unconditioned and conditioned rewarding stimuli (positive incentive stimuli) activate a motivational system of incentive motivation, which energizes approach to a rewarding goal. Extraversion, then, would represent individual differences in the threshold for positive incentives to (1) facilitate an emotional state that supports approach behavior, including a positive

affective state of desire, strong, peppy, enthusiastic, excited, and self-confidence; and (2) elicit approach, forward locomotion, and engagement with rewarding stimuli.

Conceptualizing extraversion as based on incentive motivation, which is a behavioral system found at all phylogenetic levels of animals, allows for the drawing of an analogy between human personality patterns and the animal neurobehavioral research literature. Animal research demonstrates that behavioral facilitation reflecting the activation of incentive motivation is associated with the functional properties of the ▶ ventral tegmental area (VTA) ▶ dopamine (DA) projection system. Thus, just as extraversion emerges as a higher-order construct that incorporates a modulatory mechanism that operates across lower-order traits, the VTA DA projection system might also be considered a higher-order modulator of a neurobiological network that integrates behavioral functions associated with extraversion. Indeed, DA agonists or antagonists in the VTA or ▶ nucleus accumbens (Nacc), which is a major terminal area of VTA DA projections, in animals facilitate or markedly impair, respectively, incentive-elicited locomotor activity to novelty and food; exploratory, aggressive, social, and sexual behavior; and the acquisition and maintenance of approach behavior.

In humans, DA agonists, such as ▶ amphetamine, ▶ cocaine, and ▶ methylphenidate, also elicit facilitated motor activity, as well as both positive emotional feelings such as elation, and a sense of reward, and motivational feelings of desire, wanting, craving, potency, and self-efficacy (Canli 2006; Depue 2006; Depue and Collins 1999). Moreover, neuroimaging studies have found that, during acute cocaine administration, the intensity of a subject's subjective euphoria increased in a dose-dependent manner in proportion to cocaine binding to the DA uptake transporter (and hence DA levels) in the striatum.

A number of pharmacological protocols have been used to explore the relation of extraversion to DA functioning in humans. A widely used protocol involves use of a DA agonist-induced challenge of (1) variables that are known to be modulated by DA activation, such as hormones like growth hormone and prolactin, eye-blink rates, rate of switching between percepts (e.g., ascending vs. descending views of a staircase), motor velocity, positive affective reactivity, and visuospatial working memory; or (2) fMRI-imaged, DA-relevant brain regions during the performance of psychological tasks (Canli 2006; Depue 2006; Depue and Collins 1999). Such studies have consistently shown a strong, positive correlation between degree of DA-induced modulation of the variable in question and questionnaire-assessed extraversion, often accounting for over 40% of the observed variance.

Another important protocol is the use of a pharmacological agent that binds to specific DA receptors, where the level of competitive binding with natural DA, measured by ▶ PET scanning, is inversely related to the natural level of DA functioning. This protocol has been used to assess D2-like DA autoreceptor density. Since D2 autoreceptors are localized to the soma and dendrites of VTA DA neurons and provide one of the most potent inhibitory modulations of DA cell firing, reduced autoreceptor availability in the VTA region is related to increased DA cell firing and enhanced postsynaptic activation. Extraversion-like traits have been found to be inversely related (approximately −0.68) to D2 autoreceptor availability in the VTA region (e.g., Zald et al. 2008).

Finally, use of a pharmacological challenge protocol has recently been used in much more detailed ways to assess the nature of the relation of DA to psychobiological processes associated with extraversion. A major effect of DA release in the Nacc is to enhance the binding of (1) corticolimbic inputs to Nacc dendrites that carry information about the current context and (2) the magnitude of context-induced reward (Depue and Collins 1999; Depue and Morrone-Strupinsky 2005; Kauer and Malenka 2007). That is, DA plays an important role in binding contextual ensembles to the occurrence of reward, an important predictive function of the brain. As animal research has shown, enhanced state or trait DA functioning increases the binding of contextual cues to the experience of reward. Similarly, we have found that increasing levels of extraversion are strongly associated with the ability to bind together the experience of DA agonist (methylphenidate)-induced reward and contextual cues, as evidenced in DA modulated processes of motor velocity, positive affective reactivity, and working memory (Depue 2006).

These findings have relevance for the maintenance of drugs of abuse that activate DA release into the Nacc, which most do (Kauer and Malenka 2007). Indeed, DA-induced synaptic changes in the Nacc are likely to facilitate the formation of powerful and persistent links between the rewarding aspects of the drug experience and the multiple cues associated with that experience – that is, to facilitate long-lasting memories of the drug experience. In light of our findings discussed above, it may be that extraversion represents one modifier of the strength of drug (reward)-context conditioning, and hence of relapse rates.

Neuroticism. Adaptation to aversive environmental conditions is crucial for species survival, and at least two distinct behavioral systems have evolved to promote such adaptation. One system is fear (often labeled *Harm Avoidance* in personality literature), which is a behavioral

system that evolved as a means of escaping very specific and explicit aversive stimuli that are inherently dangerous to survival, such as tactile pain, predators, snakes, spiders, heights, and sudden sounds. There are, however, many aversive circumstances in which *specific* aversive cues do not exist, but rather the stimulus conditions are associated with an elevated *potential* risk of danger, such as darkness, open spaces, strangers, unfamiliarity, and predator odors. Conceptually, these latter stimuli are characterized in common by their unpredictability and uncontrollability – or, more simply, uncertainty.

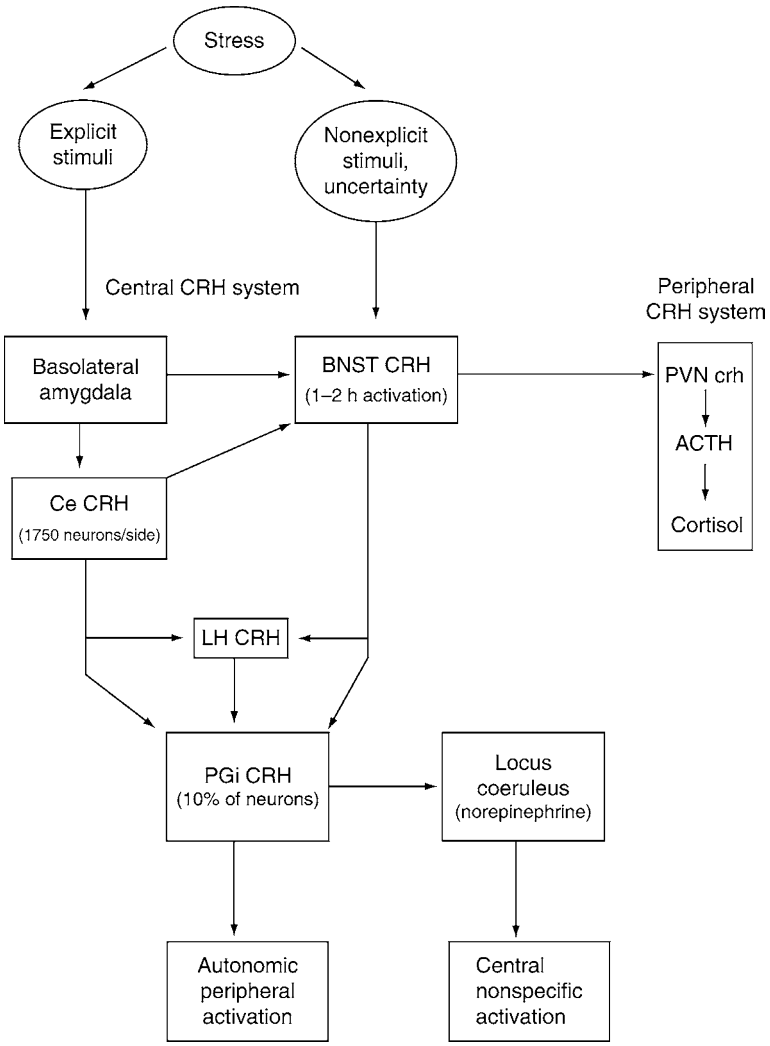
To adapt to these latter stimulus conditions, a second behavioral system evolved, *anxiety*, and it is this system that is thought to underlie the trait of Neuroticism. ► Anxiety is characterized by negative emotion or affect (anxiety, depression, hostility, suspiciousness, distress) that serves the purpose of informing the individual that, though no explicit, specific aversive stimuli are present, conditions are potentially threatening (White and Depue 1999). This negative affective state continues or reverberates until the uncertainty is resolved. It is the prolonged negative subjective state of anxiety that distinguishes its subjective state from the rapid, brief state of ► panic associated with the presence of a specific fear stimulus. The trait literature supports the *independence* of anxiety and fear, which as personality traits are completely uncorrelated, and are subject to distinct sources of genetic variation (White and Depue 1999).

The psychometric independence of fear and anxiety is mirrored in their dissociable neuroanatomy (Depue and Lenzenweger 2005; Davis and Shi 1999) and neurochemistry (White and Depue 1999; White et al. 2006). Whereas fear is dependent on output from the central nucleus of the ► amygdala to various brainstem regions, anxiety is subserved by outputs to similar brainstem regions from the bed nucleus of the stria terminalis (BNST), a structure that receives visual information via glutamatergic efferents from the perirhinal+basolateral amygdala (e.g., light–dark conditions) and parahippocampal+entorhinal+hippocampal (contextual and unfamiliarity stimuli) regions, as opposed to specific objects or sounds converging on the basolateral amygdala (Davis and Shi 1999; White and Depue 1999). The dissociation between fear and anxiety has also been found repeatedly with monoamine agonist challenge, such that trait fear but not trait anxiety predicts mood, cortisol, and physiologic responses to general monoamine challenge and to alpha-1 noradrenergic challenge, suggesting a role for ascending catecholamine systems in trait fear but not trait anxiety in humans (White and Depue 1999; White et al. 2006).

Animal research has demonstrated that naturally occurring chronic stress activates the central CRH system, which, as shown in Fig. 1, is composed of CRH neurons located in many different subcortical brain regions that modulate emotion, memory, and central nervous system arousal (Bale 2005; Depue and Lenzenweger 2005). Importantly, CRH neurons in the central amygdala induce prolonged elevated levels of CRH in BNST, which accounts for the potentially long endurance of anxiety as opposed to fear responses (Bale 2005). For instance, marked anxiety effects lasting longer than 24 h can be produced experimentally after three doses of CRH administered centrally over 1.5 h, but with no lasting effect on peripheral release of CRH from the ► hypothalamus. Anxiogenic effects and an aversion to a CRH-paired environment, both via CRH-R1 receptors, are dependent on intra-BNST administration of CRH. Furthermore, transgenic mice with elevated CRH-R1 (but not with R2) receptors in the central forebrain (but not peripherally in hypothalamus or pituitary), or conditional activation of CRH-R1 gene expression centrally, show extreme indications of anxiety. Thus, anxiety is a stress response system that relies on a network of central CRH neuron populations, in conjunction with the peripheral CRH system, that provide integrated responses (hormonal, behavioral, autonomic and central arousal) to a stressor, and in lateral BNST mediate prolonged anxiogenic effects and aversive contextual conditioning.

Pharmacological protocols used in exploring the psychobiology of extraversion have not been applied in human studies of anxiety, and so this type of research is sorely needed. One important avenue of this research would be the development of CRH-R1 antagonists that act centrally as anxiolytic agents. That such an approach may be significant is supported by a recent study of such an antagonist (antalarmin) in monkeys: Oral antalarmin impaired development and expression of contextual fear conditioning, and decreased stress-induced increases in anxiety behaviors, ACTH, cortisol, ► norepinephrine, epinephrine (i.e., HPA axis), CSF CRH concentration, and locus coeruleus neuronal firing (Habib et al. 2000).

One additional area of research is worth noting. A form of chronic stress reactivity is jointly correlated with the trait of neuroticism and a polymorphism in the promoter region of the gene that codes for the serotonin (5-HT) uptake transporter, creating two common alleles – long (l) and short (s). The s-allele is associated with (1) twice the risk of anxiety, depression, and suicide attempts in a context of childhood maltreatment and stressful life events; and (2) persistent enhanced amygdala activation to emotional stimuli – and thus persistent vigilance for threat, increased aversive conditioning to context, and negative thoughts and emotional memories. One important hypothesis is that, due to the significant



Personality: Neurobehavioural Foundation and Pharmacological Protocols. Fig. 1. CRH stress-response systems. Components of the central and peripheral corticotropin-releasing hormone (CRH) systems, which together coordinate emotional responses to stressful stimuli. Explicit stressful stimuli (e.g., predator cues, heights, tactile pain) are processed by the basolateral amygdala, whereas nonexplicit stressful stimuli (e.g., open spaces, context, darkness, strangers) are processed by the BNST. The basolateral amygdala activates Ce CRH neurons (about 1,750 neurons per hemisphere) which, together with nonexplicit stressful cues, release CRH in the BNST to produce prolonged neural activation in the BNST. In both cases, the Ce and/or BNST activate CRH neurons in the LH, which integrates and activates ANS activity in response to the stressor. In turn, Ce, BNST, and LH activation of the PGi (a major integrative nucleus in the rostroventrolateral medulla) CRH neurons (about 10% of PGi neurons) facilitate ANS activity via afferents to the spinal cord. The PGi CRH neurons also activate LC norepinephrine neurons, which project broadly to the CNS and elicit activation of all CNS regions. The peripheral CRH system is activated by the Ce and BNST CRH output neurons to the PVN. *Ce* central amygdala nucleus; *BNST* bed nucleus of the stria terminalis; *LH* lateral hypothalamus; *PGi* medullary paragiganticocellularis nucleus; *PVN* paraventricular nucleus of the hypothalamus; *ACTH* corticotropic hormone from the anterior pituitary; *CNS* central nervous system; *ANS* autonomic nervous system.

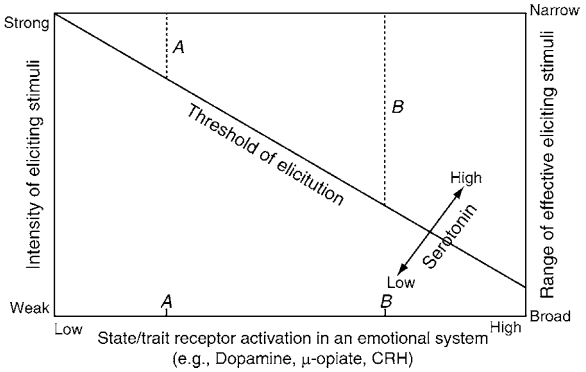
effects of 5-HT on early exuberant development of connectivity within forebrain regions, that the amygdala is less well modulated by emotion regulating regions such as the rostral anterior cingulate cortex. Indeed, these two regions show significantly less coherence in activity in s- versus l-allele individuals, accounting for ~30% of the variance in neuroticism scores (Pezawas et al. 2005). There has been little use of human pharmacological

protocols to explore the mechanisms of how 5-HT modulates stress reactivity, vigilance, and memory formation in these polymorphic conditions, again suggesting an area ripe for pharmacological exploration.

Social Closeness/Agreeableness. Social Closeness reflects the capacity of an individual to experience reward elicited by affiliative stimuli (e.g., soft tactile stimulation associated with grooming, caressing, and sexual intercourse). This capacity is reflected in the degree to which people value close relationships and spend time with others, as well as the desire to be comforted by others at times of stress. There has been very little human neurobiology research on the capacity to become attached to another person. While vole research has focused on the roles of oxytocin and vasopressin, genetic knockout studies have not demonstrated a *necessary* role for these ► neuropeptides in social bonding, suggesting that they may be affecting other variables that influence bonding, such as facilitation of sensory receptivity and subsequent acquisition of memories (Veenema and Neumann 2008). Human studies, on the other hand, are few, but some have used a promising pharmacological protocol: intranasally administered oxytocin is used to modulate short-term neural states and is then correlated with affective processes.

Noting that these neuropeptides do not mediate a sense of reward elicited by affiliative stimuli, we detailed a comprehensive role for mu-opiates in affiliative reward (Depue and Morrone-Strupinsky 2005). Recent primate research supports the *necessary* aspect of mu-opiates for social bonding (Barr et al. 2008). Practically no human pharmacological work has been done on mu-opiate mediation of affiliative reward, but the recent animal studies above are concordant with findings of regulation of human affective responses by limbic-opioid neurotransmission. They are also consistent with our results of enhanced human affiliative responses in individuals scoring high versus low in trait levels of social closeness, and with the elimination of those differences by use of the mu-opiate antagonist, ► naltrexone. Clearly, additional pharmacological work along these lines is strongly encouraged.

Constraint/Conscientiousness. Constraint is a poorly conceptualized personality trait, but is clearly related to a generalized behavioral impulsivity. Recent models of this behavioral profile have begun to clarify the nature of this trait (Depue and Collins 1999; Depue and Morrone-Strupinsky 2005). Elicitation of behavior can be modeled neurobiologically by use of a minimum threshold construct, which represents a central nervous system weighting of the external and internal factors that contribute to the probability of response expression (Fig. 2). We and others have proposed that constraint is



Personality: Neurobehavioural Foundation and Pharmacological Protocols. Fig. 2. Minimum threshold model. A minimum threshold for elicitation of a behavioral process (e.g., incentive motivation-positive affect, affiliative reward-affection, anxiety-negative affect) is illustrated as a trade-off function between eliciting stimulus magnitude (left vertical axis) and postsynaptic receptor activation in a neurobiological system (e.g., dopamine, mu-opiate, CRH) underlying an emotional trait (horizontal axis). Range of effective (eliciting) stimuli is illustrated on the right vertical axis as a function of level of receptor activation. Two hypothetical individuals with low and high *trait* postsynaptic receptor activation (demarcated on the horizontal axis as *A* and *B*, respectively) are shown to have narrow (*A*) and broad (*B*) ranges of effective stimuli, respectively, which influences the frequency of activation of the processes associated with a personality trait. Threshold effects due to serotonin modulation are illustrated as well.

the personality trait that reflects the greatest CNS weight on the construct of a minimum emotional response threshold. As such, constraint exerts a general influence over the elicitation of *any* emotional behavior. In this model, other higher-order personality traits would thus reflect the influence of neurobiological variables that strongly contribute to the threshold for responding, such as DA in the facilitation of incentive motivated behavior, mu-opiates in the experience of affiliative reward, and CRH in the potentiation of anxiety.

Functional levels of neurotransmitters that provide a strong, relatively generalized *tonic inhibitory* influence on behavioral responding would be good candidates as significant modulators of a response elicitation threshold, and hence may account for a large proportion of the variance in the trait of constraint. We and numerous others have suggested that 5-HT, acting at multiple receptor sites in most brain regions, is such a modulator (see review by Carver and Miller 2006). 5-HT modulates a diverse set of functions – including emotion, motivation,

motor, affiliation, cognition, food intake, sleep, sexual activity, and sensory reactivity, and reduced 5-HT functioning is associated with many disorders of impulse control (Depue and Lenzenweger 2005). Thus, 5-HT plays a substantial modulatory role that affects many forms of motivated behavior. Therefore, constraint might be viewed as reflecting a modulatory influence of 5-HT over the threshold of elicitation of emotional behavior (Fig. 2).

The variety of pharmacological protocols described above have been used extensively in animal research with 5-HT, and most show that reduced 5-HT functioning is indeed related strongly to a reduced threshold of emotional reactivity. However, such studies have been few in the human personality area, despite the fact that we found strong evidence for a role of 5-HT in constraint using a protocol of 5-HT-activation of prolactin secretion. Therefore, there is a strong need for additional pharmacological research on constraint to detail the manner in which 5-HT modulates emotional and cognitive processes associated with personality traits.

Conclusion

The use of pharmacological protocols to explore the neurobiological basis of higher-order personality traits is an underutilized research strategy. Clearly, such an approach has been quite informative with respect to the neurobiological nature of extraversion and neuroticism. However, pharmacological research on the nature of social closeness and constraint lags far behind. In particular, recent work suggests that a particularly powerful research strategy is the use of pharmacological protocols in defining the relation between behavioral processes and neurobiology in personality groups defined on the basis of genetic polymorphisms associated with DA, CRH, 5-HT, and mu-opiate systems.

Pethidine

Synonyms
Demerol; Meperidine

Definition
Pethidine is a synthetic, addictive opioid analgesic drug. Like other opioids, it can be used for treating moderate to severe pain but it has few unique indications. It has a rapid onset and short duration of action. Its analgesic effects are due to its action as an agonist at μ-opioid receptors. In accordance with this mode of action, it produces a morphine-like abstinence (withdrawal) syndrome and is subject to abuse and dependence. Pethidine also inhibits the dopamine and norepinephrine transporters, leading to psychomotor stimulant effects and a euphoric mood. Its efficacy as an analgesic is less than that of morphine and the side effects may be greater, due to the actions of a more toxic metabolite (norpethidine).

P-Glycoprotein

Definition
A 170 kD transmembrane glycoprotein from the superfamily of the adenosine triphosphate (ATP)-binding cassette (ABC) transporters that functions as ATP-dependent efflux pump able to extrude many classes of lipophilic and cationic chemicals. This protein is extensively expressed in intestinal epithelium, hepatocytes, renal proximal tubular cells, and in the luminal membrane of the endothelial cells of the BBB where it transports compounds out of the brain. P-glycoprotein (abbreviated as P-gp or Pgp) is also called ABCB1 (ATP-ABC subfamily B member 1), MDR1 (for multiple drug resistance).

Pharmacodynamic Tolerance

Department of Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, VA, USA

Definition
Tolerance is a drug-induced reduction in subsequent drug effect. Pharmacodynamic tolerance refers to instances of tolerance that involve either (a) adaptive changes in

receptor binding, or (b) recruitment of processes that limit or oppose the effects of the drug on receptor-mediated signaling pathways.

Impact of Psychoactive Drugs

Overview

Tolerance refers to a phenomenon in which the potency and/or maximal effectiveness of a drug to produce some effect is reduced after a regimen of prior exposure to that drug. Tolerance may be expressed as a reduced effect produced by a given drug dose, a requirement for higher drug doses to sustain a given effect, or a rightward and/or downward shift in a drug dose-effect curve. Tolerance may result from a variety of different mechanisms. Pharmacodynamic tolerance refers to instances of tolerance associated with pharmacodynamic mechanisms that are described below. It can be distinguished from pharmacokinetic tolerance (tolerance related to processes of ▶ pharmacokinetics: drug absorption, distribution, metabolism, and excretion) and ▶ behavioral tolerance (tolerance related to whole-organism learning processes).

Pharmacodynamics is the study of drug action on a biological system, and pharmacodynamic mechanisms can be divided into two dissociable but complementary components of drug action: ▶ receptor binding and pharmacodynamic efficacy. Receptor binding quantifies the direct physical interaction between a drug and one or more target receptor(s). The degree of receptor binding produced by a given concentration of a drug is determined by the density of a given receptor type in a biological system (often expressed as ▶ Bmax; receptors per unit mass of tissue) and by the ▶ affinity of the drug for that receptor type (often expressed as Kd; the concentration of drug required to bind 50% of the receptor population). Pharmacodynamic efficacy describes the degree to which a drug activates, inactivates, or otherwise modulates signaling pathways coupled to a receptor. These signaling pathways originate with changes in receptor conformation/function and are transduced into downstream changes in intra- and intercellular biochemistry, physiology, and behavior. ▶ Agonists stimulate these pathways, ▶ inverse agonists reduce ▶ constitutive activity in these pathways, and ▶ antagonists have no effect on their own but block effects of agonists and inverse agonists. Pharmacodynamic tolerance can be mediated by drug-induced changes in either receptor binding or receptor-mediated signaling. Moreover, these mechanisms are not mutually exclusive to each other or to nonpharmacodynamic mechanisms of tolerance. Rather, tolerance to a given effect of a given drug may involve multiple mechanisms, and mechanisms that underlie tolerance to one effect of a drug may differ from the mechanisms underlying tolerance to another effect of that same drug or to other drugs.

Tolerance and Receptor Binding

One mechanism that may contribute to tolerance is a drug-induced change in the density of receptors to which a drug binds. Depending on the drug, either decreases in receptor density (receptor downregulation) or increases in receptor density (receptor upregulation) may contribute to tolerance. Thus, receptor downregulation can reduce the effects of an agonist by reducing the number of receptors available for agonist-induced stimulation. Conversely, receptor upregulation can reduce the effects of an inverse agonist or antagonist by increasing the number of constitutively active receptors or the number of receptors available for stimulation by endogenous neurotransmitter agonists. Examples of tolerance-associated changes in receptor density include the downregulation of ▶ cannabinoid CB1 receptors produced by chronic exposure to cannabinoid agonists such as Δ^9-tetrahydrocannabinol (Martin et al. 2004) and upregulation of dopamine D2 receptors produced by chronic exposure to antipsychotic dopamine D2 receptor antagonists such as ▶ haloperidol (Sibley and Neve 1997). The precise mechanisms that underlie drug-induced changes in receptor density vary as a function of such variables as the drug, treatment regimen and receptor type, and in many cases, these mechanisms remain unknown. However, the density of available receptors is determined by rates of ▶ gene expression, protein synthesis, receptor trafficking to and from the membrane, and degradation. Drug exposure may modulate each of these processes. One illustrative mechanism will be described below in the context of receptor desensitization.

It is also theoretically possible for tolerance to occur as a result of reduced affinity of a drug for its receptor; however, tolerance-associated reductions in affinity have usually not been observed. Chronic drug exposure may promote changes in the relative abundance of different receptor subtypes for which a drug has differing affinities (e.g., Wafford 2005), but this mechanism can best be conceptualized as a change in the relative densities of different receptor types rather than as a change in the affinity of the drug for a single receptor type.

Tolerance and Receptor-Mediated Signaling Pathways

Although changes in receptor binding may contribute to some forms of pharmacodynamic tolerance, mechanisms involving changes in receptor-mediated signaling appear to

be more commonly involved. The wide variety of signaling pathways associated with different receptor types creates a multitude of potential mechanisms whereby prior drug exposure can modulate subsequent drug effects. In general, these mechanisms have the effect of limiting or opposing the effects of the drug, and these mechanisms can act at the level of the receptor itself, the intracellular signaling pathways coupled to the receptor, or the intercellular neural circuits containing cells that express the receptor. Examples will be provided from the literature on tolerance to ► morphine and other ► opioids acting at the mu-opioid receptor (Christie 2008).

Drug binding sites on receptor proteins are coupled to proximal transduction mechanisms that consist of either separate domains of the receptor itself (e.g., ion channels in the case of ligand-gated ion channels) or separate proteins located immediately adjacent to the receptor (e.g., G-proteins associated with ► G-protein coupled receptors (GPCRs)). For example, mu-opioid receptors are GPCRs, and receptor-mediated signaling begins with agonist-induced interactions between the receptor and an adjacent G-protein to activate the G-protein and initiate multiple cascades of downstream neurochemical processes that affect ion channels, intracellular enzyme activity, and gene transcription. The drug-binding site and proximal transduction mechanism can be uncoupled in a process also referred to as receptor desensitization, and this process is thought to be especially important for drugs that act as direct agonists at a receptor. With mu-opioid receptors, agonist binding promotes the phosphorylation of the receptor by G-protein-coupled receptor kinases (GRKs) that recognize and phosphorylate amino acids on the intracellular C-terminus of the agonist-bound conformation of the receptor. Receptor phosphorylation itself may reduce the efficiency of G-protein activation by the receptor. In addition, the phosphorylated region of the receptor may also become bound by another protein called β-arrestin, which is thought to further obstruct the receptor's ability to interact with and activate the adjacent G-protein. As a result, the receptor is effectively uncoupled from the G-protein and other downstream signaling processes (Gainetdinov et al. 2004; Martini and Whistler 2007).

Another role of β-arrestin in the regulation of GPCRs like the mu-opioid receptor is to facilitate internalization by endocytosis. Specifically, the β-arrestin-bound receptor migrates to clathrin-coated pits in the cell membrane, and these pits are then invaginated and pinched off to form intracellular vesicles. Internalized receptors can then be destroyed (via degradation by proteases in lysosomes, a process that may contribute to receptor downregulation) or recycled to the membrane (via dephosphorylation of the receptor and subsequent fusion of the vesicle with the extracellular membrane). Through this latter mechanism, β-arrestins may contribute not only to the negative regulation of receptor signaling, but also to the resensitization of the receptor. Thus, it has been suggested that short-term desensitization, internalization, and recycling of receptors could prevent the development of longer-term tolerance mediated by the activation of compensatory adaptations in signaling pathways downstream of the receptor (Martini and Whistler 2007, see below). Furthermore, the interaction of internalized receptors with β-arrestins can result in signaling through alternative (non-G-protein mediated) pathways. Thus, roles of GRKs and β-arrestins in mediating acute drug action and tolerance are complex (Gainetdinov et al. 2004; Schmid and Bohn 2009). For example, the genetic knockout of the β-arrestin-2 subtype of β-arrestin increases sensitivity to some of morphine's effects (e.g., supraspinal antinociception), while decreasing sensitivity to other effects (e.g., constipation). Moreover, tolerance to the antinociceptive effects of morphine is attenuated in β-arrestin-2 knockout mice, whereas antinociceptive tolerance to more potent or efficacious opioids, such as etorphine or ► methadone, is unaffected by the loss of β-arrestin-2. Interestingly, antagonist-precipitated withdrawal after chronic morphine was also unaffected in β-arrestin-2 knockout mice. Overall, then, the roles of GRK/β-arrestin regulatory mechanisms in drug tolerance are likely to be multifaceted, and could in some cases mediate while in other cases oppose drug tolerance.

Reductions in drug effects can also be produced by a compensatory recruitment of intracellular opponent processes downstream from the receptor. For example, in many cell types that express mu-opioid receptors, agonist binding initiates a series of biochemical events that includes (1) activation of Gi/Go proteins, which (2) inhibit adenylyl cyclase, an enzyme that converts adenosine triphosphate (ATP) into cyclic adenosine monophosphate (cAMP), resulting in (3) reduced levels of cAMP and (4) reduced activity of protein kinase A (PKA), an enzyme that is activated by cAMP. This in turn results in (5) decreased phosphorylation of other downstream proteins, including membrane-bound ion channels that can influence short-term patterns of cell activity and transcription factors that can influence gene transcription and longer-term cell structure and function. Tolerance to the effects of a mu agonist can result from the regulation of any step in this pathway. For example, chronic exposure to mu-opioid receptor agonists may promote a compensatory upregulation in adenylyl cyclase, the enzyme normally inhibited by mu receptors (Nestler and Aghajanian 1997). This upregulation in adenylyl cyclase may be sufficient to offset the inhibitory effect

mediated by mu-opioid receptors and restore enzyme activity to basal, pre-drug levels despite continued drug presence.

In multicellular biological systems, opponent processes can be recruited not only in the cell that contains the receptor at which the drug acts, but also in other cells involved in circuits that mediate drug effects on physiology and behavior. Thus, to the degree that a drug produces a net change in activity of a downstream cell, opponent processes may be recruited to oppose the drug effect and shift cell activity back toward basal levels. As one example from the mammalian central nervous system, mu-opioid receptors are located on inhibitory interneurons that regulate the activity of a population of dopaminergic neurons collectively referred to as the mesolimbic dopamine system. The agonist-induced activation of these mu receptors inhibits the interneurons, and thereby disinhibits the dopamine neurons to increase dopamine release. This increased mesolimbic dopamine release is a shared property of many drugs of abuse, and it is thought to play a key role in the neurobiology of addiction. However, sustained increases in dopamine (produced by mu agonists or by other drugs of abuse) may then act on postsynaptic D1 dopamine receptors to promote synthesis in those neurons of the endogenous opioid peptide ▶ dynorphin, which can be released by recurrent collaterals that feedback onto the dopamine neurons. Dynorphin can then act at kappa opioid receptors on the dopamine neurons to inhibit further neural activation and dopamine release. Thus, mu agonists may activate dopamine neurons via one process, but this activated dopaminergic activity may then trigger a dynorphin/kappa opioid receptor-mediated opponent process that opposes further activation of dopaminergic neurons (Chartoff et al. 2006; Shippenberg et al. 2007).

It should also be noted that the recruitment of opponent processes may contribute not only to tolerance, but also to the expression of ▶ withdrawal syndromes and ▶ addictive disorders. Thus, when drug is present, the drug and its opponent processes oppose each others' effects in a dynamic balance that shifts the level of cell or circuit activity toward basal, predrug levels and results in the phenomenon of tolerance. However, when the drug is removed, the opponent processes are released from drug opposition, and the disinhibited opponent processes may then produce effects different from and often opposite to those originally produced by the drug. For example, withdrawal from a mu agonist may release both upregulated adenylyl cyclase activity within mu-receptor-containing cells and upregulated dynorphin release from downstream cells, and these disinhibited opponent processes may then contribute to physiological and behavioral signs of opioid withdrawal that contribute to opioid addiction (Christie 2008; Nestler and Aghajanian 1997; Shippenberg et al. 2007).

Definition

Pharmacogenetics (PGx) refers to the influence of genetic variations on drug responses. More specifically, it is the study of how ► polymorphic genes that encode the function of transporters, metabolizing enzymes, receptors, and other drug targets in humans and other animals are related with variations in responses to drugs, including toxic and therapeutic effects. PGx, which may be considered to be a subfield of ► ecogenetics, tends to be used interchangeably with ► pharmacogenomics, with the same imprecision that conflates "genetics" with "genomics."

Current Concepts and State of Knowledge

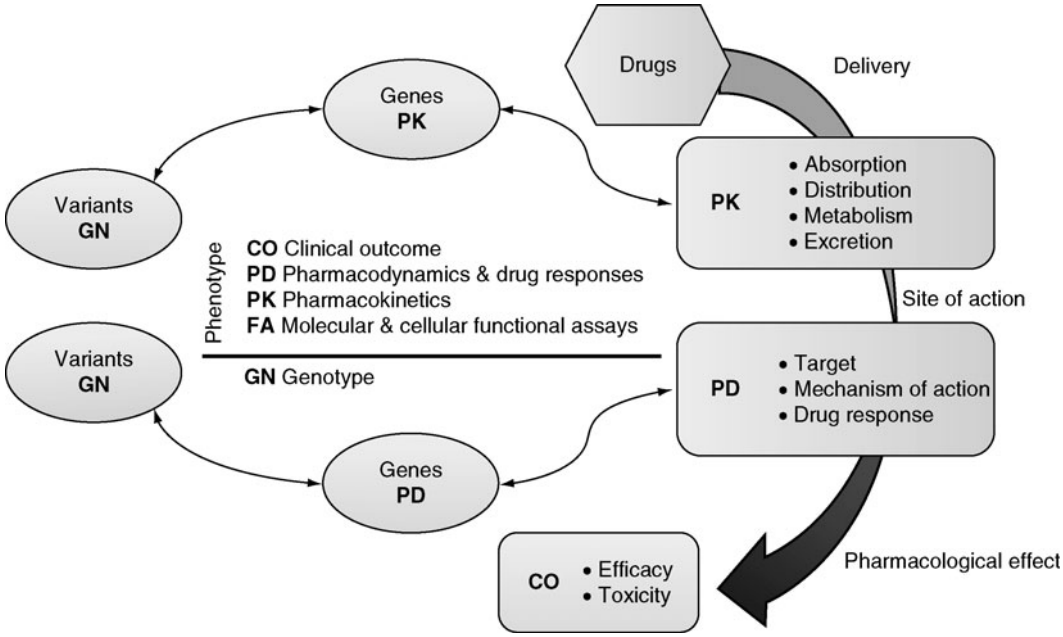
One thread of the origin of PGx dates back to the 1950s (see Box 1) when pharmacologists began to incorporate genetics into their studies of adverse drug reactions. Examples of classical PGx studies include the observations that at doses tolerated well by others, the muscle relaxant succinylcholine, the antimalarial drug primaquine and the antituberculosis drug isionazid induced life-threatening effects, such as respiratory arrest, hemolytic anemia and neuropathies, in some patients. By studying families and ethnic populations as well as through careful phenotyping, pharmacologists demonstrated that these unusual drug responses were inherited and due to certain enzyme variations controlled by single-genes. The understanding of the molecular genetic basis for the phenotypes came later, with the development of DNA technology (► Single nucleotide polymorphism testing and, more recently, ► haplotype testing) and in vitro molecular tests allowing the exact identification of the gene sequences responsible for variations in drug responses. The recent flourishing of genomics with development of new technologies such as microarrays has changed the focus of PGx from study of the effect of single gene sequence polymorphisms in two ways. First, the search has broadened to multiple genes (i.e., from monogenic to polygenic traits), and second, gene expression is now known to play an important role in affecting variations in drug responses. Indeed, modern PGx (pharmacogenomics) often uses a reverse approach, studying whether sequence variations and/or gene expression are in any way related to variations in drug response phenotypes (see methods).

The second thread antecedent to PGx can be traced to the field of behavioral genetics. Studies of behavioral responses to a variety of drugs, often in mice and rats, employed genetically varying populations and consistently found that different genotypes had characteristic, and widely varied, responses to many drugs. Starting in the late 1940s, this field also pioneered the use of selective breeding to create rat and mouse lines with extreme drug responses. The earliest systematic summary of this work was a monograph by Broadhurst (1978). Behavioral genetic studies now also incorporate ► genetically modified animals and the studies of gene-targeted mutant lines and selected lines have contributed much to our understanding in drug action, particularly in the addictions field.

Defining Pharmacogenetics

Pharmacology often divides drug's interactions with the body into their ► pharmacokinetic and ► pharmacodynamic aspects. Pharmacokinetics, sometimes described as what the body does to a drug, incorporates drug absorption, distribution, metabolism, and excretion. Pharmacodynamics, described as what a drug does to the body, involves receptor binding, post-receptor effects, and chemical interactions. Drug's pharmacokinetics and pharmocodynamics are both genetically and environmentally influenced. Genes contain information that determine the structure of proteins and any variations in the DNA sequence (mutation) may alter the expression or the function of proteins. DNA mutations that occur at a frequency of 1% or greater are termed polymorphisms. Polymorphisms in genes coding for a protein that carries a drug to its target cells or tissues may cripple the enzyme that activates a drug or aid its removal from the body, and thus may induce pharmacokinetic or pharmacodynamic variations leading to individual differences in the response to the drug (see Fig. 1).

The majority of pharmacogenetic studies have focused on drug metabolizing enzymes. For example, ► cytochrome P450 (CYP, P450) is a large superfamily of metabolizing enzymes. Within the CYP2 family, polymorphic CYP2D6 was one of the first and most important drug-metabolizing enzymes to be characterized at the DNA level. By using response to a "marker" drug (i.e., dextromethorphan), four phenotypes may be described: "poor metabolizers," "intermediate metabolizers," "extensive metabolizers," and "ultrarapid metabolizers." Ultrarapid metabolizers have multiple copies of the *CYP2D6* gene



Pharmacogenetics. Fig. 1. Schematic representation of how gene variants affect pharmacokinetic and pharmacodynamic factors resulting in potential modifications in the pharmacological effect of drugs (from http://www.pharmgkb.org).

expressed, and greater-than-normal CYP2D6 activity. Therefore, ultrarapid metabolizers may not achieve therapeutic levels with usual doses and may require several doses to show a response. On the other hand, poor metabolizers are at increased risk of toxicity from CYP2D6 substrate drugs (e.g., codeine). In addition to CYP2D6, polymorphisms have now been identified in more than 20 drug metabolizing enzymes in humans. Some of these polymorphisms show different distributions in racial groups and phenotypically relevant consequences from a clinical point of view (see Table 1). More recently, there has been increased recognition in the contribution of genetic variation in proteins involved in drug responses. For example, a polymorphism in the ▶ serotonin transporter protein that affects serotonin availability in brain has been reported to be associated with a predisposition to depressive illness as well as with therapeutic response to antidepressive or antipsychotic pharmacotherapy.

Methods

PGx may use a phenotype-driven or a genotype-driven approach for understanding the genetic contributions to variations in drug responses in humans and nonhumans. In the phenotype-driven approach (i.e., from phenotype to genotype), once a genetic contribution to the phenotype of interest has been confirmed (with family analysis, animal models analysis and/or linkage studies), genetic markers reliably associated with the phenotype are identified by genome-wide- and/or –candidate-gene approaches. Such studies must first identify the rough genomic locations of causative genetic variation. These locations are called quantitative trait loci (QTL), and QTL-analysis is the first step for identifying the subset of chromosomal areas containing genes responsible for the genetic variation in a specific trait, and to locate these areas on a genomic map. QTL analyzes have been widely used in animal models with inbred and recombinant strains of rats and mice, as well as in lines selectively bred for extremes in response to various

drugs. When chromosomal regions associated with the magnitude of the phenotype have been identified, the QTL initially span genomic regions containing dozens or even hundreds of genes. Fine-mapping can be carried out to refine the search, narrow the confidence intervals, and, finally, identify potential susceptibility genes. Eventually, candidate-genes remaining in the QTL interval are sequenced to identify the specific sequence variants associated with the phenotype. Alternatively, or additionally, in a genotype-driven approach (i.e., from genotype to phenotype), pharmacogeneticists characterize the functional significance of polymorphisms with high population frequency for a gene for which previous knowledge suggests that it could influence drug responses. In this approach, the development of genetically modified animals such as transgenic and knock-out mice has been particularly useful for investigating the direct effects of gene mutation on responses to drugs. In both approaches, analyses of gene expression are now commonly evaluated as well to identify candidate genes within each QTL.

Methods used for genotyping involve a series of molecular biological, physical, and chemical procedures used to distinguish among the alleles of a SNP or the measurement of the allele-specific products. PGx principally use methods applied in genetics and pharmacology but also borrow the knowledge and progress available in other fields such as bioinformatics. Because final proof of a quantitative trait gene (QTG) nearly always involves behavioral assessment of genetically modified animals, the tools of behavioral analysis are also employed.

Clinical Applications

The clinical consequences of Interindividual differences in drug responses are manifested in a variety of ways such as acute or delayed toxicity, unusual response, resistance to a drug or unwanted drug interactions (when combined with use of other agents). Adverse side effects of drugs represent a significant public health and economic problem, affecting more than 2 million people annually in the United States, including 100,000 deaths and costing more than $100 billion. The use of PGx in a clinical setting could reduce these costs, and help to determine the most appropriate treatment for individual patients according to their unique genetic make-up (personalized medicine). Indeed, identification of relevant polymorphisms known to affect drug effects could help treatment providers determine which available drugs would ensure maximum efficacy with minimal adverse effects.

However high expectations surrounding "personalized medicine" remain unfulfilled and only a few products have reached the market and clinical practice. One example is the DNA chip AmpliChip® (developed by Roche Molecular System Inc.) used for testing variations in expression of the CYP2D6 and CYP2C19 genes, which play a major role in metabolism. Another is the HER2 test which is used prior to prescribing Herceptin® to breast cancer patients. HER2 is the receptor for the epidermal growth factor which can stimulate cells to divide and grow. HER2 testing measures the number of copies of HER2 gene (*neu)* in each cell and/or the level of HER2 protein in the tumor sample. Only people showing HER2 gene amplification and overexpression are prescribed Herceptin®, which attaches to the HER2 protein, and stops human epidermal growth factor from reaching the breast cancer cells. A third is a test for variants of the enzyme thiopurine methyltransferease (TPMT) before prescribing thiopurine (i.e., antileukemic drugs such as 6-mercaptopurine and 6-thioguanine) for the treatment of acute lymphocytic leukemia. Genotype-based testing allows the identification of individuals showing a reduced TPMT enzyme activity. Because these people may show a toxic accumulation of thiopurine in the body responsible for bone-marrow suppression, they are not prescribed thiopurine drugs. Pharmacogenetic testing is currently used in only a limited number of teaching hospital and specialist academic centers.

Some genetic and non-genetic factors may explain why, despite the well- documented functional relevance of many-drug-metabolizing enzymes, the translation of PGx into clinical practice has yet to reap its benefits. First, drug responses are likely due to many genes, each bearing many polymorphisms. Identification of all these genes and polymorphisms is difficult and time-consuming, and would have to be performed before the selection of the right drug and the right dose for the individual patient. Second, genotyping is not sensitive to drug-drug interactions or to environmental factors, which can affect treatment response. For example, dietary intake may influence drug metabolism, as in the case of ► monoamine oxidase inhibitor (MOAI) drugs for the treatment of ► depression or ► Parkinson's disease. Patients using these drugs need to avoid food containing the amino acid "tyramine" (i.e., such as cheese and fish), because accumulation of this amino acid leads to a hypertensive crisis with headache and high blood pressure. This example shows how pharmacogenetic information alone will not predict the variation in efficacy or safety of a drug.

Besides enabling clinicians to select the most effective drugs for treatment of individuals, PGx could also be used for salvaging drugs that have been withdrawn from the market because of adverse drug reactions – so-called "drug rescue." Retrospective genotyping of clinical trial subjects could help to distinguish patients who were susceptible to an adverse response from those patients who showed benefit from the drug. Finally, PGx could also have an impact on the process of drug research and development, by helping to develop specific drug targeting proteins with variant structures resulting from the presence of genetic polymorphisms. Such research could assist pharmaceutical companies to develop more effective drugs with fewer side effects.

Currently, no countries have clinical practice regulations relating to PGx or pharmacogenomics. Such regulations, including prescription guidelines, testing, and usage labels, will be needed if the techniques are to be widely used. However, before regulation can be introduced to guide prescribing practices, the field needs more robust prospective data from well-designed studies.

Conclusion

PGx provides an experimental framework to understand variation in human drug responses as a function of inherited material. Recently, the field has experienced a period of rapid growth with the initiative of the human genome project. With the improvement and the wide availability of sequencing technology, the use of PGx in clinical practice is expected to increase.

Definition
Pharmacogenomics can be defined as the study of variations of DNA and RNA characteristics as related to drug response. However, there is no consensus about the semantic differences between pharmacogenetics and pharmacogenomics, and these two terms tend to be used interchangeably. The history of usage generally parallels the development of the new field of genomics from the old field of genetics. The older term "pharmacogenetics" is now generally thought of as the limited study of single or few genes and their effects on interindividual differences in drug responses while the newer term "pharmacogenomics" is thought to refer to the application of genomic technologies to the study of drug discovery, pharmacological function, disposition, and therapeutic response.

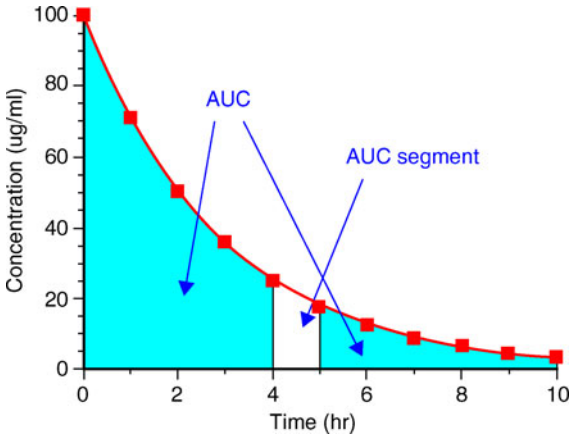
Definition
Pharmacokinetics (in Greek "pharmacon" meaning drug and "kinetikos" meaning putting in motion and the study of time dependency) has been variously defined as the study of the relationship between administered doses of a drug and the observed blood (plasma or serum) or tissue concentrations. It is a branch of pharmacology that explores what the body does to a drug and hence concerns itself with the quantitation of drug absorption, distribution, metabolism and excretion (ADME).

Impact of Psychoactive Drugs
Despite the enormity of the pharmaceutical industry and the vast array of psychoactive substances used in an illicit manner, the mode of action of drugs in the body can be understood by reference to basic pharmacokinetic principals, assuming a linear relationship between blood and tissue (brain) exposure. Understanding the pharmacokinetic principles of a drug often explains the manner of its use and aids the clinician in a number of ways: in anticipating the optimal dosage regime; in predicting what may happen if the dosage regime is not followed; in responding to over dosing and; to monitor the consequences of harmful or dependent use.

Pharmacokinetic parameters describe how the body affects a specific drug after administration and explains how the variables such as the site of administration and the dose and dosage form in which the drug is administered can alter this response. Pharmacokinetic analysis is performed by noncompartmental (model-independent) or compartmental methods. Noncompartmental methods estimate the exposure to a drug by evaluating the ► Area Under the curve (► AUC) of a concentration-time graph. Compartmental methods estimate the concentration-time graph using kinetic modeling. Compartment-free methods are often more versatile in that they do not assume any specific compartmental model and produce more accurate results.

Noncompartmental Analysis
Noncompartmental pharmacokinetic analysis is highly dependent on the estimation of total drug exposure; most often estimated by AUC methods, using the trapezoidal rule, which is the most common area estimation method (Fig. 1).



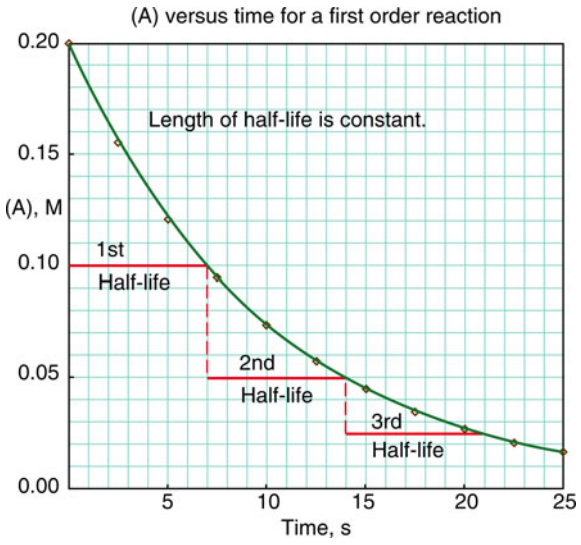
Pharmacokinetics. Fig. 1. Calculation of area under the curve (AUC) using the Trapezoidal Rule showing a linear plot of concentration of drug in plasma (Cp) versus Time showing AUC and AUC segment (http://www.boomer.org/c/p4/c02/c0208.html).

The AUC is very useful for calculating the total body clearance (► CL) and the ► apparent volume of distribution (see later). In the trapezoidal rule, the area estimation is highly dependent on the blood/plasma sampling schedule. That is, the more frequent the sampling, the closer the trapezoids to the actual shape of the concentration-time curve (Fig. 1). Intravenous administration of a developmental drug can provide valuable information on fundamental pharmacokinetic parameters, but may often be biased towards an apparent rapid peak plasma concentration and short lasting exposure when compared to oral administration.

Compartmental Analysis

Compartmental pharmacokinetic analysis use kinetic models to describe and predict the concentration-time curve. The advantage of compartmental to some non-compartmental analysis is the ability to predict the concentration at any time. The disadvantage is the difficulty in developing and validating the proper model. Compartment-free modeling based on curve stripping does not suffer this limitation. The simplest PK compartmental model is the one-compartmental PK model with IV bolus administration and ► first-order elimination kinetics, (Neligan 2009) where a constant fraction of the drug in the body is eliminated per unit time as shown in Fig. 2.

Pharmacokinetics is predominantly studied in a laboratory setting using advanced chromatographic technology (gas GC, or liquid ► HPLC) coupled to ► mass spectrometry (MS). This is because of the complex nature of the matrix (blood (or brain tissue extracts in animals)) to be analysed; the need for high sensitivity to detect low drug concentrations (10^{-6} to 10^{-9}g) and the long time-point data. Blank or $t = 0$ samples taken before administration are important in determining a baseline and ensure data integrity with such complex sample matrices. There is currently considerable interest in the use of very high sensitivity LC-MS-MS for micro dosing studies, which are seen as a promising alternative to animal experimentation.



Pharmacokinetics. Fig. 2. First-order elimination for a drug (A) administered by the intravenous route showing elimination over time.

Population pharmacokinetics is the study of sources and correlates of variability in drug concentrations among individuals who are the target patient population receiving clinically relevant doses of a drug of interest. This methodology seeks to identify the measurable pathophysiologic factors that cause changes in the dose-concentration relationship and the extent of these changes. The industry standard software for population pharmacokinetics analysis is NONMEM.

A basic tenet of clinical pharmacokinetics is that the magnitudes of both desired response and toxicity are functions of the drug concentration at the site(s) of action (Rowland and Tozer 1995). Using this definition, "therapeutic failure" results when either the concentration of the drug at the site of action is too low, giving ineffective therapy, or is too high, producing unacceptable toxicity. For example, in drug treatment services, relapse and a return to illicit drug use has been frequently observed when the maintenance dose of ► methadone is too low to stop opioid withdrawal symptoms or ► craving for heroin. The concentration range in between these limits, the range associated with "therapeutic success" is often regarded as the "therapeutic window or range" (Fig. 3). However, these definitions are sometimes difficult to interpret for drugs that are not controlled by pharmaceutical regulations (► cocaine or ► cannabis or, ► MDMA) or are difficult to apply to drugs consumed without restriction (► alcohol and ► nicotine).

In practice, the measurement of a drug in the body is usually determined in blood or urine, because measurement of the drug concentration at the site of action is not easily achievable.

For some drugs with variable pharmacokinetics such as *Warfarin* (*Coumadin*), biological monitoring is required to ensure that the blood concentration of the drug is strictly maintained within the therapeutic window (normal reference range, Fig. 3). Warfarin used for preventing thrombosis and embolism (abnormal formation and migration of blood clots) interacts with

many common medications and some foods. Its activity has to be monitored by frequent blood testing for the international normalized ratio (INR) to ensure an adequate yet safe dose is taken. Other compounds, for example, *clozapine* have a risk of serious side effects. ▶ Clozapine is used principally in treating ▶ schizophrenia and also for reducing the risk of suicide in patients with chronic risk for suicidal behavior. Plasma concentration of clozapine and norclozapine need to be measured regularly in order to assess adherence to the dosing regime, prevention of toxicity, and in dose optimization.

The discipline of pharmacokinetics is concerned with the quantitation of the mechanisms of ▶ absorption. The process by which a drug enters the blood stream; ▶ distribution of an administered drug; the rate at which a drug action begins; the duration of the effect; the ▶ metabolism of the drug in the body and; the effects and routes of ▶ excretion of the drug and its metabolites. These processes together are commonly referred to as *ADME* (Jacobs and Fehr 1987). More recently biopharmaceutics has emerged as a new body of science that links traditional pharmacokinetics with pharmaceutics and the acronym *LADME* (http://en.wikipedia.org/wiki/Pharmacokinetics) has been used to describe the processes studied by biopharmacists. Essentially adding the term "▶ Liberation" to the well recognized ADME acronym.

Understanding Drug Effects

In order for a drug to exert its pharmacological effect, it must first gain entry into the body, be absorbed into the blood stream and transported to the site of action (usually in the brain for CNS active drugs). The intensity of effect of a drug is governed by two major factors:

- The concentration of drug at the site of action in the body; and
- The sensitivity of the target cells (i.e., the magnitude of their response to a given concentration of drug).

The Concentration of Drug at the Site of Action

The concentration of drug at the site of action in the body at any given time after administration is determined by both the size of the dose and the pharmacokinetics of the substance.

Liberation

Biopharmaceutics has brought to the fore the importance of the physicochemical properties of a drug, the dosage form (or design) and the route of administration, all of which are key parameters when considering drug "Liberation." Once administered, the drug must be liberated from its dosage form. Tablets and capsules may require disintegration (forming smaller particles) before dissolution and entry into the systemic circulation can occur. Similarly, the delivery of drug particulates into the lung from passive inhaler products is only achieved after "Liberation" of the drug from the formulation during inhalation activation. The science of drug formulation design has rapidly grown over the last decade and is a thriving discipline.

Drug Dissolution

Drug dissolution usually occurs in the stomach and is dependent upon gastric activity. Many factors influence the dissolution of tablets and capsules, including particle size, chemical formulation, the inclusion of inert fillers, and the outer coating of the tablet. It is not unusual, therefore for proprietary or generic preparations of a drug to have different dissolution characteristics and produce a range of plasma concentrations after oral administration. Dissolution characteristics of a dosage form are thus important considerations when interpreting pharmacokinetic data.

Absorption and Routes of Administration

As explained above, the extent and rate of absorption of a substance depends on the chemical properties of the drug itself and the way in which it is administered. The rate of absorption depends on the concentration of the drug, its degree of lipid solubility, the surface area of absorption, and the diffusion distance (i.e., the number of membranes it must cross before it reaches the bloodstream). Peak plasma concentration-time is the most widely used

general index of absorption rate; the slower the absorption, the longer period of time to reach peak plasma concentration.

There are four principle methods of drug administration: oral/ingestion, across mucous membranes, by inhalation, and by parenteral process (injection).

Oral (*by swallowing*): Drugs taken orally are generally absorbed primarily in the small intestine rather than in the stomach. The ▶ benzodiazepines comprise a large family of lipophilic drugs. ▶ Diazepam for instance, is rapidly absorbed, with peak concentration occurring within an hour for adults and, as quickly as, 15–30 min in children (Jenkins 2008). This route is characteristically slow and may be delayed by the presence of food in the digestive tract. The oral route may be ineffective for certain drugs because the acidity of the stomach renders them ineffective. Heroin provides a good example of the latter phenomenon. Drug users looking for an immediate or intense effect or "rush," avoid the oral route. Nonlipophilic (nonionized) compounds such as ▶ alcohol, readily cross cell membranes by passive diffusion and are easily and rapidly absorbed from the gut, particularly on an "empty" stomach.

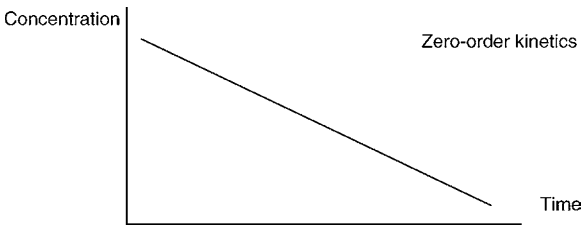
Transmucosal Absorption: Mucous membranes (that form the moist surfaces that line the mouth, nose, eye sockets, throat, rectum and vagina, etc) are thinner, have a greater blood supply and, are more permeable (lack keratin) compared with the epidermis (skin). For these reasons, absorption across mucus membranes is rapid and drugs (especially lipophilic compounds) are effectively absorbed into the bloodstream. ▶ Nicotine in the form of chewing tobacco and buprenorphine placed sublingually (under the tongue) is successfully absorbed through the mucous membranes of the mouth. Drugs can be administered rectally including aminophylline, a drug used in the treatment of bronchial asthma and tribromoethanol, an anesthetic. Drugs can also be absorbed by insuffalation (sniffing, snorting), which allows ▶ cocaine, ▶ ketamine amylnitrite and tobacco stuff to be absorbed across the mucous membranes of the nose and sinus cavities. Nasal administration (a preferred route for users of illicit substances) enables rapid absorption into the cerebrospinal fluid (CSF) and hence, the cerebral circulation. After nasal administration, the concentration of some drugs in the CSF may be higher than in plasma (Calvey 2007).

Inhalation: In the case of inhalation, a drug is absorbed into the bloodstream across the alveolar membranes of the lung. This occurs in gas form (e.g., the vapors of solvents), in fine liquid drops (heroin or cocaine), or in fine particles of matter suspended in a gas (e.g., aerosols or the smoke from tobacco or cannabis). For many drugs, inhalation is the most rapid method of absorption into the general circulation. Glue "sniffing" is actually an incorrect description; technically, glue vapors are inhaled and absorbed via the linings of the lung.

Parenteral (*Injection*): The term "parenteral" denotes those pathways through which drugs are injected directly into the body. There are three principle parenteral routes: subcutaneous, intramuscular, and intravenous. Subcutaneous injection ("skin popping" to street users) involves injecting the drug under the skin. The rate of absorption from the site of injection is slower than the intravenous injection, but faster than the oral route. Intramuscular injection involves deeper penetration of the drug into the body tissue. The drug is injected either in solution or in suspension directly into the muscle mass, where it is slowly absorbed into the bloodstream. Intravenous injection (popularly known as "mainlining") involves the direct injection of the drug into the veins. It is one of the fastest ways of getting a drug into the bloodstream and also allows relatively large amounts of a drug to be administered at one time. Intravenous drug administration poses the highest risk of toxicity and overdose (Wolff 2005).

Kinetics of Absorption The oral absorption of drugs often approximates first-order kinetics, especially when given in solution. Under these circumstances, absorption is characterized by an absorption rate constant, K_a, and a corresponding half-life. ▶ First-order kinetics depend on the concentration of only one reactant and a constant fraction of the drug in the body that is eliminated per unit time. The rate of absorption is proportional to the amount of drug in the body.

Sometimes a drug is absorbed essentially at a constant rate, called zero-order absorption. ▶ Zero-order kinetics is described when a constant amount of drug is absorbed (or eliminated) per unit time but the rate is independent of the concentration of the drug (Fig. 4). Zero-order kinetics explains the way in which alcohol is handled in



Pharmacokinetics. Fig. 4. Schematic representation of the absorption of a drug by zero-order kinetics.

the body and several other drugs at high dosage concentrations, such as phenytoin and salicylate (Neligan 2009).

The pharmacokinetic parameter linked to the passage of a drug into the systemic circulation is known as ► Bioavailability. It is a measurement of the amount of active drug that reaches the general circulation and is available at the site of action (although this parameter is difficult to establish for CNS active drugs, due to the need to cross the blood-brain barrier). It is expressed as the letter *F*.

It is assumed that a drug given by the intravenous route will have an absolute bioavailability of 100% or 1 ($F = 1$), while drugs given by other routes usually have an absolute bioavailability of less than one. *F*, is often calculated as the proportion of drug that reaches the systemic circulation after oral compared to IV administration. It is the fraction of the drug absorbed through non-intravenous administration compared with the corresponding intravenous administration of the same drug. The formula for calculating *F* for a drug administered by the oral route (p.o.) is given below.

$$F = \frac{[\mathrm{AUC}]_{\mathrm{po}} * \mathrm{dose}_{\mathrm{IV}}}{[\mathrm{AUC}]_{\mathrm{IV}} * \mathrm{dose}_{\mathrm{po}}}$$

F is measured by comparing the AUC for oral and i.v. doses from zero to the time point for which elimination is complete.

The calculation of *F* requires an intravenous reference, that is, a route of administration that guarantees the entire administered drug reaches the systemic circulation. Such studies come at considerable cost, not least because of the necessity to conduct preclinical toxicity tests to ensure adequate safety.

Bioavailability is usually calculated by determining the maximum (peak) plasma drug concentration (C_{max}), the time that it takes to reach the peak (T_{max}), and AUC. Plasma drug concentration increases according to the extent of absorption; the T_{max} is reached, when drug elimination rate equals absorption rate. Bioavailability determinations based on the C_{max} however can be erroneous because drug elimination begins as soon as the drug enters the bloodstream.

For drugs excreted primarily unchanged in urine (amphetamine), bioavailability can be estimated by measuring the total amount of drug excreted after a single dose. Ideally, urine is collected over a period of 7–10 elimination half-lives for complete urinary recovery of the absorbed drug.

The Distribution of Drugs in the Body

Once a drug is absorbed into the systemic circulation, distribution occurs throughout the body. The distribution for most drugs in the body is not even; some drugs bind to plasma proteins, while others are sequestered into adipose tissue, and a few have great affinity for bone tissue. Drugs must be highly fat soluble in order to enter the brain. Similarly, fat-soluble drugs can cross the placenta to affect the fetus; these same drugs are also found in the milk of lactating women.

Unevenness of distribution is a barrier to the accurate interpretation of the concentration of a drug in the body and complicates efforts to correlate blood concentrations with behavior. High blood drug concentrations are usually related to greater behavioral effects than low concentrations. However, some drugs (the barbiturates) have passed their peak plasma concentration before peak behavioral effects are seen. In the case of alcohol, some of the above differences do not apply, since alcohol crosses all barriers to distribute uniformly in total body water. Therefore, in the non tolerant individual blood alcohol concentrations are highly correlated with behavioral effects.

In pharmacokinetic terms, the ► Volume of Distribution (V_{D}) also known as the apparent Volume of Distribution is the parameter used as a direct measure of the extent of distribution. V_{D} is purely hypothetical and does not represent an actual physical volume inside the body. It is defined as the volume in which the amount of drug would need to be uniformly distributed to produce the observed blood concentration, by supposing that its concentration is homogeneous, i.e., the average tissue concentration is identical to that of the plasma. V_{D} is expressed as:

$$V_{\mathrm{D}} = \mathrm{dose}/\mathrm{C}_0\,(\text{initial concentration})$$

For example, after intravenous injection of 100 mg of a drug whose initial concentration, C_0, in plasma is 10 mg/L, the V_{D} would be 10 L. For a given drug, the knowledge of its desirable concentration in blood and V_{D} allows evaluation of the dose to administer.

It is possible for V_{D} to be close to a recognizable volume, such as plasma volume (~0.05 L/kg), extracellular fluid (~0.2 L/kg), or total body water (~0.7 L/kg). This would happen if the drug is uniformly distributed in one of these "compartments," but this is rare. Indeed, when a drug binds preferentially to tissues at the expense of plasma (a drug that is highly lipophilic), the plasma concentration will be extremely low (e.g., methadone, Δ^9-tetrahydrocannabinol). This will result in a large V_{D}, that may be larger than the actual volume of the individual itself (>1 L/kg) e.g., digoxin. A large V_{D} implies wide distribution, or extensive tissue binding, or both.

The V_{D} is thus a mathematical method for describing how well a drug is removed from the plasma and distributed to the tissues. However, V_{D} does not provide

any specific information about where the drug is or whether it is concentrated in a particular organ. V_D may be increased by renal failure (due to fluid retention) and liver failure (due to altered body fluid and plasma protein binding). Conversely V_D may be decreased in dehydration.

The ► distribution phase is so called, because distribution determines the early rapid decline in plasma concentration. However, changes in plasma concentration reflect primarily movement within, rather than loss from the body. In time, equilibrium is reached between the drug present in tissue and that in plasma, and eventually plasma concentration reflects a proportional change in the concentrations of drug in all tissues and hence in the body. At this stage decline in drug concentration is only due to the elimination of drug from the body (elimination phase). Two pharmacokinetic parameters describe the elimination phase, the V_D (as described above) and the biological or ► elimination half-life.

The elimination half-life of a drug is the time taken for the plasma concentration as well as the amount of drug in the body to fall by one half and is usually denoted by the abbreviation $t_{1/2}$. Knowledge of the $t_{1/2}$ is useful for the determination of the frequency of administration of a drug (the number of intakes per day) and to calculate the desired plasma concentration. Generally, the $t_{1/2}$ of a particular drug is independent of the dose administered (Table 1).

The Elimination of Drugs from the Body

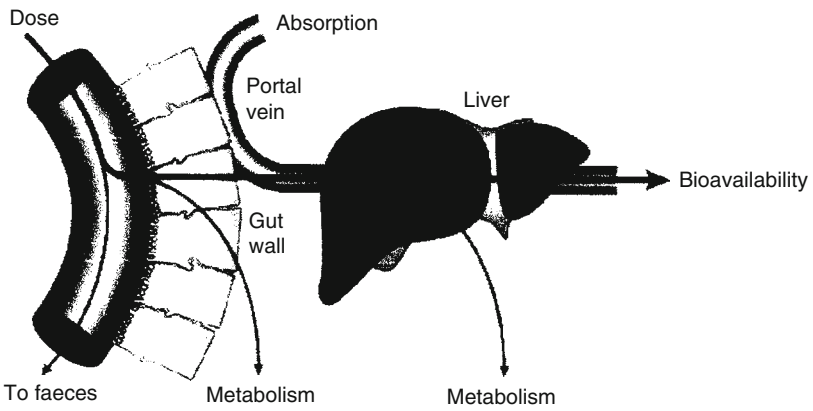
Elimination occurs by metabolism and excretion. Some drugs are eliminated via the bile and others in the breath, but for most drugs the primary route of excretion occurs via the kidneys.

Metabolism: Drugs are eliminated from the body in both changed and unchanged states: that is, part of the drug eliminated is chemically identical to the drug which was administered, and part has been changed (metabolized). The proportion of a drug dose eliminated in a particular state is determined by the nature of the drug, the dose, the route of administration, and the physiological characteristics of the user. The excretion of unchanged psychoactive drugs via the urine or faeces is generally inefficient because of their high fat solubility. As a result, fat-soluble substances are metabolized into water-soluble products that can be readily excreted by the kidneys and/or the intestines (Fig. 5).

Drugs are metabolized by specialized proteins called enzymes, which act as catalysts in the metabolic reaction. Most drug metabolism occurs in the liver, although enzymes in the kidneys, gut, lungs, and blood may also aid in the process. In the liver, there are two types of enzymes: microsomal (insoluble) drug metabolizing enzymes, and cytoplasmic (soluble) metabolizing enzymes (which metabolize alcohol and similar drugs). The conversion of a fat-soluble drug to a substance that has sufficient water solubility for efficient excretion may involve several sequential chemical reactions, each step rendering the molecule slightly more water soluble than before (Feldman et al. 1997). Thus many metabolites are often derived from the same parent drug (for example, there are at least 25 known metabolites from tetrahydrocannabinol (THC), the main psychoactive ingredient of cannabis).

Pharmacokinetics. Table 1. Plasma elimination half-life for a selection of different compounds.

Substance	Half-life	Notes
► Diazepam (Valium)	20–50 h	Rapid absorption and fast onset of action with peak plasma concentration achieved 0.5–2 h after oral dosing. Active metabolite desmethyldiazepam has a half-life of 30–200 h
► Carbamazepine	18–60 h	Carbamazepine exhibits auto induction: it induces the expression of the hepatic microsomal enzyme system CYP3A4, which metabolizes carbamazepine itself
► Haloperidol	14–36 h	Fifty times more potent than chlorpromazine. Rapidly absorbed and has a high bioavailability
► Fluoxetine	1–6 days	The active metabolite of fluoxetine is lipophilic and migrates slowly from the brain to the blood. The metabolite has a biological half-life of 4–16 days.
► Methadone	24–36 h	Orally effective. Exhibits auto induction: it induces the expression of the hepatic microsomal enzyme system CYP3A4, which metabolizes methadone itself
Water	7–10 days	Drinking large amounts of alcohol will reduce the biological half-life of water in the body.
► Alcohol	No half-life	Percentage of alcohol in your blood goes down by 0.015/h at a constant rate. Metabolism is zero-order kinetics (enzymes are saturated, and the rate of disappearance of ethanol in the body is INDEPENDENT of concentration. Thus, concentration falls off linearly, not exponentially. No half-life



Pharmacokinetics. Fig. 5. Schematic representation of where metabolism occurs during the absorption process. The fraction of the initial dose appearing in the portal vein is the fraction absorbed, and the fraction reaching the blood circulation after the first-pass through the liver defines the bioavailability of the drug administered orally (www.nature.com/.../v2/n3/images/nrd1032-i2.gif, Image at: www.nature.com/.../v2/n3/box/nrd1032_BX3.html).

As the drug becomes progressively less fat soluble it simultaneously loses the ability to cross the blood-brain barrier and to produce a pharmacological effect. However, some drug metabolites are pharmacologically active, producing the same effects as the parent drug. For example, heroin is metabolized to a number of metabolites, including ▶ morphine, N-morphine, ▶ codeine, and 6-monoacetylmorphine, all of which have pharmacological properties characteristic of the original drug.

Other drug metabolites can produce a completely different activity from the parent drug. Certain drug metabolites may be even more toxic than the parent drug: Methanol (methyl alcohol) is an example of a drug metabolized to produce two very toxic metabolites, formaldehyde and formic acid. It is these metabolites which are considered responsible for disruption of the acid-base balance in the body and for damage to the optic nerve, both of which pose serious problems in methanol poisoning.

Both types of liver enzymes, microsomal and cytoplasmic, are inducible – therefore, repeated drug exposure causes the enzymes to increase in number; the result is a faster metabolic rate – that is, a more rapid conversion of the ingested drug into its metabolites. This increased metabolic rate (speeding up of the process) can result in increased intensity and speed of onset of drug effects if the original drug was inactive and the metabolites active. This process can result in decreased intensity and duration of effect, if the original drug was active and the metabolites was inactive. Many enzymes are genetically polymorphic, and their presence and number in the body is under genetic control. Three main phenotypes occur in these cases with individuals categorized as extensive, intermediate, or poor metabolizers accordingly. For instance, this applies to ▶ MDMA (ecstasy) metabolism and nicotine metabolism as a result of the genetic polymorphism of CYP2D6 and CYP2A6, respectively.

▶ Zero-order elimination is described when a constant amount of drug is eliminated per unit time, independent of the concentration of the compound. Zero-order reactions are typically found when the enzyme required for elimination to proceed is saturated by the drug. Zero-order kinetics explains when an individual, who drinks 20 units of beer before midnight will fail a breathalyzer test at 8 am the following morning. In this instance, the pathways responsible for alcohol metabolism are rapidly saturated and work to their limit. The removal of alcohol through oxidation by ▶ alcohol dehydrogenase in the liver is thus limited. Hence the removal of a large concentration of alcohol from blood may follow zero-order kinetics.

Excretion: The kidney acts as a pressure filter through which the blood passes. Most of the water and some of the dissolved substances contained in the blood are reabsorbed during its passage through the kidney. Substances that are fat soluble tend to diffuse back into the bloodstream, whereas residual water and unreabsorbed substances are eliminated during urination. The process of reabsorption and active excretion in the tubules of the kidneys and the time lapse between urine formation and urination, make it is difficult to use urine concentrations of drugs and drug metabolites as a base for accurate estimates of blood concentration of these substances. The drug concentrations determined in urine drug screening are therefore, only a rough indication of blood

concentrations (Jenkins 2008). Salivary drug concentrations on the other hand have a much better correlation with blood (Wollff et al. 1999).

The intestines are a site of drug excretion as well as a site of drug absorption. Some drugs and drug metabolites have chemical characteristics which cause them to be actively secreted (or "pushed out") into bile as they pass through liver cells, and the drug-containing bile then empties into the intestines. Thus, these drugs and metabolites may be excreted in the faeces. As is the case with the kidney, however, the net excretion by this route may be greatly reduced by subsequent reabsorption into the bloodstream of the fat-soluble compounds (including psychoactive drugs) further along in the intestines. In this instance, the drugs will go through the process of excretion all over again (► enterohepatic cycling), and the drug effect may be prolonged.

Volatile drugs such as solvents are commonly excreted in the breath and for general anesthetics; breath may be the major route of elimination. For substances such as alcohol however, it is a minor route. Nevertheless, it is possible through stimulation of breathing to increase the loss of drug from the body. Since the amount excreted in the breath can be reliably related to the blood level, the concentration of alcohol in the breath, as measured by the Breathalyzer test, serves to estimate the degree of intoxication. There are many routes of elimination, including sweat and saliva (and in lactating women, milk) and these all play a role in drug elimination. Though the latter are minor routes, they can be important in forensic analysis.

Just as the parameter, V_D is required to relate blood concentration to the total amount of drug in the body, so there is a need to have a parameter to relate drug concentration to the rate of elimination. ► Clearance, denoted by CL, is that factor. The CL of a drug is the volume of plasma from which the drug is completely removed per unit time. The elimination half-life is related to CL and V_D by the following equation:

$$t_{1/2} = \frac{\ln 2 \cdot V_D}{CL}$$

In clinical practice, this means that it takes just over 4.7 times the $t_{1/2}$ for a drug's concentration in plasma to reach steady state after regular dosing is started, stopped, or the dose changed (Table 2). For example, methadone has a half-life of 24–36 h; this means that a change in the dose will take the best part of a week to have full effect. For this reason, drugs with a very long half-life (e.g., amiodarone, elimination $t_{1/2}$ of about 58 days) are usually started with a loading dose to achieve their desired clinical effect more quickly (Hallworth and Watson 2008).

Pharmacokinetics. Table 2. The elimination of a compound from the systemic circulation expressed as a function of its half-life.

Number of half-lives elapsed	Fraction remaining	Percentage remaining	
0	1/1	100	
1	1/2	50	
2	1/4	25	
3	1/8	12	0.5
4	1/16	6	0.25
5	1/32	3	0.125
6	1/64	1	0.563
7	1/128	0	0.781
...	...	...	
N	$1/2^n$	$100(1/2^n)$	

The CL of a drug: The amount eliminated, is proportional to the concentration of the drug in the blood. The fraction of the drug in the body eliminated per unit time is determined by the elimination constant (kel). This is represented by the slope of the line of the log plasma concentration versus time.

$$CL = kel \times V_D$$

Rate of elimination equals clearance times the concentration in the blood. It can be shown that the kel equals the log of 2 divided by the $t_{1/2} = 0.693/t_{1/2}$ and likewise, $CL = kel \times V_D$, so, $CL = 0.693 V_D/t_{1/2}$, which shows $t_{1/2} = 0.693 \times V_D/CL$.

The rate of elimination (R_{oe}) is thus the clearance (CL) times the concentration in the plasma (Cp).

$$R_{oe} = CL \times Cp$$

While the fraction of the total drug removed per unit time is CL/V_D

If the volume of distribution is increased, then the kel will decrease, the $t_{1/2}$ will increase, but the CL would not change.

Physiological Tolerance or Drug Tolerance

► Drug Tolerance is encountered when an individual's reaction to a drug decreases so that larger doses are required to achieve the same effect. It can involve both psychological and physiological factors. The main characteristic of drug tolerance is that the process if reversible. That is, cessation of use of the drug will diminish the degree of tolerance. The rate at which tolerance develops and is lost depends on the particular drug, the dosage, and the frequency of use. Another feature

of tolerance is that differential development occurs for different drug effects.

When considered in the context of pharmacokinetics, tolerance can be conveniently divided into a number of forms that relate to the mechanisms involved (Pratt 1991).

- *Dispositional (pharmacokinetic) tolerance*: results from a change in absorption, distribution, metabolism or excretion of a drug which leads to a decreased quantity of the substance reaching the site it affects.
- ▶ *Pharmacodynamic tolerance*: arises from adaptational changes occurring in the brain. These include cellular adaptive processes like *down regulation* (reduced number) and/or *desensitization* (reduced sensitivity) of drug receptors at the primary site of drug action as well as changes in neurotransmitter function in neuronal pathways downstream from the initial interaction. In opioid tolerance, several mechanisms contribute to opioid receptor desensitization, but the N-methyl-D-aspartate (NMDA) receptor cascade seems to be a common and important link.
- ▶ *Cross tolerance*: results when tolerance to one drug is extended to another of a different chemical class.

phMRI

Definition

Pharmacological MRI (phMRI) refers to the assessment of the functional response to ligand-induced receptor stimulation or inhibition after drug administration. For this purpose, different functional MRI methods including CBF-, CBV- or BOLD-fMRI can be applied to measure changes in cerebral perfusion. Image recording before, during, and after drug administration allows for drawing conclusions on the effect of pharmacological compounds on brain activity. With such an experimental design, one tests acute effects of the drug itself in the brain ("challenge

phMRI"). With "modulation phMRI" on the other hand, one investigates how neurotransmitter systems are involved in neuronal systems engaged by other processes, such as cognitive challenge.

Phase I Clinical Trial

Definition
Phase I clinical trials are often the first time a potential new medication is given to humans. It follows extensive animal testing for both efficacy and safety. Typically, healthy paid volunteers are administered progressively higher doses in the same session or, more commonly, over several sessions that are conducted in specialized laboratories equipped and staffed to monitor carefully the subject's physiological and behavioral response. In most phase I trials, plasma samples are taken to measure levels of the drug and its metabolites to determine rates of metabolism and elimination and develop a pharmacokinetic model of the drug's biodisposition.

Controlled clinical trial

Definition
Phase II clinical trials are designed to assess both safety and efficacy of new medications or new uses of existing medications. Subjects are patients with the disorder that the medication is intended to treat. There are usually rigorous inclusion and exclusion criteria for selecting subjects for study. Typically, Phase II trials are preceded by a Phase I trial. Early Phase II trials may be used to select doses for more extensive later Phase II trials. Phase II trials include at least one dose of the proposed new treatment and at least one comparison group. The comparison may be a ► placebo; it may be an existing approved medication or both. Thus, Phase II trials are often called controlled clinical trials.

Controlled clinical trial

Definition
Phase III clinical trials are designed to assess both safety and efficacy of new medications or new uses of existing medications under conditions similar to those where it would be used clinically. Subjects are patients with the disorder that the medication is targeted to treat. Phase II trials include the study medication and one or more comparison groups. The comparison may be a ► placebo, an existing approved medication, or both. Typically, Phase III trials are preceded by one or more Phase II trials; however, Phase III studies enroll a greater number of subjects. Many Phase III trials utilize several clinical sites and are referred to as multisite or multicenter trials. In one variation of a randomized controlled trial, patients are switched from one medication to another using a crossover design. In another variation, patients receive sequenced treatment utilizing a specific protocol for moving them from one treatment to another. A well-known sequenced clinical trial in psychopharmacology is known as the STAR*D trial of treatment alternatives for depression (http://www.nimh.nih.gov/health/trials/practical/stard/backgroundstudy.shtml). Phase III trials are

often referred to as pivotal clinical trials with positive results and a reasonable balance of benefits and risk needed for regulatory approval of the new medication. After approval, a medication enters Phase IV testing which is comprised primarily of post-marketing surveillance (or pharmacovigalence) of adverse side effects.

Phasic Neurotransmission

Synonyms

Phasic neuronal firing; Phasic neurotransmitter release

Definition

Phasic neurotransmission is characterized by a bursting mode of neuronal firing that quickly releases high quantity of neurotransmitter in the synapse. This form of neural transmission is usually triggered by behaviorally relevant signals and is opposed to "tonic" neurotransmission, which instead is the maintenance of low steady levels of extracellular neurotransmitter.

Phencyclidine

Synonyms

Angel dust; PCP

Definition

Phencyclidine (PCP) was originally developed as a general anesthetic agent by Park-Davis & Co. in the late 1950s, but during the initial clinical trials it was discovered that approximately 30% of the patients, as they emerged from anesthesia, developed psychotic reactions that had a close resemblance to ► schizophrenia. Subsequent studies found that after intravenous administration PCP induced a dysphoric, confusional state characterized by feelings of unreality, changes in body image, profound sense of aloneness or isolation, and disorganization of thoughts and amnesia; in many subjects negativism and hostility also occurred together with ► hallucinations and repetitive motor behavior. PCP could in healthy volunteers produce schizophrenia-like impairment of primary attention, motor function, proprioception, and symbolic and sequential thinking. Despite its ► dysphoric profile in patients, PCP was subject to abuse under the street name "Angel dust." Its primary mechanism of actions is noncompetitive inhibition of the ion channel of the ► NMDA receptor, by binding inside the channel. However, PCP is also a muscarinic antagonist, a dopamine, 5-HT and noradrenaline reuptake inhibitor, a sigma 1 and 2 ligand, a cholinesterase inhibitor, and can block voltage-gated potassium channels.

Phenelzine

Synonyms

Nardil

Definition

Phenelzine (2-phenylethylhydrazine) is an antidepressant that inhibits irreversibly and nonselectively monoamine oxidase (MAOI), still in widespread clinical use, that is claimed to be effective against major depressive disorders, particularly in treatment-resistant patients. It is also used in the treatment of dysthymia, bipolar depression,

panic disorders, social anxiety disorder, bulimia, and post-traumatic stress disorder. As is the case for many other antidepressants, phenelzine requires ca. 2–6 weeks of daily treatment to become therapeutically effective.

Due to its prominent side effects, phenelzine is considered only as a treatment of last resort. Among the adverse side effects are dizziness, disturbances in vision, appetite and food, sleep, blood pressure, thermoregulation, and sexual functions. Like other MAOIs, phenelzine interacts with tyramine-containing foods (the so-called cheese effect), overindulgence of which can result in a hypertensive crisis.

Phenobarbital

Synonyms
Phenobarbitone

Definition
Phenobarbital is a barbiturate drug used widely as an anticonvulsant agent. It has a very long duration of action after a relatively slow onset of effects. It was synthesized at the Bayer pharmaceutical firm by 1904 and first marketed in 1912. It has been superseded with respect to its original use as an anxiolytic, sedative, and hypnotic agent, partly because of the dangers of overdose leading to coma and death. It shares many other properties with its shorter-acting relative pentobarbital.

Definition
Animal behavior can be viewed as the outward manifestation of an orchestrated and complex functioning of the central nervous system (CNS) and how it interacts with the internal and external environment. Phenotyping of behavioral characteristics in its widest sense refers to behavioral paradigms in which aspects of the behavioral

repertoire of a subject are analyzed, either under baseline conditions or after an experimental challenge, with the aim to assess CNS function. Most frequently sensory, locomotor, motivational, emotional, social, cognitive, consumptive, reproductive or reward-related behaviors are assayed. The subjects participating in a study may be either animal or human.

Principles and Role in Psychopharmacology

The goal of phenotyping of behavioral characteristics is usually either (1) the assessment of the neurobiology of certain behaviors by the use of lesions, systemic or local drug applications, or other experimental manipulations or (2) the examination of the effects of drugs in a drug-discovery screening or profiling context, or (3) the analysis of CNS-specific gene function by the use of genetically altered animals, for example, knockout mice, or in the case of human subjects, by relating human genetic haplotypes to disease-relevant behavioral characteristics assessed with neurophysiological or neuropsychological methods. Moreover, all three aspects are important for the development and assessment of animal models of neurological and psychiatric disorders. These are generated by combining manipulations (e.g., stress, chemical, lesion, surgical, genetic, environmental) with a test which has a robust behavioral readout.

Most behavioral phenotyping methods carried out in animals were initially developed either for studying the neuronal circuits involved in normal and pathological behaviors, or for the preclinical analysis of compounds in pharmaceutical industry – whereby rats, birds, or monkeys were primarily used as subjects (Sahgal 1993). With the completion of the genome sequences of human and several other species, the determination of gene and protein function, and understanding their role in disease mechanisms, became one of the major challenges in biomedical science. Due to its amenability to transgenic techniques, the mouse became the most used model organism in the endeavor to develop a complete functional annotation of the human genome and to employ the same information to better understand human disease and its underlying physiological and pathological basis. In this context, the experimental designs for characterizing rat behavior were transformed to successfully work in mice, and the term "Behavioral Phenotyping" is most frequently used in the context of behavioral characterization of mouse mutants. The development of this field owed much to the publication of reviews suggesting "test batteries" and to the publication of comprehensive guidebooks on mouse-behavioral phenotyping methodology (e.g., Crawley 2000; Crusio and Gerlai 1999), which encouraged many molecular geneticists and neuroscientists to use these techniques for their research. While, behavioral phenotyping is also growing among other model organisms including the fruitfly (*Drosophila melanagoster*), the worm (*C. elegans*), the sea slug (Aplysia), and the Zebrafish (*Danio rerio*) we will focus this article on rodents.

Examples of Frequently Used Behavioral Phenotyping Tests in Lab Rodents

Behavioral phenotyping procedures were developed to analyze animal models for human neuropsychiatric dysfunctions like ▶ posttraumatic stress disorder, other ▶ anxiety disorders, ▶ depression, ▶ schizophrenia, ▶ autism, attention-deficit hyperactivity disorder (▶ ADHD), ▶ addiction, mental retardation, or motor, sensory, or cognitive deficits related to neurodegenerative diseases like ▶ Parkinson's Disease, ▶ Alzheimer's Disease, ▶ Huntingtin's Disease, Stroke, or Prion Diseases.

For the analysis of emotionality, most frequently tests for unconditioned anxiety-related behavior are applied, in which the animals are usually exposed to novel environments, which puts them in the conflict between the urges to explore and to avoid possible dangers. Most frequently, the ▶ open-field test and the ▶ elevated plus-maze test are used to this end, and an elevated zero-maze is sometimes used as an alternative to the plus-maze. Additionally, light–dark avoidance tests are used to assess anxiety, and the ▶ social interaction test is applied to assess social anxiety.

Rodent tasks relevant to human depression are primarily stress-induced reductions in avoidance or escape, termed behavioral despair. The most widely used rodent models of symptoms of depression are the ▶ forced swim test and the ▶ tail suspension test. The ▶ learned helplessness paradigm may also be used.

▶ Prepulse Inhibition is a frequently used task that assesses sensorimotor-gating phenotypes, and is considered to have face, construct, and a high-predictive validity for schizophrenia and other neuropsychiatric diseases involving dysfunctions of sensorimotor integration in man.

To assess motor functions, frequently the open-field test and voluntary wheel-running are used to assess locomotor activity levels. The accelerating rotarod, balance-beam tests, and the vertical pole test are often used to assess motor coordination and balance. In addition, grip strength is measured using a specialized grip strength meter, and gait abnormalities can be analyzed by manual or automated analysis of the footprint pattern. Assessment of swimming ability can reveal motor or vestibular deficits not detected by other motor coordination and balance tests.

For behavioral assessment of sensory abilities, reflex responses are used whenever possible to reduce possible confounding factors, for example, the motivation of the animal to participate in the test. Elicitation of the optokinetic nystagmus is a reflex response that is used to assess functionally intact vision. Hearing deficits can be revealed by measuring the acoustic startle reflex, either by the use of a clickbox or, more precisely, by specialized acoustic startle chambers. Pain sensitivity is frequently assessed using the hot-plate test (requiring circuitry in the brain and the spinal cord) or the tail-flick test (spinal reflex). Taste and olfactory abilities are often assessed in choice tests.

Aversively and appetitively motivated tasks are used to assess cognitive function. For the analysis of conditioned anxiety or fear learning, most frequently, procedures like, for example, ▶ active avoidance, ▶ contextual-fear and ▶ cued-fear conditioning, or fear-potentiated startle are applied, in which the animals have to learn the association between a conditioned stimulus and a mild footshock. The ▶ Morris water-maze or the ▶ radial arm-maze are most frequently used to assess ▶ spatial learning, reference memory, and ▶ working memory, and appropriate versions of the T-maze and the Y-maze task are also used to assess working memory. ▶ Social recognition tasks are applied to analyze social memory and olfactory function, and object recognition tasks are applied to assess object memory. Schedule-controlled operant tasks can also be used to assess different aspects of learning and motivational behavior; and one such task, the ▶ five-choice serial reaction-time task has been developed to assess sustained and divided ▶ attention.

Repeated testing on the accelerated rotarod is applied to assess motor learning. Rodent tasks relevant to human addiction are primarily procedures that assess the rewarding properties of substances like ▶ self-administration of drugs, ▶ conditioned place preference paradigms, or generalization to drugs of abuse in ▶ drug discrimination procedures.

Applications

Behavioral phenotyping methodology has been used in the search for new and improved pharmaceuticals. It may be used not only to identify compounds with specific actions, but also to exclude unwanted side effects of a new compound, for example, motor effects or abuse potential.

Since the advent of functional genomics, behavioral phenotyping is frequently applied in the analysis of genetic and molecular functions, with the aim to identify new targets for therapeutic development. Genetic studies in the mouse are important for the elucidation of molecular pathways underlying behavior. The goal of this endeavor is not only the identification of genes that control brain function and influence behavior, but also the understanding of genetic factors involved in human psychiatric disorders (Tarantino and Bucan 2000). These disorders are associated with quantitative phenotypes called "intermediate traits" or "▶ endophenotypes," some of which, in contrast to the full-complex disorder, can readily be modeled in mice. These traits are risk factors which are considered to be closer to the genetic etiology than the full syndrome. Examples of such endophenotypes are anxiety in depression, prepulse inhibition and working memory deficits in schizophrenia, and social interaction deficits in autism and schizophrenia (Gottesman and Gould 2003). Since the rather recent emergence of the endophenotype concept in neuropsychiatric research, some work has been devoted to appropriately modeling human endophenotypes in mice and inspecting the function of candidate genes for human endophenotypes identified, for example, by human association or linkage studies in adequate genetic mouse models.

Since 1997, behavioral phenotyping methodology has been used in many large-scale mouse projects (see Gondo 2008 for overview). In several European, North American, and Asian large-scale phenotype-driven random-mouse mutagenesis screens aiming for the discovery of novel genes, among other techniques also behavioral phenotyping methodology was applied to detect so far unknown genes involved in defined behaviors. The development of large-scale mouse mutagenesis projects increased the demand for comprehensive robust and reliable phenotyping platforms for all body systems, including CNS function. In this context, the German National Genome Research Network established in collaboration with the pan-European consortium EUMORPHIA, a mouse phenotyping center with open access to the scientific community, called "German Mouse Clinic" (http://www.mouseclinic.de/, Gailus-Durner et al. 2005).

To overcome the bottleneck of comprehensive phenotypic characterization of the large number of mutants generated by the large-scale mutagenesis projects, several mouse phenotype assessment centers were built in Europe that work together under the roof of EUMODIC (European Mouse Disease Clinic, http://www.eumodic.org/). These mouse clinics use the standardized tests contained in EMPReSS (the European Mouse Phenotyping Resource of Standardized Screens, empress.har.mrc.ac.uk), and make their phenome data publicly available in the EuroPhenome database (http://www.europhenome.org/).

Pitfalls

Several factors can influence behavioral phenotyping results, and therefore need to be considered in the context of data reproducibility (Wahlsten 2001). Due to developmental and degenerative processes, the age of the subject can play a role, as well as the time point of testing due to circadian rhythms of many biological processes. Therefore, experimental subjects and controls of the same age should be tested concurrently; in the case of mutants, ideally littermates are used as controls. Caution should be made in extrapolating data between species as the effects of manipulations may vary. Moreover, within a given species there are marked differences between strains, and this should also be taken into account when phenotyping or analyzing behavioral data.

Because the previous experience of handling experimental manipulations or drug injections can influence the performance of a subject in a particular test, it might be desirable to use experimentally naive subjects for each kind of experiment. Practically, this approach increases the number of animals needed and is simply not feasible when mouse mutants are used, due to the comparatively long time needed to breed a sufficient amount of animals for concurrent testing of mutants and littermate controls in a statistically meaningful number. As a solution to this problem, frequently a series of tests is applied, in which the tests are usually ordered from those that are considered the least stressful for the subject to those considered the most stressful. Likewise, in comprehensive phenotyping platforms like mouse clinics behavioral phenotyping is done first, before more invasive experimental manipulations are performed on the animals, and the experimental history is documented. In case of a positive phenotyping result using such "test batteries," the putative phenotype should be confirmed in a new batch of subjects.

The more comprehensive the phenotyping, the less likely are mis- or overinterpretations of individual data sets. This is particularly important when screening for phenotypes in mutants of genes with unknown functions. For example, locomotor, exploratory, or emotional phenotypes may be confounded or even caused by sensory deficits, skeletal malformations, or metabolic alterations, and may thus not inevitably reflect the effects on brain function. Likewise, apparent cognitive phenotypes may not be centrally mediated but may be caused by alterations in sensory perception. Because one of the goals of behavioral phenotyping is the analysis of endophenotypes related to human neuropsychiatric disorders, it seems important to exclude alternative, not CNS-specific explanations for putative phenotypes.

Experimenter and the kind of equipment used are also known to influence phenotyping results. Therefore, careful descriptions of experimental procedures and thorough training of an experimenter are essential, as well as precise (technical) specifications of the (automated) equipment. For example, consortia like EUMORPHIA and EUMODIC (see above) that share the phenotyping effort and put particular emphasis on data reproducibility, undergo considerable efforts to ensure their procedures yield comparable results and validate them in cross-laboratory comparisons (Mandillo et al. 2008). However, since also environmental factors like diet, animal husbandry, housing conditions, cage structure, and so on, can have an impact, there may be practical limitations to standardization.

Advantages and Limitations of Behavioral Phenotyping Procedures

The advantages of behavioral phenotyping procedures reside in (1) their applicability to a wide range of scientific questions, from drug profiling to functional genomics; (2) their utility in the analysis of functions at the molecular level, as shown in many pharmacological studies as well as in studies with mouse mutants, for example, mutants of the dopaminergic and serotonergic neurotransmitter systems; and (3) relative ease of collecting high-quality quantitative data. On the other hand, the more comprehensive the analysis is supposed to be, the more time and the more animals are needed. If mouse mutants are used, the time and costs required for breeding have to be taken into account, which can be particularly high in the case of conditional mutants. However, mutant mice are extremely valuable when dissection of the functional role of a molecule cannot be approached using other techniques – for example, when pharmacological compounds are unavailable or have poor selectivity for a particular receptor subtype (Cryan and Holmes 2005).

If mutants of genes of completely or mainly unknown function are analyzed, behavioral phenotyping results should be interpreted in the context of analyzes of other body systems, particularly neuropathological and pathological analyzes. Especially, locomotor and motor-related emotional phenotypes should be comprehensively investigated, to check for possible dysmorphological, sensory, or metabolic contributions to the phenotype.

We suggest that it is prudent and most appropriate to use convergent tests that draw on different aspects of the behavioral system under investigation. In general, behavioral techniques are most effective when used in conjunction with other techniques to generate converging lines of evidence regarding the role of a molecule in a neural pathway.

Phentermine

Definition

Phentermine is an ▶ amphetamine derivative that is used as an antiobesity agent. It was present in the fenfluramine–phentermine association known as Fen–Phen, which has been withdrawn from the market because of the risk of heart valve disease. In contrast to ▶ fenfluramine, it is still available in many countries. In addition to its appetite-suppressant effects, it induces most of the sympathetic effects of amphetamine derivatives, with increased blood pressure, heart rate, agitation, and insomnia, and carries the risk of abuse and dependence.

Phenylalanine and Tyrosine Depletion

Marco Leyton
Department of Psychiatry, McGill University, Montreal, QC, Canada

Synonyms

Acute tyrosine depletion; Acute tyrosine/phenylalanine depletion

Definition

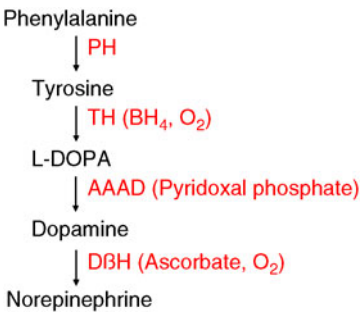
The acute phenylalanine/tyrosine depletion (APTD) method was developed as a safe and rapid way to transiently decrease ▶ dopamine (DA) neurotransmission in humans. The method entails the administration of a protein mixture that is selectively deficient in amino acids (AA) that are used to make DA. Since ingestion of this mixture decreases the availability of the necessary raw material, the neurotransmitter's synthesis and availability for release decrease as well. A manipulation based on the same principles – ▶ acute tryptophan depletion (ATD) – is widely used to transiently decrease serotonin transmission.

Current Concepts and State of Knowledge

The Catecholamine Metabolic Pathway

DA is a monoamine. As the name suggests it is made from a single amine, in this case the essential AA, phenylalanine. Essential AAs are those that we need to obtain from our diet. When we ingest protein, phenylalanine is cleaved and the liver enzyme, phenylalanine hydroxylase (PH), adds a hydroxyl group (oxygen+hydrogen, OH) to yield tyrosine. Tyrosine, in turn, can also be obtained from our diet. Irrespective of how we obtain it, tyrosine can then be carried across the ▶ blood brain barrier by a two-tiered transport system (one active and saturable, the other

diffusional) that acts on various large neutral AAs (LNAA: phenylalanine, tyrosine, tryptophan, valine, leucine, isoleucine, histidine, and methionine). Tyrosine can then enter DA neurons via a similar transport system on the cell's membrane. Inside the DA cell, tyrosine is a substrate for tyrosine hydroxylase (TH). TH adds a second OH group to yield 3,4-dihydroxy-L-phenylalanine, more commonly known as L-DOPA. L-DOPA is then a substrate for L-aromatic amino acid decarboxylase (AAAD or AADC) producing DA. Finally, vesicular monoamine transporters remove DA molecules from the cytosol and place them in storage vesicles. Within noradrenergic neurons, these vesicles contain dopamine-β-hydroxylase (DβH), an enzyme that hydroxylates the DA to ► norepinephrine (NE). DβH and AADC are 100–1,000 times more active than TH, and the hydroxylation of tyrosine to L-DOPA is considered the rate-limiting step (Fig. 1).



Phenylalanine and Tyrosine Depletion. Fig. 1. The catecholamine metabolic pathway. The essential amino acid, phenylalanine, is hydroxylated to tyrosine in the liver. Tyrosine from this dietary sources is then carried into the brain. Within catecholamine neurons, tyrosine is then hydroxylated by tyrosine hydroxylase into 3,4-dihydroxy-L-phenylalanine, and this constitutes the rate-limiting step in catecholamine synthesis. Decreases in tyrosine availability within a cell act like a drain, drawing in more of the amino acid. If tyrosine levels are insufficient, dopamine synthesis decreases. Tyrosine hydroxylase activity is also influenced by the availability of three other substrates, molecular oxygen, tetrahydrobiopterin, and dopamine itself. The first two increase tyrosine hydroxylase activity, while the latter is inhibitory. Similarly, the decarboxylation of L-DOPA to dopamine is affected by concentrations of pyridoxal phosphate (vitamin B_6), while the hydroxylation of dopamine to norepinephrine is affected by oxygen and ascorbate acid (vitamin C). *PH* phenylalanine hydroxylase; *TH* tyrosine hydroxylase; l-*DOPA* 3,4-dihydroxy-L-phenylalanine; *AAAD* aromatic amino acid decarboxylase; *DβH* dopamine beta hydroxylase; BH_4 tetrahydrobiopterin; O_2 molecular oxygen.

Acute Phenylalanine/Tyrosine Depletion (APTD)

Under normal physiological conditions, TH is only 75% saturated. Since TH is also the rate-limiting enzyme in DA synthesis, manipulations of tyrosine availability affect DA production. These effects might be particularly pronounced when the cell firing rate and precursor use is high. A method that exploits these features is called APTD.

In APTD studies, participants ingest an AA mixture that either does or does not contain phenylalanine and tyrosine (Table 1). Ingestion of the mixture induces protein synthesis in the liver. If the mixture lacks phenylalanine and tyrosine, the liver uses what it can extract from plasma. Since these plasma quantities are modest, levels decrease substantially. At the same time, plasma levels of AAs that were in the ingested mixture increase. This combination of effects markedly decreases the ratio of tyrosine to other LNAAs. Since this increases competition for access to the LNAA transporter, the amount of tyrosine that is able to enter the brain plummets (Wurtman et al. 1974; Fernstrom and Fernstrom 1995).

Studies conducted in rats, nonhuman primates, and humans indicate that the achieved tyrosine depletion significantly decreases DA synthesis and release. This includes evidence from postmortem tissue and in vivo microdialysis studies in rodents, cerebrospinal fluid (CSF) studies in monkeys, and both neuroendocrine and functional neuroimaging studies in humans. Although APTD might also affect NE metabolism, most evidence suggests an absence of significant effects on NE release. This preferential effect on DA was not predicted a priori, but the feature has been exploited to use APTD as a more selective probe than originally envisaged. Although effects of APTD on the trace amines are theoretically possible also, this has not been reported.

AA Mixture Composition: Rats, Vervet Monkeys, and Humans

Multiple APTD mixture recipes have been developed (Table 1). The two most common versions for the use in humans were developed by research groups at McGill University and Oxford University. The McGill recipe contains 16 AAs given in the proportion that is found in human milk. The Oxford recipe has similarities, but it is without histidine and six nonessential AAs: alanine, arginine, cysteine, glycine, proline, and serine. Compared with the McGill mixture, the Oxford control mixture contains proportionally more phenylalanine and tyrosine, exactly 10.8% for both, as compared to 5.4% and 6.6%, respectively in the McGill recipe. Both APTD mixtures yield decreases in plasma phenylalanine and tyrosine levels within the range of 50–70%, and decreases in their

ratio to LNAAs in the range of 80–90%. Unequivocal differences in the elicited behavioral effects have not been identified. Direct comparisons between the two mixtures, though, have not been conducted.

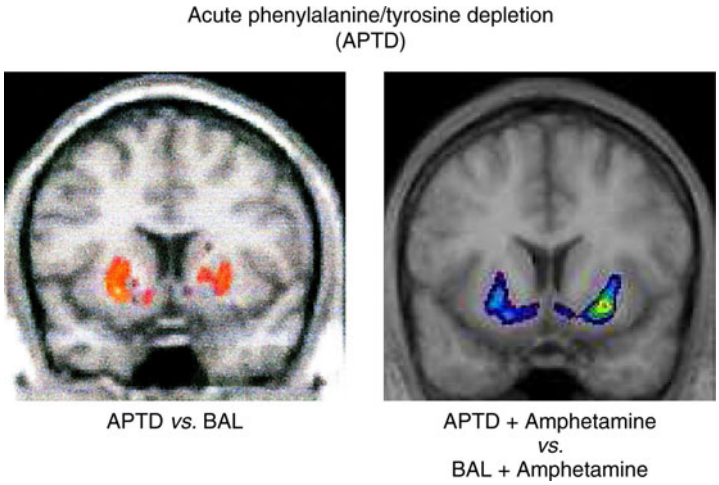
The McGill group has also developed a version of the APTD mixture for use in vervet monkeys. The formula is identical to that used in humans, though adjusted accordingly for the monkey's lower body weight. At least two versions for use in rodents have also been described, and they can be administered by gavage or intraperitoneal injection. Again, direct comparisons of their effects have not been reported but unequivocal differences are not evident in the literature.

Advantages and Disadvantages of APTD

Compared with the other methods for decreasing DA transmission, APTD has both advantages and disadvantages. On the plus side, the effects develop and dissipate rapidly, beginning as soon as 3 h after ingestion and disappearing three to four hours later. Transient nausea is sometimes reported, and 5–10% of subjects will regurgitate the mixture, but these sensations subside. Experience suggests that subjects who retain the mixtures for a minimum of 45–60 min achieve a decrease in plasma phenylalanine and tyrosine levels within the usual range. These mild adverse effects compare well to those associated with other methods for decreasing DA transmission. For example, administration of the competitive TH inhibitor, α-methyl-*para*-tyrosine (AMPT) typically requires 48–72 h inpatient observation, and can lead to motor dyskinesias and crystalluria. The former effect likely reflects large DA depletions within the nigrostriatal pathway, and this can be either an advantage or a confound depending on the outcome of interest. DA receptor antagonists can also be used. Positron emission tomography ► PET imaging studies suggest that receptor blockade up to 70% or 80% can be achieved without eliciting extrapyramidal side effects or hyper-prolactinemia, but available compounds either do not bind to all DA receptor subtypes or are nonspecific, binding also to multiple non-DA receptors.

Neurophysiological Effects of APTD

► Microdialysis studies conducted in rats suggest that APTD does not affect extracellular DA levels when animals are tested at rest, but potent effects are seen during



Phenylalanine and Tyrosine Depletion. Fig. 2. The figure depicts functional neuroimaging evidence that acute phenylalanine/tyrosine depletion (APTD) decreases extracellular dopamine levels in human striatum. At left, the colored t-map superimposed on the anatomical magnetic resonance image delineates regions where binding of the D2/D3 receptor ligand [^{11}C]raclopride was significantly higher following APTD versus ingestion of a nutritionally balanced control mixture (BAL), indicative of decreased extracellular dopamine levels (Montgomery et al. 2003). The image at right shows regions where [^{11}C]raclopride binding was higher on a test day with amphetamine plus APTD, as compared to amphetamine plus BAL, indicative of decreased drug-induced dopamine release (Leyton et al. 2004). Both effects occurred primarily within more ventral than dorsal regions of the striatum. The right side of each image represents the right side of the brain.

periods of increased DA cell firing (Jaskiw and Bongiovanni 2004) or release (McTavish et al. 1999b). These effects are dose-dependent, and APTD can diminish stimulated DA release by up to 70% (McTavish et al. 1999b). In humans, APTD increases circulating levels of prolactin, a neuroendocrine index of decreased DA transmission within the tuberoinfundibular pathway. In functional neuroimaging studies, APTD also decreases striatal DA release (Fig. 2), and this has been seen in the absence of an experimental challenge (Montgomery et al. 2003); however, whether this reflects a decrease in resting DA release or a diminished response to the mild stress of having an hour-long brain scan is difficult to disentangle. Irrespective, larger changes are reported to occur when participants are given a pharmacological challenge; that is, APTD decreases amphetamine-induced DA release, and the magnitude of this effect is twice of what is seen in subjects tested at "rest" (Leyton et al. 2004). One consequence of the APTD-induced decrease in DA transmission appears to be a disruption in the ability of different components of cortical–subcortical neurocircuits to work in coordination; that is, whereas cortical and basal ganglia structures exhibit high intercorrelations in activity levels when participants are engaging in a familiar neurocognitive task, these correlations are significantly reduced following APTD (Nagano-Saito et al. 2008). Based on these observations, it was proposed that normal DA tone is required to permit the efficient transfer of information throughout cortico-striatal circuitry.

Neurocognitive Effects of APTD

The APTD literature remains relatively small, but a number of behavioral effects have been reported. These include changes in the ability of subjects to preferentially respond to reward-related cues, to adjust responding appropriately when reward parameters change, and to sustain selective, focused interest in affectively relevant events. Some studies have also identified effects on spatial working memory, but an equal number of published studies yielded negative results; functional neuroimaging studies suggest that the variable results might reflect individual differences in the magnitude of DA depletion achieved.

Effects of APTD on Mood and Motivational States

APTD alone does not appear to lower mood in healthy individuals. In comparison, a now replicated finding is that APTD potentiates the mood-lowering effect of a psychological challenge. In people with mood disorders, a dissociation is seen also; tyrosine depletion reduces manic symptoms in bipolar patients but does not

reinstate depressive symptoms in recovered patients with a history of major depression.

Effects of APTD on Substance Use

A frequent application of the APTD method has been in addiction research. APTD is reported to decrease psychostimulant effects of amphetamines, the ability of ► cocaine and cocaine-paired cues to elicit ► craving, alcohol self-administration in a free-choice task when the participants are light social drinkers, and the tendency to sustain responding on a ► progressive ratio breakpoint task for successive units of an alcoholic beverage when the participants are heavy social drinkers. In comparison, in nicotine-dependent smokers the results have been quite variable.

Conclusions

Overall, the APTD method has proven to be an effective method to decrease DA transmission in human brain. Although, the effects might be smaller than those produced by other methods, the rapid, transient, and selective effects as well as more modest side effect profile are compelling for ethical reasons and simplify the interpretation of results.

Phenylketonuria

Synonyms

PKU

Definition

Phenylketonuria is a genetic disorder (autosomal recessive) in which the body lacks the enzyme required to break down the amino acid phenylalanine. Failure to break down phenylalanine leads to its, and related compounds, buildup, causing damage to the central nervous system. A strict diet begun at birth can help mitigate the negative consequences, namely mental retardation, hyperactivity, and motor control problems. Screening newborn infants for phenylketonuria is a standard medical practice.

Phenylpropanolamine

Synonyms

Norephedrine

Definition

Phenylpropanolamine is an amphetamine derivative that has been used as a stimulant, decongestant, and anorectic agent. Its psychomotor stimulant effects are much weaker than those of ► amphetamine in humans. It has been widely used in cough and cold preparations. It has been withdrawn from several countries because of the risk of

stroke. It has been subject to abuse in mixtures with other mild stimulants such as ► caffeine and ephedrine, with which it interacts to produce more powerful psychomotor activation.

Definition
Phenytoin is an antiepileptic drug that controls seizure activity in epilepsy patients in much the same way as drugs such as ► carbamazepine, namely, by controlling the over activity of nerve cells during an epileptic attack by acting at a protein called sodium channels. In addition to its antiepileptic effects, phenytoin like a number of other antiepileptic drugs has been used clinically to treat various ► mood disorders, although it is not registered for these uses.

Pheromones

Definition
Pheromones are chemicals transported outside of the body to send messages to individuals of the same species. There are many different pheromones, for example, alarm, food trail, or sex pheromones, that affect both behavior and physiology. Pheromones are detected by the olfactory epithelium and also in most mammals (but not humans) by the vomeronasal organ, a patch of G-protein-coupled receptor tissue in the nasal cavity.

Phosphodiesterase Inhibitors

PDE inhibitors

Definition
There are 11 families of ► phosphodiesterases (PDEs; PDE1–PDE11), which degrade the second messengers cAMP and/or cGMP. The activity of PDEs can be selectively inhibited with drugs. The most widely known PDE inhibitor is sildenafil, which is one of the three ► PDE5 inhibitors approved for the treatment of ► erectile dysfunction and more recently arterial ► pulmonary hypertension. In addition, two ► PDE3 inhibitors are approved for treating ► congestive heart failure or ► intermittent claudication, respectively. At the moment, PDE inhibitors are explored as possible therapeutic CNS targets for pain (PDE4, PDE5), memory loss (PDE2, PDE4, PDE5, PDE9), Alzheimer's disease (PDE4, PDE5), depression (PDE4), ► schizophrenia (PDE10), or stroke (PDE3, PDE5).

Pharmacological Properties

History
In 1886 the activity of PDEs was actually first described as it was noted that ► caffeine had bronchodilator properties. Later on, this effect was attributed to cyclic nucleotide cAMP and that caffeine-inhibited cAMP-specific PDEs. In 1970 PDEs were identified in rat and bovine tissue and it was demonstrated that PDEs hydrolyze the phosphodiesteric bond of cAMP and cGMP (Bender and Beavo 2006). From then on more PDEs were identified

and characterized. Until now 21 classes of genes for PDEs in humans, rats, and mice have been identified.

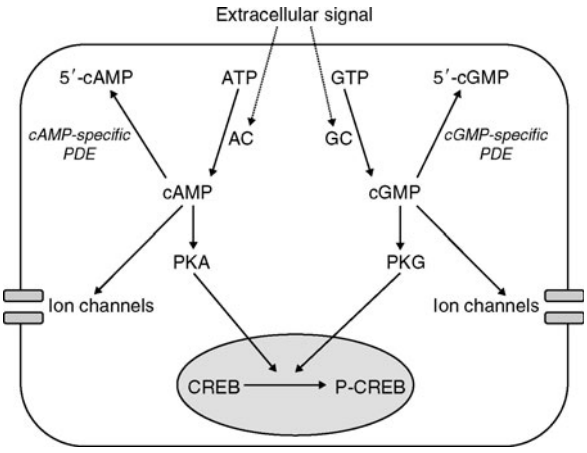
PDEs have been classified into 11 families (PDE1–PDE11) based on several criteria such as subcellular distributions, mechanisms of regulation, and enzymatic and kinetic properties. Most of these families have more than one gene product (e.g., PDE4A, PDE4B, PDE4C, PDE4D). In addition, each gene product may have multiple splice variants (e.g., PDE4D1–PDE4D9). In total, there are more than 100 specific PDEs (Bender and Beavo 2006).

Caffeine is a nonselective PDE inhibitor and it also inhibits cGMP-specific PDEs such as PDE5. cGMP causes vasodilatation in blood vessels by regulating their smooth muscle physiology. In addition, PDE5 also has an action on smooth muscles of contractile organs such as the penis. The most widely known PDE5 inhibitor is ▶ sildenafil. It was initially developed for the treatment of arterial hypertension and angina pectoris (Puzzo et al. 2008). In 1998 sildenafil was approved by the US Food and Drug Administration (FDA) for the treatment of erectile dysfunction and marketed under the name Viagra. Under the name of Revatio it was also approved for the therapy of pulmonary artery hypertension in 2005.

The discovery of sildenafil started the research and development of numerous inhibitors of PDE5. At the same time, it stimulated researchers to explore other classes of PDEs for their therapeutic potential in different disorders. In addition, the previously explored PDEs, such as PDE4 were reevaluated after first being dismissed as a fruitful target due to side effects and a lack of specificity or efficacy of the developed PDE inhibitors (Esposito et al. 2009). For instance, in 1984 the PDE4 inhibitor ▶ rolipram was developed as a putative antidepressant, but it never made it to the market due to severe emetic side effects (e.g., nausea, vomiting).

Mechanisms of Action

PDEs hydrolyze the second messengers cAMP and/or cGMP, which are synthesized by adenylate and guanylate cyclase, respectively. However, the intracellular concentrations of both cyclic nucleotides are especially regulated by the PDE activity as its hydrolysis capacity far exceeds the capacity for synthesis. Besides this absolute and temporal regulation of cyclic nucleotides, PDEs contribute to their compartmentalized signaling as different PDEs are localized at some specific sites in the cell such as the plasma or nuclear membrane, or cytosol. Thus, PDEs play a key role in the intracellular, signal transduction pathways in various biological systems as is illustrated in Fig. 1. cAMP and cGMP transfer an extracellular signal (e.g., neurotransmitter or hormone) to their effector proteins, protein kinase A and protein kinase G, respectively. Both kinases phosphorylate other enzymes or transcription factors, thus influencing the signal transduction. In addition, both cyclic nucleotides regulate their corresponding cyclic nucleotide-gated ion channels, which depolarizes synaptic terminals and thus influences signaling pathways. For instance, cGMP regulates cGMP-gated ion channels and thus directly regulates the ion flux, which depolarizes the presynaptic terminal and influences glutamate release. Eventually, changes in signal transduction are translated into a biological system-dependent physiological and cellular response (Halene and Siegel 2007; Menniti et al. 2006; Puzzo et al. 2008; Reneerkens et al. 2009).



Phosphodiesterase Inhibitors. Fig. 1. Intracellular, signal transduction pathways. An extracellular signal (e.g., neurotransmitter or hormone) activates adenylate cyclase (AC) and guanylate cyclase (GC), which produce their corresponding cyclic nucleotides out of ATP and GTP, respectively. cAMP activates protein kinase A (PKA) and cGMP activates protein kinase G (PKG). Both PKA and PKG can phosphorylate other enzymes or transcription factors such as CREB in the nucleus. Besides gene expression, cAMP and cGMP also regulate cAMP- and cGMP-gated ion channels, respectively, which depolarizes the synaptic terminals. Eventually, these processes will result in a cellular response. Phosphodiesterases (PDEs) hydrolyse cAMP and/or cGMP leading to the formation of the inactive 5′-cAMP and 5′-cGMP, respectively. PDE inhibitors are selective for cAMP and/or cGMP degrading PDEs. In this way, a selective PDE inhibitor can specifically influence the cellular response of a biological system. (Adapted from Puzzo et al. 2008.)

PDEs itself are regulated by intracellular cyclic nucleotide concentrations, phosphorylation (e.g., protein kinase G), interaction with regulatory proteins, subcellular compartmentalization, and binding of Ca^{2+}/calmodulin (Cheng and Grande 2007).

The specific localization of the different PDEs in the brain and the body will predict which certain physiological function may be influenced by some PDE inhibitors, but not by others. Table 1 gives an overview of the distribution of the different PDEs. Obviously, the PDE5-inhibitor sildenafil can be used for the treatment of erectile dysfunction since PDE5 is expressed in human cavernosal smooth muscle. Since PDE10A is highly expressed in the striatum where it regulates signal transduction in the corticostriatothalamic circuit, it is, therefore, an interesting target for schizophrenia and related disorders of basal ganglia function. In contrast, PDE4 is highly expressed in the ► hippocampus, which is a key structure in the limbic system, and is, therefore, considered as a useful target for treatment of mood disorders or cognitive deficits.

Pharmacokinetics

Only the ► pharmacokinetics of compounds that have been approved by the FDA and are also being evaluated for CNS applications are described.

The PDE3-inhibitor cilostazol is given orally and has a half-life of about 11–13 h. Cilostazol is metabolized and eliminated by CYP3A4 and CYP2C19, two isoenzymes of the cytochrome P450 system in the liver, after which it is predominantly excreted via the kidneys (Chapman and Goa 2003).

Sildenafil, vardenafil, and tadalafil are rapidly absorbed in the gastrointestinal tract at the level of the small intestine. The ► half-life of sildenafil and vardenafil is about 3–4 h. In contrast, tadalafil has a long half-life of about 18 h. All three compounds are metabolized and eliminated in the liver by CYP3A4. For sildenafil CYP2C9 is also partly involved. All three metabolized PDE5 inhibitors are excreted predominantly via the liver into the feces but also via the kidneys into the urine (Puzzo et al. 2008).

If a compound can be used to target central nervous system-related disorders it is vital that it crosses the

► blood–brain barrier. Especially when the compound itself is required centrally to be effective, as otherwise alternatives have to be developed such as a central administration application for the drug. Sildenafil has been demonstrated in preclinical animal studies to penetrate the brain. For vardenafil this still needs to be established. Tadalafil has been shown preclinically to not cross the blood–brain barrier; while in contrast to sildenafil, it did not attenuate the memory performance deficit in a mouse model of ► Alzheimer's disease (Puzzo et al. 2009).

Efficacy

Table 2 summarizes the PDE inhibitors currently on the market or in development. For CNS applications also preclinical evidence is mentioned. More detailed information about the status of clinical development of a particular compound can be found at http://clinicaltrials.gov/. To check whether a drug is approved by the FDA, see http://www.accessdata.fda.gov/scripts/cder/drugsatfda/.

The PDE1-inhibitor vinpocetine (Cavinton, Intelectol) is not approved by FDA as a drug, but it is widely used as a supplement for vasodilation and as a nootropic for the improvement of memory. The latter effect is likely to be related to vasodilatation. However, the relevance of the possible therapeutic effect of vinpocetine can be questioned as it has not been shown to be of real benefit in the clinic.

Currently, the most selective PDE2 inhibitor available is BAY 60-7550 and it has been shown to improve memory in rodents (Boess et al. 2004). Exisulind (Aptosyn) is another developed PDE2 inhibitor, which also has the PDE5-inhibiting activity. This drug induces apoptosis in a broad range of cancer cell lines and inhibits the formation and growth of cancer in several animal models. Presently, this compound has been tested in clinical Phase-III trials for breast, lung, prostate, and colon tumors.

Cilostazol (Pletal) is a PDE3 inhibitor and has been approved by the FDA for the treatment of intermittent claudication. It is also being investigated in a Phase-IV study as a prevention of stroke recurrence and safety for bleeding complications in acute stroke. Enoximone (Perfan) and milrinone (Primacor) are also PDE3 inhibitors, which have been developed for the treatment of congestive heart failure. While Milrinone has been approved by the FDA for this indication, enoximone is in the Phase III of development. Their mode of action is via cAMP/PKA-mediated facilitation of intracellular Ca^{2+} mobilization. In addition, vasodilatory action plays a key role in improving hemodynamic parameters in certain patients.

► PDE4 inhibitors were initially considered as a possible target for the development of drugs for the treatment of depressive disorders (Esposito et al. 2009). In this respect the PDE4-inhibitor ► rolipram has been widely investigated. First clinical studies showed a good antidepressant response to rolipram treatment. However, rolipram produces severe dose-limiting emetic side effects including headache, gastric hypersecretion, nausea, and vomiting in humans. This has put a serious hold on the further development of rolipram and other related PDE inhibitors. It also prevented rolipram from reaching the market. But since the approval of PDE5 inhibitors for the treatment of erectile dysfunction, PDE inhibitors in general have received renewed interest as a possible therapeutic target for the treatment of diseases. Along similar lines, a clinical ► Phase-II trial has recently started to reevaluate the antidepressant properties of rolipram.

At the moment, "second generation" PDE4 inhibitors are being developed, which are supposed to have less-emetic side effects, and are being studied for other disorders besides that of depression. Recently, a clinical Phase-II trial has been completed investigating whether the PDE4-inhibitor MK0952 improves cognition in patients with mild-to-moderate Alzheimer's disease. Furthermore, the PDE4 inhibitors cilomilast (Ariflo) and rofluminast have been clinically tested up to ► Phase III as anti-inflammatory drugs for the treatment of asthma and chronic obstructive pulmonary disease (COPD). However, they have not been approved by the FDA yet. Ibudilast (or AV-411) is another PDE4 inhibitor in development as an anti-inflammatory drug. However, this compound not only inhibits PDE4 but also serves as a glial activator, and other clinical CNS applications are being explored in Phase-II studies, i.e., pain and drug abuse.

The PDE5-inhibitor sildenafil was the first FDA-approved treatment of erectile dysfunction. Although PDE5 inhibition causes relaxation of smooth muscles in blood vessels, it is also of particular importance for the treatment of erectile dysfunction in that it causes relaxation of smooth muscles in organs such as the penis (Puzzo et al. 2008). In women, sildenafil has an effect on the contractile state of the uterus and blood flow in the clitoris. Therefore, sildenafil is also considered as a possible treatment for female sexual arousal disorder (FSAD) (completed Phase-II trial). Sidenafil is on the market as Viagra. Two more PDE5 inhibitors also reached the market for the treatment of erectile dysfunction as well, vardenafil (Levitra) and tadalafil (Cialis), respectively. Vardenafil is the more-potent PDE5 inhibitor when compared with sildenafil and tadalafil. The latter is considered

as second-generation oral drug and it has the longest half-life while its effects last the longest as well.

Because of its vasodilatatory properties, sildenafil is also FDA approved under the name of Revatio for the treatment of hypertension of the pulmonary artery. For the same application, a clinical Phase-III trial with tadalafil has just been completed, while a Phase-II trial of vardenafil is ongoing.

Sildenafil has been successfully used to treat serotonin reuptake inhibitor (► SSRI)-associated erectile dysfunction. In women, recently a Phase-IV study has been completed which assessed the efficacy of sildenafil in women with SSRI-associated sexual dysfunction. In addition, a Phase-IV study has just been completed that measured the impact of treatment with sildenafil on the depressive symptoms and quality of life in male patients with erectile

dysfunction who have untreated depressive symptoms. However, it will be difficult to disentangle whether a possible beneficial effect on mood is due to the treatment of the sexual dysfunction or whether PDE5 inhibition directly leads to an improvement in depressive symptoms and thus, an attenuation of the erectile/sexual dysfunction. Of note, no direct antidepressant potential of sildenafil has been found in preclinical rodent studies (Brink et al. 2008).

At the moment, a Phase-I study is evaluating whether sildenafil has ► neuroprotective properties in the treatment for stroke. Another interesting CNS application could be neuropathic pain as sildenafil was effective in the treatment of pain in animal models (Ambriz-Tututi et al. 2005).

There is substantial evidence that PDE5 inhibition has cognition-enhancing effects in several animal species including rodents and monkeys (Reneerkens et al. 2009). However, until now convincing evidence in humans is still lacking. Three studies have explored the effects of sildenafil on human cognition. However, in two studies with healthy human volunteers no effect or only an indirect enhancing, i.e., electrophysiological, effect on cognition was found. It is to be noted that in both studies the number of participants could have been too low to detect any subtle effect. Hemodynamic studies in humans indicate that possible effects on cognition after sildenafil administration are not likely to be related to cerebrovascular mechanisms. Preclinical animal studies indicate that an improved second-messenger signaling in synaptic transmission between neurons might be a more plausible mechanism. A third study tested the cognition in patients with schizophrenia, who received sildenafil added to antipsychotic treatments (Goff et al. 2009). However, sildenafil was not effective. Probably, its dose was not high enough to overcome the antipsychotic medication. A very important recent finding is that the expression of PDE5 is strongly reduced in brains of Alzheimer's disease patients (Reyes-Irisarri et al. 2007). Along similar lines, PDE5 inhibition did not improve memory in aged rats. Thus, when developing a PDE inhibitor for the treatment of cognitive decline in ► dementias including Alzheimer's disease, other PDEs might provide better targets than PDE5.

PDE9 does not show an Alzheimer-related reduction in expression patterns (just like PDE2). The only available PDE9 inhibitor is BAY 73-6691 and, interestingly, it improved memory performance in rodents (Van der Staay et al. 2008). This suggests that it might have therapeutic potential for the treatment of memory dysfunction.

Until very recently, the PDE10A-inhibitor PF-2545920 (or MP-10) was in a Phase-II clinical study for the treatment of schizophrenia. However, this study has just been terminated for a reason unknown. The action mechanism of PDE10A inhibition was attributed to be modulation/normalization of dopaminergic cortico-striatothalamic function. In this respect, increased cAMP levels are assumed to be of more importance than cGMP, although PDE10A itself predominantly hydrolyses cGMP.

Safety/Tolerability

Only safety and tolerability of compounds which have been approved by the FDA and are also being evaluated for CNS applications are discussed.

Possible side effects of the PDE3-inhibitor cilostazol include, most commonly, not only headache, but also diarrhea, abnormal stools, irregular heart rate, and palpitations. Since cilostazol is a quinolinone derivative, it is therefore dangerous for people with severe heart problems and hence, can only be given to people without this indication.

Sildenafil, vardenafil, as well as tadalafil have side affects such as headaches, facial flushing, nasal congestion, and dyspepsia (indigestion). However, these effects are transient. All three PDE inhibitors can act on PDE6, which is present in the retina; and high doses have been reported to cause adverse visual events, including nonarteritic anterior ischemic optic neuropathy; and thus, can cause vision problems (e.g., blurred vision). Moreover, tadalafil also potently inhibits PDE11, an enzyme with an unknown physiological function. Because of the possible vasodilatatory effects, these compounds are not suited for patients with cardiovascular indications or hypotensives.

An approach to circumvent the side effects of PDE inhibitors is to develop very selective inhibitors at the level of the isoform or splice variant. At the same time, the function of interest may be more specifically targeted. For example, there are three splice variants of PDE5, PDE5A1–PDE5A3 (Puzzo et al. 2008). While the first two are found nearly in all tissues, the third one is specific to smooth muscles.

The emetic side effects of the available PDE4 inhibitors, which inhibit more or less all four isoforms – PDE4A, PDE4B, PDE4C, and PDE4D, prevented until now that they have reached the market (Esposito et al. 2009). Preclinical animal research already indicated that the antidepressant potential of PDE4A in the hippocampus was related to specific splice variants of PDE4A. Moreover, in a patient with Alzheimer's disease it was found that the expression of most splice variants of PDE4D were decreased in the hippocampus, whereas two variants were increased. These findings underscore the need to develop specific inhibitors of PDE4-splice variants as cognition enhancers or antidepressants (Reneerkens et al. 2009).

Conclusions

Besides the already approved clinical application of erectile dysfunction, pulmonary hypertension, congestive heart failure, and intermittent claudication, PDE inhibitors offer a promising target for a wide array of diseases including CNS-related disorders such as Alzheimer's disease, depression, schizophrenia, or stroke. Yet, the future in disease-specific PDE inhibitors lies in the development of splice variant-specific inhibitors that have limited aversive side-effect profiles within the effective dose range for its clinical application. Whether this will be achieved remains a challenge thus far.

Phosphodiesterases

Definition

Phosphodiesterases are enzymes that hydrolyze the second messenger cyclic nucleotides cAMP and/or cGMP. Thus, phosphodiesterases influence intracellular signal transduction pathways in various biological systems. There are 11 families of phosphodiesterases, PDE1–PDE11. This classification is based on their subcellular localizations, mechanisms of regulation, and enzymatic properties. Each family consists of multiple splice variants. In total, there are more than 100 specific PDEs. They are specifically distributed over the body and the brain.

Physical Dependence

Synonyms

Abstinence syndrome; Physiological dependence; Withdrawal syndrome

Definition

Physical dependence results when certain drugs are administered or self-administered regularly for extended periods of time and is revealed when drug administration is discontinued and a typical withdrawal syndrome appears. The time to onset for the withdrawal effects depends upon how rapidly the drug is eliminated from the body. For example, in ▶ alcohol physical dependence, the withdrawal signs and symptoms emerge within 12–24 h of discontinued use whereas for ▶ benzodiazepine physical dependence, the withdrawal syndrome may not emerge for several days corresponding to the slow elimination of active metabolites from the body. The extent or magnitude of the withdrawal signs and symptoms is related to the amount and duration of drug exposure preceding withdrawal. Each class of drugs has a typical withdrawal syndrome. Laboratory studies of physical dependence often employ antagonist drugs, which will precipitate a withdrawal syndrome. For example, ▶ naloxone or ▶ naltrexone will produce precipitated withdrawal in a person or animal made opioid-dependent, producing a constellation of signs and symptoms similar to those seen after spontaneous withdrawal. It should be noted that despite the name "physical dependence," signs and symptoms of withdrawal syndromes are often psychological and behavioral in nature, for example, an increase in anxiety in humans or impaired performance of a previously learned task in animals. Withdrawal syndromes are self-limiting in duration, subsiding after a period of time that depends upon the drug class and severity of dependence, among other factors.

Place Cells

Place fields

Definition

Place cells are neurons that exhibit a high rate of firing whenever an animal is in a specific location in an environment corresponding to the cell's "place field." Place cells were first identified in the ▶ hippocampus of rats by O'Keefe and Dostrovsky, although cells with similar properties have been found in the hippocampus of primates and humans. Furthermore, neurons that display place-selective changes in activity have been identified in a number of other brain regions, including regions of the temporal cortex, the ▶ amygdala, and the striatum. Based on this discovery, it has been proposed that a primary function of the rat hippocampus is to form a cognitive map of the rat's environment. On initial exposure to a new environment, place fields become established within minutes. The place fields of cells tend to be stable over repeated exposures to the same environment. In a different environment, however, a cell may have a completely different place field or no place field at all, a phenomenon referred to as "remapping."

Placebo response

Definition

The placebo effect is the reduction of a symptom, or a change in a physiological parameter, when an inert treatment (the placebo) is administered to a subject who is told that it is an active therapy with specific properties. The placebo effect, so far considered a nuisance in clinical research, has now become a target of scientific investigation to better understand the physiological and neurobiological mechanisms that link a complex mental activity to different functions of the body. Usually, in clinical research the term placebo effect refers to any improvement in the condition of a group of subjects that has received a placebo treatment, thus it represents a group effect. The term placebo response refers to the change in an individual caused by a placebo manipulation. However, these two terms are often used interchangeably. It is important to realize that there is not a single placebo effect but many, which occur through different mechanisms in different conditions, systems, and diseases.

Current Concepts and State of Knowledge

Methodological Aspects

The identification of a placebo effect is not easy from a methodological point of view and its study is full of drawbacks and pitfalls. In fact, the positive effects following the administration of a placebo can be due to many factors, such as spontaneous remission, regression to the mean, symptom detection ambiguity and biases (Benedetti 2008a). All these phenomena must be ruled out through adequate control groups. For example, spontaneous remission can be discarded by means of a no-treatment group, which gives us information about the natural course of a symptom. Regression to the mean, a statistical phenomenon due to selection biases at the enrolment in a clinical trial, can be controlled by using appropriate selection criteria. Symptom detection ambiguity and biases can be avoided by using objective physiological measurements. It is also important to rule out the possible effects of co-interventions. For example, the mechanical insertion of a needle for the injection of an inert substance may per se induce analgesia, thus leading to erroneous interpretations.

When all these phenomena are ruled out and the correct methodological approach is used, substantial placebo effects can be detected, which are mediated by psychophysiological mechanisms worthy of scientific inquiry. Therefore, this psychological component represents the real placebo effect.

Mechanisms

The placebo effect is basically a context effect, whereby the psychosocial context (e.g., the therapist's words, the sight of medical personnel and apparatuses, and other sensory inputs) around the medical intervention and the patient plays a crucial role. Today, we know that the context may produce a therapeutic effect through at least two mechanisms: conscious anticipatory processes and unconscious conditioning mechanisms (Benedetti 2008b; Enck et al. 2008; Price et al. 2008). In the first case, the expectation and anticipation of clinical benefit may affect the response to a therapy. In the second case, contextual cues (e.g., color and shape of a pill) may act as ► conditioned stimuli that, after repeated associations with an ► unconditioned stimulus (the pharmacological agent inside the pill), are capable alone of inducing a clinical improvement. In the case of ► pain and ► Parkinson's disease, it has been shown that conscious ► expectancies play a crucial role, even though a conditioning procedure is performed, whereas placebo responses in the immune and endocrine systems are mediated by unconscious ► classical conditioning.

The neural mechanisms underlying the placebo effect are only partially understood and most of our knowledge comes from the field of pain and analgesia, although Parkinson's disease, immune and endocrine responses, and ► depression have more recently emerged as interesting models. In each of these conditions, different mechanisms seem to take place, so that we cannot talk of a single placebo effect but many (Benedetti 2008a).

As far as pain is concerned, there is now compelling experimental evidence that the ► endogenous opioid systems play an important role in some circumstances. There are several lines of evidence indicating that placebo analgesia is mediated by a descending pain modulating circuit, which uses endogenous opioids as neuromodulators. This evidence comes from a combination of imaging and pharmacological studies. By using positron emission tomography (► PET imaging), it was found that some cortical and subcortical regions are affected by both a placebo and the opioid agonist remifentanil, thus indicating a related mechanism in placebo-induced and opioid-induced analgesia (Petrovic et al. 2002). In particular, the administration of a placebo affects the rostral anterior cingulate cortex (rACC), the orbitofrontal cortex (OrbC) and the brainstem. Moreover, there is a significant covariation in activity between the rACC and the lower pons/medulla at the level of the rostral ventromedial medulla (RVM), and a subsignificant covariation between the rACC and the periacqueductal gray (PAG), thus suggesting that the descending rACC/PAG/RVM pain-modulating circuit is involved in placebo analgesia. In a different study with functional ► magnetic resonance imaging (fMRI), it was shown that placebo administration produces a decrease of activity in many regions involved in pain transmission, such as the thalamus and the insula (Wager et al. 2004; Price et al. 2008).

A clearcut involvement of endogenous opioids is shown by several pharmacological studies in which placebo analgesia is antagonized by the opioid antagonist naloxone. In addition, it has been shown that the endogenous opioid systems have a somatotopic organization, since local placebo analgesic responses in different parts of the body can be blocked selectively by ► naloxone (Benedetti 2008a). By using in vivo receptor binding techniques, placebos have been found to induce the activation of *mu* opioid receptors in different brain areas, such as the dorsolateral ► prefrontal cortex, ► nucleus accumbens, insula and rACC. It is also worth noting that opioids are activated together with dopamine, e.g., in the nucleus accumbens, thus indicating a complex interaction between different neurotransmitters (Scott et al. 2008).

The placebo-activated endogenous opioids do not act only on pain transmission, but on the respiratory centers as well, since a naloxone-reversible placebo respiratory depressant effect has been described. Likewise, a reduction of beta-adrenergic sympathetic system activity, which is blocked by naloxone, has been found during placebo analgesia. These findings indicate that the placebo-activated opioid systems have a broad range of action, influencing pain, respiration, and the autonomic nervous system (Colloca and Benedetti 2005). The placebo-activated endogenous opioids have also been shown to interact with endogenous substances that are involved in pain transmission. In fact, on the basis of the anti-opioid action of ► cholecystokinin (CCK), CCK-antagonists have been shown to enhance placebo analgesia, thus suggesting that the placebo-activated opioid systems are counteracted by CCK during a placebo procedure (Colloca and Benedetti 2005).

It is important to point out that some types of placebo analgesia appear to be insensitive to naloxone. For example, if a placebo is given after repeated administrations (pre-conditioning) of the non-opioid painkiller ketorolac, the placebo analgesic response is not blocked by naloxone.

The release of endogenous substances following a placebo procedure is a phenomenon that is not confined to the field of pain, but it is also present in other conditions, such as Parkinson's disease. As occurs with pain, in this case patients are given an inert substance and are told that it is an ► anti-Parkinson drugs that produces an improvement in their motor performance. A study used PET imaging in order to assess the competition between endogenous dopamine and ^{11}C-raclopride for D_2/D_3 receptors, a method that allows the identification of endogenous dopamine release (de la Fuente-Fernandez et al. 2001). This study found that the placebo-induced expectation of motor improvement activates endogenous dopamine in both the dorsal and ventral striatum, a region involved in reward mechanisms, which suggests that the placebo effect may be conceptualized as a form of reward.

Placebo administration in Parkinson patients also affects the activity of neurons in the subthalamic nucleus, a brain region belonging to the basal ganglia circuitry and whose activity is increased in Parkinson's disease (Benedetti 2008a). Verbal suggestions of motor improvement during a placebo procedure are capable of reducing the firing rate and abolishing the bursting activity of subthalamic nucleus neurons, and these effects are related to clinical improvement.

Depressed patients who receive a placebo treatment were shown to present metabolic changes in the regions

involved in reward mechanisms, such as the ventral striatum. In addition, in patients with unipolar depression, placebo treatments were also found to be associated with metabolic increases in the prefrontal, anterior cingulate, premotor, parietal, posterior insula, and posterior cingulate cortex, and metabolic decreases in the subgenual cingulate cortex, para-hippocampus, and thalamus. Interestingly, these regions are also affected by ► antidepressants, such as the selective serotonin reuptake inhibitor, ► fluoxetine, a result that suggests a possible role for serotonin in placebo-induced antidepressant effects (Benedetti 2008b).

Anxiety has also been found to be affected by placebos, with the involvement of those brain regions that also take part in placebo analgesia, e.g., the rACC and OrbC. In addition, placebo responsiveness in social anxiety has been found to be linked with genetic variants of serotonin neurotransmission, which suggests that part of the variability in placebo responsiveness may be attributable, at least in some conditions, to genetic factors (Benedetti 2008a).

Placebo responses in both the immune and endocrine systems can be evoked through classical conditioning. After repeated administrations of drugs, if the drug is replaced with a placebo, immune or hormonal responses can be evoked that are similar to those obtained by the previously administered drug, thus resembling the typical ► conditioned drug effects (Benedetti 2008b). For example, immunosuppressive placebo responses can be induced in humans by repeated administration of cyclosporine A (unconditioned stimulus) associated to a flavored drink (conditioned stimulus), as assessed by interleukin-2 (IL-2) and interferon-γ (IFNγ) mRNA expression, in vitro release of IL-2 and IFNγ, and lymphocyte proliferation. Likewise, if a placebo is given after repeated administrations of sumatriptan, a serotonin agonist of the $5\text{-HT}_{1B/1D}$ receptors that stimulates growth hormone (GH) and inhibits cortisol secretion, a placebo GH increase and a placebo cortisol decrease can be found.

The Nocebo Effect

The nocebo effect, or response, is a placebo effect in the opposite direction. Mainly due to ethical constraints, the nocebo effect has not been investigated in detail, as has been done for the placebo effect. In fact, a nocebo procedure is per se stressful and ► anxiogenic, as it induces negative expectations of clinical worsening. For example, the administration of an inert substance along with verbal suggestions of pain increase may induce a hyperalgesic effect. In this case, anticipatory anxiety plays a fundamental role. Nocebo hyperalgesia has been found to be blocked by proglumide, a nonspecific CCK-A/CCK-B receptor antagonist. This suggests that expectation-induced hyperalgesia is mediated, at least in part, by CCK (Enck et al. 2008). These effects of proglumide are not antagonized by naloxone, thus endogenous opioids are not involved.

Dopamine also plays a role in the nocebo hyperalgesic effect. In fact, whereas placebo administration induces the activation of dopamine in the nucleus accumbens, the administration of a nocebo is associated with a deactivation of dopamine (Scott et al. 2008).

Implications

According to the classical methodology of ► randomized controlled trials, any drug must be compared with a placebo in order to assess its effectiveness. If the patients who take the drug show a considerable clinical improvement than the patients who take the placebo, the drug is considered to be effective. However, in light of the recent advances in placebo research, some caution is necessary in the interpretation of some clinical trials. In fact, by considering the complex cascade of biochemical events that take place after placebo administration, any drug that is tested in a clinical trial may interfere with these placebo/expectation-activated mechanisms, thus confounding the interpretation of the outcomes (Colloca and Benedetti 2005). As we have no a priori knowledge of which substances act on placebo-activated endogenous opioids, or dopamine, or serotonin – and indeed almost all drugs, e.g., ► analgesics and ► opioids, might interfere with these neurotransmitters – one way to eliminate this possible pharmacological interference is to make the placebo-activated biochemical pathways, so to speak, "silent." This can be achieved by the hidden administration of drugs (Colloca et al. 2004).

In fact, it is possible to eliminate the placebo (psychological) component and analyze the pharmacodynamic effects of a treatment, free of any psychological contamination, by administering drugs covertly. In this way, the biochemical events that are triggered by a placebo procedure can be eliminated. To do this, drugs are administered through hidden infusions by machines, so that the patient is not made aware that a medical therapy is being carried out. A hidden drug infusion can be performed through a computer-controlled infusion pump that is preprogrammed to deliver the drug at the desired time. It is crucial that the patient does not know that any drug is being injected, so that he or she does not expect anything. The computer-controlled infusion pump can deliver a drug automatically, without a doctor or nurse in the room, and without the patient being aware that a treatment has been started. Ethical issues need to be considered.

The analysis of different treatments, either pharmacological or not, in different conditions has shown that an

open (expected) therapy, that is carried out in full view of the patient, is more effective than a hidden one (unexpected). Whereas the hidden injection represents the real pharmacodynamic effect of the drug, free of any psychological contamination, the open injection represents the sum of the pharmacodynamic effect and the psychological component of the treatment. The latter can be considered to represent the placebo component of the therapy, even though it cannot be called placebo effect, as no placebo has been given. Therefore, by using hidden administration of drugs, it is possible to study the placebo effect without the administration of any placebo.

The influence of psychological factors on drug action is also shown by the balanced-placebo design (Benedetti 2008a). In this design, four groups of patients (1) receive the drug and are told it is a drug, (2) get the drug and are told it is a placebo, (3) get a placebo and are told it is a placebo, and (4) get a placebo and are told it is a drug. This design is particularly interesting because it indicates that verbally induced expectations can modulate the therapeutic outcome, both in the placebo group and in the active treatment group. It has been used in many conditions, such as alcohol research, smoking, and amphetamine effects (Benedetti 2008a).

Platelet Activation

Definition

Platelet activation represents a central moment in the process that leads to thrombus formation. When endothelial damage occurs, platelets come into contact with exposed collagen and von Willebrand factor, becoming

activated. They are also activated by thrombin or by a negatively charged surface, such as glass. Platelet activation further results in the scramblase-mediated transport of negatively charged phospholipids to the platelet surface, providing a catalytic surface for the tenase and prothrombinase complexes. Activated platelets change in shape and pseudopods form on their surface, determining a star-like appearance.

Platelet Storage Granules

Definition

Platelets contain numerous storage granules. Activated platelets excrete the contents of these granules into their canalicular systems and, then, into surrounding blood. There are two types of granules: dense granules (containing ADP or ATP, calcium, serotonin, and other monoamines) and alpha-granules (containing platelet factor 4, PDGF, fibronectin, B-thromboglobulin, vWF, fibrinogen, and coagulation factors V and XIII).

Thrombocytes

Definition

Platelets are small cytoplasmic bodies derived from ▶ megakaryocytes. They circulate in the blood and are mainly involved in ▶ hemostasis. Platelets have no nucleus and display a lifespan of 7–10 days. When damage to the endothelium of blood vessels occurs, platelets go through ▶ activation, change shape, release granule contents and, finally, aggregate and adhere to the endothelial surface in order to form the blood clot.

Besides their chief role in the process of hemostasis, platelets express several signaling molecules, including various ▶ neurotransmitters. Therefore, considering the accessibility of platelets by a simple blood withdrawal, it is not surprising that several researchers tried to take advantage of this opportunity to get a glimpse on a variety of molecules involved in neural transmission.

Current Concepts and State of Knowledge

Platelets as Peripheral Markers of Neurotransmitter Dysfunction

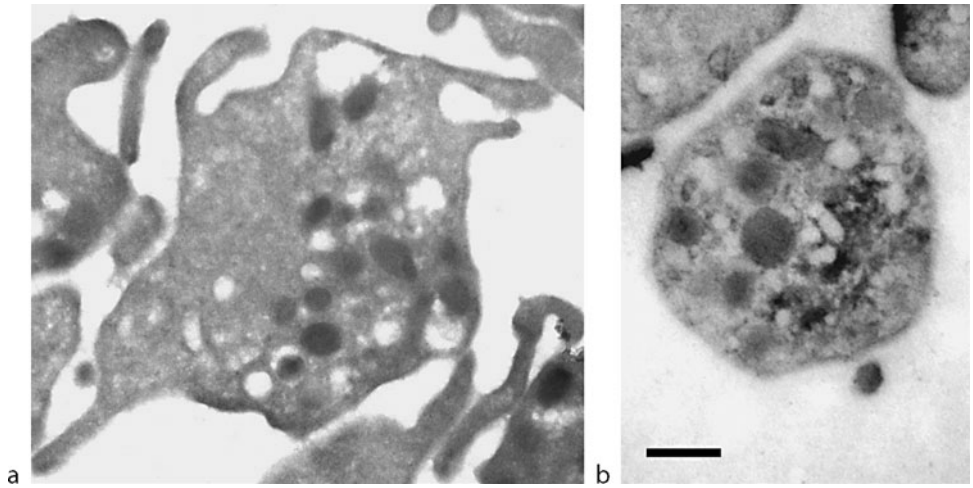
Human platelets have been repeatedly considered as potentially useful tools for modeling neurochemical dysfunctions in neurological and psychiatric patients. In fact, although the main function of the platelet is related to hemostasis, they are implicated with various signaling molecules that operate into the CNS as well. More specifically, platelets store, release, and ▶ uptake several neurotransmitters, such as serotonin, dopamine, glutamate, and GABA, frequently expressing cognate functional receptor molecules.

Considering that most of the neuropsychiatric disorders do not allow to study in details the involved pathomechanisms directly into the nervous system, platelets offer the advantage of being readily accessible upon a simple blood withdrawal. Hence, in this chapter we will consider them as ▶ peripheral markers of neurotransmitter dysfunction in neuropsychiatry.

However, as a final caveat we should remember that technical factors and reproducibility obviously play an extremely important role and influence the characterization of any suitable peripheral neurochemical marker. Platelets unfortunately display quite a strong tendency to activation, changing shape, and releasing granule contents, if careful procedures are not used when performing blood sampling and platelet separation. As an example, a generous needle gage and avoiding the tourniquet use might be critical issues for circumventing these phenomena, especially when measuring granule contents or performing electron microscopy procedures (see Fig. 1A, with respect to a less activated platelet shown in B).

Serotonin Uptake and Release

Human platelets are capable of producing very little amounts of ▶ serotonin (5-hydoxytryptamine, 5-HT) but represent the major storage site for this neurotransmitter outside the central nervous system. Platelets actively uptake serotonin, store it in electron-dense granules and release it, together with other platelet factors, in response to a number of signals (Paasonen 1965). Specific transporter molecules (SERT) located on platelet membranes are responsible for the highly selective uptake of serotonin, although there is some affinity for the other ▶ monoamines (e.g., norepinephrine, dopamine) (Omenn and Smith 1978). Molecular cloning has revealed



Platelets. Fig. 1. Bar = 500 nm. Electron microscopy photographs courtesy of Virginia Rodriguez-Menendez.

that the amino acid sequence of the human platelet SERT protein is identical to the neuronal SERT, and platelet high-affinity uptake system for serotonin displays kinetic and pharmacological characteristics similar to those reported in brain synaptosomes. All this makes platelets good model systems for investigating alterations of monoamine neurotransmission occurring in neuropsychiatric diseases.

Platelet SERTs have been studied in psychiatric and neurological patients, both as ► binding of radioligands on platelet plasma membranes, and as activity in intact platelets (Mellerup and Plenge 1986). Platelet serotonin uptake was demonstrated to be decreased in depressed patients, both adult and children, with respect to controls, before and during antidepressant treatment, although not all the studies agree (Fisar and Raboch 2008). No significant correlations were found between serotonin uptake kinetics and the severity of the depressive disorder. Abnormalities of platelet serotonin uptake have been reported also in patients with Down's syndrome and ► Huntington's disease, and a reduced platelet content of this neurotransmitter has also been demonstrated, again, in Down's syndrome.

The use of specific serotonin receptor antagonists has shown the presence on platelet surface of the 5-HT_{2A} receptor subtype involved in the amplification of platelet aggregation by recruiting additional platelets once the process has been initiated. Using [^{3}H]-ketanserin as a radioligand, a significant decrease in the affinity of platelet 5-HT_{2A} receptors was observed in patients affected by migraine, and a significant reduction in the number of binding sites was found in tension-type headache as well. Interestingly, a role for platelet-released serotonin in the pathogenesis of migraine has also been hypothesized, and differences between serotonin and other monoamines levels claimed to explain the diversity between migraine with and without aura (Joseph et al. 1992).

Major findings related to monoamine functions in human platelets in neuropsychiatric diseases are summarized in Table 1.

Dopamine

Besides serotonin, other monoamines, such as ► dopamine, are actively concentrated by platelets within dense bodies. Although the significance of the uptake of dopamine in platelets is uncertain and the concentration gradient is very much lower with respect to serotonin, a number of clinical investigations have been performed

in samples obtained from patients affected by various neuropsychiatric disorders in order to study possible dopaminergic pathomechanisms.

The results of the studies focusing on platelet dopamine levels are quite variable. A recent study reported increased platelet dopamine levels in patients with migraine both, with, and without aura, although in an earlier study interictal platelet dopamine levels were found unchanged in women affected by migraine.

Although platelets are not generally regarded as useful models for exploring dopamine transporters (DAT), given the prevalence therein of SERTs, an increase of dopamine uptake has been described in platelets from patients with Huntington's disease, while a reduction was found in parkinsonisms.

To avoid the controversial issues deriving from assessing dopamine uptake in intact platelets (presence of a specific dopamine uptake mechanism versus dopamine entry via the serotonin uptake system) the uptake of [^{3}H]-dopamine has been measured in previously separated ▶ platelet storage granules (PSG). These granules possess the vesicular monoamine transporter 2 (VMAT2) responsible for monoamine storage into secretory vesicles (Zucker et al. 2001). An increase in dopamine accumulation has been described in platelets of acute schizophrenic patients, while a decrease was observed in Gilles de la Tourette and naïve ▶ Parkinson's disease patients. Furthermore, using high affinity [^{3}H]-dihydrotetrabenazine binding to platelets, an elevated VMAT2 density was found in untreated major depression, ▶ schizophrenia, and former heroin addict patients treated with ▶ methadone, while a decreased density was observed in children and adolescents with attention deficit/hyperactivity disorder and in both healthy and schizophrenic habitual smokers.

The Glutamatergic System

Human platelets store, release, and uptake ▶ glutamate, at the same time expressing fully functional cognate receptors. Notably, the available data indicate that platelets might represent an extremely suitable model for specifically studying the dysfunction of the glutamatergic system in neuropsychiatric disorders, since display very similar properties with respect to the CNS (Tremolizzo et al. 2004). However, although platelets do express all the components of a functional glutamatergic system, its specific role is far from being fully understood. Even so, NMDA and AMPA receptors have been repeatedly shown in both platelets and ▶ megakaryocytes, and a role for glutamate in ▶ platelet activation and/or aggregation has already been proposed. Moreover, platelets express the three major glutamate transporters, EAAT1, EAAT2, and EAAT3 (Zoia et al. 2004), and a functional high affinity sodium-dependent glutamate reuptake system has been successfully described more than 20 years ago. Apparently this reuptake system might represent a major source of the amino acid removal from blood, and also displays very similar regulatory mechanisms and susceptibility to toxins with respect to the CNS homologue. The two major vesicular glutamate transporters (VGLUT-1, VGLUT-2) are expressed as well, packing glutamate (probably in dense bodies), and releasing it following aggregation together with several other mediators (as a counterproof aspirin treatment reduces glutamate release). Although the possible significance of these findings still need to be definitively addressed in relation to platelets and hemostasis physiology, current data indicate that those functions involved in glutamate homeostasis in platelets may represent suitable windows for studying CNS alterations.

As a matter of fact, glutamate receptor sensitivity, for example assessed by flow cytometry, has been studied in platelets obtained from patients affected by schizophrenia, psychotic depression, and major depression, suggesting the possibility of mirroring an hypofunction of glutamate receptors that may be implicated in the pathogenesis of these psychiatric disorders (see Table 1). Moreover, glutamate/aspartate uptake, assessed as [^{3}H] glutamate influx (Mangano and Schwarcz 1981), has been investigated in platelets obtained from patients affected by various neuropsychiatric conditions, such as bipolar disorder, ▶ Alzheimer's disease, ▶ Parkinson's disease, amyotrophic lateral sclerosis, ▶ Huntington's disease, migraine, acute ischemic stroke, and Down syndrome, in the attempt of mirroring an excitotoxic dysfunction previously demonstrated in the CNS of these patients. Also glutamate release following aggregation, assessed by ▶ HPLC as the difference between pre and post plasma levels, has been investigated in disease, mainly in a setting of migraine and stroke, since the release of this amino acid might mediate, at least in part, the experienced symptoms, activating both central and peripheral (i.e., endothelial, leukocytic) receptors (keeping in mind that the release function might be especially prone to the already discussed methodological issue of preparation-induced activation). Interestingly, ▶ lamotrigine, a drug able to interfere with the symptoms of migraine aura, works by blocking glutamate release, possibly, at least in part, directly from platelets.

Major findings related to the glutamatergic system in human platelets in neuropsychiatric diseases are summarized in Table 2.

GABA and Peripheral Benzodiazepine Receptors

Platelets express ► GABA transporters and the uptake of this amino acid has been reported disrupted in patients affected by absence epilepsy, although the functional impact of the antiepileptic drugs taken by the patients has not been completely clarified. Also GABA transaminase (GABA-T) has been studied, mainly in a setting of various epileptic syndromes, such as juvenile myoclonic, refractory localization-related, and childhood absence epilepsy, showing different modifications. GABA-T represents the main enzyme responsible for GABA catabolism and the inhibition of this enzyme produces a considerable elevation of GABA concentrations: often the modulation of such elevation has been correlated with many pharmacological effects, mainly in the field of antiepileptic drugs. GABA-T activity in blood platelets might be altered also in some neuropsychiatric disorders, such as alcoholism, epilepsy, and Alzheimer's disease.

A related GABAergic marker, the 18 kDa Translocator Protein (TSPO) (the new nomenclature for the peripheral-type benzodiazepine receptor, PBR) has also been studied in human platelets, evaluating the binding of the radioactive antagonist [^{3}H]PK11195; a decrease of this parameter was shown in platelets obtained from patients affected by ► depression with associated adult separation anxiety disorder, ► panic disorder, and ► schizophrenia with aggressive behavior, among other psychiatric diseases. On the other hand, no changes were shown in a population of untreated depressed patients, while an upregulation was present, for example, in primary fibromyalgia patients. Interestingly, ► Bmax values of PBR binding have been shown to be positively correlated with scores for trait anxiety, suggesting that it might be associated with the personality trait for anxiety tolerance (Nakamura et al. 2002).

Major findings related to the GABA and PBR in human platelets in neuropsychiatric diseases are summarized in Table 2.

Polymorphism

Definition

In biology, polymorphism is the presence of distinct subtypes of gene products within a single family. Genetic polymorphisms are the result of evolution and are hereditable. Of great interest for psychopharmacology are polymorphisms characterized by variations in the genetic sequence coding for specific receptor subtypes, which often confer higher or lower ► affinity for the ligand, or influence functionality of the receptor (or plasma membrane transporter) itself. These differences in affinity/functionality are hypothesized to be important for the manifestation of certain psychiatric disorders, personality traits, and different responses to medications between individuals. Polymorphisms are variations in DNA that are too common to be attributable to new mutations; the frequency of a polymorphism has been defined as at least 1% in a given population.

Definition

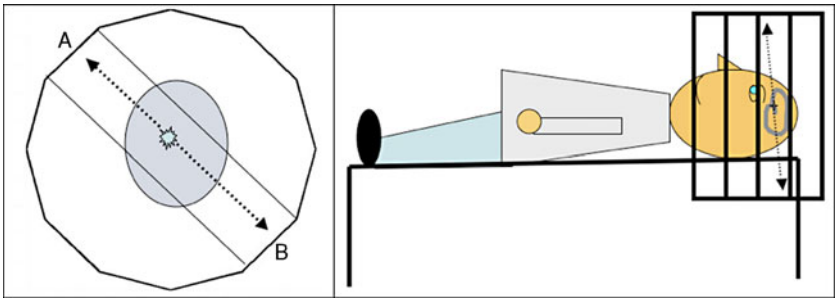
PET is a noninvasive technique that allows quantitative imaging data to be obtained from internal organs (including brain) in vivo, in humans as well as in animal models. Molecules that interact with biologic systems of interest are tagged with positron-emitting isotopes and injected into subjects, usually in very small quantities (► tracer dose). The decay process of the isotope results in the emission of photons that are detectable by the imaging system. These data can be used to infer the concentrations of the radiolabeled molecule (► radiotracer) in the tissues being imaged. Depending on the nature of the radiotracer, the technique can be used to estimate parameters related to receptor density and availability, drug occupancy, fluctuations in endogenous transmitter levels at neurotransmitter receptors/transporters, and rates of various metabolic processes.

Principles and Role in Psychopharmacology

PET imaging has been used as a noninvasive tool to probe many questions with implications for the field of psychopharmacology. Some of these are examination of receptor/transporter availability at many different neuroreceptor targets in patient populations relative to healthy control subjects, measurement of drug receptor occupancy through competition models, detection of fluctuations in endogenous neurotransmitter levels following pharmacologic or task-based stimulation, and examination of various metabolic processes. This essay is organized in three sections, followed by brief concluding remarks: (1) a brief description of the physical principles underlying the imaging system, (2) a description of the pharmacokinetic methodology common to most PET studies, and (3) a survey of the currently available probes and targets studied with PET.

Physical Principles of PET

Positrons are the antiparticles of electrons. They have the same mass as electrons but positive, rather than negative electric charge. Unstable isotopes that emit positrons when they decay can be produced in a cyclotron; many academic medical centers currently have onsite cyclotrons that can produce isotopes for PET imaging. Several of these isotopes can be readily incorporated into small molecules suitable as biologic tracers. Among these are carbon (^{11}C, half-life = 20.4 min), fluorine (^{18}F, half-life = 109.8 min), and oxygen (^{15}O, half-life = 122 s). When a positron is emitted, it briefly interacts with local atoms, losing kinetic energy during the resulting collisions. When its energy is low enough, the positron will be attracted to and captured by an electron; the pair will mutually annihilate and emit a pair of 511 keV photons. Conservation of momentum dictates that the total momentum of the 2 photons is equal to that of the positron–electron pair at the time of their annihilation. As this momentum is small, the photons travel in nearly opposite directions (their momenta cancel each other), approximately along a line from the location of the annihilation event (Fig. 1, left panel). The imaging system contains



Positron Emission Tomography (PET) Imaging. Fig. 1. *Left:* A schematic detector ring. An annihilation event occurs in an imaged object as seen along the long axis of the subject (from head to toe). If the emitted photons (paths represented by dashed arrows) strike detectors A and B within a coincidence timing window (several nanoseconds for most scanners), a coincidence event is recorded along the line between A and B. Right: A schematic stack of rings, viewed from the side. A tomographic image is formed by combining data from all the rings.

rings of detectors composed of scintillating materials that surround the imaged object. Combined with electronic components that are attached to these detectors, the arrival of photons at the detector arrays can be counted with very high temporal resolution (on the order of nanoseconds). If a pair of photons are detected in two different detectors within a specified time interval (a "coincidence timing window," typically 4–12 ns), the scanner treats these as having originated from a single annihilation event occurring somewhere along the line between the two detectors (a "line of response"). Computer-intensive mathematical methods can then be applied to this collection of coincidence event data to infer the original distribution of the annihilation events. Typical modern systems contain from 20 to 40 of these detector rings stacked in parallel to form a cylindrical field of view (Fig. 1, right panel); the data from these can then be recombined to form a three dimensional image of the original distribution of the radiotracer, composed of a series of slices through the object (a "tomogram," literally a "slice picture," see Fig. 2).

The preceding description of the data acquisition and reconstruction is greatly simplified – there are many confounds and sources of noise and image degradation that must be accounted for. For example, many of the photons produced by annihilation events interact with the tissues intervening between the locus of the annihilation and the detector; some of these are scattered in different directions and others absorbed completely ("attenuated"). A description of the methods for correcting these confounds is beyond the scope of this chapter (see Cherry et al. 2003; Valk et al. 2003 for detailed expositions) but a key point is that PET utilizes coincidence detection, in contrast to the related technologies such as single photon computed tomography (SPECT). This results in an accurate estimate of the fraction of photons that are attenuated in any line of response through an imaged object, and this, in turn, leads to a level of quantitative accuracy that is not practically attainable with other technologies. Because of this level of quantitative accuracy, the concentration of radiotracer in tissues can be accurately inferred, during a single contiguous interval of time, or dynamically over a sequence of sampling times after injection of the tracer. The implications for psychopharmacology are that detailed mathematical models can be formed of the tracer pharmacokinetics, the interaction between tracer pharmacokinetics and endogenous transmitters or

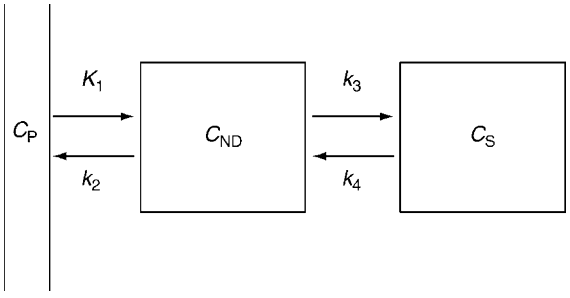
exogenously administered drugs, or, of rates of metabolic processes. Physiologic parameters can be estimated by fitting data to these models.

Pharmacokinetic Models and Methods

General principles: The ▶ pharmacokinetic schemes used to estimate parameters both for ▶ reversible binding receptor radioligands and for many metabolic processes are called compartment models. Compartments can be spatially distinct, but they can also be different states of the radiolabel occupying the same spatial domain, such as bound versus unbound, or parent radiotracer versus metabolic product. Figure 3 is a schematic representation of a standard compartment model used with reversibly binding radioligands.

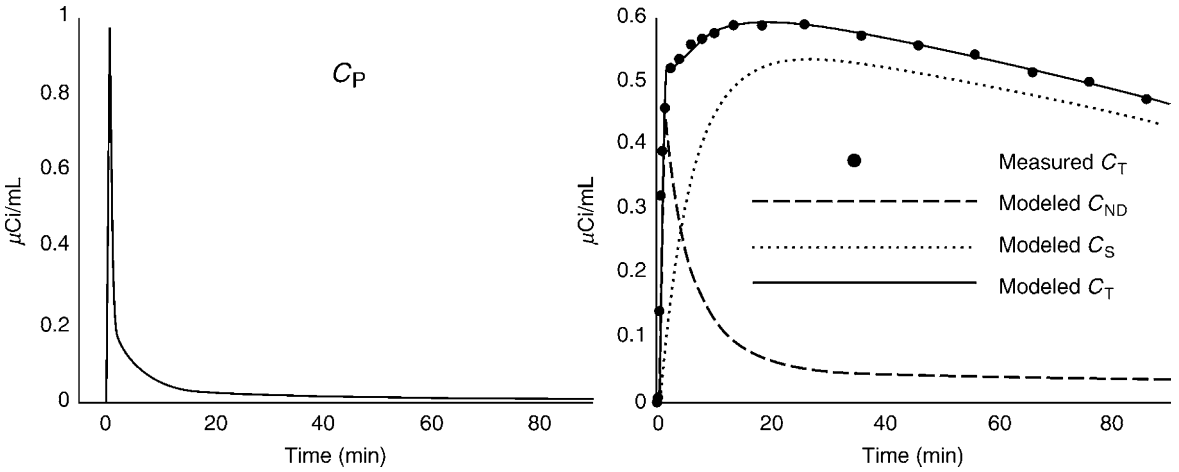
Corresponding to the compartment model, are systems of linear first-order, ordinary differential equations (ODEs). The ODEs express the temporally dynamic relationship between the input source of radioligand to the tissue (either the concentration in arterial plasma, or the concentration in a tissue devoid of the biologic process of interest, but similar to the tissue of interest in other respects, a "reference tissue") and the resulting concentration in the tissue of interest (usually brain or specific brain regions for targets of interest in psychopharmacology). "First-order" implies that the models operate according to the convention that movement from a source compartment to a target compartment is proportional to the concentration in the source compartment; the validity of this assumption in the case of reversibly binding receptor ligands is predicated on the use of tracer dose so that the associated mass action law, which is second-order when higher concentrations are used, can be treated as pseudo



Positron Emission Tomography (PET) Imaging. Fig. 3. A 2-tissue compartment model (2TC). C_P radioligand concentration in arterial plasma; C_{ND} nondisplaceable compartment, the sum of free and nonspecifically bound tracer in tissue; C_S specifically bound ligand, i.e., ligand-receptor complex; K_1 through k_4 are rate constants governing the fractional transfer between compartments per unit time.

first-order. By using some data-fitting method such as least squares minimization to regress observed data onto the model, the rate constants can be estimated. In turn, various mathematical combinations of the rate constants represent physiological parameters of interest. There is an extensive literature on methods for data fitting and parameter estimation in PET (see Slifstein and Laruelle 2001; Slifstein et al. 2004; Valk et al. 2003 for overviews).

Receptor imaging: The form of PET imaging most frequently used in applications relevant to psychopharmacology involves the use of radioligands that bind selectively and reversibly to target neurotransmitter receptors and transporters. These are usually administered as a single ▶ bolus injection, though there are some tracers amenable to a ▶ bolus plus constant infusion administration that induces steady-state conditions in ligand concentrations. The compartment configuration shown in Fig. 3 presents a model frequently used with reversible tracers. In the figure, C_P represents the concentration of radioligand in the arterial plasma, the input to brain tissue. C_{ND} ("nondisplaceable") is the sum of freely dissolved tracer in the brain and tracer that is nonspecifically bound to membranes. These quantities are combined to a single compartment based on the assumption that equilibration between free and nonspecifically bound ligand occurs on a much more rapid time scale than the specific binding process does, and can therefore be treated as if constantly in equilibrium. Models in PET frequently involve simplifying assumptions of this type in order to insure that they are not over-parameterized for statistical fitting. C_S represents specifically bound ligand–receptor complex. The movement of tracer between C_P and C_{ND} is governed by a transport law, whereas exchange between the states C_{ND} and C_S is governed by a mass action law. These various states of the radioligand cannot be distinguished in the PET signal; it is comprised of the sum of all sources of radioactive decay in the spatial locus being imaged, and is sometimes referred to as C_T (total concentration, Fig. 4). The parameters of greatest interest in receptor imaging are the density of receptors available for binding to the radioligand (▶ B_{max} or B_{avail}, nM) and the ▶ affinity of the radioligand for receptor (K_D^{-1} where K_D (nM) is the ▶ equilibrium dissociation constant). These quantities cannot be estimated separately from single tracer dose scans – multiple scanning sessions with increased radiotracer concentrations that bind to a significant fraction of receptors would be required for this purpose. The quantity that is readily estimated is the ▶ binding potential, a parameter that is proportional to the product of B_{max} and affinity, or B_{max}/K_D. There are several possible constants of proportionality, according to which



Positron Emission Tomography (PET) Imaging. Fig. 4. Arterial plasma input and resulting PET data and model fit. These data show the time course of the dopamine D_1 receptor tracer [^{11}C]NNC112 in the striatum of an anesthetized baboon. of several approaches to experimental design and derivation of the binding potential estimate is used. The version appearing most frequently in the literature, however, is called BP_{ND} (Innis et al. 2007), equal to $f_{ND}\ B_{max}/K_D$ where f_{ND} is the fraction of C_{ND} that is freely dissolved, f_{ND} = free ligand/(free + nonspecifically bound ligand). The rate constants can be shown to have the following physiological interpretations: $K_1 = FE$, where F is flow (actually, perfusion, mL cm^{-3} min^{-1}) and E is the first-pass extraction fraction (unitless), $k_2 = K_1/V_{ND}$ where V_{ND} is the nondisplaceable equilibrium distribution volume, C_{ND}/C_P at equilibrium, (mL cm^{-3}), $k_3 = k_{on} f_{ND} B_{max}\ (\text{min}^{-1})$, where k_{on} is the association rate of the receptor-ligand complex and k_4 (min^{-1}), is k_{off}, the dissociation rate of the receptor ligand complex. As K_D is equal to k_{off}/k_{on}, it is apparent that k_3/k_4 is equivalent to BP_{ND}. However, BP_{ND} is rarely estimated directly from the fitted values of k_3 and k_4. Rather, more involved methods utilizing various constraints to make the estimated BP_{ND} more statistically robust are employed (see Slifstein and Laruelle 2001; Slifstein et al. 2004; Valk et al. 2003 for further details).

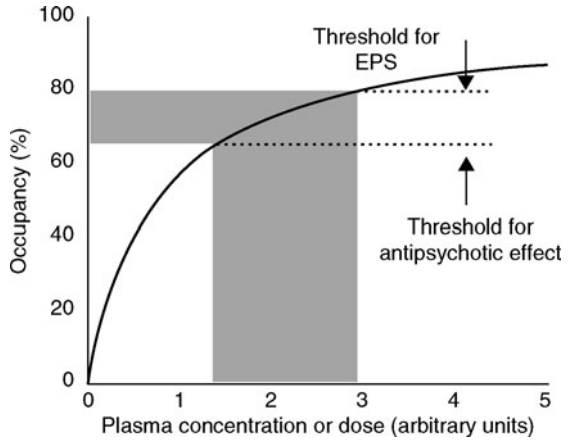
Applications of receptor imaging to psychopharmacology: If another ligand – an endogenous transmitter or an exogenously administered drug – competes with the radioligand at the binding site on the receptor, then it can be shown, again invoking tracer dose conditions for the radioligand, that the binding potential is reduced by the factor $1/(1+L/K_i)$, where L is the concentration of the ligand and K_i is its affinity for the binding site. This in turn implies that the relative difference between the binding potential with and without the competing ligand on board, [BP_{ND}(competitor on board) − BP_{ND}(baseline)]/BP_{ND}(baseline), is equal to $L/K_i/(1+L/K_i)$, the fraction of receptors occupied by the competitor. This technique can be used to infer the occupancy of a receptor by a drug, or to demonstrate that a stimulus induces transmitter release.

In a seminal study, Farde et al. (1988) used the dopamine D_2 receptor radioligand [^{11}C] raclopride to measure the occupancy of D_2 receptors by the antipsychotic drug ▶ haloperidol in patients with schizophrenia, and presented the concept of a therapeutic window – the idea that there is a minimal receptor occupancy necessary to achieve antipsychotic efficacy, but a maximum tolerable occupancy above which extrapyramidal symptoms would appear (Fig. 5). The in vivo competitive binding technique has subsequently been used in many published studies examining drug receptor occupancy. While a large number of these have continued to examine D_2 occupancy by antipsychotics, the method has been used to look at other receptor systems as well, including various 5-HT receptors, nicotinic and muscarinic ACh receptors, NK1, adenosine 2, histamine, CB1, mu-opioid receptors, 5-HT and DA transporters, and other targets. The approach has been widely used by pharmaceutical companies in both drug development and in postmarketing studies characterizing efficacious occupancies.

A similar imaging technique can be used to infer fluctuations in endogenous neurotransmitters as a result

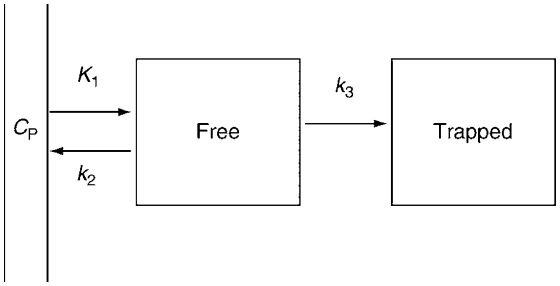


Positron Emission Tomography (PET) Imaging. Fig. 5. The concept of a therapeutic window, showing a range over which an antipsychotic drug is efficacious, but below the threshold for extrapyramidal symptoms. (After Farde et al. 1988.)

of either pharmacological or task-based stimuli. Again, the system that has been the most amenable to this type of study has been dopamine release at the D_2 receptor. Many studies have been performed in which dopamine release and/or inhibition of reuptake has been induced by ► amphetamine, ► methylphenidate, or other compounds, or by tasks hypothesized to induce dopamine release, for example, by incorporating a monetary reward for accurate task execution. There has been considerable evidence that the simple competitive interaction model described earlier is not adequate to explain the decrease in binding potential following amphetamine. In particular, the decrease lasts much longer than the apparent increased dopamine release as measured with ► microdialysis in animal models. On the other hand, the binding decrease is highly correlated with amphetamine dose and with the microdialysis measurements, and does not occur if dopamine stores have been pharmacologically depleted prior to the scan, suggesting that the competitive binding plays at least some role in the observed effect. Also, while an effect consistent with the occupancy model has been detected with several radioligands in the benzamide ([^{123}I]IBZM, [^{11}C]raclopride, [^{18}F]fallypride) and catecholamine ([^{11}C]NPA) classes, paradoxical *increases* in radioligand binding following amphetamine have been observed using the ► butyrophenone radioligand *N*-[^{18}F]methylspiperone. A number of mechanisms have been proposed to explain both the extended duration of the amphetamine effect and the different results observed with different radioligands, including receptor trafficking and differential responses to internalized receptors, differences in binding sites, and differences in ► pharmacokinetic properties with concomitant differences in robustness of quantification of the various radioligands. At this time, these issues remain unresolved. Recently, there has been some investigation of the use of agonist, rather than antagonist radioligands, based on the premise that they may be more sensitive to the affinity state of the receptor for endogenous neurotransmitters, and, therefore, endogenous dopamine might compete more successfully with these, leading to greater sensitivity to the differences across conditions or populations in stimulated dopamine release. Studies using anesthetized animals have demonstrated increased sensitivity of [^{11}C]NPA and [^{11}C]PHNO, both $D_{2/3}$ agonists, to amphetamine stimulation relative to [^{11}C]raclopride, and early studies with [^{11}C]PHNO in healthy human volunteers have also shown increased amphetamine effect in the dorsal striatum compared to previously published reports utilizing [^{11}C]raclopride. The competitive binding method has proved to be much more difficult to use with receptors other than the dopamine D_2 receptor. Several investigators have been unable to detect the amphetamine effect on binding of dopamine D_1 radioligands. Researchers have had mixed results detecting pharmacologically-induced increases in serotonin levels as well, with some investigators reporting decreases in [^{18}F]MPPF or [^{18}F]MEFWAY binding to 5-HT_{1A} receptors in animal models following stimulated increases in serotonin levels either by ► fenfluramine or ► SSRIs, while others have been unable to detect changes with [^{18}F]MPPF or [^{11}C]WAY100,635. See Laruelle (2000) for a comprehensive examination of competitive binding techniques in PET and SPECT, especially as pertains to dopamine $D_{2/3}$ receptor imaging.

Finally, it is worth noting that receptor imaging has been used to infer some more subtle pharmacological effects, such as the "GABA-shift" observed at the ► benzodiazepine binding site on the $GABA_A$ receptor with the PET radioligand [^{11}C]► flumazenil, in which radioligand binding increased when GABA levels were increased by reuptake inhibition (Frankle et al. 2009), presumably due to increased affinity through allosteric interaction between the GABA and benzodiazepine binding sites.

Metabolism imaging: The models used for metabolism imaging can vary potentially according to the mechanism being studied. In this section, two widely used metabolism tracers are described: [^{18}F]DOPA and [^{18}F]FDG. Both of these ligands are substrates for some, but not all enzymes that act on an endogenous compound, and thus partially follow the same metabolic pathway. Both of these reach a stage in the metabolic process in which they are



Positron Emission Tomography (PET) Imaging. Fig. 6. An irreversible trapping model.

assumed to be irreversibly trapped, and thus the model is based on the assumption of irreversible accumulation. In each case, there has been a considerable body of literature demonstrating that this assumption is oversimplified and that more accurate estimates of the measured process can be obtained using more complex models that account for the further progress of the radiolabeled metabolites after the putative trapping stage. Nonetheless, the trapping models are still widely used due to their simplicity and ease of implementation, and so are described here. A basic compartment model for ► irreversible trapping is shown in Fig. 6. Unlike the receptor models in the previous section, there is no notion of equilibrium. As long as free radioligand is in the tissue, the concentration in the trapped compartment continues to increase as k_3 times the free concentration. However, one can envisage a hypothetical steady state in which influx to the tissue from plasma just balances the sum of efflux back to the plasma plus the conversion into the trapped form, so that the free concentration is constant. Under these conditions, the free concentration equals $K_1/(k_2+k_3)$ times the plasma concentration C_P, and the steady state rate of conversion into the trapped form, therefore, equals $K_1k_3/(k_2+k_3)$ times the plasma concentration. This parameter is often referred to as K_{in}, the steady state uptake rate for an irreversible compartment model.

[^{18}F]DOPA is a substrate for amino acid decarboxylase (AADC), the enzyme that catalyzes L-dihydroxyphenylalanine (DOPA) into ► dopamine within the dopaminergic terminals. [^{18}F]DOPA readily passes the ► blood–brain barrier and cell membranes, and is metabolized by AADC into 6-fluorodopamine (6-FDA), effectively ^{18}F labeled dopamine, in dopaminergic terminals. 6-FDA, like endogenous dopamine, does not cross the blood–brain barrier and so is "trapped" in the proximity of the terminals at the stages of loading into vesicles, release through exocytosis and reuptake into the terminal, the main path followed by endogenous dopamine in the striatum, where reuptake through dopamine transporters is the dominant mode of clearance from the synapse. Thus K_{in}, estimated with the irreversible trapping model, represents a lumped marker of presynaptic dopaminergic condition. 6-FDA is, however, a substrate for monoamine oxidase (MAO) and for catechol-*O*-methyltransferase (COMT). Both of these enzymes are present in the extracellular environment, and the radiolabeled metabolic by-products from 6-FDA metabolism can readily diffuse across the blood–brain barrier. Numerous studies have demonstrated that failure to account for this loss of radiolabel from the brain results in underestimation of the true uptake rate, and several approaches have been proposed for its incorporation into the modeling and design of [^{18}F]DOPA experiments. See Cumming and Gjedde (1998) for a detailed discussion of the metabolism of [^{18}F]DOPA.

^{18}F labeled 2-fluoro-2-deoxy-*D*-glucose (FDG) is arguably the most extensively used PET radioligand. The development of FDG for use with PET followed the groundbreaking work of Sokoloff et al. (1977) with [^{14}C]DG, a ^{14}C labeled tracer which is an analog of glucose and partially follows its metabolic pathway. Thus, FDG is a useful probe for measuring the cerebral glucose metabolism rate (CMR_{glu}). In more recent times, techniques such as fMRI have become more prevalent for studies measuring brain metabolic activity, owing to their better temporal and spatial resolution and the less invasive nature of the procedure. FDG has gone on to be used extensively as a clinical tool in radiological diagnostic procedures in other fields such as oncology. But given the historic nature of the role of FDG in the use of PET to study the brain, a brief description of the model is included here. FDG is a substrate for the same carrier protein that transports glucose into brain tissue. It is also a substrate for hexokinase, the enzyme that metabolizes glucose, and is phosphorylated into FDG-6-PO4. FDG-6-PO4 does not follow further steps of glucose metabolism. It does dephosphorylate, but because dephosphorylation of FDG-6-PO4 is slow compared to the forward process, FDG-6-PO4 is treated as a trapped state. Here, K_{in} represents the steady state phosphorylation rate of FDG. This is proportional, not identical, to CMR_{glu}, owing to the fact that the transport and phosphorylation rates are different for the two compounds. When multiplied by a conversion factor accounting for this difference (1/LC, the "lumped constant," because it lumps two conversion factors together) then K_{in}/LC times the plasma glucose concentration is taken as an estimate of brain glucose metabolism. In analogy with observations made about metabolism of [^{18}F]DOPA, the dephosphorylation step, while small, still contributes to

Survey of Probes and Targets

Table 1 in this section is intended to give a general sense of the targets relevant to psychopharmacology that are currently accessible by PET imaging. It is extensive, but not necessarily exhaustive. Criteria for inclusion are that radioligands have been used with human subjects in at least one published study (there are many, many more that never progress that far, for one reason or another) and that use is ongoing – ligands that appear to be obsolete due to absence from publications for many years are not included. The table demonstrates that by far the most explored system in PET is the dopaminergic, followed by the serotonergic, but many other systems have or are beginning to be imaged as well.

Conclusions and Future Directions

PET imaging is unique among methods in pharmacology, for it provides highly quantitative measurements of relevant properties noninvasively in vivo. The studies described in this chapter have provided important data about neurochemical processes in living human brains that are not attainable through any other currently available technology. The field is limited by the availability of probes; any system can be studied provided a suitable radiotracer can be developed. The dopaminergic and serotonergic receptor systems have proved particularly amenable to probing with PET, and this has been fortuitous for the field of psychopharmacology due to the prominent role these systems play in psychiatric and neurologic conditions. Less progress has been made in the study of other systems, especially amino acid transmitters, but these systems are also of great interest to psychopharmacology – for example, many studies have implicated dysfunction in the glutamate and GABA systems in schizophrenia. The challenge of the future for PET is to continue to expand into these and other neurochemical systems.

Definition

Postpsychotic depressive disorder of schizophrenia (PPDDS) is a clinical condition that occurs when an individual with the pre-existing diagnosis of ► schizophrenia manifests the syndrome of ► depression subsequent to the remission, or partial remission, of a florid psychotic episode of schizophrenia. PPDDS is diagnosed only during the residual phase of schizophrenia that follows the active psychotic phase (the active phase representing the presence of symptoms meeting Criterion A of schizophrenia according to the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition – DSM-IV) (American Psychiatric Association 2000) (► DSM-IV). Negative symptoms or attenuated manifestations of active phase symptoms (e.g., odd beliefs or unusual perceptual experiences) may, however, persist at the time of diagnosis of PPDDS. The diagnosis of PPDDS requires the presence of features sufficient to meet the DSM-IV criteria for the diagnosis of a major depressive episode and must also, specifically, include the presence of depressed mood (► Emotion and Mood). Symptoms that are due to the direct physiological effects of medication, a substance of abuse, or general medical condition are not counted toward the diagnosis of PPDDS.

Context of the Definition of "Depression"

"Depression" is a term that can be used in a variety of contexts. It can refer to an affect, a symptom, a syndrome, or a disease. As an affect, the term "depression" refers to the experience of sad mood, which is an appropriate response to a stimulus such as a sad event or sad story. This is part of a full range of appropriate affect and is not pathological.

As a symptom, the term "depression" refers to a mental state involving an experience of sadness, joylessness, and/or emptiness, which is exaggerated in comparison to the circumstances and is associated with psychic pain or distress. The degree to which this type of "depression" is pathological depends on the degree of exaggeration and the amount of suffering that is involved.

The syndrome of "depression" occurs when a defined group of signs and symptoms is present simultaneously with adequate severity and duration. The DSM-IV definition of "depression" is the most common contemporary definition of "depression" and this definition is at the level of a syndrome. It includes features such as sad mood or tearfulness, sleep disturbance, appetite disturbance or fluctuations in weight, reduced energy level or excessive

fatigue, psychomotor agitation or retardation, anhedonia, reduced interest level, impaired concentration or ability to think or make decisions, feelings of excessive or inappropriate guilt and/or worthlessness, pessimism, feelings of helplessness and/or hopelessness, recurrent thoughts of death, and suicidal ideation, intent, or behavior. Interestingly, many of these features were initially incorporated into the DSM-III diagnosis of "depression" (the predecessor of DSM-IIIR and, more recently DSM-IV) on the basis of their being associated with a favorable response to an antidepressant (at that time meaning a tricyclic or MAO-inhibitor) medication. Other widely recognized features of depression at the syndrome level that were not quite as predictive of response to early antidepressant medications (e.g., diurnal variation) did not become part of the DSM-III diagnostic definition.

The definition of "depression" as a disease state would require an in-depth understanding of the causation and pathophysiology of depression as a distinct biomedical condition – which is arguably still beyond our grasp. To wit, we as yet have no "tissue level" diagnostic criteria (such as a blood test, electrophysiological or imaging test, biopsy, or even autopsy finding), which confirms the diagnosis of "depression." Indeed, we cannot even be certain that the diagnosis of "depression" really belongs at the disease level, or whether "depression" is better characterized (like fever, seizures, or congestive heart failure) as being a clinical syndrome (syndrome-level diagnosis), which can occur in a variety of different "disease" states.

The definition of PPDDS given earlier is at the level of a syndrome.

Epidemiology

"Depression" has long been described as a feature in many patients diagnosed as having schizophrenia (McGlashan and Carpenter 1976), and many studies have been undertaken to explore and/or document the frequency of occurrence of depressive symptoms and/or depressive syndromes in people with schizophrenia (Siris and Bench 2003). These studies have varied considerably in terms of the populations that were assessed, the definitions of schizophrenia and depression, which were employed, the interval of observation which was involved, and the setting and treatment situation of the patients. The results for the observation of depression occurring in schizophrenia have ranged from a rate of 6% to 75%, but both the modal and the median frequency of occurrence was 25%. "Depression" has been associated with higher rates of adverse outcomes in schizophrenia, such as poor social adjustment, reduced quality of life, undesirable life events, relapse into psychosis, and rehospitalization. Additionally, it is of importance that the symptom or syndrome of depression, along with the symptom of hopelessness and the occurrence of events involving loss, have been identified as the most frequent correlates of suicidal ideation and behavior in schizophrenia, a tragic outcome that has been estimated to occur at a frequency of 4–12% in schizophrenia (Siris 2001) (► Suicide).

Differential Diagnosis

There are a variety of conditions that can present with the clinical features representative of PPDDS (Siris 2000; Siris and Bench 2003). These include medical disorders, effects of treatments used for medical disorders, effects of other substances, ► neuroleptic side effects (including ► akinesia, ► akathisia, and neuroleptic-induced dysphoria), negative symptoms of schizophrenia, acute and chronic disappointment reactions, the prodrome of psychotic relapse, ► schizoaffective disorder, and the expression of an independent primary diathesis for depression in an individual who also has schizophrenia.

Sad mood and/or a syndrome that can mimic depression can be a feature of a variety of medical conditions including anemias, endocrinopathies, metabolic abnormalities, infectious diseases, cancer, cardiovascular, autoimmune, or neurological disorders. Many commonly prescribed medications can also have depression occurrence as a side effect. These include beta-blockers, various other antihypertensive medications, sedative hypnotics, antineoplastic agents, nonsteroidal anti-inflammatory agents, sulfonamides, and indomethacin. Other medications can be associated with depression at the time of their discontinuation (► Withdrawal Syndromes). Examples of these include corticosteroids and ► psychostimulants. Various substances of use and/or abuse (e.g., alcohol, cannabis, or cocaine) can also be associated with depression-like presentations, either at the time of their acute use, chronic use, or discontinuation. Additionally, the withdrawal state from two commonly used legal substances, ► nicotine and ► caffeine, can also involve dysphoria and other features that can easily be interpreted as the syndrome of depression.

Antipsychotic medications, perhaps more frequently, first-generation antipsychotics, have been associated with side effects that can also be phenocopies of depression (Awad 1993) (► First-Generation Antipsychotics). It may be relevant to this observation that ► dopamine is an important neurotransmitter in the "pleasure" pathways of the brain. Thus, blocking dopamine receptors, as antipsychotic medications do, could lead to an experience that is the opposite of pleasure. This effect has been described either as a primary impact of neuroleptic agents on mood or as a component of one of the two classical

► extrapyramidal neuroleptic side effects of akinesia or akathisia (► Medication-induced movement disorder). Akinesia is marked by a general diminution of motor behavior, causing patients to appear to be non-spontaneous, i.e., "as if their starter-motor is broken." Akathisia reflects the opposite of this: patients' appearance (frequent fidgeting and/or restless movements) and subjective experience is "as if their starter-motor won't turn off." Both akinesia and akathisia can be associated with substantial dysphoria, and akathisia has been associated with suicide risk. Both akinesia and akathisia can also be present in subtle rather than blatant forms. Subtle akinesia can occur in the absence of large muscle stiffness or cogwheel rigidity. Subtle akathisia may be reflected in a generalized tendency toward behavioral excesses, such as over-talkativeness or wandering into other people's territory.

"Negative" symptoms of schizophrenia can also present as a phenocopy of depression. Loss of pleasure, loss of interest, and decreased activity and/or initiative are features of the negative symptoms syndrome, which have their counterparts in depression, and this is a central reason why affective features (manifest sad mood) and cognitive features (guilt, hopelessness) are so important in distinguishing depression from negative symptoms in schizophrenia. The phenotypic similarities between "negative" symptoms, "parkinsonian" symptoms, and "retarded depression" have given rise to speculation that each of these expressions may represent the common syndrome of "akinesia" being manifest in each of these situations (Bermanzohn and Siris 1992).

In addition to the aforementioned biological and pharmacological issues, persons with schizophrenia often have much to be disappointed about in terms of how their lives are progressing in comparison to their hopes and original expectations. Consequently, both acute and chronic disappointment reactions are common. Acute disappointment reactions are generally relatively brief and can be linked to some recent event that was damaging to the patient's wishes, prospects, self-concept, or self-esteem (taking into account, of course, that such an insult is not always obvious in the face of potential idiosyncrasies of the patient's thinking or communication). Chronic disappointment reactions (also sometimes referred to as the demoralization syndrome) of longer, even open-ended, duration are based on a history of repeated failures or losses, and consequently can be more difficult to disentangle from other types of depression occurring in the course of schizophrenia (Frank 1973).

Another important condition that can mimic depression in schizophrenia is the prodrome of psychotic relapse (► Prepsychotic States and Prodromal Symptoms). When decompensating into a new psychotic episode, a patient may become dysphoric, anhedonic, restless and/or withdrawn, pessimistic, or apprehensive. Such an individual may also experience sleep or appetite disturbances, unstable energy levels and/or difficulty concentrating. The feature that distinguishes this state from depression is the eventual emergence of frank psychotic symptomatology, but this feature may not make its appearance for a week or more. In the interim, the patient's condition may strongly mimic that of depression.

Schizoaffective disorder also enters into the differential diagnosis of PPDDS (► Schizoaffective Disorder). To be diagnosed with schizoaffective disorder, a patient must have a period of overlap between florid psychotic symptoms and either a major depressive episode, a manic episode, or a mixed episode, as well as a period of at least 2 weeks of florid psychotic symptoms (including ► hallucinations or ► delusions) in the absence of prominent mood symptoms during the same episode of illness. Additionally, for the diagnosis of schizoaffective disorder, the symptoms that meet the criteria for the mood episode must be present for a "substantial portion" of the total duration of the active and residual phases of the illness (American Psychiatric Association 2000). Some authors also consider it to be a case of PPDDS when a patient with schizoaffective disorder (rather than the diagnosis of schizophrenia) manifests the syndrome of depression subsequent to the resolution of florid psychotic symptomatology (Siris and Bench 2003).

Finally, there is the case where PPDDS may be manifest in a patient who has co-existing independent diatheses for the psychosis of schizophrenia and for the syndrome of depression. The argument that this, logically, would be a statistical rarity is countered by the argument that the respective diatheses may well be continuous variables rather than categorical ones – and that each diathesis may promote or aggravate the expression of the other (Siris 2000).

Role of Pharmacotherapy

Initial Approaches

When a patient presents with a new episode of PPDDS, the first response should not necessarily be to change medications. Rather, a careful study of history needs to be done, which would include an assessment of any recent changes in medications (psychiatric or otherwise and including attention to adherence issues), a consideration of possible medical conditions, an exploration of potential psychosocial stressors, and an investigation of the possible use (or discontinuation) of substances. An exploration of risk factors for suicide is also indicated, and protective steps to safeguard the patient should be taken if necessary (Siris 2001). The

initial intervention would be to raise the level of monitoring and provide supports. If the "depression" is an acute disappointment reaction, it will resolve itself. If it is a component of the prodrome of a new psychotic episode, that also will soon declare itself, and the increased monitoring will maximize the opportunity to attenuate the episode with appropriate treatment, thereby limiting psychiatric and social/vocational morbidity. Medical conditions, the role of medications employed to treat medical conditions, and the possible role of substance use or abuse can also be addressed in this initial phase.

Treatment of the Persisting Syndrome of PPDDS

When it is apparent that the syndrome of PPDDS is stably present, and in particular it is clear that the patient is not in the process of deteriorating into a new psychotic episode, it is appropriate to consider whether the dosage of antipsychotic medication is excessive (► Antipsychotic Drugs). Unnecessary high doses of antipsychotic medication may contribute to neuroleptic-induced ► dysphoria or the neuroleptic side effects of akinesia or akathisia. Once antipsychotic medications have been established at the lowest doses, which are consistent with adequate antipsychotic activity in a given patient, the treatment of akinesia can be undertaken with adjunctive antiparkinsonian medication (► Anti-Parkinson Drugs). For example, benztropine may be tried in doses up to a full dose of 2 mg po TID, ► anticholinergic side effects permitting. Occasionally, even higher doses of antiparkinsonian medications may be tried if anticholinergic side effects such as constipation, difficulty in urinating, or dry mouth (a crude but meaningful test for the bioavailability of the anticholinergic effect) are not present and the akinesia persists. Alternatively, a non-anticholinergic antiparkinsonian agent such as amantidine may be tried as an adjunct to the antipsychotic medication. In the case of akathisia, anticholinergic antiparkinsonian medications are unlikely to be helpful, but benzodiazepines are often useful (► Benzodiazepines), and beta-blockers often work as well (► Beta-Adrenoceptor Antagonists).

Switching from a "typical" (first-generation) antipsychotic agent to an "atypical" (second-generation) antipsychotic agent is another adjustment of the medication regimen to consider in cases of PPDDS (Siris 2000) (► Second and Third Generation Antipsychotics). The literature is inconsistent, but suggests that, in some cases, negative symptoms are reduced with second-generation antipsychotics (SGAs), and/or extrapyramidal side effects are lessened (Möller 2008). There is also a literature suggesting, subject to a variety of methodological limitations, that rating scores for depression may be improved by the use of SGAs in schizophrenia (Möller 2008). Indeed, SGAs have sometimes been touted as possessing augmenting antidepressant effects when used as adjunctive agents in patients with major depression.

There is also a role for adjunctive antidepressant medications in the treatment of PPDDS, particularly when extrapyramidal side effects have been ruled out (Siris and Bench 2003) (► Antidepressants). Patients must be maintained on adequate doses of antipsychotic medications when antidepressants are used, but the antidepressant drugs can gradually be raised to full therapeutic dosages. Vigilance should be maintained, however, for the possibility that the antipsychotic and the antidepressant might each interfere with the metabolism of the other, resulting in the possibility of adverse pharmacokinetic interactions (► Drug Interactions), perhaps particularly when specific serotonin reuptake inhibitors (SSRIs) are involved (Möller 2008). Although most of the controlled studies of adjunctive antidepressant use in PPDDS come from the era of first-generation antipsychotics (FGAs) and ► tricyclic antidepressants, the subsequent wide use of combinations including both FGAs and SGAs and a wide variety of more novel antidepressants nevertheless suggests both safety and utility for a variety of regimens (Siris et al. 2001).

Although proper studies have not been done to support the use of lithium (► lithium) or anticonvulsants (► Mood Stabilizers) (► Anticonvulsants) in PPDDS, it is rational to consider a trial of these agents, perhaps particularly in patients who manifest features of schizoaffective disorder, have a history of excitement or an episodic course as a component of their illness, or have family histories of affective disorders. Similarly, although there are not specific data to support it, ECT can be on the list of other treatments that might be useful in cases of PPDDS.

It is additionally important to provide adequate psychosocial support, increasing structure, reducing stress, and building skills, confidence, and self-esteem for patients during their treatment for PPDDS. This is particularly the case when the patient is suffering from a chronic disappointment reaction (demoralization syndrome) and needs to learn new strategies of thinking to foster success and happiness. However, proper psychosocial supports may be pivotal as well during pharmacological interventions because, from the patients' point of view, these interventions can literally change their world and they may need help in moving ahead from long-held, but now suboptimal, old ways of adapting to their old worlds toward new ways of productively adapting to their new worlds.

Conclusion

A syndrome of post-psychotic depressive disorder of schizophrenia (PPDDS) is commonly noted to occur in the residual phase of schizophrenia, after the resolution of florid psychotic symptoms. PPDDS can be a source of considerable morbidity, and even mortality, and consequently merits clinical attention.

The phenomenology of PPDDS may represent any one of a number of conceptually distinct states, including organic or medical factors, acute or chronic use, discontinuation of a variety of medications or substances, mood or parkinsonian side effects to antipsychotic medications, an expression of the "negative" symptoms of schizophrenia, an acute or chronic disappointment reaction, the prodrome of relapse into a new psychotic episode, an expression of schizoaffective disorder, or the expression of a diathesis of affective disorder distinct from the schizophrenia diathesis. In each case, appropriate psychopharmacologic and psychosocial management of the condition is crucial for preventing suffering and promoting functioning.

Definition

Proteins present at the dense postsynaptic membrane complex characteristic of excitatory glutamatergic synapses in the brain. Definition

Post-translational modifications (PTMs) are chemical alterations to a primary protein structure, often crucial for rendering a protein its biological activity. PTMs are usually catalyzed by substrate-specific enzymes (which themselves are under strict control by PTMs). The covalent alteration of one or more amino acids occurring in a protein after the protein has been completely translated and released from the ribosome.

Post-Traumatic Stress Disorder

PTSD

Definition
This is an emotional condition or illness resulting from quite frightening or life-threatening experiences. Those who suffer from the disorder continually reexperience the precipitating traumatic events in some way and tend to avoid all places and people that are associated with those events. They are usually quite sensitive to normal life experiences (hyperarousal). Although the symptoms of PTSD were described during the American Civil War and World War I, only since 1980 has PTSD been recognized as a formal diagnosis. Approximately 7 to 8% of people in the USA develop PTSD in their lifetime, while the prevalence of the disorder among combat veterans and rape victims ranges from 10 to as high as 30%.

Potency

Synonyms
Measure of drug activity

Definition
A measure of the concentration of a drug at which it is effective. Commonly expressed as the ED_{50} or EC_{50}, the concentration of an agonist or PAM that produces 50% of its maximal possible effect, or IC_{50}, the concentration of a compound that produces 50% of its maximal possible inhibition. A highly potent drug evokes a larger response at low concentrations. A compound's potency is proportional to its affinity and efficacy.

Power Spectral Analysis

Synonyms
Fourier analysis of time series; Fourier transform; Frequency estimation

Definition
Power spectral analysis refers to a collection of methods used to decompose a time series of data into its elementary frequency (i.e., defined physically in cycles/s or Hertz) components. A power spectrum is a function that describes the frequencies of oscillation present in the original time series and the power or variance that each frequency contributes to the amplitude changes recorded in the original time series. The method allows one to discover in the power spectrum the presence of repeatable rhythms in what may appear to be a largely random process when seen in the original time series.

Pramipexole

Definition

Pramipexole is a non-ergot dopamine D2, D3, D4 agonist with strong preference for the D3 receptor. It is approved for the treatment of ► Parkinson's disease (PD) and restless leg syndrome (RLS). The mechanism of action of pramipexole in the treatment of PD is believed to be related to its ability to stimulate dopamine receptors in the striatum. Side effects in patients treated for PD include ► hallucinations and somnolence, including falling asleep during activities of daily living. There have also been occasional reports of ► gambling, compulsive shopping, and other excessive behaviors. The mechanism of action for RLS is not clear, as the neurobiology of RLS is still largely unknown. Pramipexole is currently being investigated for usage in severe fibromyalgia and depression.

Prediction Error

Definition

The mismatch between the unconditioned stimulus (UCS) expected and the UCS that in fact occurs, which generates new learning. The concept of prediction error arises directly from discrepancy theories of associative learning, for example, Rescorla–Wagner (1972). This is a terminology applied in classical (Pavlovian) conditioning and the importance of prediction error for new learning provides a constraint on the general importance of temporal coincidence as the sole determinant of new learning.

Predictive Validity

Definition

The term refers to one of the criteria used to assess the validity of animals models for psychiatric states. A similarity in response to a manipulation in the model and in the human syndrome is indicative of predictive validity. Most commonly, this refers to the actions of drugs that alleviate or worsen the condition; predictive validity is high if drugs known to alleviate the disease in humans also attenuate the measures taken in the model, and if drugs that do not work in the human are also ineffective in the model. Such a model may have the ability to predict the effectiveness of a drug in humans.

The prefrontal cortex is the entire part of the cerebral cortex that is located in front of the premotor areas. It plays an important role in ► executive function, complex cognitive behaviors, ► working memory, ► attention, expression of personality, and appropriate social behavior. It has been subdivided into the medial prefrontal cortex, involved in behavioral error monitoring; ventral/orbital prefrontal cortex, related to emotional control; and dorsolateral prefrontal cortex, related to spatial working memory and executive functions. Recent evidence suggests that additionally, the frontal pole (the anterior tip of the brain) is an important component involved in executive functions. The prefrontal cortex is needed for behavioral planning, categorizing and sequencing complex actions. It is supplied by inputs from association cortices and receives strong dopaminergic, noradrenergic, serotonergic and cholinergic inputs that modulate its activity. Premenstrual Dysphoric Mood Disorder

Synonyms
Late luteal phase dysphoric disorder; Premenstrual syndrome; Premenstrual tension

Definition
Premenstrual dysphoric disorder (PMDD) affects 3–5% of premenopausal women and is characterized by moderate to severe mood symptoms, with or without physical symptoms. Symptoms are present during the week prior to menstrual flow and absent in the postmenstrual week. Women must experience at least one of four key mood symptoms (irritability, mood lability, anxiety/tension, or depressed mood) and have at least five symptoms in total in order to meet the research diagnostic criteria included in the Diagnostic and Statistics Manual for Mental Disorders, Fourth Edition [DSM-IV] (American Psychiatric Association 2000). Physical symptoms frequently include breast tenderness, bloating, fatigue, and cramping, while irritability, anxiety/tension and depressed mood are the three most common mood symptoms, in that order). Women with

PMDD are symptomatic during the majority of menstrual cycles and note a significant impairment in important areas of daily functioning during the ► premenstruum. PMDD is not merely the worsening of an on-going psychiatric disorder or a state that is secondary to a general medical condition. Importantly, two months of ► prospective daily ratings are required to confirm the diagnosis of PMDD.

Relationship of PMDD to Other Premenstrual Syndromes

After some debate, late luteal phase dysphoric disorder was renamed PMDD and included in Appendix B of the ► DSM-IV, which provides research criteria for disorders requiring further study. PMDD and PMS are often used interchangeably; however, there are diagnostic differences that warrant consideration (Table 1). Much of the world refers to premenstrual mood and physical distress as premenstrual tension syndrome (PMTS), a diagnosis found in the World Health Organization (WHO)'s International Classification of Diseases, tenth edition (► ICD-10). PMDD has several features that distinguish it from PMS (American College of Obstetrics and Gynecology [ACOG] criteria) and PMTS (ICD-10 criteria), as outlined in the following text. The timing of symptoms with respect to the menstrual cycle is consistent among the two diagnoses. However, the number, type, and severity of symptoms are highly divergent, with the diagnosis of PMDD being far more stringent, emphasizing the affective symptoms that are not merely the worsening of an ongoing psychiatric disorder (Freeman 2003; Halbriech 2007).

PMDD is also associated with significant impairment in at least one domain of daily functioning. Women typically report that impairment is greatest in the interpersonal realm, at home with family and friends.

Role of Pharmacotherapy

The symptoms of PMDD occurring during the luteal phase suggest that ovulation and its associated fluctuations in ovarian steroids are important for the manifestation of symptoms. A seminal study found that women with PMDD experienced symptom improvement with ► gonadotropin releasing hormone (GnRH) agonist treatment, only to experience a return of mood symptoms when estradiol or progesterone was added back. These data support the theory that women with PMDD, but not healthy controls, are "sensitive" to ovarian hormone exposure. While the suppression of ovulation with GnRH agonist treatment is effective in the majority of women with PMDD, it is not a long-term treatment option secondary to the negative health effects of extended hypoestrogenism in young premenopausal women. Interestingly, ovulation suppression with oral contraceptives is not effective and can worsen mood symptoms in women with PMDD. An exception to this is contraceptive treatment with agents containing the progestin drosperinone, which have shown greater efficacy than placebo in controlled trials (Pearlstein et al. 2005; Yonkers et al. 2005).

The mainstay of treatment for PMDD includes daily or luteal phase administration of a selective serotonin reuptake inhibitor (SSRI). SSRIs are well tolerated and a majority of women respond within the first few days of medication use. That PMDD is preferentially responsive to treatment with SSRIs versus antidepressants with alternative mechanisms of action is one factor that implicates

► serotonin in the pathogenesis of PMDD. However, the rapid onset of symptom relief with SSRI administration suggests that the pathogenesis of PMDD is distinct from other disorders (e.g., ► major depression, ► panic disorder, ► obsessive–compulsive disorder) for which SSRIs are effective therapies. Moreover, the rapid onset of effectiveness also appears to implicate other neurotransmitter systems, such as gamma aminobutyric acid (► GABA), in symptom expression and response to treatment (Amin et al. 2006; Epperson et al. 2002). ► SSRIs increase allopregnanolone, a potent $GABA_A$ receptor agonist. Table 2 provides doses of each of the SSRIs that have been shown to be effective in the treatment of PMDD.

Daily Administration

A recent meta-analysis of 12 randomized, placebo-controlled studies confirmed that the daily administration of an SSRI is effective in the treatment of PMDD (Brown et al. 2009). Several, but not all, of these studies found clinically meaningful improvement in physical symptoms such as breast tenderness, cramping and bloating, in addition to improvements in irritability and other behavioral symptoms. Daily administration is ideal for women with shorter cycles who have severe symptoms starting at the time of ovulation that extend into the first week of menstrual flow. Such women are symptomatic much of the month and could benefit from continued treatment. Certainly, if there is any question that a woman may have mild depression, recurrent brief depression, dysthymia, or generalized anxiety disorder, it would be preferable to use daily administration until one of these other disorders that frequently masquerade as PMDD could be ruled out. In a study of women claiming to have PMDD who presented to a premenstrual dysphoric disorder specialty program, over 30% were diagnosed with a mood and/or anxiety disorder (Bailey and Cohen 1999). As the overlap in the type of symptoms seen in PMDD and a number of other psychiatric disorders is considerable, the importance of using daily ratings to examine the pattern of symptom onset and offset cannot be underestimated.

Luteal-Phase Administration

A review of 12 randomized, placebo-controlled clinical trials provides strong evidence that intermittent or luteal phase treatment with an SSRI is effective in the treatment of PMDD (Brown et al. 2009). Luteal phase administration is best reserved for women whose daily ratings and clinical evaluation clearly confirm the diagnosis of PMDD. The benefit of luteal phase administration is considerable. Drug costs are lower and many women prefer to use a medication on an as-needed basis. Luteal phase administration with a shorter half-life SSRI (e.g., sertraline, paroxetine CR) is preferable for women who experience significant changes in sexual function/interest when using an SSRI. Interestingly, the tolerability of going on and off an SSRI seems to be more than adequate. However, women who discontinue SSRI treatment for PMDD are at high risk for having a return of symptoms in the subsequent luteal phase (Pearlstein et al. 2003).

Conclusions

PMDD is a relatively common clinical phenomenon with the onset during the teen years and the early 20s. That PMDD is preferentially responsive to SSRI treatment and returns upon medication discontinuation provides support for serotonin and menstrual cycle related fluctuation in ovarian hormones in the pathogenesis of PMDD. The completion of 2 months of prospective daily ratings is not only required for the diagnosis, but it is also crucial for women who wish to use the luteal phase administration of an SSRI.

Premenstruum

Definition

The premenstruum is a term used by clinicians and researchers for the portion of the menstrual cycle that occurs immediately prior to the onset of menstrual flow. While there is no specified number of days referred to as the premenstruum, it typically includes the few days to a week prior to the onset of menses.

Premonitory Urge

Definition

By age 10 years, many patients with ► tic disorders will describe a feeling or urge prior to the execution of their tics. This sensation or warning may be located at the anatomical site of the tic or may be described as a more general feeling of unease or discomfort. Patients who describe the premonitory urge often report that there is momentary relief from this sensation following the performance of the tic.

Prenatal MAM Model

Definition

An animal model in which pregnant female rats are treated with the drug methylazoxymethanol (MAM). MAM blocks mitosis for a period of about 24 h and thus interfere with normal (brain) development. Depending on the timing of the MAM treatment, different brain regions will be more or less affected, leading to different behavioral alterations in adulthood. Although different protocols exist, the model most often used as a simulation model for ► schizophrenia involves treatment on gestational day 17. Definition

The "prodromal phase" that precedes a first psychotic episode is a period characterized by increasing levels of nonspecific subthreshold symptoms associated with significant distress and growing functional impairment. This phase often continues for several years prior to the emergence of diagnostically-specific psychotic symptoms, with significant social disability becoming apparent well before the first psychotic episode. Because the psychotic disorders usually manifest during adolescence, a period of major developmental change, they may have particularly devastating consequences on lifetime functioning, highlighting the need for early intervention in order to minimize ongoing disability.

Role of Pharmacotherapy

The psychotic disorders occur at a frequency of around 2% in the general population and thus are relatively rare. However, their onset is most common during late adolescence and early adulthood, a period of life where critical developmental tasks are being accomplished in the psychological, social, educational, and vocational domains. Because serious mental illness substantially disrupts these processes and often leads to ongoing long-term disability, the early detection and treatment of people at risk of psychosis, before the onset of frank psychotic disorder, has long been a major goal in psychiatric practice.

The existence of a prodromal phase prior to a first episode of psychosis or a relapse of ► schizophrenia was noted over a century ago, prompting the first calls for early treatment as a means of preventing serious illness and ongoing disability. However, until relatively recently, research into the possibilities for early intervention has been limited by the lack of effective treatments, as well as the widespread perception that the ongoing disability associated with the psychotic disorders was inevitable. Over the last decade the advent of more effective drugs, particularly the atypical antipsychotics, and the development of better psychosocial treatments has led to the realization that good long-term outcomes are possible for patients and rekindled interest in the area of early intervention. An important result of this renewed research effort is a series of careful epidemiological studies that have enabled the characterization of the "psychosis prodrome," a significant advance which has finally allowed early therapeutic intervention in the psychotic disorders to become a real possibility. These research findings have now been translated into evidence-based clinical practice in a growing number of specialized early intervention services worldwide and have made a major contribution to the improved outcomes that are now expected for young people who are experiencing the onset of a psychotic illness (Yung et al. 2004).

Retrospective studies of first-episode psychosis patients, examining the course of illness from the premorbid period through to the emergence of frank psychosis, have shown that the first episode is almost always preceded by a prodromal period of several years that are characterized by increasing levels of psychological symptoms, significant distress, and a marked decline in social and vocational functioning compared to pre-morbid levels. In general, negative symptoms such as decreased concentration, reduced drive, and lack of energy predominate early in the prodromal phase, accompanied by nonspecific symptoms including sleep disturbance, anxiety, and irritability. Affective symptoms, primarily depression, are also common. These symptoms tend to accumulate exponentially until relatively late in the prodrome, when subthreshold positive symptoms (psychotic symptoms) emerge. Ultimately, these positive symptoms intensify and culminate in the transition to frank ► psychosis. Typically, increasing levels of social and vocational disability accompany the increase in symptomatology, with significant disability becoming apparent well before the first psychotic episode. The degree of disability that develops during the prodromal period appears to set a ceiling for the extent of the eventual recovery, highlighting the need for early intervention (Yung et al. 2004).

Because these prodromal symptoms, including subthreshold psychotic-like experiences, are nonspecific and occur frequently in the general population, especially among adolescents and young adults, they cannot be considered as diagnostic of a pre-psychotic state in their own right. Additional risk factors and specific criteria are necessary to exclude false positive cases in order to avoid unnecessary treatment and the stigma often associated with the diagnosis of a mental illness. In order to increase the prognostic specificity of these prodromal symptoms, two additional risk factors have been developed based on

our clinical experience and the available epidemiological evidence, to add to the screening criteria. The first of these is being aged between 14 and 30, since young people in this age range are at greatest risk of developing a psychotic disorder. The second is a need for clinical care, since young people who are not distressed by their symptoms and who have not experienced a decline in their functioning are less likely to become seriously unwell in the near future. A careful prospective study of a young, help-seeking population identified a subset of young people who appear to be at incipient risk of frank psychosis. The specific criteria defining this ultra-high risk (UHR) group fall into three groups (1) having experienced attenuated psychotic symptoms during the previous year; (2) having brief episodes of frank psychotic symptoms that resolve spontaneously over the previous year; and (3) having a schizotypal personality disorder, or a first degree relative with a psychotic disorder, and recently experiencing a significant decline in functioning (Table 1) (McGorry and Singh 1995; Yung and McGorry 1996). Up to 40% of the young people who met these UHR criteria made a transition to psychosis within the following year, a rate several hundred-fold greater than the expected incidence rate for first-episode psychosis in the general population. These criteria have since been validated in a series of international studies. However, it should be borne in mind that while they do identify a group of young people who are at incipient risk of psychosis, the identification itself is by no means a diagnosis per se; the majority of young people who fulfill the UHR criteria do not develop a full-threshold psychotic disorder.

The elaboration of operationalized criteria that significantly reduce the risk of inappropriate treatment has not only proven to be clinically useful, but has also catalyzed renewed efforts into developing effective early intervention strategies designed to prevent, or at least delay the onset of psychosis and other serious mental illness. Clearly, the young people who fulfill these UHR criteria have demonstrable clinical needs, and thus effective treatment is called for not only on human, but also on medical and ethical grounds. Current early intervention strategies range from the psychologically-based, including psychoeducation, supportive psychotherapy, cognitive behavioral therapy (CBT), and family work; to the biologically-based, including symptomatic treatment for depression, anxiety and any sub-threshold psychotic symptoms, through to experimental neuroprotective approaches. The global aim of treatment in the prodromal phase is to provide comprehensive clinical care designed to reduce presenting symptoms, and if possible, to prevent these symptoms from worsening and developing into an acute psychosis.

Currently Accepted Strategies for Treatment of Prodromal Symptoms

Studies have shown that around 25% of these at-risk young people have a concomitant diagnosis of depression, and that over 60% of UHR patients will experience a depressive disorder during their lifetime. Thus, treatment

Pre-psychotic States and Prodromal Symptoms. Table 1. Ultra High Risk criteria: (1) must be aged between 14 and 29 years, (2) have been referred to a specialized service for help, and (3) meet the criteria for one or more of the following three groups.

Group 1: Attenuated positive psychotic symptoms	• Presence of at least one of the following symptoms: ideas of reference, odd beliefs or magical thinking, perceptual disturbance, paranoid ideation, odd thinking and speech, odd behavior and appearance • Frequency of symptoms: at least several times a week • Recency of symptoms: present within the last year • Duration of symptoms: present for at least 1 week and no longer than 5 years
Group 2: Brief limited intermittent psychotic symptoms	• Transient psychotic symptoms. Presence of at least one of the following: ideas of reference, magical thinking, perceptual disturbance, paranoid ideation, odd thinking or speech • Duration of episode: less than 1 week • Frequency of symptoms: at least several times per week • Symptoms resolve spontaneously • Recency of symptoms: must have occurred within the last year
Group 3: Trait and state risk factors	• Schizotypal personality disorder in the identified individual, or a first-degree relative with a psychotic disorder • Significant decline in mental state or functioning, maintained for at least 1 month and not longer than 5 years • This decline in functioning must have occurred within the past year

with cognitive behavior therapy and/or antidepressants, most commonly the ► SSRIs, may be indicated. These therapies are generally well-accepted and well-tolerated by this patient group, and lead to significant clinical improvement. Some preliminary evidence suggests that antidepressants may have a protective effect if initiated early enough in the illness process; effective treatment of depression may help to limit the development of negative symptoms and social withdrawal. ► Anxiety is also extremely common in this patient group, with around 25% of these young people having a current diagnosis of an anxiety disorder, while around 30% experiences an anxiety disorder in their lifetime. ► Benzodiazepines may be prescribed to relieve short-term anxiety and sleep disturbance and to reduce agitation. Because anxiety tends to increase as positive symptoms develop, effective treatment of anxiety may help to relieve the stress associated with any subthreshold psychotic symptoms that may be present, and allow the patient to better cope with social and vocational difficulties as they arise, limiting the functional decline that occurs during the prodromal period (Yung et al. 2004).

Subthreshold psychotic symptoms are almost inevitably present in UHR patients. However, in general, antipsychotic treatment should be avoided if at all possible. Indications for antipsychotic treatment include rapid deterioration, hostility, and aggression that poses a risk to the patient or others, severe suicidality, or depression that does not respond to other treatments. Antipsychotics may also be trialed for patients who have not responded to psychosocial interventions and who are still unwell and functioning poorly. If medication is warranted, the ► atypical antipsychotics should be used on a trial basis for a limited time only, and at the lowest dose possible, to minimize the risk of extrapyramidal side effects (see below). If there is clinical benefit and resolution of symptoms after 6 weeks, the medication may be continued for a further 6 months to 2 years, with the consent of the patient (Yung et al. 2004).

The atypical antipsychotics are the agents of first choice for young patients since they have been shown to be associated with fewer extrapyramidal side effects than the potent first-generation agents. Apart from the movement disorders, the major side effects reported for the atypical agents include significant weight gain and an increased risk of diabetes and metabolic disturbance. Other common side effects include sedation, fatigue, and decreased libido, and less commonly, prolactinemia and cardiac arrhythmias. In the few studies involving first-episode and prodromal patients that have been published so far, apart from weight gain, the other side effects reported have been relatively mild and/or transient, and thus the atypical antipsychotics appear to be well tolerated in this vulnerable patient group (International Early Psychosis Association Writing Group 2005).

Experimental Strategies for Short-Term Symptomatic Treatment of Prodromal Patients

The safety and efficacy of two atypical antipsychotics, ► amisulpride and ► aripiprazole, for the relief of symptoms in young people at incipient risk of psychosis has been tested in two recent clinical trials. One of these involved a group of 124 young people, where participants received amisulpride (flexibly dosed at 50–800 mg/day) plus needs-based psychosocial support, or psychosocial support alone for a period of 12 weeks (Rurhmann et al. 2007). Regardless of their treatment group, participants were permitted to take ► citalopram for moderate to severe depression, and ► lorazepam, ► temazepam, or ► chloral hydrate for agitation or sleep disturbances, and if necessary, biperiden was prescribed for extrapyramidal symptoms. While both groups improved over the course of this study, the amisulpride group showed a reduction in symptoms that was at least double that of the control group across a range of measures designed to assess the levels of positive and negative symptoms, as well as general psychopathology. Both groups also showed an improvement in their levels of functioning, and again, this was significantly greater in the amisulpride group than in the control group.

The final mean daily dose of amisulpride was 118.7 ± 10.7 mg, which was well within the lower end of the dose range. Four of 61 participants in the amisulpride group developed ► akathisia, compared to 1 of 43 in the control group, with biperidin being prescribed for 3 of the 4 participants from the amisulpride group. The most frequent side-effects associated with amisulpride were related to a marked increase in prolactin levels, commonly seen in response to the benzamides, particularly when associated with an SSRI. As a consequence, transient menstrual disturbances emerged in 4 females, 1 developed a prolonged cycle, and 1 dropped out due to amenorrhoea. Two males developed erectile and ejaculatory dysfunction, and 1 other decreased desire and ► erectile dysfunction (Rurhmann et al. 2007).

In the second study, the safety and efficacy of 5–30 mg/day aripiprazole for symptomatic relief was been tested in an 8-week pilot trial of 15 young people experiencing attenuated positive symptoms (Woods et al. 2007). All participants were permitted to continue any antidepressant, mood stabilizing, or stimulant medication that they had been prescribed, but not to begin new

medications or change existing doses during the study period. However, lorazepam was allowed for anxiety or agitation, and benztropine was prescribed for extra-pyramidal symptoms, if necessary. Individual and family-centered psychosocial support was available for all participants.

At the end of the study, the mean daily dose of aripiprazole was 15.67 mg, and adherence to medication was over 90% for the entire study period. Eleven of the 15 participants were no longer experiencing positive symptoms, and all participants showed a significant improvement in their levels of positive, negative and general symptoms and in their overall functioning. Notably, while the 2 participants who completed the study without responding to aripirazole chose not to continue treatment, the remaining 11 participants elected to remain on medication. The most common adverse effect reported was emergent akathisia, which occurred in 8 participants, though this usually remitted after management, with 4 participants requiring benztropine at the end of the trial. Weight gain was minimal, with a mean of 1.2 kg gained over the trial period (Woods et al. 2007).

Experimental Strategies Designed to Prevent the Onset of Psychosis

To date, only three clinical trials of pharmacological treatments specifically designed to prevent the onset of psychosis have been published. Our group ran the first of these trials, which aimed to test the efficacy of 6 months of low dose ▶ risperidone treatment plus CBT in preventing the onset of psychosis in a group of 59 UHR young people recruited from within our clinical service (McGorry et al. 2002). Participants were randomized to either the control group or the intervention group, with the control group receiving supportive psychotherapy and general case management. As well as these elements, the intervention group undertook a CBT program designed to develop an understanding of their symptoms, to learn strategies to enhance their control of these symptoms and to reduce associated distress. In addition, this group received 1–2 mg of risperidone daily for the 6 months of the treatment phase. Risperidone therapy was commenced at 1 mg/day then increased to 2 mg/day provided no adverse effects were experienced, and if necessary, the dosage was reduced to 1 mg/day. All participants were permitted to take sertraline for moderate to severe depression, and temazepam for insomnia.

At the end of the 6-month treatment phase, 3 of the 31 young people in the intervention group had developed frank psychosis, compared to 10 of the 28 in the control group. However, by the 12-month assessment another 3 patients in the intervention group had made a transition to psychosis, while no more transitions had occurred in the control group. Adherence to the CBT component was high, while adherence to risperidone therapy was variable; 13 patients were classed as non-adherent (<50% of doses taken), 4 as partially adherent (>50% of doses taken), while 14 were considered fully adherent (almost 100% of doses taken). Interestingly, only 1 of the patients considered fully adherent developed frank psychosis. Adverse effects were noted in only 4 patients; 1 developed minor rigidity and 3 experienced mild sedation, and all were relieved by lowering the dose of risperidone. The mean final dose was 1.3 ± 0.901 mg/day. Not surprisingly, the use of ▶ sertraline was lower in the intervention group (41.9%) than in the control group (60.7%). Sertraline treatment did not affect the rate of transition to psychosis in the control group, since this was not significantly different in those who had been prescribed sertraline and those who had not (McGorry et al. 2002).

Medium-term follow-up of our study cohort 3–4 years after initial assessment showed that a further 4 patients from the intervention group and 2 from the control group had become psychotic since their 12-month assessments, which indicates that the "window of vulnerability" in these UHR young people continues well beyond the first year after their presentation to a clinical service and initial treatment. Over 80% of all participants reported that they had sought professional help for psychological concerns since their 12-month assessment, and among those who had not developed frank psychosis, 70% of those in the control group and 54% of the intervention group had been prescribed either antidepressants or anxiolytics over this period, emphasizing the need for care in these young people who although not psychotic, are significantly compromised by their illness (Phillips et al. 2007).

The second trial was designed to test the safety and efficacy of ▶ olanzapine at doses of 5–15 mg/day in preventing the onset of psychosis in a group of 60 UHR young people (McGlashan et al. 2006). Participants were recruited after referral by clinicians or in response to advertisements, and randomly assigned to either the olanzapine or the placebo groups. In this study, concomitant psychoactive medications were not allowed, and all participants had access to supportive psychosocial interventions as needed. The treatment phase ran for 12 months, and was followed by a 12-month follow-up period and a 6-month period of open-label olanzapine treatment for all patients who experienced a conversion to psychosis.

At the end of the 12-month treatment phase, 5 of the 31 participants who had received olanzapine treatment had become psychotic, compared to 11 of the 29 participants in the placebo group. All 5 patients from the olanzapine group who converted to psychosis did so within the first 4 weeks of the treatment phase, while the 11 patients from the placebo group who made this transition did so throughout the entire 12 months of the treatment phase. Those in the olanzapine group showed an improvement in their levels of positive symptoms that was not seen in the placebo group, while both groups showed an improvement in their overall levels of functioning. Notably, during the 12-month follow-up after all medication was ceased, positive symptoms worsened in both groups, with the participants from the former olanzapine group showing a statistically significant increase in the levels of positive symptoms experienced. During this period, 3 of the 9 patients remaining in the study from the former olanzapine group converted to psychosis, while 2 of the 8 remaining placebo group patients developed psychosis. The only significant adverse effects associated with olanzapine treatment were fatigue and weight gain, with 29% of the participants in the olanzapine group reporting fatigue compared to 3% in the placebo group, and 61% of the olanzapine group showing weight gain compared to 17% in the placebo group. The mean weight gain in the olanzapine group was 8.79 ± 9.05 kg, or 12.7% of the mean body weight, while that in the placebo group was 0.3 ± 4.24 kg, in line with other studies in patients suffering from schizophrenia. However, this weight gain was not accompanied by changes in blood laboratory values suggesting an increased risk of cardiovascular disease or diabetes (McGlashan et al. 2006).

A very recent study involved the use of omega-3 essential fatty acids (EFA) for indicated prevention of psychosis in a group of 81 UHR young people (Amminger et al. 2009). Participants were randomized to either the placebo group or the EFA group, and underwent a 12-week trial of treatment with 1.2 g/day EFA (a balanced mix of 700 mg EPA+480 mg DHA) and a 12-month follow-up period. All participants were offered the same psychosocial support package, and antidepressants and benzodiazepines were allowed for the treatment of depression and anxiety, if necessary. Significantly, at the end of the 12-month follow-up period, 2 of the 41 (4.9%) participants in the EFA group had made the transition to frank psychosis, compared to 11 of the 40 (27.5%) participants in the placebo group. Significant reductions in the levels of positive, negative, and general symptoms were seen in the EFA group, along with an increase in overall functioning, and most interestingly, these benefits were continued after the cessation of the 12-week intervention phase. Furthermore, the number needed to treat (NNT) of 4 calculated in this study compared favorably to the NNTs of 4 and 4.5 that were reported in the trials of the antipsychotics described earlier (McGlashan et al. 2006; McGorry et al. 2002). No adverse effects were reported in either group, while the high level of compliance (over 80%) and low withdrawal rate (6% overall) indicate that this intervention was very well accepted by the participants.

This extremely promising study is the first trial of a natural substance for the indicated prevention of psychosis and the alleviation of prodromal symptoms. The evident clinical benefits and the absence of side effects suggest that the omega-3 fatty acids may indeed be a viable alternative to antipsychotic medication, offering a similar degree of overall therapeutic gain without the potentially serious and often distressing side effects associated with these agents.

Given the marked symptomatic improvements seen in response to low doses of antipsychotic medication, these preliminary studies suggest that the atypical antipsychotics may provide significant therapeutic benefits to prodromal patients, particularly those with subthreshold psychotic symptoms. Furthermore, these agents, either alone or in combination with CBT, may at least delay progression to full-blown psychosis in UHR patients. Their relatively favorable side-effect profiles means that at low doses the atypical antipsychotics were generally safe and well tolerated in this patient group; however, further large scale placebo-controlled trials are necessary to establish the risk/benefit ratio of these interventions before evidence-based treatment recommendations can be made for either the antipsychotic medications or more experimental neuroprotective agents such as the omega-3 fatty acids.

Conclusions

Current clinical experience indicates that young people experiencing prodromal symptoms, and in particular those at UHR of developing a psychotic disorder, should be treated with the aim of ameliorating their symptoms and preventing further deterioration in the course of their illness. The results of the few experimental trials that are currently available indicate that these young people may benefit from various therapeutic intervention strategies including cognitively-oriented psychotherapy and/or specific indicated prevention with low-dose atypical antipsychotic medication or neuroprotective agents such as the omega-3 fatty acids, and that treatment should be continued for longer than 6 months, given that these patients remain symptomatic and vulnerable to the onset of psychosis well after their initial detection and

treatment. However, since the evidence for the use of antipsychotics in prodromal patients is still preliminary, their use has not yet been endorsed in routine clinical practice. At this stage, indicated prevention for the psychotic disorders remains a major goal for researchers in this area.

Apart from relieving the increasing distress and disability associated with prodromal symptoms, early intervention provides numerous other advantages to these vulnerable young people. Effective treatment allows them to remain in education, training, or employment, with minimal disruption due to illness and thus they maintain better levels of social functioning and a higher quality of life than might otherwise be expected. Early engagement in therapy means that even those who do become psychotic can be treated promptly without needing emergency or inpatient care, thereby avoiding the distress and trauma associated with psychiatric hospitalization. Finally, early intervention and effective treatment allows the best chance of a full social and functional recovery, the best possible outcome in both economic and human terms.

Prepulse Inhibition

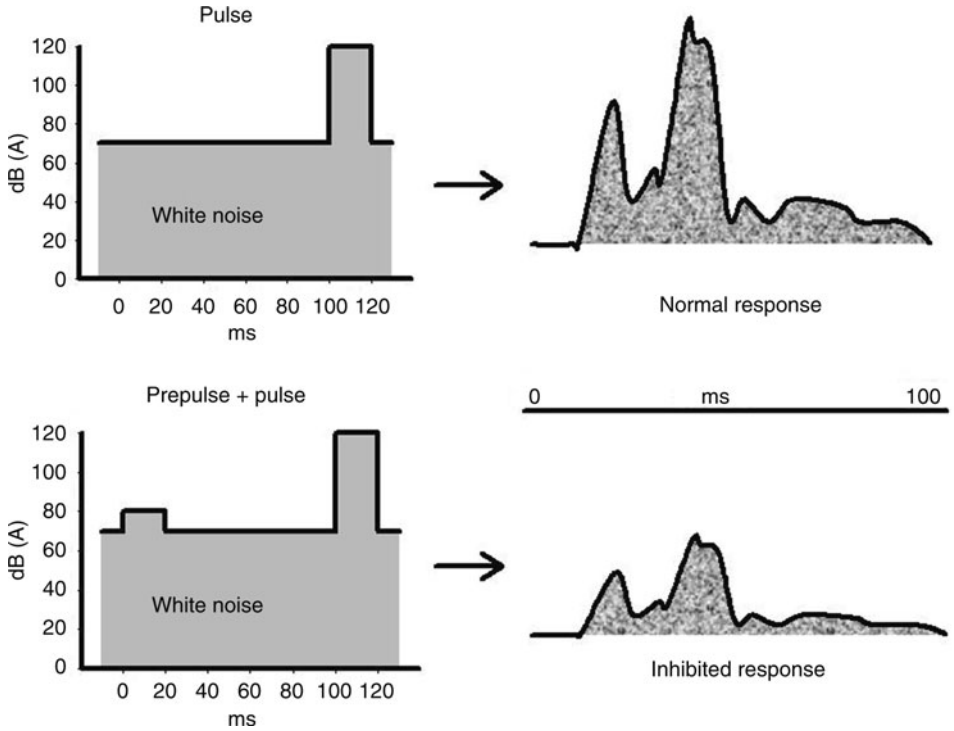
Definition

When mammals are exposed to a sudden stimulus, typically a loud acoustic noise, a startle response is elicited. Prepulse inhibition of the startle response, an operational measure of sensorimotor gating, is a cross-species measure of the normal decrement in startle when a barely detectable prestimulus immediately precedes (30–500 ms) a startling stimulus (see Fig. 1) (Graham 1975; Ison and Hoffman 1983). While the startling event is typically an acoustic or tactile (e.g., airpuff or shock) stimulus having a rapid onset, the prepulse or prestimulus can be in the same or different modality, including light, electrical shock, airpuff, sound, or brief gap in the background noise.

Impact of Psychoactive Drugs

Attentional and information processing dysfunctions have long been considered important in understanding schizophrenia and other psychiatric disorders. Prepulse inhibition is disrupted in certain neuropsychiatric disorders that are characterized by an inability to filter or "gate" sensory (and, theoretically, cognitive) information. Theoretically, impairments in basic information processing functions such as sensorimotor gating contribute to disordered thought and cognitive fragmentation observed in psychotic disorders such as ► schizophrenia (Braff and Geyer 1990). Prepulse inhibition is used commonly as an operational measure of sensorimotor gating in studies in rodents, infrahuman primates, and humans. Patients with schizophrenia exhibit reduced sensorimotor gating as indexed by prepulse inhibition when compared to healthy control subjects and several categories of nonpsychotic



Prepulse Inhibition. Fig. 1. Diagrammatic representation of prepulse inhibition of startle. The top panel illustrates a pulse-alone trial in which startle is elicited by a 120 dB(A) noise burst above a 70 dB(A) background. The startling stimulus is presented for 20 msec in this example. The startle response is typically measured for 100 (rodents) or 250 (humans) msec after the on set of the pulse. The lower panel illustrates the prepulse-plus-pulse trail, in which startle inhibited by a weak (e.g. 80 dB(A) prepulse given 30-1000 msec (in this example 100 msec onset-to-onset) before the same startle-eliciting noise used in the pulse-alone trial. In experiments examining tactile rather than acoustic startle, the pulse is an air-puff or mild electric shock to the neck (humans) or back (rodents). The right side of each panel illustrates the measured response, typically assessed using the electromyographic signal from orbicularis occuli muscle as a measure of the eyeblink response in humans or using an accelerometer-based signal as a measure of the whole-body flinch response in rodents. A typical test session includes presentations of serveral pulse-alone trials and several occasions of prepulse trials that may vary in the intensity of the prepulse stimulus or the interval between the prepulse and pulse onsets.

psychiatric disorders (Braff et al. 2001). Strikingly, similar prepulse inhibition abnormalities have also been observed in unmedicated and non-psychotic schizotypal patients and asymptomatic first-degree relatives of schizophrenia patients, supporting a strong role for genetic influences on sensorimotor gating. The reproducibility of the finding in schizophrenia, the fact that abnormal prepulse inhibition parallels a putative central abnormality in the disease, and the fact that prepulse inhibition is a conserved phenomenon among vertebrates make prepulse inhibition a promising candidate ► endophenotype to use in genetic association studies and animal models of schizophrenia (Swerdlow et al. 2009). The identification of genetic contributions to startle and prepulse inhibition in humans can be readily confirmed and extended in parallel studies using genetically engineered mice or other relevant strains of rats or mice (Geyer et al. 2002).

Using startle plasticity measures such as prepulse inhibition is advantageous in neuroscientific research for a number of reasons. First, startle plasticity in rodents has proven face, predictive, and construct validity for startle plasticity in humans. Second, startle behavior remains relatively stable across repeated testing sessions in mice, rats, healthy humans, and clinically stable psychiatric patients. This stability enables one to use longitudinal designs to explore developmental and environmental perturbations on prepulse inhibition over time and across experience. Third, startle and prepulse inhibition involve fairly rapid tests that do not involve complex stimuli, increasing their ease of use and their reliability. Since

startle relies on a simple reflex measure, its reliability and reproducibility is greater than more complex behavioral measures that are modulated by competing behaviors or motivations (e.g., approach/avoidance behavior), and increases the chances of translation of these effects to humans. Fourth, the neuroanatomical and neurochemical substrates mediating and modulating startle plasticity are well defined, allowing greater hypothesis generation and interpretability before and after obtaining results.

The neuroanatomical substrates that contribute to the modulation of prepulse inhibition in rats have been studied extensively, providing an excellent example of the regulation of behavior by integrated neuronal circuits (Swerdlow et al. 2001). The deficits in prepulse inhibition observed in psychiatric patient populations appear to reflect abnormal information processing and may result from pathology within forebrain cortico-striato-pallidopontine circuitry that modulates this form of startle plasticity (Koch 1999; Swerdlow et al. 2001). Furthermore, a wide range of developmental and pharmacological manipulations have been found to alter prepulse inhibition in rats, leading to multiple rat models having utility in the identification of antipsychotic medications (Geyer et al. 2001). Prepulse inhibition has shown good predictive validity as a screen for ▶ antipsychotic drugs. In keeping with the ▶ dopamine hypotheses of psychotic disorders such as schizophrenia and mania, dopamine agonists such as ▶ apomorphine and ▶ amphetamine disrupt prepulse inhibition in rodents. These effects can be reversed by antipsychotics having selective antagonist effects at dopamine D2, but not dopamine D1 receptors. One important aspect of animal models of schizophrenia is their ability to distinguish between typical and atypical antipsychotic drugs. Prepulse inhibition deficits induced by apomorphine are reversed by both typical and ▶ atypical antipsychotics. Thus, although the ability of antipsychotics to restore prepulse inhibition in apomorphine-treated rats strongly correlates with their clinical potency, when used with the dopamine agonist apomorphine, this paradigm fails to make the important distinction between these two classes of antipsychotic drugs. In contrast, the prepulse inhibition disruptions produced by glutamate antagonists (e.g., ▶ phencyclidine, dizocilpine, and ▶ ketamine) differentiate between typical and atypical antipsychotics to some degree (Geyer et al. 2001). Specifically, typical antipsychotics such as ▶ haloperidol do not attenuate the prepulse inhibition-disruptive effects of glutamate antagonists in rats, while ▶ clozapine and some other atypical antipsychotics reduce the disruption in prepulse inhibition produced by these psychotomimetics in both rats and mice. Thus, prepulse inhibition already serves an important role in the identification of novel treatments for schizophrenia (Braff and Light 2004) and may ultimately contribute to our understanding of other psychiatric disorders such a ▶ bipolar disorder, ▶ panic disorder, and ▶ post-traumatic stress disorder.

Primary Insomnia

Definition

Primary insomnia is a complaint of difficulty in initializing or maintaining sleep or of non-restorative sleep that lasts for at least 1 month and causes clinically significant distress or impairment in social, occupational, or other important areas of functioning. The disturbance in sleep does not occur exclusively during the course of another sleep disorder or mental disorder and is not due to the direct physiological effects of a substance or a general medical condition.

Primate Models of Cognition

Angela Roberts

Definition

Cognition is an array of higher-order processes that occur between sensory processing and motor output and that are inferred from animals' behavior. It includes constructs such as attention, memory, and executive control, and the behavioral tests used to study such constructs need to provide specificity, selectivity, and reproducibility. All behavioral tests have in common the need for perception, action, and attention to varying degrees, and so it is important for any drug study that the test employed should differentiate effects caused by the modulation of one or the other of these processes, as well as the particular cognition under investigation. This is especially true when studying the actions of drugs given peripherally, which can have widespread influences in all regions of the brain including regions primarily involved in sensory processing or motor output.

Principles and Role in Psychopharmacology

Behavioral tests of cognition have had a long tradition in the field of primate neuropsychology. Originally, testing took place in the Wisconsin General Test Apparatus (WGTA) with the experimenter sitting in front of the monkey, behind a one-way mirror. Given that vision is an extremely important sense for monkeys, tests tended to be designed around objects or spatial locations. This contrasted with that of human neuropsychology in which the tests so often involved language and pen and paper. Consequently, the extrapolation of results from primate studies into the clinic was fraught with difficulty, as the tests used to measure a particular cognitive process differed considerably between humans and monkeys. After a seminal paper by L Weiskrantz, in 1977, the recognition of the advantages of testing humans and monkeys on the same tests led to much closer integration of human and monkey neuropsychological studies. In addition, the important advantages of automated and computer controlled testing devices over manually operated ones (e.g., WGTA) were recognized, eliminating experimenter–subject interactions and increasing the degree of experimental control and efficiency (Bartus and Dean 2009). However, the ease of presenting tests in the WGTA or other manually operated environments should not be underestimated, not least due to the comparative ease at which monkeys can learn a range of different cognitive tests when the response and the reward are spatially contiguous. The spatial (and thus also temporal) separation of a response and the associated reward recruits additional cognitive processes, probably dependent on the frontal lobes, which may not be the focus of interest, but may need to be taken into account when interpreting the results.

Currently, there are an array of cognitive tests designed to measure specific aspects of primate cognition, which are available for the psychopharmacologist. In many cases, it is possible to test monkeys on a battery of such tests allowing the effects of drugs to be compared across a range of different cognitive functions within the same animal.

Attention

Attention can be selective or ► divided, ► sustained or not. If selective, the attention may be directed at a specific spatial location or a particular sensory cue e.g., red circle. Alternatively, ► attention may transcend specific sensory cues and occur instead at the level of higher-order perceptual dimensions e.g., color or shape, in which case, it is said that an animal has developed an ► attentional set (see the section on Cognitive Flexibility). A variety of tests have been developed to study attentional abilities in monkeys and the majority of them are dependent on an intact frontal and parietal cortex. The serial reaction time task, first developed in humans and later used to study attention in rats, investigates the ability of monkeys to locate a briefly presented target in one of a number of

spatial locations (Spinelli et al. 2004; Weed et al. 1999). It tests aspects of both divided and selective attention. In a version for monkeys (Cambridge Neuropsychological Test Battery, ► CANTAB: Lafayette Instrument company), five circles are presented on a touch sensitive computer screen, and a small colored stimulus is briefly presented in one of those locations (Fig. 1a). To start each trial, the monkey must perform an orienting response to ensure readiness to perform the trial, i.e., press down a lever, and after a variable delay, respond to where they saw the colored stimulus. The demands on divided attention can be increased or decreased by altering the number of spatial locations in which the target stimulus may appear. In contrast, the level of selective attention can be modulated by varying the duration of the target presentation. Other manipulations involve altering the lengths of the inter-trial interval and the length of time the animal waits at the start of a trial for the onset of the target stimulus, both of which increase overall difficulty and reduce successful performance. Such manipulations are especially useful if the cognitive enhancing effects of a drug are under investigation. Another test of attention that assesses the monkey's ability to focus attention using advanced information is a cued reaction time test. Here, four outlines of circles are presented on a touch sensitive computer screen and similar to that described earlier, the monkey must depress a lever to start the trial and respond to the circle that turns white as quickly as possible. In a cued version, a cue light appears above the circle that will become the next target thereby improving the speed of reaction time to that target. By comparing reaction and movement times in the cued and uncued conditions, a specific measure of selective attention can be obtained (Decamp and Schneider 2004). A variation of this task, first developed by MI Posner and colleagues, tests the abilities of monkeys to shift visuospatial attention and includes trials in which the cue is invalid and the target appears on the side opposite to that of the cue. The difference in the speed of responding to a target at expected (valid) and unexpected (invalid) locations is taken as a measure of ability to shift attention.

Memory

Recognition Memory

The classic test of recognition memory or the judgment of the prior occurrence of an object involves monkeys being presented with a novel object and then, after a variable delay (e.g., 5 s to 24 h) being presented with two objects, the previously seen object and a novel object. In the ► delayed "match to sample" (DMS) version, monkeys have to select the previously seen object while in the ► delayed "non-match to sample" (DNMS) version monkeys have to choose the novel object. It was first described by M Mishkin and J Delacour in 1975. This test differs from the working memory tasks described in the following text in that each pair of objects is only seen once, or at least only once within a session and therefore tests the ability of monkeys to recognize objects as familiar or not. The presence of delay-dependent deficits is taken to indicate a mnemonic impairment while poor performance at very short delays might indicate, instead, a perceptual deficit. However, to avoid artifacts attributable to the provision of extensive experience at short delays, followed by testing with less familiar long delays, it is important to intermix different delay lengths. For psychopharmacological studies, it is often beneficial to titrate the duration of the delay interval of each monkey to obtain matched levels of performance accuracy. This helps to equate levels of difficulty across monkeys and to avoid ceiling effects in the highest performing monkeys (Buccafusco 2008). More recently, D(N)MS has been run with computer graphic stimuli presented on touch screen monitors (e.g., Fig. 1b) by a number of different research laboratories including those of D Gaffan and EA Murray. In the DMS version, the number of stimuli at the time of choice can be varied, along with the degree to which the different choices differ from one another perceptually. Drug manipulations during sample presentation, choice phase and during the retention interval can target ► encoding, ► retrieval and ► consolidation, respectively. Two distinct processes may underlie recognition memory, recollection, and familiarity judgment. Performance on this test is dependent upon an intact perirhinal cortex.

Visuospatial Memory

A variety of tests have been used to study visuospatial memory, which is the ability to integrate visual and spatial information and to recall that information subsequently. It is dependent on the ► hippocampus and related circuitry. One such test is a scene discriminations task in which, on each trial, an artificially constructed unique "scene" is presented consisting of randomly selected attributes including a colored background containing ellipse segments of different colors, sizes, and orientations and typographical characters (Gaffan and Parker 1996). In the foreground, one of two objects is rewarded. Monkeys learn these discriminations over a series of sessions in which each unique scene is presented once each session. Subsequently it is possible to investigate the ability of monkeys to recall these discriminations, to relearn them as well as to acquire new discriminations and thus, as for recognition memory,

to investigate encoding and retrieval. An alternative test, known as the paired associate learning test (vsPAL, CANTAB) involves learning to associate different patterns in distinct spatial locations (Fig. 1c). On any one trial (sample phase), one or more patterns may be presented, one at a time, in distinct spatial locations and the monkey must learn which pattern(s) is(are) associated with which spatial location(s). The monkeys are subsequently tested on this knowledge (choice phase) by presenting the pattern in two or more spatial locations and requiring them to respond to the pattern in the correct spatial location (Taffe et al. 2004). Performance on the first attempt of the choice phase is a test of how well monkeys recall the information. However, subsequently monkeys are presented the sample and choice phases, an additional number of times to determine how rapidly they can learn this information. Because on the first attempt, monkeys have to remember multiple information across a short delay, this test loads quite heavily on working memory and is sensitive to frontal lobe dysfunction. This particular test is able to differentiate probands who will subsequently be diagnosed with Alzheimer dementia as opposed to other forms of mnemonic deficit related to normal aging and depression.

Executive Functions

Executive functions can be thought of as general-purpose control mechanisms that coordinate specific cognitive processes in order to optimize performance. They include holding information on-line and updating information in working memory, marshaling attentional resources, monitoring behavior and its outcomes, and inhibiting inappropriate strategies and responses.

Working Memory

► Working memory is a short-term memory system that allows for the active maintenance and manipulation of information that is not present in the outside world. This concept of working memory involves temporary buffers of information and an attentionally constrained central executive. Tests of working memory measure a monkey's ability to remember information for a short period of time when that information is no longer present in the environment. Whether the information is remembered or not is determined by how well their response is guided by this information after a variable delay. The information to be remembered is usually visual, i.e., remembering the spatial location of a stimulus or the form/color of a stimulus, but other sensory modalities can be used. It involves presenting a stimulus to the monkey for a brief period of time (seconds) and then after a variable delay requiring the subject to use that information to guide their subsequent responding. One of the most well-known versions of this test is the spatial working memory test, whereby a monkey either watches food reward being hidden in one of two food wells to the left and right of the animal or alternatively fixates a central cross while a spot of light is briefly flashed (e.g., 100 ms) in one of eight spatial locations in the surround. In both cases, the animal must remember the location of the stimulus for a brief delay, e.g., 1–30 s, and then make a response (arm reach/saccade) to the remembered location at the end of the delay period. In object working memory tests, an object is presented centrally in a WGTA or a visual pattern is presented on a computer screen (sample phase) for a short period of time during which the monkey may have to respond to the stimulus to demonstrate that the stimulus has been seen (Weed et al. 1999). Following a variable delay the same visual stimulus, along with another one is presented to the left and right of the center, and the animal has to choose the object/pattern that matches the sample object/pattern. The smaller the stimulus set used and thus, how frequently the same stimulus is seen across trials, increases the level of interference between trials and increases the load on working memory. By comparing responding following a delay with that at zero delay it is possible to look at the effects of a drug on those processes specifically involved in short term/working memory as compared to other more general perceptual and rule learning processes. In the spatial versions of the test it is important to ensure that the monkey does not use a mediating response to bridge the delay between the stimulus disappearing and the response being made and thus reducing the load on working memory. The addition of distraction during the delay period allows for attentional mechanisms and working memory processes to be assessed within the same session. The distractor can take the form of additional, related stimuli presented during the delay that are irrelevant to the task or alternatively, a burst of loud noise may be presented.

Monitoring Behavior

Self-ordered search tasks. Self-ordered search tasks were originally used in studies of human frontal lobe and were later adapted for studies in monkeys by M Petrides. In these original versions, monkeys were presented with variable numbers of objects (usually three) and across a series of three trials they were presented with the same three objects. Food could be retrieved each trial as long as they selected a different object on each occasion. Thus, the monkey must monitor within working memory its earlier choices in order to avoid returning to objects that have already been selected. Spatial versions require animals to

search through a series of spatial locations in order to find food reward. In those versions of self-ordered tasks in which food is obtained by selecting an object or spatial location for the first time, but not on repeated selections, the task is very similar to a foraging test. Alternative, computerized versions in which stimuli are presented on a touch sensitive computer screen (Fig. 1d) tend not to reward monkeys until they have responded once and once only to a series of spatial locations (Collins et al. 1998). In the latter, monkeys are having to perform sequences of actions in order to gain reward, which may depend upon distinct prefrontal circuitry to those tasks in which the stimuli themselves are associated with reward. Besides monitoring of actions, the spatial search tasks can also be used to assess simple planning ability, especially if the number of boxes/locations is increased, as implementation of a strategy, such as following a clockwise or anticlockwise strategy reduces demands upon working memory.

Cognitive Flexibility

Cognitive flexibility is the ability of animals to adapt their responding to changes in the environment. In the tasks described in the following text, previously rewarded responses or strategies have to be inhibited in favor of the development of new responses and strategies. Different aspects of cognitive flexibility are associated with different regions of ▶ prefrontal cortex, with many neuropsychiatric disorders being associated with cognitive inflexibility.

Discrimination reversal tasks. These typically involve presenting two stimuli to a monkey, usually two visual objects, and the animal learns, through trial and error, that a response to one of the objects leads to food reward while a response to the other does not. Having learnt this discrimination to a particular level of performance, usually around 90% correct over a series of trials, the reward contingencies reverse such that the previously rewarded stimulus is no longer associated with reward but the previously unrewarded stimulus is now associated with reward. How rapidly an animal learns to reverse their responding to match the change in reward contingencies is a measure of how flexible their behavior is. The stimuli can be from any sensory dimension, smell, audition, somatosensation, and vision. Visual discriminations are used most commonly in primate studies as visual cues are particularly salient for primates. The stimuli are either spatial in nature, i.e., left is rewarded, but right is not, or they involve visual features such as shapes or color. A typical discrimination reversal task is shown in Fig. 1ei where an animal may receive a series of reward contingency reversals.

A selective deficit in cognitive flexibility is shown by intact performance on the original discrimination, ruling out perceptual deficits, and an impairment on the subsequent reversal or series of reversals; a deficit seen following damage to the orbitofrontal cortex and ventromedial striatum. A more fine-grained analysis is then required to determine the nature of the underlying reversal deficit. Some useful information can be gleaned from a careful analysis of the errors that are made while performing the reversal. The pattern of errors on a reversal task is very distinctive. First monkeys tend to respond to the previously rewarded stimulus, almost exclusively, known as the perseverative stage. Then, they respond randomly to both stimuli (chance stage) and finally begin to respond more to the previously unrewarded, but now rewarded stimulus (learning stage). By analyzing the numbers and proportions of errors made at these three stages some insight can be gained as to whether animals have problems (1) disengaging their attention and inhibiting their responding to the previously rewarded stimulus (▶ perseveration) or alternatively (2) learning to respond to a stimulus that they had previously learnt was not associated with reward (learned avoidance). If it is the former, animals would make more errors in the perseverative stage, but if it is the latter, then they may make more errors in the chance and/or learning stages. It has been highlighted that in the classic discrimination reversal task, there are only two stimuli to choose from, and thus the only error is a response to the previously rewarded stimulus. A better measure of whether the deficit is truly perseverative in nature may be gained by requiring the animal to perform a three-stimulus visual discrimination reversal task as highlighted by JD Jentsch and JR Taylor. In which case, an error would include, not only a response to the previously rewarded stimulus but also a response to the other, previously unrewarded stimulus. Thus, a more generalized impairment in reversal learning may manifest itself as errors made equally to both of the currently, unrewarded stimuli while a perseverative deficit would still be characterized by errors made primarily to the stimulus that had been previously rewarded. This version can rule out perseverative responding as an underlying cause of a reversal deficit.

However, if perseverative responding is seen, the underlying cause of the perseverative deficit is still unclear. It may still be a consequence of the subject avoiding the two, previously unrewarded stimuli, rather than due to a failure to inhibit responding to the previously rewarded stimulus. To differentiate these two possibilities, the following design can be used. At the reversal stage of the discrimination task, one of two different versions of the discrimination is given. One version includes the previously rewarded stimulus and a novel stimulus and the monkey has to choose the novel stimulus. The other version includes the

previously unrewarded stimulus and a novel stimulus and the monkey has to select the previously unrewarded stimulus (Fig. 1eii). If the perseverative deficit seen in the original, discrimination reversal task is truly perseverative then the monkey should be impaired on the former but not the latter. In contrast, if the deficit is due to the animal actively avoiding the previously unrewarded stimulus, then they should be impaired on the latter and not the former (Clarke et al. 2006).

Object Retrieval test. Another commonly used test of cognitive flexibility that has proven useful in psychopharmacological studies is a test of object retrieval in which monkeys have to make a detour reach around the sides of a clear Perspex box in order to retrieve the food reward inside. Performance on this test is dependent upon the orbitofrontal cortex and the caudate nucleus (and also large lesions of dorsolateral prefrontal cortex including Walker's areas 9,46 and 8). It not only investigates the ability of monkeys to inhibit a prepotent response tendency to reach directly for the food reward but also their ability to switch their responding between the left and right sides of the box, as on some trials the opening is on the left and other trials, on the right (Jentsch et al. 1999).

Attentional set (rule) -shifting tasks. The psychological and neural mechanisms underlying flexible responding to changes in stimulus-reward contingencies are not the same as those required for the flexible use of rules to guide responding. One of the most commonly used tests to study rule switching in humans is the Wisconsin Card Sorting Test (WCST), which requires subjects to sort a pack of cards according to one particular perceptual dimension, e.g., shape, and then to switch to sorting them according to another dimension, e.g., number. A number of different versions of this test have been adapted for use in nonhuman primates, the different versions focussing on different aspects of the original task. In one such version (Roberts et al. 1988), monkeys are presented with a series of visual discriminations composed of bidimensional stimuli using abstract dimensions of "shape" and "line" (Fig. 1f). The monkey has to learn that one particular perceptual dimension is relevant to the task and that an exemplar from that dimension is associated with food reward, i.e., the blue boat, regardless of the white line superimposed over it. Animals then perform a series of such discriminations in which the same dimension remains relevant throughout but each discrimination is composed of novel bidimensional stimuli in which one exemplar from the relevant dimension is associated with food each time (► intradimensional shift, IDS). In the critical set-shifting test (or ► extradimensional shift, EDS) a discrimination is presented in which the previously relevant dimension is no longer relevant and the subject has to learn, through trial and error, that an exemplar from the previously irrelevant dimension is now rewarded. This requires monkeys to shift their ► attentional set from one dimension to another and is similar to the shift of category in the WCST. Impairment at the EDS stage is dependent upon the lateral PFC. The advantage of this test is that it separates out some of the component parts of the WCST, including the ability to develop an attentional set, to apply the rule across different discriminations and then to switch from using one rule to using another. A distractor probe test, in which the exemplars from the irrelevant dimension of a well-learned discrimination are replaced for one session only with novel irrelevant exemplars, can be used to investigate how much an animal is distracted by the irrelevant dimension. This particular task has a major emphasis on learning. In contrast, other primate rule switching tests are more akin to the WCST and require monkeys to learn to select, from a set of three stimuli, the stimulus that matches the sample stimulus according to a particular perceptual dimension (Mansouri et al. 2006). In these tasks, the monkeys receive extensive training on the matching to sample rules before they are able to perform the task successfully. Both these and the previously described discrimination tests require subjects to use feedback in the form of reward to guide their responding at the time of the shift. In contrast, another set of task-switching paradigms focus on the mechanisms underlying task switching per se, and in these cases, cues signal which particular rule is in operation at any one time (Stoet and Synder 2008).

Definition

Numerous studies support the prevalent hypothesis that the lasting storage of new information requires a

sequence of tightly intertwined and precisely regulated molecular steps necessary for the initiation of protein synthesis in certain areas of the brain. Thus, the induction of protein synthesis is understood as a key molecular element not only for the ▶ consolidation but also for ▶ extinction, ▶ reconsolidation and persistence of ▶ long-term memory.

Impact of Psychoactive Drugs

Protein Synthesis as a Mechanism of Memory

Protein synthesis is necessary for a variety of functions in diverse systems, including ▶ long-term potentiation and the consolidation, extinction, reconsolidation, and persistence of long-term memory (Abraham and Williams 2008; Alberini 2008; Quirk and Mueller 2008; Tronson and Taylor 2007), (▶ Inhibition of memory), (▶ Declarative and Non-Declarative Memory), (▶ Reference Memory and Consolidation). This assertion relies mainly on findings showing the amnesic effect of protein synthesis inhibitors, including ▶ anisomycin, ▶ cycloheximide, ▶ puromycin and ▶ emetine. The use of most of these antibiotics has been criticized since the finding that some of them produce brain lesions and therefore their amnesic effects can be explained by these rather than by a time-dependent, specific influence on protein synthesis. However, at the doses regularly used in memory experiments, anisomycin appears to be devoid of such effects, and thus has been for the past 30 years the most widely used protein synthesis inhibitor (but see Canal et al. 2007).

By far, the brain structure best studied in terms of the involvement of protein synthesis both in long-term potentiation and in long-term memory consolidation is the ▶ hippocampus, particularly the CA1 area (▶ Long-Term Potentiation and Memory), (▶ Molecular Mechanisms of Learning and Memory). Many studies have been carried out observing similar effects in mammalian septum, ▶ amygdala, and thalamus, as well as in the auditory, ▶ prefrontal, and entorhinal cortices. It is indeed likely that the changes in the expression of proteins related to memory consolidation are, similar to many other neuronal molecular changes, very specific as to brain regions as they are to behavioral tasks. And of course in many tasks more than one brain area is involved in consolidation, and protein synthesis may be required in all of them. This appears to be the case in auditory fear conditioning and in conditioned taste aversion, in which the insular cortex and the central amygdaloid nucleus are involved, and also in one-trial inhibitory avoidance (▶ Classical (Pavlovian) conditioning), (▶ Conditioned place preference and aversion), (▶ Conditioned Taste Aversions), (▶ Passive avoidance), and (▶ Pavlovian fear conditioning). Studies with anisomycin on reconsolidation show that, depending on the task, protein synthesis in the hippocampus or the amygdala is also involved. However, for other learning tasks, such as conditioned taste aversion for example, protein synthesis in the central amygdala is important for consolidation, but not reconsolidation of the task.

The findings on the influence of anisomycin and other protein synthesis inhibitors on hippocampal long-term potentiation and long-term memory consolidation correlate quite well, particularly when examined together with the large number of timed biochemical events and effects that have been measured in the CA1 region in both physiological processes, (▶ Synaptic Plasticity). Indeed, except perhaps by the finding that in the chick brain and in mammalian CA1 there are two peaks of sensitivity to mRNA and protein synthesis inhibitors in memory formation – one shortly after learning and another one about 3 h later – in most types of learning so far analyzed, only the second peak has been unequivocally detected. Importantly, not only the consolidation of brief forms of learning is followed by a series of clear-cut biochemical events in CA1 identical both in nature and in timing to those of long-term potentiation (Izquierdo et al. 2006), but potentiation of the CA3–CA1 synapses has been in fact observed during long-term memory consolidation of both one-trial avoidance and trace eye-blink conditioning, which strongly suggests that consolidation relies on long-term potentiation at least in these tasks.

The effects of protein synthesis inhibitors, particularly anisomycin, on memory are well established. The amount of inhibition needed in order to observe amnesia or lack of memory formation has been determined to be around 85%. The duration of the inhibition needed to cause amnesia has been determined in various tasks and structures, and ranges between 1 and 2–3 h. For a variety of reasons, anisomycin effects on acetylcholinesterase, tyrosine hydroxylase, corticosteroidogenesis, or MAPK activation are unrelated to its amnesic effects.

Some recent findings indicate proteins synthesized via intervention of the mTOR pathway in the consolidation of long-term memory and long-term potentiation. Also, a role in the maintenance of long-term facilitation in the mollusk *Aplysia* has been described for proteins synthesized locally in dendrites (Hawkins et al. 2006). Facilitation in *Aplysia* is quite used as a model of memory formation, and there is evidence that protein synthesis in dendrites may be important for memory formation but not reconsolidation.

Several of the proteins synthesized in the hippocampus 3 h or less after behavioral training have been

identified, and many of them are known to play a major role in memory formation. In fact, at least 33 different genes have been shown to be modulated by one-trial avoidance training; most of them were upregulated.

Traditionally, new memories are associated with the need for ► gene expression and protein synthesis in areas of the brain relevant to each learning. Curiously, from time to time there have been proposals that protein synthesis may not be necessary for memory formation, and that protein synthesis inhibitors cause amnesia for some other reason. Certainly, ► short-term memory (► Short-Term and Working Memory in Animals), (► Short-Term and Working Memory in Humans) lasting a few minutes or hours is not dependent on gene expression or protein synthesis, but no doubt long-term memory certainly is fully dependent on both. Among the recent alternative proposals, there is one suggesting that long-term memory may rely on post-transcriptional changes only, such as indeed short-term memory has been shown to be, or alternatively, that it might depend on an indirect modulatory effect of peripheral or central catecholamines. For a careful analysis and strong refutations of these proposals, see Alberini (2008) and Hernandez and Abel (2008).

Definition

The proteome is the genome complement of proteins, and proteomics is the study of proteomes in a cell at any given time. Neuroproteomics defines the entire protein complement of the nervous system. It represents a higher complexity than the transcriptome, and it displays a higher degree of dynamics due to ► posttranslational

modifications (► PTMs). Two main approaches of this field are profiling and functional proteomics. Profiling proteomics includes the description of the whole proteome of a cell, tissue, organ or organism and comprises organelle mapping and differential measurement of expression levels between cells or conditions. Functional proteomics aims to characterize protein activity, by determining protein interactions and the presence of PTMs.

Current Concepts and State of Knowledge

The analysis of proteomes is significantly more challenging than that of genomes. Measuring ► gene expression at the protein level is potentially more informative than the corresponding measurement at the mRNA level. Though certain RNAs are known to function as effector molecules, proteins are the major actors and catalysts of biological function. Proteins contain several dimensions of information, which represent the actual rather than the potential functional state as indicated by mRNA analysis. These dimensions include the abundance, state of PTM, (sub) cellular localization and association and interaction with each other. PTMs of a protein can determine its activity state, localization, turnover, and interactions with other proteins. More than 300 different types of PTMs are currently known. Changes in gene expression at the level of the message, mRNA expression, may not directly correlate with protein expression since mRNA is not the functional endpoint of gene expression. Recent investigations show that differences in protein concentrations are only 20–40% assigned to variable mRNA levels, emphasizing the importance of posttranscriptional regulation. In general, protein concentrations depend on the translation rate and the degradation rate, i.e., the protein turnover. In addition to the complexity at the transcriptional level, proteome approaches have to deal with the considerable increase in isoforms due to multiple PTMs (Tyers and Mann 2003).

Proteomics Methodologies

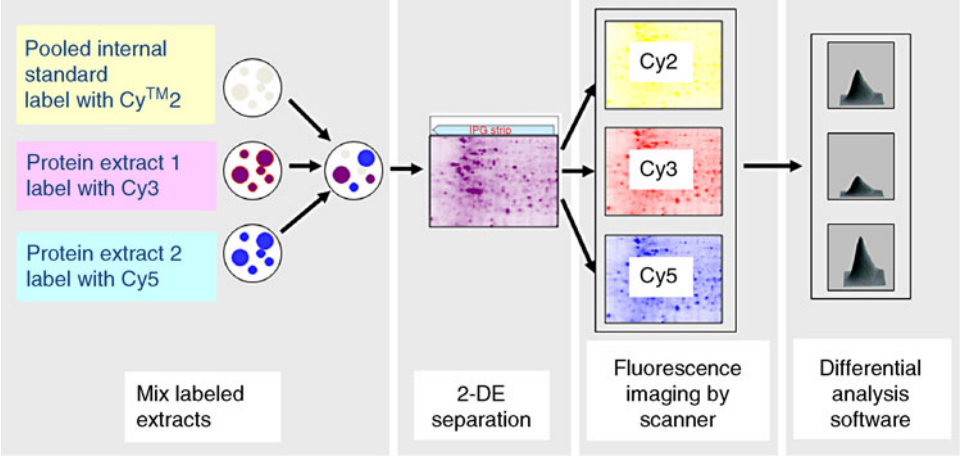
Proteomics technologies (both expression profiling and functional approaches) have widely expanded in recent years. Because of protein diversity, a range of techniques have emerged, which depend on integration of biological, chemical and analytical methods. The main proteomic technologies of today utilize ► mass spectrometry (MS) coupled with global protein separations (Aebersold and Mann 2003) and methods based on protein arrays (Phizicky et al. 2003). The global protein separation methods are conventionally divided into gel-based and gel-free, where the gel-free are all MS based. The protein arrays are not global in the sense that they typically depend on the availability of antibodies. The methodologies are complementary and are increasingly used in combination with each other. Even though their analytical windows overlap, each of them covers selected sets of proteins that are not identified by the other techniques (Choudhary and Grant 2004).

► Two-dimensional gel electrophoresis. The global protein separation method two-dimensional gel electrophoresis (2-DE) enables the possibility to resolve several thousand proteins in a single sample. 2-DE mainly produces data which allow the investigator to determine whether a particular protein shows an increase or decrease when comparing two different conditions. The limited dynamic range and poor reproducibility between gels have been of major concern with traditional 2-DE experiments (Westermeier et al. 2008).

In a typical gel-based proteomics experiment the proteins in a sample are separated by 2-DE, stained, and each observed protein spot is quantified by its staining intensity. Selected spots are excised, and analyzed by MS after "digestion" (see below). Pattern-matching algorithms as well as interpretation by skilled researchers are required to relate the 2-DE patterns to each other in order to detect characteristic patterns and differences among samples. The major limitation of 2-DE techniques is a relatively low throughput particularly in cases where many proteins have to be identified with subsequent MS analysis which is very time-consuming (Westermeier et al. 2008).

Detecting changes in protein expression is improved by the introduction of fluorescence difference gel electrophoresis (DIGE). 2-D-DIGE enables the pre-labeling and separation of up to three samples on a single 2-D gel providing quantitation of proteins. Up to three protein samples are labeled with size- and charge-matched CyDye DIGE fluorochromes and co-separated on the same 2-D electrophoresis gel. Gels using the 2-D-DIGE method usually contain three samples labeled with three distinct fluorescent dyes, Cy2, Cy3 and Cy5. The Cy2 dye is typically used to label an internal standard, which is a mix of all samples in the experiment, and the other two dyes are then employed to label two biological samples of interest. The strength of the internal standard is to help the mapping of spots/proteins between gels and thus make the different gels more comparable. The internal standard is also used in some methods for normalization within and between gels (Westermeier et al. 2008) (Fig. 1).

Mass spectrometry-based proteomics. The coupling of chromatographic separation methods with MS is commonly utilized for qualitative and quantitative characterization of highly complex protein mixtures. The advances in chemical tagging and isotope labeling techniques have



Proteomics. Fig. 1. Workflow for a standard 2-D difference gel electrophoresis (DIGE) experiment. Samples are labeled with molecular weight and charge matched CyDye DIGE Fluors, minimal dyes. improved the quantitative analysis of proteomes. ► High performance liquid chromatography (► HPLC) methods provide powerful tools of protein and peptide separation of protein mixtures. Primary advantages of liquid chromatographic (LC) separation are the flexibility of the methods and the possibility to link LC directly to MS. Proteins and peptides can be separated based on their physical properties, including affinity, charge (ion exchange), hydrophobicity (reversed phase), and size (size exclusion) (Aebersold and Mann 2003).

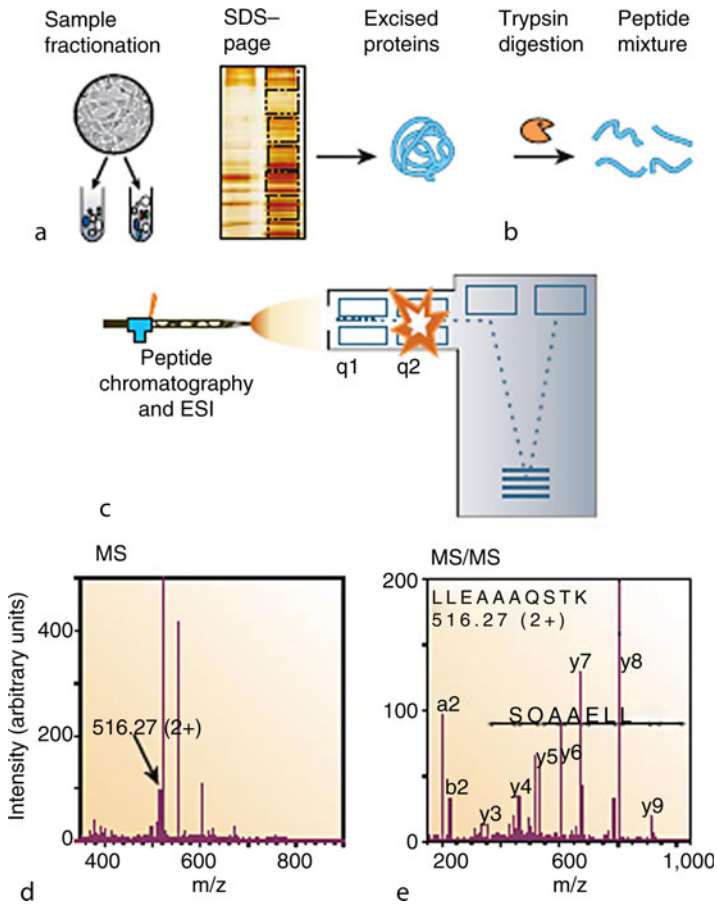
Presently two ionization techniques, ► electrospray ionization (► ESI) and ► matrix-assisted laser desorption ionization (► MALDI) are playing a significant role in the field of MS-based proteome analysis. ESI ionizes the analytes out of a solution and is therefore readily coupled to chromatographic and electrophoretic separation tools. MALDI sublimates and ionizes the samples out of a dry, crystalline matrix via laser pulses. There are four basic types of mass analyzers currently used in proteomics research. These are the ion-trap, time-of-flight (TOF), quadrupole, and Fourier transform ion cyclotron (FT-MS) analyzers. These analyzers can be stand alone or, in some cases, put together in tandem to take advantage of the strengths of each (Aebersold and Mann 2003).

There are two complementary approaches for the MS analysis of proteins (Aebersold and Mann 2003). The bottom-up method is generally used for identifying proteins and determining details of their sequence and PTMs. Proteins of interest are digested with a sequence specific enzyme such as trypsin, and the resulting tryptic peptides are analyzed by ESI or MALDI, which allow intact peptide molecular ions to be put into the gas phase. The MS analysis takes place in two steps. The masses of the tryptic peptides are determined; next, these peptide ions are fragmented in the gas phase. The masses of the peptide fragments yield information on their sequence and modifications. Prior to being introduced to the MS the tryptic peptides usually are separated on reversed phase LC directly coupled to the ESI source (Fig. 2). For quantitative analysis of proteins by MS stable-isotope labeling of proteins can be used. These methods utilize either metabolic labeling, tagging by chemical reaction, or stable-isotope incorporation via enzyme reaction of proteins or peptides (Aebersold and Mann 2003). Labeled proteins or peptides are combined, separated and analyzed by MS and/or tandem MS for identifying the proteins and determining their relative abundance.

In the top-down approach, intact protein ions are introduced into the gas phase and are then fragmented in the mass spectrometer. If enough numbers of informative fragment ions are observed, the analysis can provide a complete description of the primary structure of the protein and reveal all of its modifications. Until recently, it has proved difficult to produce extensive gas-phase fragmentation of intact large protein ions, but novel techniques such as electron transfer dissociation promise to drastically improve this situation.

► Neuropeptidomics. The core proteomics tools, including 2-DE in combination with MS, are limited to the analysis of proteins >10 kDa. Other technologies are



Proteomics. Fig. 2. Typical MS-based proteomics experiment. The general proteomics experiment consists of five stages. (**a**) the proteins to be analyzed are isolated from cell lysate or tissues by biochemical fractionation (such as SDS polyacrylamide gel electrophoresis (PAGE) or multidimensional LC) for reduction of the sample complexity or affinity selection (for enrichment of a sub-proteome), (**b**) the proteins are degraded enzymatically to peptides, usually by trypsin, (**c**) the peptides are separated by one or more steps of high performance liquid chromatography (HPLC) in very fine capillaries and eluted into an electrospray ionization (ESI) ion source, (**d**) after evaporation, multiply protonated peptides enter the mass spectrometer and a mass spectrum of the peptides eluting at this time point is taken, (**e**) the computer generates a prioritized list of these peptides for fragmentation and a series of tandem mass spectrometric (MS/MS) experiments follows. The outcome of the experiment is the identity of the peptides and therefore the proteins making up the purified protein population (modified from Aebersold and Mann 2003).

therefore necessary to identify small endogenous proteins and peptides such as present in brain samples. Neuropeptidomics is the technological approach for detailed analyses of endogenous peptides from the nervous system/brain. It is a relatively new direction in proteomics research that covers the gap between proteomics and ► metabolomics and overlaps with both areas. Peptidomics methodologies are generally based on separating complex endogenous peptide mixtures by multistep LC approaches, usually nL/min flow capillary reversed-phase LC (nanoLC), or gel- or liquid-based isoelectric focusing combined with MS for sequence analysis. The levels of peptides in the brain reflect certain information about physiological status; this information can be revealed when MS is used to generate broad profiles of the dynamic neuropeptide patterns (Svensson et al. 2007).

MALDI ► imaging mass spectrometry. MALDI mass spectrometric tissue imaging (► MALDI-IMS) of peptides and proteins in the brain is performed in thin (10–20 µm) tissue sections *in situ* (Stoeckli et al. 2001). The sections are typically coated with a raster of matrix droplets before an ordered array of mass spectra is

acquired from each matrix spot. This way each spectrum reflects the local molecular composition at known *x*, *y* coordinates. Image profiles of selected peptides and proteins in the section are generated by extracting their corresponding mass-to-charge (m/z) ranges from the spatially acquired MS data files. The approach yields information on the spatial localization of the peptides and proteins in the tissue analyzed, without the requirement of extensive sample manipulation. Applications of MALDI-IMS range from low-resolution peptide and protein profile images of selected areas in e.g., mouse brain to single neural cell peptide profiling analyzes and high-resolution imaging of proteins and drugs.

► Protein microarrays. Protein and peptide microarrays involve the spotting of proteins (including antibodies or other affinity reagents directed against defined proteins) and peptides at high density on surfaces such as glass slides and can be used for both profiling and functional proteomics. Antibody microarrays hold potential for high-throughput protein profiling. A complex mixture, such as a brain cell lysate, is passed over the microarray surface to allow the antigens present to bind to their cognate antibodies or targeted reagents. The bound antigen is detected either by using lysates containing fluorescently tagged or radioactively labeled proteins, or by using a secondary antibody against each antigen of interest. Functional protein arrays allows for testing of activities and interactions with lipids, nucleic acids and small molecules as well as other proteins (Phizicky et al. 2003).

Understanding the Brain Molecular Organization and Complexity

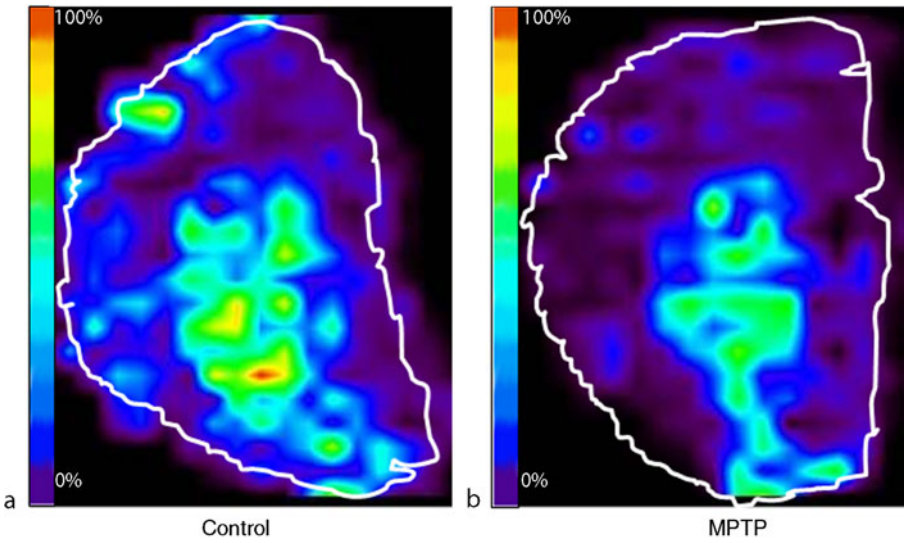
There are a variety of applications for proteomic technology in psychopharmacology and neuroscience. These range from defining the proteome of a particular cell type, identifying changes in brain protein expression under different experimental (including pathological) conditions, profiling protein modifications and mapping protein-protein interactions. All of them have their strengths and limitations and a major challenge is to determine the most appropriate proteomic technology to the system studied. Large-scale proteomic analysis can help unravel the complexities of brain function as many of the activities of the brain involve intricate signaling networks and changes in PTMs (Choudhary and Grant 2004). Clinical research aims to benefit from proteomics by both the identification of new drug targets and the development of new diagnostic markers.

Proteome global mapping. Detailed analysis of the mouse brain proteome has established 2-DE protein indices of thousands of proteins, with MS annotations of ~500. Proteins from all functional classes have been identified by such analyses. However, membrane proteins are typically underrepresented in 2-DE due to poor solubility in the initial isoelectric focusing step of the method, which requires relatively large amounts of starting material. Another approach using multidimensional LC coupled to ESI MS/MS does not have this bias against membrane proteins and identified close to 5,000 proteins from 1.8 mg of rat brain homogenate with an average of 25% protein sequence coverage. The proteins identified included membrane proteins, such as neurotransmitter receptors and ion channels implicated in important physiological functions and disease.

Neuropeptidomics has been used to profile a large number of neuropeptides from the brain and the central nervous system. Strategies that reduce complexity and increase the dynamic range of endogenous peptide detection, particularly fractionation methods and separations based on the peptides' chemical and physical properties and bioinformatics approaches, have resulted in the discovery and chemical characterization of novel endogenous peptides. Some of these, such as peptides originated from the secretogranin-1, ► somatostatin, prodynorphin (► endogenous opioids), and ► cholecystokinin precursors appear differentially expressed in the ► striatum with and without 3,4-dihydroxy-L-phenylalanine (► l-Dopa) administration in 6-hydroxydopamine (► 6-OHDA) ► animal models for ► Parkinson's disease (Nilsson et al. 2009).

The MALDI IMS technique has been applied to animal models of ► neurodegenerative (► neurodegeneration) disorders to investigate peptide and protein expression, particularly to compare patterns in pre- and post-lesions using 6-OHDA and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (Fig. 3). In these affected brains, the IMS molecular tool identified changes in complex protein patterns and identified specific proteins involved in specific brain regions (Svensson et al. 2007). IMS has also been utilized to reveal the regional distribution of psychopharmacology agents in the brain such as ► clozapine (► atypical antipsychotic drugs). IMS images revealing the spatial localization in rat brain tissue sections following administration of ► clozapine were found to be in good correlation with those using an autoradiographic approach. The results are encouraging for the potential applicability of this technique for the direct analysis of drug candidates in intact tissue slices (Cornett et al. 2007).

The utility of *functional proteomics* has been recently exploited to elucidate cellular mechanisms in the brain, of particular importance in the area of signal transduction. Reversible phosphorylation of proteins is the most widely



Proteomics. Fig. 3. IMS analysis of brain tissue sections after 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) treatment. The relative ion density of PEP-19 from one control (**a**) and one MPTP-treated animal (**b**) shows that there is a reduction of PEP-19 expression in the striatum. Typically, in this experiment, about 400 distinct mass signals were detected in the mass range of 2–30 kDa (modified from Svensson et al. 2007).

studied type of signal transduction. Recent synapse phosphoproteomics studies analyzing phosphorylation sites of proteins identified 974 sites in mouse synaptosomes and 1,563 in postsynaptic densities isolated from mouse cortex, midbrain, cerebellum and hippocampus. Phosphoproteomics has identified phosphorylation sites that are altered in Alzheimer's disease, particularly in the microtubule-associated ▶ protein Tau (Bayes and Grant 2009).

Characterization of protein complexes provided information about molecular organization as well as cellular pathways. A multi-bait yeast two hybrid screen of proteins relevant to ▶ Huntington's disease, found 186 protein-protein interactions, of which 165 had not been previously described and which might be relevant to the pathology of Huntington's disease (Bayes and Grant 2009).

Advantages and Limitations in Neuroproteomics

While many of the proteomics approaches have focused on determining the proteins or peptides present in the cell and their relative expression levels, the specific aim of proteomics would be to simultaneously identify, quantify and analyze a large number of proteins within their functional context. The shift in focus from a proteomics discovery mode to a functional approach creates challenges that are at present unmet in all aspects of the proteomic experiment, including the experimental design, data analysis, storage, and publication of data. (Choudhary and Grant 2004).

Sample preparation is a major source of variation in the outcome of proteomic experiments. After tissue or body fluid sampling, proteases and other protein-modifying enzymes can rapidly change composition of the proteome. As a direct consequence, analytical results will reflect a mix of *in vivo* proteome and *ex vivo* degradation products. Vital information about the pre-sampling state may be destroyed or distorted, leading to variation between samples and incorrect conclusions. Sample stabilization and standardization of sample handling are imperative to reduce or eliminate this problem. A recently introduced tissue stabilization system which utilizes a combination of heat and pressure under vacuum has been used to stop degradation in brain and loss of PTMs (e.g., phosphorylations) tissue immediately after sampling (Soloview et al. 2008; Svensson et al. 2007). This methodology provides an improvement to proteomics by greatly reducing the complexity and dynamic range of the proteome in tissue samples and enables enhanced possibilities for discovery and analysis of clinically relevant protein and peptide biomarkers. Rapid removal of neuronal tissue, dissection, and freezing are obvious important procedures for the maintenance of the proteome state in the animal. Human *post mortem* studies present problematical challenges in neuroproteomics, where careful documentation of *post mortem* time interval, brain pH, and agonal state is of greatest importance (Soloview et al. 2008).

Proteomic studies by definition result in large amounts of data. The analysis as well as interpretation of the enormous volumes of proteomic data to effectively use their content remains an unsolved challenge, particularly for

MS-based proteomics. The development of tools for the integration of different experimental approaches enabling analyses of such proteomic data sets using statistical principles is an important task for the future (Aebersold and Mann 2003).

MS-based peptidomics technologies in combination with sophisticated bioinformatics tools have great potential for the discovery of novel biologically relevant neuropeptides. It is likely that a considerable number of ▶ neuropeptides are still to be discovered. The human genome contains ~550 genes belonging to the G protein-coupled receptor class of proteins. For 25% of these the natural endogenous ligands remain elusive until today, and novel neuropeptides are very plausible candidates. Improved peptidomics approaches and technologies may therefore identify novel biologically important neuropeptides (Svensson et al. 2007).

MALDI-IMS has become an important tool for assessing the spatial distribution of molecular species in brain tissue sections and for the elucidation of molecular signatures indicative of disease progression and drug treatment. The technique allows simultaneous measurements of hundreds of different molecules in tissue specimens without disrupting the integrity of samples. It can trace the distribution of pharmaceuticals and their various metabolites in the brains of dosed animals and can be successfully applied to monitor the changes in the proteome organization upon drug application. Functional information obtained in MALDI-IMS studies can be correlated with proteomic profiles and routine immunohistochemical staining, thereby providing an in-depth comprehension of molecular mechanisms underlying health and disease (Cornett et al. 2007; Stoeckli et al. 2001).

A catalog of the complete neuroproteome will propose new directions to understand brain function. Differential proteomics permits correlations to be drawn between the range of proteins produced by a cell or tissue and the initiation or progression of a disease state. It permits the discovery of new protein markers for diagnostic purposes and the study of novel molecular targets for brain drug discovery. The markers identified may have a wide range of potential applications, such as clinical diagnostic and prognostic tools. Proteomic information has superior functional value and can generate knowledge of cellular protein networks. Proteomics technologies are progressing fast and their increasing usage as a functional high-throughput approach is adding to vital biological findings in areas not accessible to genomics studies.

Definition

Humans have an innate capacity to react to environmental stimulation which, by way of learning and experience, develops into a range of coordinated motor behaviors that are appropriate responses to the sensory information perceived by an individual. These motor behaviors range in complexity from the instantaneous reflex reactions that follow the accidental grasping of a hot poker, through simple ► sensori-motor behaviors such as poking a fire, climbing stairs, steering a car, to the skilled psychomotor functions necessary to climb a rickety staircase at night or drive a car in heavy motorway traffic during a rainstorm. Such highly complex motor behaviors, i.e., psychomotor performance, result from the ► cognitive processing of sensory and perceptual information.

The sense organs receive and convey information to the brain but rarely, except in the case of reflex reactions and simple sensori-motor behaviors, are such data transmitted without interpretation by the cognitive system. The perception, i.e., interpretation, of environmental events and circumstances allows sensory information to be

manipulated within the cognitive system and decisions made regarding the appropriate motor response(s) necessary for an immediate adaptive motor reaction. An individual will select from the array of stimuli available and choose to place more reliance on some cues and ignore others in accordance with prior learning, previous experiences, prejudices, and established habits. Such over/under-emphasis of some stimuli augments inter-individual differences in overall psychomotor performance due to the individual's concurrent needs, motivations, and expectations. Perception is dependent on maintaining an appropriate level of ► attention and remaining vigilant. The extent to which an individual is able to divide or shift attention between two or more relevant stimuli is an important variable in determining the overall capacity for psychomotor performance.

The motor component of psychomotor performance becomes more coordinated with sensory input because of learning and practice. Basic sensori-motor skills (e.g., steering a car) are quite robust and resistant to environmental influences but any faulty cognitive judgment or decision can cause a major impairment of psychomotor performance (e.g., car driving) if "unrealistic" demands are made on motor reactions.

It is the speed, reliability and validity of the processing of environmental information, particularly where the circumstances are complex or rapidly changing, which determine the appropriateness and precision of psychomotor performance. Any alteration in the reliability or validity of perceptual input will increase the possibility of errors in cognitive processing which, in turn, will be reflected as an impairment of overall psychomotor performance. However, if the cognitive system itself is directly affected by trauma, disease or the administration of a psychoactive drug, then the processing of perceptions will be similarly influenced and the associated motor reactions will necessarily change. Such changes in the integrity of the coordination between sensory and motor functions will lead to an impairment of psychomotor performance together with a subsequent loss of competence and increased risk of accident when undertaking the activities of everyday living in the home, at work, and on the road ► driving and flying under influence of drugs

It is virtually impossible, within the context of everyday scenarios, to measure psychomotor performance reliably: there are too many uncontrolled influences and variables and inter- and intra-individual differences are too great. The measurement of psychomotor performance requires an instrument where the relevant stimulus is readily perceived and its inherent information processed in a straightforward manner, without the necessity of having to rely on learning, previous experience, or the adoption of particular viewing strategies. The cognitive processing requirements have to be easy to understand and the motor responses undemanding and uncomplicated. Overall, psychomotor performance is dependent on vigilance, attention and the speed, accuracy and coordination of sensori-motor behavior, and, most importantly, the speed, capacity, and flexibility of the cognitive system. The basic elements (sensory, cognitive, and motor) can be measured using the standardized application of ► psychometric tests within a controlled environment to minimize the effects of the numerous extraneous influences both on the individual and on the test performance.

Psychopharmacologists are primarily interested in the behavioral effects of drugs but it is a basic assumption of human psychopharmacology that the effects of a particular psychoactive drug will be manifest by the changes it produces in psychomotor performance, as measured by psychometric tests. The major task of a human psychopharmacologist is not only to devise valid and reliable psychometrics by which such characteristic drug-induced changes can be measured but also to develop appropriate methodologies to control the studies by which the effects of drugs are to be assessed.

The successful assessment of the effects of drugs by way of the changes produced in psychomotor performance can only by done with studies in which the intrinsic and extrinsic sources of variability in psychomotor performance are controlled.

Inter-Individual Variability

A major variable in determining the effect of a drug on psychomotor performance is the psychological state of the individual at the time of testing. Most pharmacodynamic studies of drugs are performed in healthy, psychologically "normal" volunteers. This certainly does not preclude the use of psychometric tests in patient populations but study design issues will be different. As it is not possible to obtain psychologically identical individuals with comparable levels of psychomotor ability, the underlying inter-subject variability must be reduced by controlling it via the use of a crossover-design where each subject acts as their own control and receives each and every treatment in a random order. A parallel group design, where individuals are randomly allocated to receive only one of the treatment conditions, is much less suitable to control individual differences, even when large group numbers are used and subjects are screened and pre-assigned to treatments to ensure similar mean psychometric test scores across treatment groups. Pre-assignment does nothing to reduce the magnitude or speed of individual

reactions to a particular drug. Individual differences can also be reduced by using a neuropsychological test to screen out potential subjects with a pre-existing abnormal or reduced cognitive function (e.g., Mini-Mental State Examination, ►Wisconsin Card Sorting Test; Wechsler Adult Intelligence Test, especially the sub-scales for block design and picture completion). Neuropsychological test results indicate an individual's degree of abnormality in comparison with normative values from large-scale databases. They are not, in themselves, reliable in the test–retest protocols necessary for studying the pharmacodynamic effects of a drug on psychomotor performance. However, a similar pre-screening of experimental subjects' levels of neuroticism and extraversion/introversion (e.g., Eysenck Personality Inventory) can help reduce the influence inter-subject personality differences have on psychometric test performance. The established effects of age and sex, etc., on psychomotor performance can be simply controlled by pre-selecting and stratifying groups of subjects.

Treatment Variables

All treatments must be identical and matching with no discernible difference in color, size, shape or taste and they must be administered ►double-blind where neither the subject nor the person collecting the psychometric test scores are aware of the order in which the treatments are given. The subjective experiences of taking a substance believed to be a "drug" – even when it is actually pharmacologically inert – change psychometric test scores in susceptible subjects. These effects are controlled by the use of a ►placebo effect condition, which is regarded as another drug and included in the randomization and allocation of treatments. The psychometric test scores following active drug treatments can then be compared to those obtained following treatment with the placebo condition to indicate the psychoactive effects of the drug itself. A placebo control is an essential feature of all psychometric assessment of drug effects. Changes in psychomotor performance observed with active drugs are valid only if seen to be significantly (from the application of appropriate statistical analysis, probability levels, confidence intervals, etc.) different with respect to the results obtained with a matching placebo.

Testing Variables

Not all psychometric tests have an established sensitivity for the detection of changes produced by psychoactive drugs and an individual test will not always detect the particular effects of a specific drug. As well as reinforcing the need to use a psychometric test battery assessing a range of psychomotor activities, such considerations clearly show the need to demonstrate the sensitivity of a particular test battery to drug induced change for a specific, especially unknown, drug. This is done by the use of a ►verum (positive internal control), a drug with well-understood and robust effects on the psychometric tests to be used. It is usual for the positive controls to belong to the same pharmacological or therapeutic class as the drug under investigation although they are often used at supra-therapeutic doses to ensure that performance is reliably changed. The verum is used only to demonstrate the sensitivity of the psychometric battery and the results obtained with it must not be included in comparisons with active treatments to demonstrate the latter's improved side-effect profiles, etc. Most positive internal controls (e.g., lorazepam, alprazolam, zolpidem, amitriptyline, promethazine, mirtazepine, etc.) are used because they are known to lengthen reaction time, impair working memory and thinking, disrupt sensori-motor coordination and cause an overall impairment of psychomotor performance. However, the use of ►psychostimulants (e.g., amphetamine, methylphenidate) as positive internal controls will indicate the extent to which a test battery is able to detect changes in psychomotor performance due to CNS activation. Unpredictable variation in psychometric test scores can occur with repeated testing if there are auditory/visual distractions present during testing or if noticeable changes in ambient temperature or lighting occur. Psychometric testing must be conducted in a stable environment that remains constant both during each test period and between each occasion testing is conducted. As some external events are unpredictable, e.g., power failures, thunderstorms, etc., the sequence of administration of treatments should be balanced across the various days when testing takes place in accordance with a ►Latin Square design to ensure that any random effects of extraneous variables on psychometric test scores will be spread equally across all treatment conditions.

Psychometric Tests

Below is a list of some of the psychometric tests that have been used in published studies of the effects of psychoactive drugs: there are many more (Baselt 2001; Hindmarch 2004). The three part division of the tests does not imply a rigid classification, but shows that although some psychometric tests might emphasize individual sensory, cognitive, or motor functions, it is overall psychomotor performance – the integration of sensory and motor systems via the cognitive processing of information – which is measured (Table 1).

Psychomotor Performance in Humans. Table 1. Psychometric Tests Used to Measure the Effects of Drugs.

Psychometric Tests Used to Measure the Effects of Drugs		
Sensory Ability	**Attention and Cognition**	**Motor Ability**
pursuit rotor; Gibson Spiral Maze; dynamic visual acuity; angle perception; Maddox-Wing test; auditory discrimination; letter cancelation; simple reaction speed (visual, auditory).	critical flicker fusion frequency; two-flash threshold; rapid visual information processing; memory tests with immediate and/or delayed recall for short-term (Sternberg test), executive, recognition (pictures, words, faces, numbers, prose, semantic categories, nonsense syllables, music) and spatial (Corsi blocks) abilities; syntactic/logical reasoning (Tower of London); learning (Rey's test, paired associates); CDR test systems; vigilance (continuous performance, Pauli test, auditory vigilance, divided attention tasks, Dinges' psychomotor vigilance test, Erikson and Erikson's response competition test); mental arithmetic; time estimation; Stroop test; verbal fluency; free word association; on-the-road car driving (brake reaction time); digit-symbol-letter-manipulation (copying, substitution, matching, differentiation); mental arithmetic (serial subtraction of numbers, simple mathematics with or without auditory interference).	peg board; card dealing; trail making; on-the-road car steering (standard deviation of lateral position); body balance; finger tapping; compensatory, continuous or adaptive tracking; wrist actigraphy.

Although the effects of a particular drug on psychomotor performance can be assessed by an individual psychometric test, it is usual to employ a test battery (group of tests each reflecting a different aspect of psychomotor performance) particularly when a new substance with unknown or supposed psychoactive effects is to be investigated.

There is no consensus as to which tests are the most suitable for combination and inclusion in a psychomotor performance test battery. Some researchers place emphasis on the sensitivities and robustness of a particular test that other authors may find less reliable. The choice of tests may be influenced by the level of existing information regarding the known, or expected, effects of the drug(s) to be assessed.

It is most usual to regard impaired psychomotor performance as a necessary consequence of the administration of a sedative drug but psychostimulants, by causing over-activation of the sensory input of information, can also impair psychomotor performance.

Typically, a psychomotor test battery will involve assessments of sensori-motor coordination, vigilance, and/or ► divided attention, complex reaction time, executive or short-term memory and mental ability (arithmetic, logical reasoning). The exact composition of any test battery is not crucial but the proven sensitivity of the component tests to the psychoactive effects of drugs is a prerequisite for the inclusion of a particular individual test.

Psychophysiological measures, e.g., saccadic eye movements, sleep ► polysomnography (including the multiple sleep-wakefulness test and the maintained- wakefulness test) and continuous 24-h ► electroencephalography; can provide objective measures of the effects of drugs on sleep and daytime arousal. There is no doubt that lowering of arousal , as revealed by these psychophysiological assessments, will directly impair psychomotor performance. However, psychophysiological assessments are not, in themselves, tests of psychomotor performance. Similarly, subjective ratings of sleepiness e.g., Stanford Sleepiness Scale, visual analog rating scales, Epworth Sleepiness Scale and especially the Leeds Sleep Evaluation Questionnaire (Parrott and Hindmarch 2008), which was specifically developed to measure the changes in the subjective ratings of sleep and early morning performance following the administration of psychoactive drugs, will not automatically indicate the psychomotor effects of a drug but such subjective data can provide valuable information regarding the total impact of a psychoactive drug in clinical use.

Current Concepts and State of Knowledge

Psychometric tests have to be parsimonious in the demands they make on sensory, cognitive and motor systems if they are to be reliable measures of psychomotor performance suitable for use in a wide population of individuals of different ages, personality traits, skill levels and intellectual abilities. The increased availability of computer programs to present, control and collect results from psychometric tests has led to the automation of many psychometric test batteries. Such accurate and consistent presentation of the stimulus component of a psychometric test and the error free recording of results are efficient ways of ensuring the reliability of a test battery. However, the programming of computerised test batteries must take into

account important inter-subject differences in speed of reaction, comprehension of test instructions, etc. particularly when several tests are presented one after the other. The pace at which the individual tests are presented may give rise to pressures on performance and cause unpredictable effects which are not due to the effects of study medications. If psychometric tests are developed in a straightforward manner with realistic stimulus recognition, information processing and motor response requirements (especially the demands made on ► short-term and working memory in humans) then the effects of learning on psychomotor performance can be minimized although pre-study practice on even the simplest of psychometric tests is always required.

Computerised tests are able to present information at a rate and magnitude which can exceed the information processing capacity of some subjects, especially the elderly and those under the influence of drugs. When faced with too much information, individuals will adopt various strategies-some of which will require extensive learning-as in the playing of a computer game. Strategic perceptual and/or complex information processing requirements and/or the need for a finely controlled or coordinated motor response will increase the effects of inter- and intra-individual variability and effect the validity and reliability of the results obtained.

In short, psychometric tests for the measurement of psychomotor performance must be straightforward in their stimulus perception, information processing and motor response requirements. Furthermore, their sensitivity to drug activity has to be demonstrated by way of the use of verum controls. It is also necessary to evaluate a range of doses of a particular drug, not only because in clinical use patients often take 'supra-dose' regimens but also because psychomotor impairment effects might be dose related (Holgate et al. 2003).

Although measuring different aspects of psychomotor performance, many individual psychometric tests utilize speed of reaction as one of the motor response measures. Research on age-related changes in mental capacity suggests that a fundamental part of the cognitive system governs the speed of processing information (Kail and Salthouse 1994). Use can be made of this concept when assessing the effects of drugs on psychomotor performance by combining the reaction time components from each of the response-based tests in a particular test battery.

Tests of psychomotor performance are primarily used to assess the effects of CNS active drugs. A major step forward in validating this use of psychometrics has been the advent of human positron emission tomography (► PET) studies of the effects of psychoactive drugs, e.g., antihistamines (Yanai and Tashiro 2007). PET studies have differentiated between antihistamines in their capacity to penetrate the brain and occupy, ranging from virtually 0 to 90%, histamine -1 receptors ► histaminic agonists and antagonists.

The extent a particular antihistamine occupies H1-receptors in the brain is generally correlated with the degree of psychomotor impairment found from placebo and verum controlled studies of the same drug, (Shamsi and Hindmarch 2000). This not only helps elucidate the mechanisms by which drugs, in this instance antihistamines, act but also validates the use of psychometric tests to measure drug induced changes in human psychomotor performance.

Definition

Stern (1964), in the first edition of the journal *Psychophysiology* established by the Society for Psychophysiological Research, defined the field as where behavioral variables are manipulated and the effects of these independent variables are observed on physiological measures as dependent variables. This definition has been expanded by Furedy (1983) in the first edition of the International Organization of Psychophysiology's *International Journal of Psychophysiology* to "the study of physiological processes in the intact organism as a whole by means of unobtrusively measured physiological processes." Clearly, the nature of what constitutes "unobtrusive" in this context is subjective, but is an acknowledgment that the process of measurement can influence the measure itself. At least in some senses, the relationship between physiology and psychology implied by the term "psychophysiology" is the converse of that described by "physiological psychology" or "biological psychology" which relate to the study of the biological and physiological underpinnings of psychological processes. Psychophysiological methods are utilized in both human and animal studies. Furedy (1983) argues that this is only the case when the interest of the experimenter is focused on psychological processes of the whole intact organism.

Principles and Role in Psychopharmacology

The Role of Psychophysiology and Breadth of Techniques

As suggested earlier, the very definition of psychophysiology is a subject of some debate. Nathan Kline (1961) took an existential approach in his paper "On the relationship between neurophysiology, psychophysiology, psychopharmacology, and other disciplines." He argued that ambiguities in bioscience arise from asking a question in one "universe of discourse" (e.g., psychology) and seeking the answer in quite a different one (e.g., physiology). This is a potential issue with respect to the term psychophysiology and, indeed, psychopharmacology. Kline developed a number of laws regarding the relationship between disciplines including the "Law of Technique." This law states that the technique used to obtain information does not necessarily determine the "universe of discourse" in which it is used. This remains relevant, especially to the use of psychophysiological methods within psychopharmacology, as this spans three or more disciplines. To illustrate this, consider an example based on one given in Furedy's (1983) discussion of the definition of psychophysiology. ► Anxiety, via effects on the autonomic nervous system (ANS), causes changes in heart rate and other cardiac parameters such as the electrocardiograph (ECG) T-wave amplitude. If during a stress-exercise test in a patient with suspected cardiac pathology, a decrease in T-wave amplitude is seen, a physiological explanation will relate to cardiac pathology. However, from a psychophysiological perspective, the effects of the ANS on the myocardium need to be considered. For example, if the patient has great anxiety regarding his or her heart, the test may constitute a psychological as well as a physical ► stressor. Further, the psychopharmacologist would also take into account the antidepressant or anxiolytic medication that the patient may be taking which may be modifying the psychophysiological response. The technique or measurement (T-wave amplitude) is common to these three "universes of discourse," but each views or uses it in different ways.

It can therefore be seen that within the research area of psychopharmacology, psychophysiology is a tool to assist in the measurement of drug-induced changes in psychological

processes. When studying the effects of potentially psychoactive drugs, one of the greatest challenges is having objective "outcome measures" that demonstrate the effect of the drug. It is essential to measure the effect of a drug on mood, for example, when developing an antidepressant. Such an outcome has fundamental importance regarding the therapeutic use of the drug. However, the psychological process involved can only be measured in a subjective way in humans and only very indirectly in animals. Alternative and additional outcome measures, which can be assessed more objectively and in a range of situations, are essential to facilitate a number of investigations including the study of the ▶ pharmacokinetics of a drug, understanding dose–response relationships and the mechanism of action of the drug itself, drug safety, and investigating ▶ drug interactions.

There is almost an infinite number of psychophysiological (as defined earlier) outcome measures used in psychopharmacology, limited only by the ingenuity of the scientists involved. These include, for example, direct methods of investigating the effects of a drug on the physiological function of the central nervous system such as measuring changes in the brain electrical activity using ▶ electroencephalography (EEG) and magnetoencephalography (MEG). These techniques can be utilized in a myriad of ways. A common method of using the EEG to acquire information is to record ▶ event-related potentials (ERPs), that is, EEG activity recorded time locked to some event such as the presentation of a stimulus to a subject, or a subject's response. Examples of ERPs include the "▶ P300" (referring to a positive voltage deflection occurring around 300 ms after the presentation of rare or task relevant stimuli) and "▶ mismatch negativity" (a negative voltage deflection occurring after presentation of a stimulus that is deviant, for example, in terms of loudness, duration, or frequency), both of which have been widely used as outcome measures in psychopharmacological research. In recent years, there has been an explosion of novel analysis techniques of EEG data, much of which is focused around exploration of the frequencies of the signals contained within the EEG, which further enhances its potential utility as an outcome measure. At their heart, EEG and MEG techniques offer the opportunity for investigating the effects of psychopharmacological agents with high temporal resolution.

Recent decades have seen an explosion of neuroimaging techniques including their application in psychopharmacology. In the simplest types of paradigms, the notion is that a psychoactive substance leads to changes in psychological processes that are reflected by changes in the cerebral blood flow which can be measured using positron emission tomography (▶ PET) or functional ▶ magnetic resonance imaging (fMRI). Such techniques offer the opportunity of providing high-resolution spatial information regarding the site of action of the drugs. PET and other imaging methodologies can also be utilized with radio-labeled ligands to investigate a whole range of pharmacological processes including transmitter release and receptor binding.

Perhaps the most direct method of exploring the effects of a psychopharmacological agent on psychological processes is the use of neuropsychological tests to examine changes in cognition. ▶ Cognitive enhancement is a particular goal of a branch of psychopharmacology, for example, in the treatment of ▶ dementias. However, in addition, cognition can be utilized as an objective outcome measure in treatment studies using reliable neuropsychological tests of proven validity. Such tests can be combined with, for example, EEG or fMRI to provide additional information regarding which temporal and spatial component of a cognitive task is being influenced by the psychopharmacological agent.

Historically, some of the most widely used psychophysiological techniques have utilized the close interaction between the central nervous system and the ▶ neuroendocrine system. Such neuroendocrinological techniques offer the advantage of the simplicity of sample collection by measuring hormonal levels most commonly in plasma. The technique can be used in a number of different ways. For example, ▶ stress in a number of forms leads to the activation of the ▶ hypothalamic–pituitary–adrenal (HPA) axis with a consequent release of corticosteroids. The effect of a psychopharmacological agent on stress can be assessed by examining changes in peripheral corticosteroids. This is a classic example of where Furedy's (1983) point about the measures being "unobtrusive" is a key issue. If the method by which samples are collected is stressful, this may lead to an alteration in the measured levels of corticosteroids. An alternative neuroendocrinological strategy is to assume that changes in transmitter systems in higher centers are reflected in similar changes in these transmitter systems that control neuroendocrine function. An example of this approach, much in evidence in the 1980s and 1990s, is the use of growth hormone and prolactin responses to serotonergic probes such as ▶ tryptophan or ▶ buspirone, to assess the presumed functional status of hypothalamic 5-HT_{1A} receptors in mood disorders and following administration of ▶ antidepressants.

All of the above-mentioned methods can be considered as within Furedy's (1983) definition of "psychophysiological." However, within the specialty of psychopharmacology, the term in common usage usually refers to the more peripheral physiological effects of changes in the central

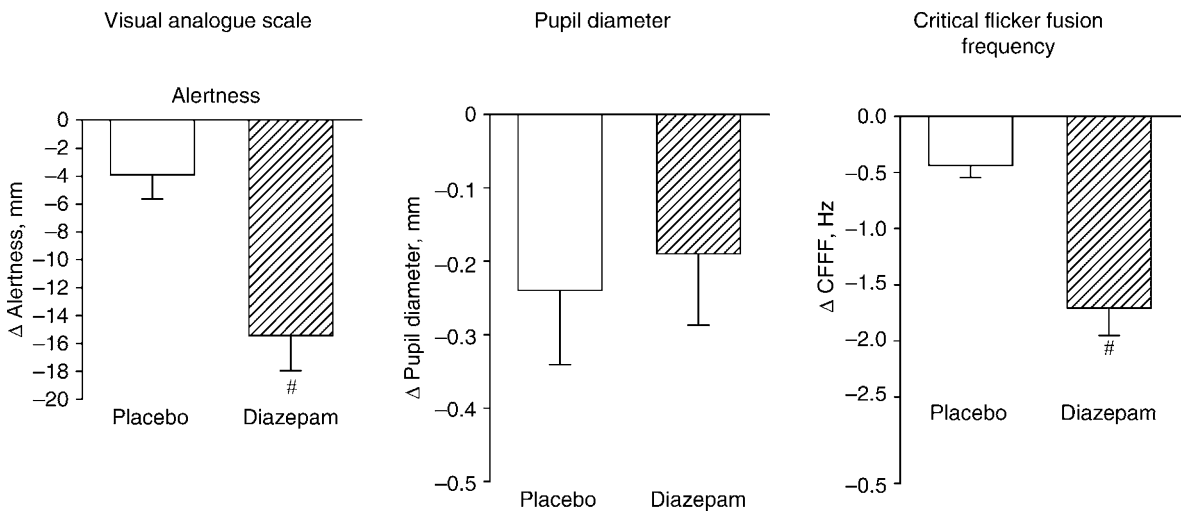
(psychological) function. Many, but certainly not all, of these effects relate to changes in the autonomic nervous system function as indexed by, for example, changes in pupil diameter, heart rate variability, and electrodermal responses.

Principles of Psychophysiological Methods as Applied in Psychopharmacology

Furedy (1983) argued that psychophysiology is different from physiological psychology in that the latter is related to the study of the physiological underpinnings of psychological processes. However, this is a "legitimate" area of study for the psychophysiologist, as perhaps the most important principle of psychophysiology is that the mechanism connecting the psychological process with the physiological response is known. Essentially, the issue here is the same as in any area of research when two measures are correlated; correlation does not imply causation. Heart rate may well be observed to increase when a person is anxious. However, it is necessary to be convinced that it is anxiety (a psychological process) in any particular circumstance that is leading to an increase in heart rate, to make it a viable psychophysiological measure. In psychopharmacology, the situation is even more complex when using psychophysiological outcome measures, because it is also important to know if the drug could be directly influencing the physiological response. A good example of this is the use of PET and fMRI imaging exploring blood flow changes in response to administration of a pharmacological agent. Before concluding that changes in the image signal relate to the effects of the drug on a particular psychological process, it is essential to know if the drug has direct effects on cerebral blood flow.

To illustrate the issues around the importance of understanding the mechanisms underlying psychophysiological effects and other principles of these methods, work in the area of arousal will be described.

A potential psychophysiological outcome measure to assess arousal is the diameter of a subject's pupil. Pupil diameter has a close relationship with arousal, with decreased arousal being accompanied by constriction of the pupil (miosis). This is believed to reflect decreased sympathetic activity as levels of arousal drop. The ▶ benzodiazepines, (e.g., ▶ diazepam), as anxiolytic and sedative drugs, cause a decrease in arousal. This can be assessed subjectively, for example, using visual analog scales (Fig. 1). Psychophysiology offers a more objective outcome measure. However, diazepam does not lead to any change in papillary diameter (Hou et al. 2007, Fig. 1). Does this paradox suggest that either diazepam is not sedating or pupillary diameter is a poor psychophysiological outcome measure? The former option seems an unlikely explanation. In the study by Hou et al. (2007), additional psychophysiological measures of alertness were also conducted. These included the ▶ critical flicker fusion frequency (▶ CFFF) test. This involves determining the frequency at which a flickering light gives rise to the sensation of a steady light. This is measured by



Psychophysiological Methods. Fig. 1. Level of alertness following a single oral dose of diazepam 10 mg given to 16 healthy male volunteers. exposing the subjects both to a low-frequency flicker and increasing the frequency to the point at which the subject has the sensation that the flickering stops, and a high-frequency flicker that decreases to the point at which the flicker is detected. The CFFF is the mean of the two. As in all areas of science, having well-designed methodology that is objective, valid, and replicable is essential. The CFFF is a test that has been in usage since the 1950s and it is well accepted as a psychophysiological measure of arousal (Tomkiewicz and Cohen 1970). Hou et al. (2007) showed a significant effect of diazepam on the CFFF (Fig. 1), suggesting that diazepam does indeed have an effect on arousal and this can be measured both subjectively and objectively. They provided data that suggest that the paradox of the lack of effect of diazepam on pupil diameter relates to a lack of effect on either the sympathetic or parasympathetic influence on the iris. This highlights the importance of being aware of both the pharmacology of the drug being studied and the mechanism of the psychophysiological tests being used.

However, it is incorrect to think that diazepam has no effect on the pupil. In addition to simply measuring the pupil diameter, Hou et al. (2007) also measured spontaneous pupillary fluctuations, by analyzing these data in two ways: first, by performing an analysis of the frequency of fluctuations using a ► Fast Fourier Transformation to obtain an assessment of power, and second, by a "pupillary unrest index," (PUI) which is the distance travelled by the margin of the pupil in 1 min. These two measures reflect "pupillary fatigue waves" (Ludtke et al. 1998) that are believed to closely parallel fluctuations in the activity of the noradrenergic neurons of the locus coeruleus (Aston-Jones and Cohen 2005), influenced by arousal. While diazepam has no effect on static pupil diameter (Fig 1), it significantly increases the pupillary fluctuation power and PUI (Hou et al. 2007, Fig. 2), in line with its proposed sedating effects and the results from the CFFF test. The study illustrates the importance of utilizing a range of methodologies relating to different mechanisms and pathways whenever possible to be able to draw legitimate conclusions regarding the effect of the drug. Further, the study illustrates the complexity and ingenuity of many modern psychophysiological tests.

Advantages and Limitations of Psychophysiological Methods

As described earlier, the most obvious advantage of psychophysiological methods is their use in providing objective outcome measures of the effects of psychopharmacological agents, and as such, they relate to the very essence of the discipline. There is an enormous range of such techniques and it is impossible to delineate all their advantages and limitations here. The various methods span a range of ease of use, cost, and utility. Their main limitations are when there is a lack of a clear understanding of the mechanism underlying the response being measured, and the direct and indirect effects that a drug may be having on it.

Psychosis

Definition
The word "psychosis" is used to describe conditions that affect the mind, in which there has been some loss of contact with reality. A psychotic episode can be caused by several psychiatric disorders. Somatic disorders can also cause psychotic symptoms, as well as prescribed and non-described drugs.

Psychosocial Interventions

Definition
Psychosocial interventions are measures usually provided in addition to medical treatment for psychiatric patients. They can consist of counseling through social workers, different psychotherapeutic methods such as cognitive behavioral therapy (CBT), interpersonal therapy, subliminal stimulation, supportive-expressive therapy, and contingency management approaches such as voucher incentives.

Psychostimulant Addiction

Synonyms
Psychostimulant dependence

Definition
Psychostimulant addiction (dependence) is a chronic, relapsing disorder diagnosed by the hallmark of compulsive drug-taking and drug-seeking to the exclusion of other important life activities. The feeling states of craving (an intense desire for the drug) and euphoria are primary correlates of the addiction. Brain areas important for decision making, learning, memory, and behavioral control are altered in individuals addicted to psychostimulants and other abused drugs.

Pharmacological Properties

History

Psychostimulants are a broad family of drugs that include compounds from naturally occurring plant alkaloids (e.g., ▶ caffeine, ▶ cocaine, ephedrine, ▶ nicotine) to synthetic ▶ amphetamine derivatives such as D-amphetamine, ▶ methamphetamine, and 3,4-methylenedioxymethamphetamine (▶ MDMA; ecstasy) as well as ▶ methylphenidate. Some of these psychostimulants are available over-the-counter (e.g., caffeine) or under prescription for a given medical indication (e.g., ▶ methylphenidate), while others are illicit and available only on the black market (e.g., MDMA). The use of psychostimulants has been recorded throughout history, dating back to Paleolithic times when Ethiopian nomads brewed *Coffea arabica* (coffee) into a stimulating beverage, North American Indians smoked wild tobacco *Nicotiana* variants, and Peruvian Indians chewed the leaves of *Erythroxylum coca* (cocaine) to enhance endurance and energy, while Chinese physicians utilized *Ephedra vulgaris* (ephedrine) to treat fever, nasal congestion, and asthma. The scientific literature has focused on several members of the broad family of psychostimulants, including caffeine, cocaine, amphetamine derivatives, and nicotine.

Caffeine has been consumed in concoctions derived from plant sources since prehistoric times. This mild stimulant and diuretic found naturally in coffee, tea, and cocoa is currently the most widely used psychoactive substance in the world. Employed to enhance alertness and reduce fatigue, caffeine is now an additive to many other food substances, including beverages which boast names such as *Jolt*, *Surge*, and *Full Throttle*. Caffeine is used medically to enhance the ▶ efficacy of medications used in the treatment of migraine and pain, and is occasionally used to stimulate respiration, or to overcome the sedative effects of antihistamines.

Cocaine is one of about a dozen alkaloids of the Coca plant and was first isolated in 1855. By the late 1800s, cocaine was widely used for its analgesic properties and was sold over-the-counter until 1916. By the early twentieth century, the addictive properties of cocaine were well known, and, in 1970, cocaine was officially made illegal and classified as a ▶ Schedule-II drug (limited medical uses) in the United States under the ▶ Comprehensive Drug Abuse Prevention and Control Act of 1970 (Controlled Substances Act). Cocaine is used in various forms including powder, freebase, and crack, and is currently one of the most-popular, abused street drugs in Western society. The powder form of cocaine is snorted or injected while freebase or crack cocaine is smoked. The therapeutic uses of cocaine are limited to its application as a topical analgesic in ear, nose, and throat surgeries. Street names abound for the various abused forms of cocaine, including coke, snow, flake, blow, candy, rock, and toot, for example.

The use of amphetamine derivatives dates back to Neolithic times in China and Africa where herbs in the genus *Ephedra* (Ma huang) and *Catha edulis* (khat or qat) were employed for their stimulant properties. Ephedrine was isolated from the *Ephedra* plant in the late 1800s, and was soon utilized widely to treat asthma. In the 1920s, interest in finding a synthetic substitute for ephedrine brought about the extensive characterization of the structurally similar compound amphetamine which had first been synthesized in 1887. Soon thereafter, amphetamine was marketed to treat nasal congestion, ▶ narcolepsy, and ▶ attention deficit hyperactivity disorder (ADHD) and subsequently, a number of amphetamine analogs were developed and characterized, including the now-popular street drugs, methamphetamine and MDMA (ecstasy).

Amphetamine use was common during World War II when soldiers were issued the stimulant to decrease fatigue and increase alertness. In the 1950s, legally manufactured tablets of amphetamine and methamphetamine were utilized by college students, truck drivers, and athletes across the United States to stay awake and get more energised. Amphetamines were widely prescribed through the 1960s to suppress appetite and enhance weight loss. While effective for this purpose, the high abuse liability of amphetamine outweighed their utility for this indication. Due to the epidemic of amphetamine use, the US Bureau of Narcotics and Dangerous Drugs [BNDD; later named the Drug Enforcement Administration (DEA)] shifted all amphetamine products to Schedule II in 1971 under the Controlled Substances Act. A prescription then became required for possession of an amphetamine. In 1988, the growth in abuse of MDMA and evidence to suggest its systemic toxicity prompted the classification of this amphetamine derivative as ▶ Schedule I-controlled substance (due to its high abuse potential and no currently accepted medical use). Street names for amphetamines include speed, uppers, crosses, and black beauties.

Nicotine is the active psychostimulant alkaloid of the tobacco plant. Introduced to Western society in the 1500s, tobacco had been used by Native Americans and Asians for centuries before. By 1964, scientists had concluded that tobacco smoking was causally linked to lung cancer and heart disease, and health warnings were deemed mandatory for tobacco products. The principal therapeutic use of nicotine and ▶ nicotine agonists (e.g., the partial ▶ agonist varenicline) is in the treatment of ▶ nicotine dependence.

Effects in Humans

The constellation of subjective effects that characterize the "intoxication" induced by psychostimulants and that capture the attention of users as "pleasant", includes euphoria, mood elevation, enhanced feelings of well-being, and motor and mental stimulation, although each psychostimulant provokes a unique subjective profile. For example, caffeine is generally not euphorigenic, while MDMA users also report feelings of closeness with other people, increased empathy, and perceptual alterations when under the influence of this drug. Despite their subjective effects that are perceived as positive, psychostimulants also have many negative consequences. Some stimulant users report anxiety, decreased appetite and weight loss, feelings of restlessness, irritability, and sleep disturbances. Other negative consequences include cardiac arrhythmia, seizures, and myocardial infarction. Higher doses, which are often used to intensify the high, may also induce aggressiveness, disorientation, hallucinations, paranoia, muscle twitches, tremors, and vertigo. Additionally, high doses of MDMA evoke hyperthermia, which can lead to life-threatening conditions such as multiple organ failure; cocaine can also elicit hyperthermia, but this effect is less reported than that evoked by MDMA.

When taken chronically, psychostimulants (especially, cocaine and amphetamine derivatives) may lead to ▶ stereotypical and repetitive behavios. Compulsive drug-taking and drug-seeking can develop while the emergence of additional psychiatric disorders can be observed, including ▶ anxiety, ▶ depression, and a paranoid psychosis that shares some features of ▶ schizophrenia. Toxic physiological reactions are also observed. Individuals addicted to psychostimulants are remarkably willing to risk death, incarceration, medical and psychiatric complications, job loss, and family turmoil in pursuit of the drug.

Mechanisms of Action

▶ Dopamine is the most-prominent, well-studied neurotransmitter involved in the effects of psychostimulants. The dopamine mesoaccumbens pathway, originating in dopamine somata of the ▶ ventral tegmental area and terminating in the ▶ nucleus accumbens, mediates the reinforcing effects of natural rewards (i.e., food and sex) and also serves as a common substrate for the acute rewarding effects of all drugs of abuse, regardless of their individual mechanisms of action (for review, see Kelley 2004). In addition, dopaminergic influence, in conjunction with glutamatergic neurotransmission, within nodes of the extended, limbic corticostriatal circuitry (▶ prefrontal cortex, ▶ amygdala, ▶ hippocampus) is integral in coordinating reward-related associative learning and motivated behaviors that contribute to aspects of addiction such as ▶ craving, ▶ withdrawal, and relapse (Kelley 2004). While dopamine is integral to the normal function of this brain circuitry, regulatory oversight of the signaling involved in reward circuits is provided by multiple ▶ neurotransmitters.

Each psychostimulant presents a distinct profile of actions that mediates its psychostimulant effects. The caffeine molecule bears structural resemblance to the endogenous neurotransmitter adenosine and appears to evoke its psychostimulant effects due to its action as an adenosine receptor ▶ antagonist in the brain (Ferre 2008). This action of caffeine occurs at the adenosine A_{2A} receptor which plays a critical role in the control of dopamine function in reward and arousal. Additional actions of caffeine in the body abound while metabolites of caffeine also contribute to its biological profile. There is also emerging evidence that selective A_{2A} adenosine receptor antagonists may prove useful in the pharmacotherapy of stimulant addiction (Ferre 2008), although this hypothesis remains to be fully explored (see Psychostimulant Addiction below).

Amphetamines and cocaine present a multifaceted regulatory impact over ▶ monoamine function, and the chemical structure of the amphetamine molecule is a determinant of its exact pattern of influence over neuronal function (Sulzer et al. 2005). The effects of cocaine and amphetamine derivatives in humans are thought to be mediated by their ability to enhance synaptic concentrations of monoamines via actions at neurotransmitter ▶ transporters for dopamine, ▶ serotonin (5-HT), and ▶ norepinephrine. These transporters are found in the outer membranes of monoamine neurons and act to reuptake neurotransmitters released by the nerve terminal. In fact, reuptake serves as the primary mechanism of inactivation for released monoamine neurotransmitters. Amphetamine derivatives display different profiles of ▶ affinity for and efficacy at the three monoamine transporters. In general, amphetamine derivatives increase synaptic monoamine levels through both the blockade of reuptake and reversal of the membrane-localized transporter for these monoamines. The reversal of the transporter results in release of monoamines from the nerve terminal, providing an additional mechanism for elevation of synaptic neurotransmitters. The parent molecule, amphetamine, has greatest affinity for the ▶ dopamine transporter, while methamphetamine and MDMA have greater affinity for the ▶ serotonin transporter when compared to the dopamine or ▶ norepinephrine transporter. Amphetamines can interfere with the storage of monoamines in compartments (vesicles) inside neurons,

and can retard degradation of monoamines. Both of these actions further result in increased accumulation of free neurotransmitter in the nerve terminal (Sulzer et al. 2005).

Cocaine binds to the monoamine transporters and inhibits reuptake of dopamine, serotonin, and norepinephrine. Thus, by blocking reuptake, cocaine increases the length of time that the monoamines remain in the synapse available to activate their receptors. Cocaine is also reported to have affinity for the serotonin 5-HT_3 receptor, M_1 and M_2 ▶ muscarinic receptor, and σ-receptors, although their roles in mediating the stimulant effects of cocaine are not clear.

Nicotine acts as a psychostimulant at very low doses through activation of endogenous nicotine receptors, proteins that are normally activated by the endogenous neurotransmitter ▶ acetylcholine. Its actions result in increased levels of DA in reward circuits of the brain, providing a neuroanatomical basis for its stimulant effects.

Psychostimulant Addiction

The new millennium dawned on a continuing societal struggle with the consequences of use and abuse of psychostimulants. Stimulant abuse remains an alarming concern and the issues are complex. On the one hand, stimulants have diverse therapeutic utility in a large population for which they are essential (e.g., attention deficit disorders). On the other hand, the abuse of illicit stimulants such as cocaine, methamphetamine, and other substituted amphetamines does not show signs of abatement. For example, the United Nations Drug Control Program (UNDCP) estimates that cocaine use affects about 13 million people (0.3% of the global population above age 15 years), making cocaine the second, most-common illegal drug of abuse (United Nations Office on Drugs and Crime 2007). Despite the general decline in illicit drug use among US teens, little systematic change for 8th–12th graders has been noted in use, perceived risk of use, or disapproval of use of crack cocaine or powder cocaine in the past 4 years (Johnson et al. 2006). In addition, a growing number of individuals now seek treatment for cocaine addiction in the United States; epidemiological studies suggest that approximately 16% of the people who use cocaine become dependent on the drug (Substance Abuse and Mental Health Services Administration 2007). The "cocaine problem," combined with the escalating abuse of methamphetamine and prescription amphetamines, is a colossal challenge which must be tackled with all available resources. The recidivism rate of stimulant users is very high, and access to effective treatment modalities are so rare, that new, easily available and effective treatments are needed. To achieve this goal, an essential understanding of the neurobiological mechanisms underlying stimulant-abuse disorders and their persistence is required. The long history and cyclical nature of stimulant abuse, the emergence and subsidence of a given psychostimulant as an abused favorite, concurrent with the emergence of yet others, suggest that there is a need to take a long and realistic view. There will be a continuing need to deal with the problems of stimulant-use disorders, either with those known or those that will emerge in the future.

The transition from psychostimulant use to addiction occurs most evidently for cocaine and amphetamines, particularly methamphetamine. Addiction in vulnerable individuals can be viewed in stages from initial use to active abuse with escalating and sustained dependence on the drug. Psychostimulant dependence (addiction) is diagnosed as the hallmark of compulsive drug-taking and drug-seeking to the exclusion of other important life activities. Although patients cite many behavioral reasons for why they use a psychostimulant, the feeling states of craving (an intense desire for the drug) and euphoria are primary reinforcers of the addiction. Drug-induced euphoria and craving alternate over time, exerting positive and negative reinforcement to form a cycle of addiction that becomes increasingly entrenched and uncontrollable. The severity of stimulant addiction can progress very rapidly in vulnerable individuals. While it may take years or decades for alcoholics to develop end-stage alcoholism, progression to severe dependence among stimulant abusers typically occurs more rapidly. Rapid progression is particularly common with the smoked, freebase form of cocaine known as crack, probably because the intrapulmonary route is the quickest means of delivering a ▶ bolus of cocaine to the brain. Because cocaine and amphetamine addiction involves brain reward centers, the strength and characteristics of stimulant use take on an almost primary survival drive. The inability of patients to control stimulant use illustrates the power of reward centers over behavior, and partially explains the relapsing nature of cocaine and amphetamine dependence (Volkow and Li 2004).

The etiology of stimulant-use disorders includes genetic, psychological, pharmacological, neural, and environmental determinants. Major advances in understanding the neurobiology of addiction have been generated over the last 25 years revealing the complex biological processes that trigger and sustain addictive behavior and the physiological ramifications of chronic exposure to abused drugs (Everitt and Wolf 2002; Kalivas and Volkow 2005; Kelley 2004). The escalation from drug use to drug addiction is linked inextricably to brain pathophysiology, composed of a myriad of neuroadaptive responses (termed ▶ Neuroplasticity), that develops during chronic drug exposure

and alters normal homeostasis. Some of these neuroadaptations underlie the evolution of strong mnemonic associations between environmental cues and the drug-taking experience as well as emerging psychiatric complications. Cessation of drug use during ▶ abstinence represents another phase of addiction during which drug withdrawal, "craving," poor impulse control, and reactivity to drug-associated environmental cues challenge the best intentions of the addict to remain abstinent. Each of these hallmark phases (predrug exposure, early drug exposure, chronic abuse, dependence, withdrawal, abstinence) are stages during which brain circuits that normally control the intertwined processes of reward, motivation, memory, stress responsivity, and emotional processing accumulate adaptations that contribute significantly to the behavioral sequelae of addiction. The normality of these circuits are dependent upon the function of overlapping neurotransmitters in the brain, and the impact of a given psychostimulant on these neurotransmitters set in motion the turmoil of addiction. Drug-induced neuroadaptations of genes and proteins in these circuits have been described and include neurotransmitter transporters and receptors, synthetic enzymes, and numerous transcription factors. However, the specific protein changes that contribute to neural plasticity associated with drug exposure, the reversibility of such modifications, how it all fits together remains to be determined.

The complex neuronal interconnectivity is genetically determined, but environmentally tweaked, to provide infinitely unique individuals. This ▶ epigenetic background provides the fertile soil into which the use of a drug of abuse is introduced; if the individual is vulnerable to the rewarding and reinforcing effects of the drug, then the transition from use to abuse and then to dependence can be set in motion. Time-locked modifications in neurotransmitter functionality culminate in neuronal plasticity in these circuits, a devolutionary process that presumably results in the patterns of drug-taking and drug-seeking behavior which characterize addiction.

Modeling Psychostimulant Addiction in Animals

The development of effective approaches to treatment of stimulant addiction relies on well-designed clinical research in drug-using subjects, as well as preclinical research in which rigorous experimental control and specific behavioral and pharmacological manipulations can be undertaken to model and control the progression of drug-taking and drug-seeking across time. These models have greatly enhanced our understanding of the roles of dopamine, serotonin, and other neurotransmitters in the rewarding, reinforcing, and conditioned effects of stimulants (Bubar and Cunningham 2008; Kalivas and Volkow 2005). These preclinical advances originally focused the field on the dopamine neurotransmitter system as a relevant target for medications development for psychostimulant abuse. However, clinical trials have not yet identified dopamine-based pharmacotherapies which lack abuse liability, yet exhibit efficacy to enhance abstinence, reduce craving, and prevent relapse. Alternative investigations now suggest that in addition to dopamine, other neural systems play equally important roles in addictive processes, including ▶ serotonin, ▶ glutamate, ▶ adenosine, ▶ GABA, and ▶ neuropeptides; and these results have generated interesting new prospects for pharmacotherapy. These systems may function to modulate the neural output of the anatomically defined reward circuit and in the wider circuit of reciprocal interactions termed the limbic cortical–ventral striatopallidal circuit (Everitt and Wolf 2002).

The animal model with the greatest face validity to model the reinforcing and rewarding effects of drugs of abuse is the intravenous ▶ drug self-administration paradigm, which has been well characterized in rodents and nonhuman primates (Mello and Negus 1996). Drugs of abuse are readily self-administered by animals and in general, drugs that are self-administered correspond to those that have a high-abuse potential in humans. The advantage of this model is that it most closely resembles the different stages of human drug dependence – acquisition, maintenance, and relapse – which have led to a greater understanding of the neurobiological underpinnings of addictive behavior. Drug self-administration is solidly based upon the ▶ operant conditioning principle of "reinforcement." In drug self-administration, the presentation of a stimulus (e.g., cocaine as an appetitive "reward") contingent upon a behavioral response increases the probability that that behavior will reoccur. Based upon the ability of an animal to make an operant response (e.g., nose poke or lever press) which is reinforced by the presentation of a psychostimulant reward, this assay is widely used to study environmental and pharmacological variables important in the initiation, maintenance, and escalation of drug-taking behavior. For intravenous self-administration studies, the subject acquires a drug infusion by performing a discrete response. The number and pattern of responding required for each infusion is determined by the ▶ schedule of reinforcement imposed by the experimenter. Drug availability typically is signaled by an environmental stimulus, and the dependent variables are the number of infusions obtained or the rate of responding (i.e., lever presses or nose pokes) during a session (Mello and Negus 1996).

Modeling Drug-Seeking and Relapse

A basic definition of relapse in the context of drug abuse and addiction is the return to drug-seeking and drug-taking behavior following a period of abstinence. Often the role of craving – defined as an intense desire for a specific object or experience – is invoked as a primary motivating force behind relapse, and pharmacological means to reduce this behavior are being sought as potential "abstinence enhancers." It is widely known that conditioned cues associated with psychostimulant use are a major factor in relapse to continued use, and it is clear that associations between environmental cues and the drug-taking experience become well consolidated into memory. In fact, the molecular pathways of drug addiction overlap prominently with those involved in learning and memory processes, as elegantly reviewed by Kelley 2004. The ▶ reinstatement of drug self-administration paradigm possesses good predictive and face validity for modeling the activation of craving states by conditioned environmental stimuli (e.g., places in which a drug was consumed or drug-associated paraphernalia) in drug-dependent individuals. In these models, conditioned cues previously associated with psychostimulant reward (e.g., lights, tones) are presented in the absence of the drug either to trigger the operant responses engendered in the drug-taking situation of self-administration or reinforce the continued drug-seeking by presentation of the cues upon the behavioral response. The use of noncontingent ("priming") injections of drugs to induce reinstatement of drug self-administration has equally been found to produce a robust degree of reinstatement and is a good model for pharmacologically induced relapse in addiction (Mello and Negus 1996). The preclinical models described have been developed and shaped to further the understanding of processes involved in the transition of psychostimulant use to addiction. In addition, the imperative to discover the means to reverse neuroplastic events resultant from psychostimulant exposure and to therapeutically improve function in the addicted brain requires refined preclinical models.

The Future

We have entered the world of personalized medicine in which a patient's unique genetic and phenotypic profile will ultimately provide the signposts to tailor diagnosis and treatment for diseases, with reduced side-effect profiles. The science in chronic diseases such as cancer and diabetes is rapidly advancing in these goals to provide new targeted diagnostics and medications for treatment tailored to provide the best clinical response in an individual. The vision to improve our diagnostic and prognostic capabilities with identified disease biomarkers for psychostimulant abuse and addiction, to understand vulnerability to addiction and relapse, and to treat this complex disorder with maximal efficacy is now within reach of addiction scientists.

One important research imperative has been the development of effective, accessible treatment medications for stimulant addiction (Mello and Negus 1996). Effective medications for alcohol, opioid, and nicotine addiction are available. For example, nicotine gum, patches, and lozenges are therapeutically useful in smoking cessation programs, and the recent launch of the nicotine receptor partial agonist, ▶ varenicline, provides an additional option. However, there are currently no approved medications for treatment of dependence on cocaine or amphetamine derivatives such as methamphetamine, although over 60 medications have been tested in clinical trials (Vocci and Ling 2005). The initial focus of medications development for cocaine addiction was to utilize compounds that act at dopamine receptors or the reuptake transporter. However, agents that act as dopamine D_1 or D_2 receptor antagonists were either ineffective or resulted in unwanted side effects. Another strategy studied was the use of the selective dopamine transporter inhibitor GBR12909; however, the ▶ Phase I trials were halted early because of potential cardiovascular toxicity. ▶ Antidepressants have also been employed in ▶ open-label and ▶ placebo-controlled clinical trials; however, both ▶ tricyclic antidepressants such as desipramine and selective serotonin reuptake inhibitors (▶ SSRIs), such as ▶ fluoxetine, were found to be ineffective in several studies.

Several drugs with various mechanisms of action are currently under study in cocaine- and/or methamphetamine-dependent subjects in outpatient clinical trials (www.clinicaltrials.gov) in which efficacy to decrease drug-positive urines and/or reduce craving are measured:

- D-*Amphetamine*: Oral administration of D-amphetamine or methamphetamine appears to be effective at reducing cocaine use and craving. Under evaluation in Phase I and ▶ Phase II trials for cocaine dependence, amphetamine pharmacotherapy is an example of an agonist-replacement therapy similar to the use of methadone for ▶ opioid dependence.
- *Aripiprazole*: An ▶ atypical antipsychotic - that acts as an antagonist at dopamine D_2 receptors and serotonin 5-HT_{2A} receptors, ▶ aripiprazole may be useful for treatment of cocaine dependence in individuals with comorbid schizophrenia. This drug is also under evaluation for treatment of cocaine-dependent polydrug users being maintained on methadone as well as in

methamphetamine-dependent patients to reduce craving and relapse.

- *Caffeine*: Preclinical studies demonstrating the involvement of adenosine receptors in the reinforcing effects of cocaine and methamphetamine prompted initiation of Phase I and Phase II clinical trials evaluating utility of the nonselective adenosine receptor antagonist caffeine to reduce cocaine use and modulate related behaviors (impulse control and cue reactivity). Basic research studies with *SYN115*, a more selective antagonist at the adenosine A_{2A} receptor, are also being initiated in cocaine-dependent subjects to determine its effects on behavior and brain function in these individuals.
- *Citalopram/escitalopram*: Unlike other SSRIs, ▶ citalopram was shown to reduce cocaine use and craving, possibly due to its additional actions as a serotonin 5-HT_{2C} receptor agonist. Phase-II and ▶ Phase III clinical trials are being conducted to evaluate citalopram and its S-enantiomer ▶ escitalopram for cocaine dependence.
- ▶ Disulfiram: An inhibitor of dopamine β hydroxylase (DβH), the enzyme that converts dopamine into norepinephrine, disulfiram has been shown to reduce craving and withdrawal associated with cocaine administration, particularly in subjects that naturally have low levels of DβH activity. Disulfiram is currently being evaluated in clinical trials for cocaine-dependent subjects who are also dependent on opioids or alcohol, as well as Phase-I and Phase-II trials for methamphetamine dependence. *Nepicastat*, a more selective DβH inhibitor, is also being evaluated for efficacy in cocaine dependence.
- *Mirtazapine*: An antagonist at serotonin 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors, ▶ mirtazapine is under evaluation for treatment of cocaine and methamphetamine dependence, and for treatment of cocaine-dependent individuals with depression.
- ▶ Modafinil: The glutamate-enhancer ▶ modafinil has shown promise in clinical trials for treatment of cocaine dependence, reducing the number of cocaine positive urines in cocaine-dependent subjects. Modafinil is currently being evaluated in Phase-II and ▶ Phase-III trials for cocaine dependence and Phase-II and Phase-IV trials for methamphetamine dependence.
- *Quetiapine*: An ▶ atypical antipsychotic that acts as an antagonist at multiple receptors, including dopamine D_1/D_2, serotonin 5-HT_{1A}/5-HT_2, and α_1/α_2 adrenergic receptors, ▶ quetiapine is being evaluated for treatment of cocaine dependence, methamphetamine dependence, and cocaine/methamphetamine dependence comorbid with either ▶ bipolar disorder or schizophrenia.
- *Topiramate*: ▶ Topiramate enhances GABA-activated chloride channels, while inhibiting excitatory neurotransmission through actions on kainate and AMPA receptors. This drug is under evaluation for cocaine dependence as well as for treatment of individuals with comorbid cocaine and alcohol or cocaine and opioid dependence.
- *Vigabatrin*: Vigabatrin enhances levels of the neurotransmitter GABA by inhibiting its catabolism via GABA transaminase. Several Phase-II trials are underway with vigabatrin for treatment of both cocaine and methamphetamine dependence.

The observation that about 60% of alcohol-, opioid-, or cocaine-dependent patients who received treatment medications relapsed into drug use within one year suggests that further research and advancement of these efforts is essential in order to improve treatment efficacy. The development of new pharmacological agents for the treatment of substance-use disorders would greatly increase treatment and access options, particularly if medications to enhance abstinence, reduce craving, and prevent relapse could be perfected. This is an important quest and one ripe for with near-term therapeutic potential with positive outcomes.

Pulmonary Hypertension

Definition

Pulmonary hypertension is an increase in blood pressure in the pulmonary artery, pulmonary vein, or pulmonary capillaries, leading to shortness of breath, dizziness, fainting, and other symptoms. Pulmonary hypertension can

involve a markedly decreased exercise tolerance and heart failure. The PDE5 inhibitor sildenafil, which is used to treat erectile dysfunction, is also used for the treatment of pulmonary arterial hypertension. But it is on the market under the name of Revatio to avoid confusion with Viagra.

Punishment

Definition

A behavioral process wherein the consequences for an operant make instances of the operant less frequent in the future. Such consequences take the form of presentations of environmental stimuli, which are thereby defined operationally as aversive (punishers). Such stimuli can either be exteroceptive (e.g., pain-inducing events such as excessive heat or pressure) or interoceptive (e.g., noxious drugs).

Definition

Punishment is defined as the suppression of behavior that results from the response-dependent delivery of a stimulus (punisher). Punishment procedures in rodents and other species have been used for nearly 50 years to detect effects of classical anti-anxiety agents (e.g., benzodiazepine receptor agonists such as valium) as well as other mechanisms that are or might prove to be anxiolytic in humans. Classical anxiolytic agents including ethanol increase behavior suppressed by punishment. The punishment procedures include passive avoidance, conflict tests, and other related methods. The conflict tests have been most widely used and include the Geller–Seifter and Vogel conflict tests of which a host of variants exist. In the Geller–Seifter test, stable baselines of responding are maintained in the presence of one stimulus and suppressed by punishment in the presence of an alternate stimulus. In the Vogel conflict procedure, drinking is suppressed by drink-dependent delivery of electric shock. The two procedures differ principally in that drug effects in the Geller–Seifter conflict test are evaluated against steady-state behavioral suppression whereas under the Vogel conflict tests, drug effects are evaluated for their ability to prevent response suppression upon the introduction of shock. A related test, albeit not explicitly a punishment procedure, is the conditioned-emotional response test (CER) in which a stimulus that is temporally paired with shock suppresses ongoing responding.

Impact of Psychoactive Drugs

Preclinical evaluation of the potential efficacy of putative anxiolytic agents has relied heavily upon the use of a variety of punishment procedures in experimental animals. Punishment is operationally defined as a decrease in the future probability of behavior subsequent to the response-dependent presentation of a stimulus (punisher). Punishment procedures have been studied widely and have been used for both behavioral analyses as well as for assessing drug action, yielding a wealth of information on both behavior and pharmacology. For the most part, the behavioral procedures have employed electric shock as the punishing event, mainly because it is discrete, readily controllable, and manipulable over a wide range of intensities. Other events have been employed (e.g., blasts of compressed air, electrical brain stimulation) but these have typically yielded a similar behavioral and pharmacological outcome. One of the earliest punishment methods to be used was the so-called *passive avoidance procedure*. Under this procedure, the movement of a rodent from one portion of an apparatus to another resulted in the delivery of electric shock. Subsequent placement of the rodent in the initial portion of the apparatus resulted in a

decrease in the probability of moving to the second location. It was found that drugs with anti-anxiety effects in humans would increase this suppressed behavior (Kelleher and Morse 1968). Despite the relative simplicity of this procedure, passive avoidance is highly influenced by variables controlling memory hence, memory disruptors can be false positives (e.g., scopolamine) in this procedure when attempting to assess potential anxiolytic drug effects. Thus, due to a host of factors including the lack of discrete responses and the detection of false positives, other punishment methods have dominated the anxiolytic drug discovery process for decades. These latter methods utilize the discrete response of a lever press, nosepoke, or lick on a drinking tube; these responses are typically controlled by ► schedules of reinforcement and are not as readily influenced by memory disruption as passive avoidance responses.

Another punishment procedure that utilizes the movement of rodents as the dependent variable is the *four-plate test*. Under this procedure, rodents are placed in an open arena in which four metal squares are situated. Contact with the metal results in electric shock to the paws and subsequent suppression of behavior. As in the case of the passive avoidance procedure, anxiolytic agents can increase movement within such an environment and the probability of contact with the metal plates.

A variant of the four-plate test involves active behaviors engendered by the punisher. Exposure to electric shock can result in burying behaviors if material is made available that permits burying to occur. For example, in the *shock-probe-burying test* (sometimes referred to as defensive burying), rodents, generally rats, are placed in a chamber with bedding material in which an electrified probe exists. Contact with the probe as a result of exploratory behavior results in the delivery and an electric shock, which generally leads to *increases* in the probability of burying of the probe. Anxioltyic drugs decrease the probability of shock-induced burying (File et al. 2004). Although not a punishment procedure per se, another highly used method for screening potential anxiolytic agents is marble burying. Mice placed in a bedding filled chamber with marbles on the top of the bedding will bury the marbles and such burying behavior is reduced by anti-anxiety drugs (Borsini et al. 2002).

Although first-and second-generation anti-anxiety drugs were not developed through the use of punishment procedures, the clinical efficacy of ► meprobamate, ► barbiturates, and later ► benzodiazepine-based anxiolytics led to more refined methods capable of detecting the distinct behavioral effects engendered by these compounds. Geller and his colleagues were the first to develop and pharmacologically characterize a punishment procedure (*Geller–Seifter conflict*) that embodied several distinctive features (Geller et al. 1962). Under the Geller–Seifter or Geller conflict procedure, lever-pressing of food-deprived rats is maintained under a variable-interval 2 min schedule of food delivery in which a lever press results in food delivery on the average of every 2 min. Interspersed throughout this initial training are 3-min periods in which a tone is presented and every lever press during the tone produces food. Subsequently, foot shock is introduced during the tone periods such that each lever response produces both food and shock. Under stable conditions, a relatively constant rate of responding occurs in the unpunished component and lower rates of responding occur in the tone period associated with punishment. The effects of drugs are assessed under this stable baseline of unpunished and punished responding. Typically, drugs are studied in the same animals with a drug free period of a day to several days allowing stable pre-drug rates of responding to become reestablished. Many variations of the Geller–Seifter conflict test have been developed and utilized over the almost 50 years since its introduction into the behavioral pharmacology arena. The most common variations have involved changes in the schedule of food delivery in either the unpunished or punished components or variations in the schedule or the intensity of shock delivery. One common variation in food scheduling is one involving fixed-ratio schedules of food delivery. Under one variation, a variable-interval schedule of food delivery is used to control unpunished responding and a fixed-ratio 10 schedule control punished responding where every tenth lever-press produces food and shock. Another common variation schedules response-dependent shock delivery for only the first response in the fixed-ratio of responses required for food delivery. In all cases, if other experimental conditions are set appropriately (see below), benzodiazepine anxiolytics such as diazepam increase the rate of suppressed or punished behavior.

A great advantage of the Geller–Seifter conflict methods are the highly reproducible behavioral baselines that are maintained and the reliable sensitivity of this behavior to drug effects engendered by the judicious scheduling of reinforcing and punishing events. In addition, the control by discriminative stimuli during the unpunished and punishment periods permits a simultaneous assessment of anxiolytic-like effects and effects on behavior not controlled by punishment. In addition, there is the benefit that comes from the ability to use the experimental subjects as their own controls, which greatly minimizes variability and the need for large numbers of animals. With

these advantages, however, comes the burden of time that is needed to establish stable behavioral performances.

In an attempt to decrease training time, the *Vogel conflict test* was developed (Vogel et al. 1971). The procedure utilizes water drinking in water-deprived rodents as the response. There is little training required to develop drinking from a drinking tube. Drug testing can occur after only a day of exposure to this procedure. During the actual assessment of drug effects, the animals are allowed to drink for a brief period (e.g., 3 min), and then an unsignalled punishment period begins in which licking results in electric shock (to the sipper tube or to the grid floor). It is critical to note that the Vogel conflict test is distinct from the Geller–Seifter procedure in that in the Vogel procedure drug effects are evaluated for their ability to prevent the response suppression following the introduction of shock, whereas in the Geller models, effects of drugs attenuate the suppression of behavior resulting from shock. Despite this difference, drug effects are often comparable across methods (see Table 1 and reviews in McMillan and Leander 1976; Millan 2003).

Although all punishment procedures cannot be described due to space constraints, it is important to mention the CER method. Under this method, originally developed by Estes and Skinner in 1941, steady rates of behavior are maintained under a variable-interval schedule of food delivery. A stimulus is then presented that terminates with the delivery of electric shock independently of responding. Repeated stimulus-shock pairings eventually result in a behavioral baseline characterized by steady rates of responding punctuated by the suppression of responding in the presence of the pre-shock stimulus. Although the outcome of this CER procedure is similar to that in the Geller–Seifter method (i.e., responding is suppressed during the stimulus associated with shock), a key difference is that in the CER procedure, the shock is independent of responding, whereas under the Geller–Seifter procedure, shock only occurs following a response. Though the behavior appears to be the same, the effects of drugs on these two different types of suppressed behavior can be quite different (Kelleher and Morse 1968).

Punished behavior as described earlier has been shown to be an effective method for studying the behavioral effects of drugs across many species including mice, rats, rabbits, pigeons, fish, nonhuman primates, and humans. Various responses have been successfully employed that include lever-pressing, nose-poking, key pecking in the case of pigeons, and chain pulling. In addition to the sensitivity of punishment to the effects of anxiolytic drugs, it is important to note that this behavior is relatively insensitive to the effects of other drug classes, such as the ▶ antipsychotics and ▶ antidepressants, which typically only further reduce punished behavior, thereby making these methods valuable assays for pharmacological evaluation (Table 1). As such, these methods have been of exceptional value in drug-screening efforts to predict potential therapeutic activity in humans.

Although large variations in the experimental conditions being studied generally do not alter the effects of drugs on punished behavior, there are conditions that easily modify the quantitative effects as well as the qualitative changes in the behavioral effects of drugs. Quantitative modifications in the magnitude of drug effects occur with variations in the reinforcement schedule, the frequency, and the intensity of the punisher, as well as the deprivation levels that are used. It is important to acknowledge that the conditions under which punished behavior is established and maintained are critical to the sensitivity to drug effects as well as to the qualitative and quantitative nature of those effects (Barrett 1987; McMillan 1975; Witkin and Katz 1990). While recognizing that human behaviors are not typically punished by electric shock but rather suppressed by a variety of social and other forms of stimuli, it appears that, based on a wide range of studies, the procedures described in this section have been generous in yielding not only an insight into the effects of punishment on behavior but also on the sensitivity and selectivity of punished behavior to the effects of various drugs. In addition, these procedures have also been applied to the investigation of ▶ anxiogenic behavioral effects and behavioral effects of drugs.

As noted earlier, the Geller–Seifter and Vogel conflict punishment procedures demonstrate a fair degree of pharmacological specificity that is exemplified in Table 1. These methods are robust detectors of compounds that are positive ▶ allosteric modulators of $GABA_A$ receptors (benzodiazepine anxiolytics, barbiturates, neuroactive steroids). Other compounds known to have antianxiety effects in humans also increase punished responding in these preclinical models (e.g., (alcohol) ▶ ethanol). However, anxioltyic-like effects (increases in punished responding) are generally not observed with a host of other drug classes and mechanisms (antidepressants, antipsychotics, opiate analgesics, psychomotor stimulants, and muscarinic antagonist amnestics) although exceptions exist (Table 1). Some of the other methods described in this chapter have broader scope in detecting pharmacological effects. Marble burying, for example, can detect the effects of acutely administered ▶ selective-serotonin reuptake inhibitors (SSRIs) as well as their subacute administration (Borsini et al. 2002). Since the SSRIs are used in the therapeutic control of anxiety symptoms and

[a]Only selected compounds are shown for purposes of comparing mechanisms/drug classes using data from two major classes of punishment procedures. Only data from systemic dosing are included. Only data from acute dosing are included. Anxiolytic-like effects of some compounds in these assays have been reported in the literature but with other procedures suggested to detect anxioltyic mechanisms (e.g., endocannabinoid uptake or enzyme inhibition; mGlu8 agonists; gabapentin). It must also be noted that sometimes the findings summarized have not been replicated.
[b]A comprehensive review of drug effects under the Vogel conflict procedure and associated mechanisms can be found in Millan (2003). General summaries of data in the Geller–Seifter procedures can be found in McMillan and Leander (1976), Kelleher and Morse (1968).
[c]Data included in this table represent results of findings from a host of sources readily accessible in the archival literature; a listing is available upon request from the authors. Data from experiments using rats are used when possible to keep the compound comparisons as uncomplicated as possible. Data are classified by activity on the basis of comparison to the maximal effect observed under the procedure. Maximal effect in each experiment was estimated on the basis of effects of a positive allosteric modulator of GABAA receptors, generally, a benzodiazepine anxiolytic. ++: maximal increase in punished responding at some dose (in comparison with a benzodiazepine anxiolytic if available); +: significant increase but less than maximal; –: no increase in punished responding or decrease at some dose; ++? An increase in punished responding was observed but the comparative magnitude of effect relative to a standard was not tested in the same study.
[d]Data from two major types of procedures are compared if available. *G-S*: Geller–Seifter conflict tests of which there are variants; *V*: Vogel conflict tests of which there are variants.
[e]Clinical efficacy is in reference to anxiety disorders. Literature inconsistent refers to both the potential qualitative differences observed with the specific compound and/or with discrpencies across compounds within a given mechanism of action.

► obsessive–compulsive disorder (OCD) as are some antipsychotic agents, the pharmacological specificity of the punishment methods clearly do not universally detect the breadth of antianxiety mechanisms known to be medically valuable (though some variations in these methods have increased sensitivity). Nonetheless, punished responding is still widely used to evaluate potential anti-anxiety compounds and mechanisms. Table 1

illustrates that novel mechanisms sometimes display positive effects in these punishment assays.

qEEG

Synonyms

Digital EEG; Quantified (wake) EEG

Definition

First an analog-amplified EEG trace is obtained in the form of equidistant samples. To minimize errors like aliasing, the signal is in practice low-pass filtered (e.g., high cutoff at 70 Hz, steepness 24 dB/oct or 48 dB/oct commensurate with Bessel characteristics). The interval is determined by the sampling rate, usually 256 samples/s or higher. From here, PC-assisted digital filtering, artifact rejection, and quantification in the frequency domain become feasible.

QT Interval

Definition

The *QT interval* is a measure of the time between the start of the *Q wave* and the end of the *T wave* in the heart's electrical cycle. The QT interval is dependent on the heart rate; (the faster the heart rate, the shorter the QT interval) and has to be adjusted to aid interpretation. The standard clinical correction is to use Bazett's formula (named after physiologist Henry Cuthbert Bazett). The corrected QT interval is denoted as QTc. Normal values for the QT interval are between 0.30 and 0.44 s (0.45 s for women). The QT interval is influenced by various antidepressants and antipsychotic drugs and thus caution must be exercised while prescribing these drugs particularly in vulnerable individuals with cardiac ailments.

Quazepam

Definition

Quazepam is a benzodiazepine with hypnotic and anticonvulsant properties. Clinically, quazepam is particularly effective in the short-term treatment of insomnia by inducing and maintaining sleep. Unlike other benzodiazepines, quazepam selectively targets $GABA_A$ type 1 receptors, but one of its major long-acting metabolites does not share this selectivity. Due to its long-lasting action, impairment of motor function is a significant side effect. Quazepam use is subject to tolerance, abuse, dependence, and withdrawal, although possibly with reduced severity as compared with other benzodiazepines.

Quetiapine

Definition

Quetiapine is a second-generation antipsychotic that acts as an antagonist at dopamine D2 and serotonin $5\text{-}HT_{2A}$ receptors, with a generally broad receptor-binding profile. Quetiapine is indicated for the acute and maintenance treatment of schizophrenia and bipolar disorder. Because of its low propensity to cause extrapyramidal symptoms, the drug can be used to treat psychosis in Parkinson's disease. It is a dibenzothiazepine derivative that dissociates quickly from the D2 receptor. Fast-dissociating D2 antagonists have been hypothesized to allow dopamine to still interact with the D2 receptor under conditions of phasic bursts of dopamine release, thereby eliciting its normal effects in the nigrostriatal and tuberoinfundibular pathways and reducing the risk of side effects. Possibly because of these properties, the risk of extrapyramidal symptoms and effects on prolactin release is lower than for first-generation antipsychotics. Quetiapine has relatively prominent histamine H1 antagonistic effects that are likely to contribute to its sedative properties. The drug also has an active metabolite, norquetiapine.

Radial Arm Maze

Synonyms
Olton maze; Radial maze

Definition
The radial arm maze, originally developed by David Olton, is an apparatus that taps into natural foraging abilities of rodents and can be used to test different types of memory, including short-term (working), long-term (reference), nonspatial and spatial memory. The arena consists of a number of arms (typically ranging from 4 to 16) that extend from a central hub, and food is placed in the ends of some or all of the arms. The food cannot be seen from the central platform. Versions that test spatial memory require rats or mice to navigate through the environment using allocentric spatial cues placed around the maze. Thus, animals must recall which arms had been entered or remain to be entered using the location of each arm relative to the different cues around the maze. Numerous studies have shown that rats do indeed use a spatial strategy to solve this task, as elaborate control experiments have been used to ensure that the rats do not simply use their sense of smell either to sense unclaimed food objects or to sense their own tracks.

Definition

A molecule containing a positron-emitting isotope, used as a tracer in PET imaging. Randomized Controlled Trials

Definition

Randomized controlled trials (RCTs) are studies in which people are allocated at random (*by chance alone*) to receive one of two or more treatments. People who take part in an RCT are called *participants* (or *subjects*). The Consolidated Statement of Reporting Trials (CONSORT) provides readers of RCTs with a list of criteria that will be useful to assess trial validity (for full details visit www.consort-statement.org) (Altman 1996).

As quantitative, comparative studies, RCTs are one of the simplest and most powerful tools in clinical research. In the field of medicine (and, of course, in psychiatry also) RCTs are recognized as the most rigorous method of assessing the efficacy of interventions, and are designed to determine whether an association exists between treatment and outcome (Rees 1997). RCTs essentially provide evidence of causality. These clinical studies point to a link between events rather than an explanation of how or why these events may be linked.

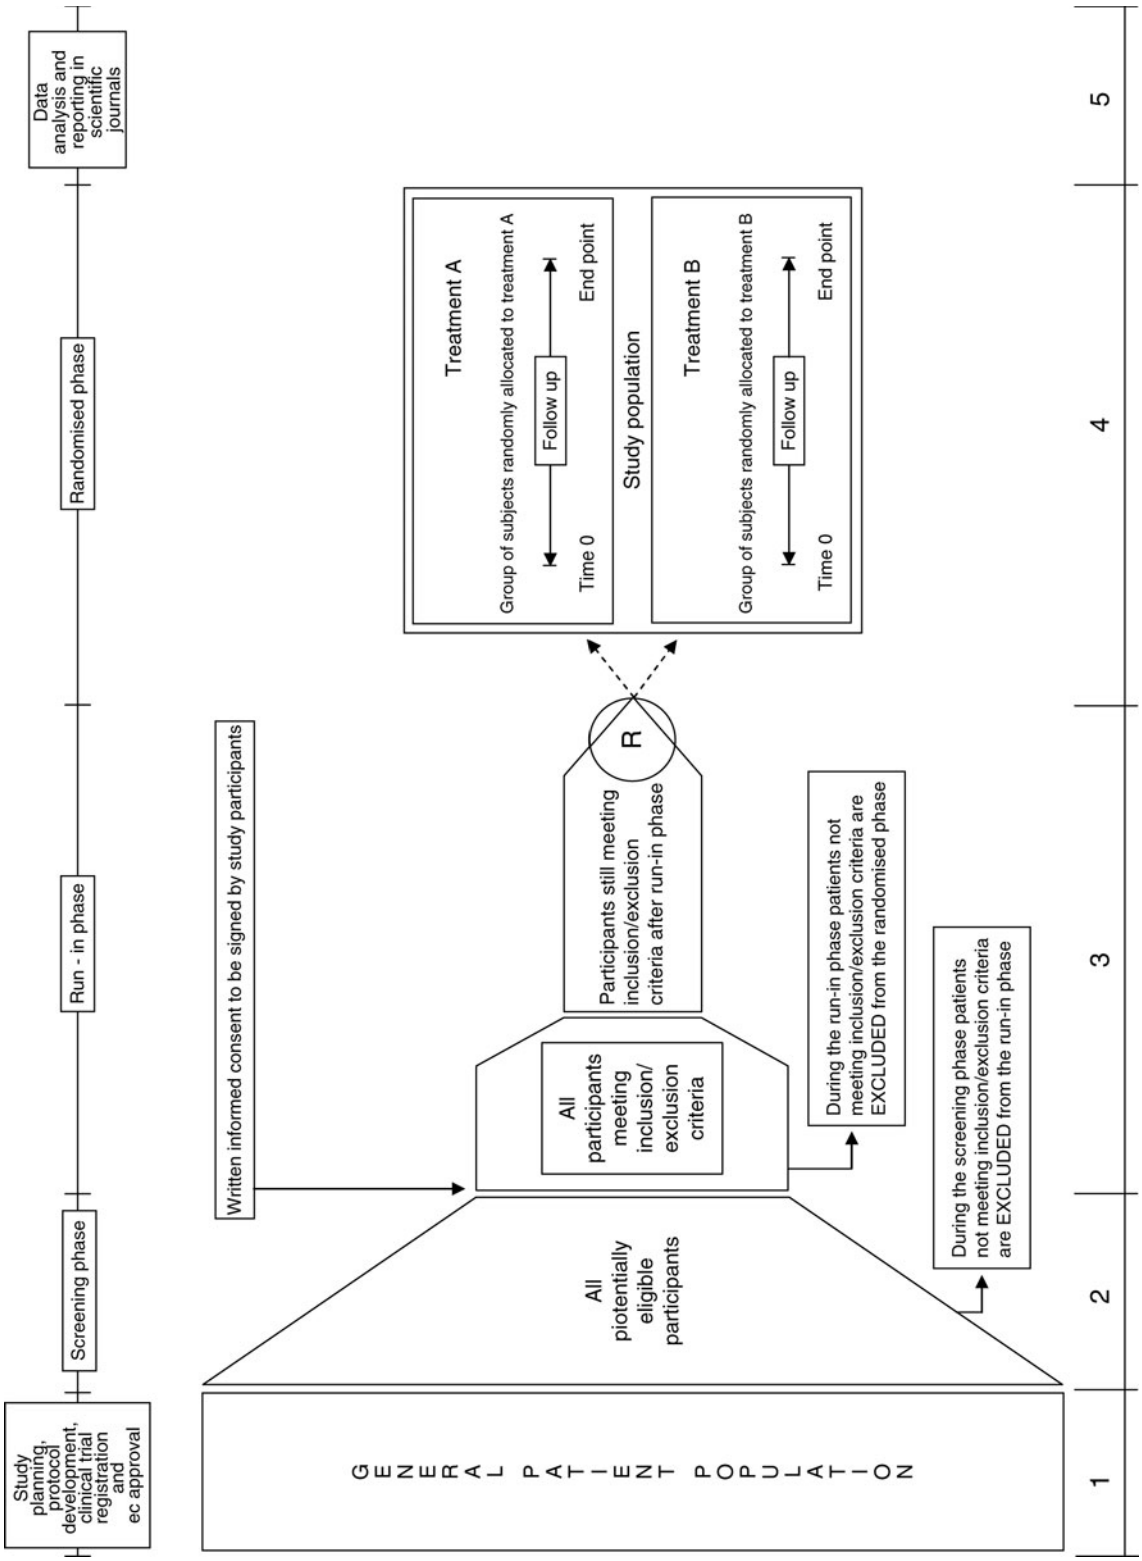
Random allocation ensures that there are no systematic differences between intervention groups in factors, known and unknown, that may affect outcome. Other study designs, including nonrandomized controlled trials, can detect associations between an intervention and an outcome; however, they cannot rule out the possibility that a third factor – or *confounder* – linked to both intervention and outcome, might have caused the association. To be convincing, observational studies need very large samples, which can provide sufficient power to control for known variables that might influence the outcome of treatment (e.g., age, sex, social class, ethnic group, and other clinically meaningful variables such as severity of illness or setting of health care). Even then, there is the risk of residual confounding, and it is impossible, of course, to control for unknown factors. Randomization is the only way of controlling for both known and unknown factors, and it is also very efficient. Nonetheless, RCTs are generally more difficult, costly and time consuming than other study designs. Careful consideration needs to be given, therefore, to their use and timing.

Current Concepts and State of Knowledge

The main phases of an RCT are shown in the Fig. 1

Study Planning and Protocol Development

Before starting to design an RCT, the two key questions to be asked are (1) whether the tested intervention is sufficiently well developed to permit evaluation, and (2) whether there is enough preliminary evidence that the intervention is likely to be beneficial (most frequently, this evidence comes from observational studies). The development of a new pharmaceutical is conventionally divided into phases, with the initial preclinical toxicity and pharmacological work leading to small preliminary trials in human volunteers (► phase I), then small (perhaps 30–50 participants), usually randomized, studies in patients, before the pivotal ► phase III RCTs of efficacy and safety. Noncommercial trials will try to replicate this approach. The retrieval of preliminary data will need to



Randomized Controlled Trials. Fig. 1. The main phases of a randomized controlled trial.

inform the estimation of the size of the likely treatment effect, dose, and safety. Such information is needed to estimate the sample size of the study and also to justify the expenses of a larger trial. When planning an RCT, it is now common for trialists to carry out a systematic review of the available evidence to answer these questions.

The trial protocol should be as detailed as possible, describing every step of the study (e.g., identification of the problem, application of the results, etc.) and answering relevant questions (Are the objectives consistent with the study question? Does the study design achieve these objectives? What is the public health impact of the findings?). In the protocol, researchers need to report all information about the conduct and analysis of the trial (e.g., criteria for the inclusion or exclusion of the study population, data handling, and data analysis plan). The lead author of the protocol needs to identify individuals with relevant experience to contribute to the protocol and to provide statistical input or technical information. All protocols must meet a standard that adheres to the principles of Good Clinical Practice, prior to being submitted to the Ethics Committee (EC) or Institutional Review Board (IRB) (for details, see the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use – ICH, available at http://www.ich.org/cache/compo/276-254-1.html). After preparation, the first draft of the protocol should be peer reviewed, ensuring that all points have been incorporated or discussed further within the review team. In parallel with finalizing the protocol, it is necessary to prepare all other necessary trial documents, such as subject information sheets and informed consent forms (an example can be found on the Web at the following address: http://www.dh.gov.uk/en/Publichealth/Scientificdevelopmentgeneticsandbioethics/Consent/Consentgeneralinformation/DH_4015950).

Ethics Committee Approval

Once the protocol and other relevant documentation are ready, applications should be made to the EC. As for experimental studies that have the potential of risk to human subjects, all related RCTs have to be approved by an EC before patient recruitment is started. All study participants must be informed about the study characteristics; they must provide written informed consent before enrollment into the trial. In some circumstances, an RCT may be ethical but difficult to carry out (or even unfeasible). One reason might be difficulties with randomization or recruitment (Fairhurst and Dowrick 1996). For example, once an intervention becomes widespread, it can prove impossible to recruit clinicians who are willing to "experiment" with alternatives. This might be true for some widespread practices in clinical psychiatry that are actually not backed by randomized evidence. For example, it is not clear whether anticholinergic drugs work better than ▶ levodopa against ▶ extrapyramidal side effects in patients with ▶ schizophrenia who take long-term antipsychotic medications; however, in daily clinical practice clinicians are reluctant to use specific antiparkinsonian drugs (such as levodopa) that might trigger psychotic symptoms. Strong patient preferences may also limit recruitment and bias outcomes if not accommodated within the study design (Brewin and Bradley 1989).

Clinical Trial Registration

The protocol should also be registered for publication in dedicated Web sites. Based on both ethical and scientific reasons, since 2000 major registries (such as ClinicalTrials.gov and Controlled Clinical trials) have been recording trial protocol information. This progress in the public registration of clinical trials worldwide is important because it allows clinicians and researchers to see in advance details about study conduct and analysis in a more transparent way. The number of registered trials increased dramatically in 2005 after the requirement for registration was introduced by several medical journals, led by the International Committee of Medical Journal Editors.

Screening Phase

All patients enrolled in the study must meet the eligibility criteria. Screening procedures are performed to determine the eligibility of participants for the study and document their baseline medical conditions. Information gathered during the screening phase is used to make decisions on participants' eligibility. Therefore, the threshold for access to assessment should be set at a low enough level to ensure people are not screened out before full information on their condition is obtained. There are usually one or two screening visits, and all screening and enrollment procedures take place within a pre-defined period (7–56 days, depending on the clinical status and diagnosis).

Run-In Phase

Run-in phases are pre-randomization periods used to select or exclude patients in a clinical trial. Run-in periods might be used to exclude non-compliant subjects, placebo responders, or subjects who could not tolerate or did not respond to active drug. For this reason, run-in periods have implications for interpreting the results of clinical trials and applying these results in clinical practice (Pablos-Méndez et al. 1998).

Run-in phases can use either ▶ placebo or active therapy, and are usually single-blind or unblinded (that is,

only the study staff is aware of the nature of the medication). A placebo run-in allows trial staff to be sure that reported side effects are not caused by treatment. By contrast, an active run-in can identify and exclude individuals who may be unable to tolerate the medication being tested in a long-term trial. For instance, the long-term treatment of ▶ bipolar disorder is supposed to be a treatment specifically intended to prevent recurrence of mood episodes. Subjects who are entering a long-term trial are asked to take the study medication (or the combined study medications) for a long period of time. In real-world clinical settings, people who are prescribed long-term treatments will usually be selected from those who have been able to tolerate the medication in the short-term – perhaps during acute phase therapy. In these studies, a run-in design (that is a run-in phase with active long-term treatments before randomization) may maximize the study power through participants' better compliance. Individuals who lose interest early on (potential "drop-outs") can then be excluded before random allocation. Similarly, subjects who become convinced about receiving the intervention treatment (potential "drop-ins") can also withdraw before randomization. This potentially lowers rates of anticipated noncompliance to allocated treatment during a trial, resulting in a smaller required sample size. Once randomized, these participants would generally be included in an intention-to-treat analysis (for details, see below).

Run-in periods can dilute or enhance the clinical applicability of the results of a clinical trial, depending on the patient group to whom the results will be applied. This approach usually enhances clinical applicability by selecting a group of study subjects who closely resemble patients undergoing active clinical management for this problem. However, compared with results that would have been observed without the run-in period, the reported results might overestimate the benefits and underestimate the risks of treatment. Because the reported results apply to subgroups of patients who cannot be defined readily based on demographic or clinical characteristics, the applicability of the results in clinical practice might be diluted. For this reason, reports of clinical trials using run-in periods should indicate how this aspect of their design might affect the application of the results to clinical practice.

Randomized Phase

RCTs have several important features:

- Randomization
- Allocation Concealment
- Blinding
- Choice of Interventions and Outcomes

Randomization

The simplest approach to evaluating a new treatment is to compare two consecutive series of patients (historical controls are undesirable because of the consistent tendency for historically controlled trials to yield more optimistic results than randomized trials). If clinicians are allowed to choose which treatment to give to each patient, there will probably be differences in the clinical and demographic characteristics of the patients receiving the different treatments. Such systematic differences are called *bias,* and bias may lead to a distortion (overestimate or underestimate) of the difference between treatments (Schulz et al. 1995). Thus, the main reason for using randomization to allocate treatments in a controlled study is to try to prevent biases. Randomization is a process that aims at producing groups that are similar in terms of clinical, demographic, and prognostic factors. Random allocation means that each patient has a known, equal chance of being given each treatment, but the treatment to be given to each patient cannot be predicted.

The process of randomization begins with the generation of a random allocation sequence. The simplest procedure to equally allocate to two treatment groups involves using a table of computer-generated random numbers. This is called simple randomization, and it is equivalent to tossing a coin. Similar lists of random numbers can be found in most statistics textbooks. From a methodological point of view, a simple randomization may remove the risk of bias from the allocation procedure; however, it cannot guarantee that the individuals in each group have a similar distribution of clinical or demographic variables. Some chance imbalance may occur, especially in small studies. An imbalance in the distribution of baseline characteristics might make the interpretation of results complicated or even impossible. There are ways to modify simple randomization, such as *block randomization* and *stratified randomization. Block randomization* ensures closely similar numbers of patients in each group; by contrast, *stratified randomization* is used to keep the groups balanced for certain important clinical or prognostic patient characteristics, producing a separate randomization list for each pre-specified subgroup based on such characteristics (each such subgroup is called a *stratum*). For instance, in multicenter studies, the stratifying variable may be the study center itself, because the patients within each center need to be equally randomized to one or the other of the two study treatments. Stratified

randomization can be extended to two or more stratifying variables, even though in small studies it is not practical to stratify on more than one (or perhaps two variables), as the number of strata can quickly approach the number of subjects. When it is really important to achieve close similarity between treatment groups for several variables, *minimization* can be used. *Minimization* is based on a different principle from randomization, and it has the advantage, especially in small trials, that there will be only minor differences between groups in those variables used in the allocation process. When using minimization, the first participant is randomly allocated to treatment, but each subsequent participant is allocated to the treatment that would lead to a better balance between the groups in the variables of interest. The chosen treatment could simply be taken as the one with the lower allocated sample (100% of probability to be allocated to this group); otherwise, a random element can be introduced (a high chance, say 80%, of probability to be allocated to the treatment that minimizes the imbalance – the so-called, *weighted randomization*). The use of a random element makes the allocation more unpredictable. Even though it may slightly worsen the overall imbalance between the groups, the balance (for the chosen variables) is usually much better than with simple randomization. Minimization is a secure allocation system when used by an independent person. In RCTs, individual patients are usually randomized to a treatment or control group, but sometimes cluster-randomized controlled trials are carried out, in which groups (or clusters) of individuals, rather than individuals themselves, are randomized. The groups may be villages, colleges, medical practices, or families. A cluster-randomized design may be used simply for convenience. One of the main consequences of a cluster design is that participants within the cluster often tend to respond in a similar manner, and thus their data can no longer be assumed to be independent of one another. In such studies, the "unit of allocation" is the cluster and not the patient. Cluster trials are increasingly common because they are often the only valid approach to evaluate certain types of interventions (such as those used in health promotion and educational or psychosocial interventions). However, cluster trials are generally more difficult to design and carry out than individually randomized studies, and some of their design features may make them particularly vulnerable to bias. A proper analysis can help overcome this risk.

Allocation Concealment

The process of randomization does not end until participants are actually assigned to their groups. Allocation concealment refers to the process used to ensure that subjects, investigators, and all other study personnel are unaware which group participants are being allocated to at the time they are enrolled in the study. Adequate methods of concealment might be centralized allocation (for instance, via telephone), computerized allocation systems (via web-based facilities) or coded identical containers (using sealed envelopes). The use of adequate methods of concealment is considered an indicator of a well-conducted study (see CONSORT Statement). There is evidence that where allocation concealment is inadequate, investigators can overestimate the effect of interventions by up to 40%. Study reports should include a description of the method used to conceal allocation, with enough technical details to let readers determine the likelihood of the success of this process.

Blinding

Blinding refers to the process whereby people are kept unaware of which treatment an individual patient has been receiving. Blinding (or "masking") is different from allocation concealment. Blinding is the prevention of knowledge of treatment assignment after randomization has been done; allocation concealment refers to the prevention of knowledge of upcoming assignment from the randomization sequence before the treatment is allocated. Allocation concealment is part of the randomization process and must always be included in the design or conduct of an RCT. By contrast, blinding, in some clinical circumstances, may not be feasible, for example in trials investigating the effect of some psychological treatments. However, blinding might be very important when the outcome for a patient has to be assessed (most of all, when using a clinician-based rating scale).

Blinding can be carried out up to four levels: (1) patient; (2) investigator (or clinical trial nurse); (3) outcome assessor; (4) biostatistician. In medical journals, the term "double-blind" is often used. This term does not have a standard definition and cannot always be relied upon to convey which groups in an RCT were truly blind (for further details, please visit www.consort-statement.org). Because of this ambiguity, descriptions of blinding in reports of RCTs ideally should be explicit, reporting precisely who was masked and how this was done.

Choice of Interventions and Outcomes

A key component of an RCT is to specify the interventions of interest and the interventions against which these will be compared (Huston and Locher 1996). These interventions are called *comparisons*. One of these treatments is a treatment commonly used in clinical practice – the

so-called *standard* (or *control*) treatment; the new treatment to be tested in the study is named *experimental* (or *investigational*) treatment. The control might be an inactive control intervention (such as placebo, no treatment, standard care, or a waiting list control), or an active control intervention (such as a different variant of the same intervention, a different drug, a different kind of therapy, or a combination treatment, when the intervention of interest is combined with another intervention). When specifying drug interventions, dosing factors such as drug preparation, route of administration, and dose, duration and frequency of administration should be considered and clearly specified in the study protocol. Regarding dose, for example, it is necessary to know whether there is a critical dose below which the intervention may not be effective. Dosing factors are important because study authors must always consider whether the characteristics of the intervention might result in substantially different effects on the participants and outcomes of interest. For instance, when comparing two drugs, it would be unacceptable to use one drug at the lower end of the therapeutic range and the second one at the higher end of the therapeutic range. This imbalance might affect the reliability of the study results, reducing the internal and external validities of the RCT. For more complex interventions (such as psychoeducational or psychotherapeutic interventions, like cognitive-behavioral or psychodynamic psychotherapy), the core features of the interventions have to be defined. In general, for psychotherapies it is useful to report exactly what is delivered, at what intensity, how often it is delivered, who delivers it, and whether people involved in delivery of the intervention need to be trained (manualized interventions).

Another key component of an RCT is the delineation of particular outcomes that are of interest. In general, an RCT should have a primary outcome (on which to base the calculation of sample size) and also include other outcomes that are likely to be meaningful to patients and clinicians. Outcomes may include survival (mortality), clinical events (recurrence, relapse, and hospitalization), patient-reported outcomes (rating of symptoms, quality of life), adverse events, and economic outcomes (costs and resource use). When planning an RCT, authors should consider how outcomes may be measured, in terms of both the type of scale to be used and the timing of measurement. Outcomes may be measured objectively (number of relapses, number of hospitalizations) or subjectively as rated by a clinician, patient, or caregiver (for instance, severity of illness scales or disability scales). In other fields of medicine, it is common to use so-called *hard outcomes* (that is, objective outcomes like mortality rates, concomitant medications, return to work). By contrast, in psychiatric trials changes in rating scale scores are more commonly reported. There are four different kinds of rating scales that can be used in psychiatric trials: (1) observer-based disease-specific rating scales, where a clinician rates a patient on items about a specific disease; (2) patient-based disease-specific rating scales, which analyze the same domains from a patient's perspective; (3) observer-based non-disease-specific scales, which are rating scales filled by clinicians and designed to measure a patient's global functioning; and (4) patient-based non-disease-specific scales of global functioning. If a psychiatric treatment really worked, one might expect the effect of treatment to show up on rating scales from all four domains of measurement. However, this often does not happen because of the complexity of psychiatric illness and because of the degree of subjectivity in assessing outcomes. This is the reason why it is important to use published or validated rating instruments. Furthermore, when defining the timing of outcome measurement, authors may consider whether all timeframes or only selected time points are to be considered.

Data Analysis and Reporting in Scientific Medical Journals

Analysis

Attrition, a ubiquitous problem in RCTs of psychotropic agents, can cause biased estimates of the treatment effect, reducing statistical power and restricting the generalizability of results. There are various approaches to data analyses in RCTs (Rennie 1999). One way is to include data only on participants, whose results are recorded, using as a denominator the total number of people who had data recorded for the particular outcome in question. Another way is to use the total number of randomized participants, irrespective of whether some participants withdrew from the study. This will involve imputing outcomes for these missing participants. There are several approaches to imputing outcome data, either for dichotomous or continuous outcomes. One common approach is to either assume that all the missing participants experienced the event, or that all of them did not. An alternative approach is to impute data according to the event rate observed in the control group, or according to event rates among completers in the separate groups (the latter provides the same estimate of intervention effect but results in an unwarranted inflation of the precision of effect estimates). The choice among these assumptions should be based on clinical judgment and should be pre-planned and clearly reported in the study protocol. Intention-to-treat analysis maintains the advantages of random

allocation, which may be lost if subjects are excluded from analysis through, for example, withdrawal or failure to comply.

Journal Reporting

When data are analyzed, results of the RCT are disseminated and published in scientific journals. To be published, study reports must undergo a peer-review process. Almost all the most important scientific journals want to see the study protocol before accepting a study for publication, in order to check the consistency between the protocol and the full report of the RCT (Gilbody and Song 2000).

The first use of an RCT in psychiatry was to demonstrate that cortisone did not work for schizophrenia. Nowadays in psychiatry, new agents are usually compared with placebo. This is because there is a high placebo response rate that varies considerably depending on chronicity, severity, and subtype of the disorder. While it has been suggested that placebo run-in periods can help to control for this, evidence is inconsistent. In an illness such as ► major depression, up to 50% of those who respond while taking a medication may improve due to placebo factors. This placebo response rate in depression RCTs varies, but is growing. In other disorders (such as ► obsessive–compulsive disorder or schizophrenia), the placebo response is much less. The use of a placebo arm in an RCT raises ethical, clinical, and methodological issues. Ethically, it may be argued that placebo is only appropriate when no established effective treatment is available. On the other hand, the dangers of marketing ineffective drugs or psychotherapies that carry risks of side effects may outweigh the modest risk associated with placebo treatment in randomized, placebo-controlled trials. A placebo group is essential to establish that a treatment is effective for any condition. However, a placebo-controlled design may also influence the outcome of the trial. For example, individuals likely to participate in a placebo-controlled trial have less severe, less chronic, and less disabling disease. Therefore, they may be the very people who are apt to respond to placebo.

One important issue for RCTs in psychiatry is the way in which the treatments are delivered. In drug trials, a dosage schedule must be specified. This can be left up to the clinician or predetermined by the investigators. Clinician titration is probably closer to clinical practice, and may reduce dropouts since sensitive patients will be maintained at lower doses and dosage increased more slowly. The exact details of treatment and comparator are also important in trials of psychotherapeutic interventions. Since different types of psychotherapies may give rise to different results, it is important to define the exact form of therapy to be given, to ensure adherence of therapists to that therapy, and to maintain its quality. In reporting the trial, it is important to describe the therapy in such a way that it can be replicated if it proves to be clinically useful. RCTs have particular problems when comparing psychotherapies, of which the most serious is that interventions do not represent distinctly different treatments (because of the many factors common to all forms of psychotherapy) and therefore violate the premise of controlled trials. Often it may not be possible to sufficiently control how treatments are conducted, leading to poor external validity of psychotherapy RCTs. In psychotherapy, for example, RCTs typically involve manual-based interventions. However, the relationship of these therapies to general practice may be unclear, since in reality most clinicians do not have the level of training and supervision provided to research therapists.

Apart from the proposed treatments under investigation in an RCT, it is important to anticipate the possibility that additional, less specific treatments will be needed during a trial. In trials for ► mania or depression, certain "rescue" medications (such as, ► benzodiazepines) may be used. The use of rescue medications may vary between study groups and could obscure a difference in outcome. This may therefore need to be considered as an actual treatment outcome. The use of additional treatments (and which medications to use) should also be predetermined and included in the protocol.

Many published trials in psychiatry have included several outcome measures. This makes it likely that at least one of them will show a difference by chance. It is not easy to decide on a single outcome measure. Differing definitions of what constitutes a response to treatment is a problem in psychiatric trials where clear outcomes, such as death or highly reliable physiological changes, are rarely suitable. In many trials of antidepressant treatment, it has been total score or change from baseline on a rating scale at a pre-defined time point. Psychiatry researchers are increasingly advocating the use of simple objective outcomes to make trials large enough (and therefore simple enough to be carried out at many sites) to show relatively small differences.

A typical psychiatric RCT has fewer than 100 subjects. Small samples are more likely to have initial group differences (despite randomization) and differential dropout rates. Statistical techniques can be used to control for differences in assignment or from dropouts, but small samples can only have adequate power to detect moderate to large treatment differences and are unlikely to detect

differences either in rare events, such as a suicide attempt, or factors that have high variability.

Randomized controlled trials often recruit different subjects from those who present to clinical services. Exclusion criteria, usually set to create a more homogeneous sample, reduce the comparability of the enrolled subjects to those in a clinical service. Excluding patients with co-occurring disorders should not occur when these comorbidities are common or they affect treatment response and prognosis. For example, in patients with major depression, comorbid Axis I and Axis II conditions are present in most patients, and may impact response to treatment. A further problem is that most RCTs are of short duration, but clinicians are interested in longer-term outcome. Many disorders are recurrent or chronic, but trials usually last between 6 and 12 weeks, and can only address short-term response or remission, since they do not deal with the clinical outcome of recovery (a sustained remission). This would not be a significant problem if short-term response was strongly predictive of recovery. However, the relationship between initial response and recovery is not consistent.

Since all treatments potentially have ► adverse effects, it is important to anticipate, measure, and report them accurately. A treatment that increases the speed of recovery from depression but gives rise to enduring side effects may not be deemed useful. This is the case with ECT, which may lead to a rapid recovery for people with severe depression, but which may lead to cognitive side effects measured in a longer-term perspective. For many conditions (for example, anorexia nervosa, somatoform disorders, or personality disorders) insufficient data are available to guide treatment. For other disorders, despite research, no consensus has been reached. RCTs are unlikely to influence practice unless they address an area of perceived uncertainty. However, RCTs are often driven by commercial interest. This leads to a focus on discrete choices, such as treatment modality or intensity, rather than practical decisions, such as when to use physical restraint or to hospitalize a patient.

To summarize, patients need individually tailored treatment. RCTs are the best way to tell clinicians what treatments are effective, but not necessarily which patients should receive them and when they should be given.

Rapid Eye Movement Sleep

Synonyms

REM sleep

Definition

REM sleep is usually associated with dreaming (also known as "dream sleep"). REM sleep is characterized by paralysis or nearly absent muscle tone (atonia; except for control of breathing and erectile tissue), periods of phasic eye movements, and a rise in cortical activity associated with dreaming. The brain however remains highly active, and the electrical activity recorded by electroencephalography (EEG) during REM sleep is similar to that seen during wakefulness. Irregular respiration and heart rate are also features. The first REM sleep period occurs 70 to 100 min after sleep onset, may last as short as 5 min and as long as 60 min (or more). In adults, about 20% of nighttime sleep is devoted to REM. In the rat, REM sleep is characterized by low-voltage fast frontal waves, a regular theta rhythm in the occipital cortex and a silent electromyogram except for occasional myoclonic twitchings.

Rasagiline

Definition

Rasagiline is an irreversible monoamine oxidase (MAO) inhibitor selective for MAO-B. MAO-B inhibition reduces dopamine breakdown in nerve terminals, resulting in increased extracellular dopamine levels in the striatum. Rasagiline is indicated for the treatment of ► Parkinson's disease (PD) either as an initial monotherapy in early PD or as an adjunct to l-DOPA in advanced PD. Rasagiline and its major metabolite 1(R)-aminoindan have neuroprotective effects *in vitro*. Early treatment with rasagiline results in better clinical outcome than drugs with a delayed start, but whether such results are due to its neuroprotective effect in patients is controversial. As with other MAO inhibitors, ingestion of tyramine-rich foods can potentiate hypertensive crisis.

Fixed ratio (FR) – a ► schedule of reinforcement under which the reinforcing stimulus is presented upon the completion of a fixed number of responses.
Fixed interval (FI) – a schedule of reinforcement under which the reinforcing stimulus is presented upon the first response to occur following the elapse of a fixed amount of time.
Interresponse time (IRT) – the time between two successive responses.
► Punishment – the decrease in the probability of a response in real time as a consequence of the presentation of a punishing stimulus upon a response.
Rate of responding – the number of responses per unit of time (e.g., responses/second).
Reinforcement – the increase in the probability of a response in real time as a consequence of the presentation of a reinforcing stimulus upon a response.

Impact of Psychoactive Drugs

Evolution of the Theory

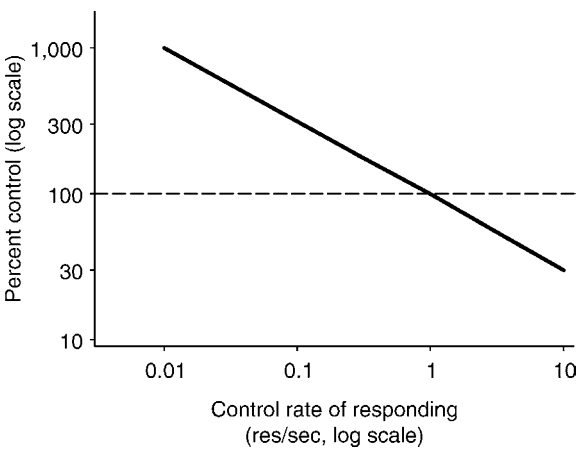
The 1950s was a time of great advances in the development of behaviorally active drugs, and a great deal of effort was spent trying to understand why drugs altered behavior in specific ways. During this period, drug action on behavior

was interpreted, for the most part, in terms of the drug's capacity to reduce a primary drive (e.g., hunger, fear, or thirst) or by the drug's capacity to interfere with a learned association between a stimulus in the environment and one of the primary drives. The work of Clark L. Hull and Neal Miller figured prominently during this period (for review see McMillan and Katz 2002). Thus, when drugs with clinically relevant effects on anxiety were examined in laboratory animals and shown to produce differential effects on behavior controlled by food presentation as compared to behavior controlled by electric shock, the observations were viewed as being consistent with the reduction of primary drives and confirmed the validity of the drive reductionist concepts of drug action. It was in this historical context that Peter B. Dews initiated a series of studies that would eventually lead to the development of what is now known as rate-dependency theory.

In 1955, Dews published the first of a series of papers in which he examined the effect of drugs in food-deprived pigeons responding under different operant schedules of food presentation (Dews 1955). In his first paper, he showed that doses of ▶ pentobarbital that produced dramatic decreases in the rate of responding under a fixed-interval 900 s (FI900) schedule did not affect the rate of responding under a fixed-ratio 30 (FR30) schedule of food presentation. Since responding under the two schedules was maintained by the same event, it was difficult to explain such profound differences based upon drive reduction theories proposed by the current theorists of the day. Alternatively, Dews suggested that rather than interacting with drive states, pentobarbital appeared to be producing the differential effect by interacting with the control of the rate of responding. In a subsequent paper, Dews showed that the effects of ▶ methamphetamine in pigeons responding under four different schedules of food presentation depended upon the length of the time between individual responses (IRT; rate of responding). When control performance was characterized by low rates of responding, low to moderate doses of methamphetamine increased rates of responding. At higher doses, methamphetamine did the same thing but it also decreased the high rates of responding (Dews 1958). Over the next several years Dews along with colleagues, William Morse and Roger Kelleher, as well as investigators from other labs showed that the control rate of responding was a key factor in determining drug effects, and that the control rate of the behavior was an important independent variable. However, it was not until 1964 that Dews formally proposed a way to express this relationship (Dews 1964). Dews argued that since one frequently had to deal with a range of doses that spanned several log units, by analogy to dose–response curves in classical pharmacology, the control rate of responding should be plotted on the abscissa using a log scale. He went on to show that if one plotted the log of the rate of responding following drug administration divided by the rate of responding under control conditions on the ordinate (Fig. 1), not only did this log–log plot aid in the uniform distribution of the data points, it yielded a linear relationship that had predictive value. As a result, one typically sees a log–log linear relationship with a negative slope. Thus, very low rates of responding tend to be increased more than moderate rates, and high rates of responding are either increased less than moderate rates or are actually decreased compared to the control rate of responding. This log–log linear relationship and the theory behind it are referred to as the rate-dependent theory of drug action.

Generality of the Theory

During the 1960s and early 1970s, numerous studies showed that the rate of responding was more important in determining the effect of drugs than the specific reinforcing event used to maintain the behavior. Furthermore, in addition to the ▶ amphetamines and ▶ barbiturates, rate-dependent drug effects were shown for many drugs including ▶ benzodiazepines, ▶ meprobamate, ▶ phenothiazines, ▶ atypical antipsychotics, anticholinergics, ▶ phencyclidine, and ▶ ketamine.



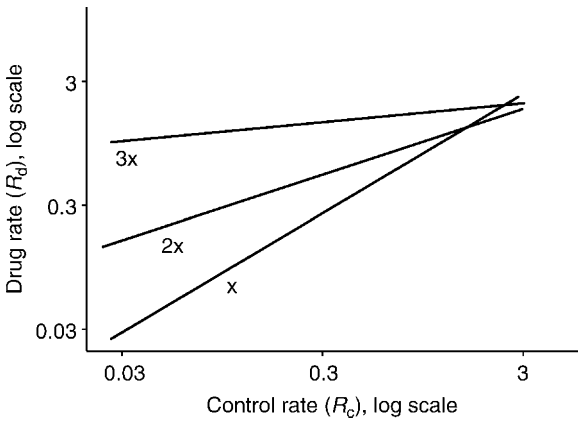
Rate-Dependency Theory. Fig. 1. Typical rate-dependency plot. *Abscissa*: control rate of responding (log scale); *Ordinate*: Rate of responding following drug administration divided by the control rate and converted to a percentage (log scale).

Although Dews and others showed that the rate-dependency theory described the actions of many drugs on schedule-controlled operant responding, a question remained about whether the rate of the ongoing behavior could account for drug effects on other behaviors (nonoperant). Looking at a wide range of behavioral effects of amphetamine in rats, Dews and Wenger (1977) could not show any separation between operant studies and nonoperant studies (e.g., locomotor activity or rearing). For the most part, data from operant and nonoperant studies fell on the same log–log regression line. Similarly, if one examined very low rates of behavior, although the variance was very high, there was no obvious break in the log–log relationship. However, there were a couple of notable exceptions for the rate-dependency of amphetamines. Control rates of behavior that were very low as a result of the presentation of an aversive event upon a response (punishment) did not appear to be increased to the same extent as equally low rates of responding in the absence of a punishment procedure. These low punished rates may, however, have their own parallel relationship between drug effect and control rate of responding. Interestingly, barbiturates, benzodiazepines, and other drugs with clinical antianxiety properties do not share this attenuated capacity of amphetamines to increase low rates under punishment situations. The barbiturates and benzodiazepines, for example, may produce an even larger increase in low rates maintained by punishment procedures compared to their effect on equally low rates maintained by procedures not involving punishment. In nonoperant experiments, there was one notable exception to the rate-dependent effects of amphetamine. The rate of licking by rats appeared to be relatively resistant to change by amphetamines. The resistance to change of licking responses has been reported for several other drug classes.

In addition to the punishment situations discussed earlier for amphetamines, there are a couple of other situations where the rate of ongoing behavior is not the sole determinant of the drug effect (for review see: McKearney 1981). As with the effect of amphetamines on low rates of behavior that have been suppressed by punishment, the ability of barbiturates to increase low rates of responding that are under strong discriminative control has been shown to be less than predicted based solely upon the rate of responding. Nevertheless, the effect of the barbiturates in this situation seemed to be strongly influenced by the control rate of responding. A third situation of note is where the rate of responding directly influences the rate of reinforcement. In many situations, the rate of responding can vary widely with minimal effect on reinforcement rate. However, in situations where an increase in rate decreases reinforcement frequency, these low rates are relatively resistant to increases by drug. Finally, although under most situations the drug effects are independent of the event maintaining the behavior, there are a few known examples where similar rates of responding are altered differently depending upon the reinforcing event. For example, the effect of ▶ morphine has been shown to alter rates of responding differentially depending upon whether the reinforcing event used to maintain the behavior is food or electric shock presentation.

Challenges to the Theory

Although a vast body of literature shows that drugs obey the rate-dependency theory of drug action as proposed by Dews, there have been several challenges and alternative theories proposed. The most significant challenge was, in part, a mathematical issue versus a biological issue, but it also raised questions about the nature of drug effects. Gonzalez and Byrd (1977) stated that the log–log linear relationship proposed by Dews (1964) can be summarized by eqn. 1. By rearranging eqn. 1 to yield eqn. 2, it can be seen that when the slope of the rate-dependency plot equals −1, then the rate following drug administration becomes independent of the control rate and all rates are equal. They further stated that, in order to make it easier to see when the rate after drug administration becomes independent of the control rate, the data should be plotted as shown in Fig. 2. As can be seen with increasing dose and increasing effect, the slope becomes less and less positive and potentially approaches zero. Furthermore, they argued that both the control rate and the rate after



Rate-Dependency Theory. Fig. 2. Rate-dependency plot according to Gonzalez and Byrd (1977). *Abscissa*: rate of responding under control conditions (R_c); *Ordinate*: rate of responding following drug (R_d). *X* dose administered.

drug administration are dependent upon the maximum possible response rate. Thus, Gonzalez and Byrd stated that the effect of a drug on the rate of responding is best considered independent of the control rate, and it is necessary to know the maximum possible rate of responding before the drug effect can be interpreted.

$$\log\left(\frac{R_d}{R_c}\right) = \log k + j \log R_c \quad (1)$$

Rearrangement yields the following:

$$\log R_d = \log k + (j+1)(\log R_c) \quad (2)$$

where, R_d – rate after drug administration
R_c – control rate
k – Y-intercept
j – slope of the regression line

In defense of Dews' position (Dews 1964), it must be remembered that drugs do not create behavior, they only modify existing behavior. Thus, the drug effect cannot be considered in the absence of a comparison to the control behavior. With respect to the contribution played by the maximum possible response rate, such a rate can only be determined experimentally, and it never will be possible to establish the true maximum rate of responding. Furthermore, there is no experimental evidence to support the need to know the maximum rate of responding (see Dews 1978).

The second major challenge to the theory was published in 1981 (Ksir 1981). Ksir's challenge can be summarized by saying that drugs tend to make the rate of responding a constant independent of the control rate of responding. Thus, with increasing doses of drug, the rate of responding approaches some constant value. If this were the case, such a nonspecific effect of a drug would be of little interest. Furthermore, few pharmacologists would accept such a conclusion. Thus, like the Gonzalez and Byrd (1977) challenge, the arguments may be mathematically correct, but they may not be correct from a biological standpoint.

Summary

In summary, a question that arises is how strongly can the theory be stated? Based upon the literature, Dews and Wenger (1977) stated that it is probably true that with all other variables unchanged, a change in the rate of responding may change the behavioral effect of a drug. It is probably also true that not only may differences in the rate of responding lead to differences in the effects of drugs, but in general, such differences will be determined by the control rate, and there will be a systematic relationship between the rate of responding and drug effect. Although there are some exceptions as noted earlier, the control rate of responding relates to the drug effect in such a manner that in most cases the log of the effect is a linear function of the log of the control rate of the behavior. However, probably it is a mistake to conclude that the control rate of responding is the sole determinant of the effect of a drug and that other factors are only important to the extent that they modify the control rate of responding.

The rate-dependency theory describes a relationship between the control rate of behavior and the rate of responding after drug administration. It was never intended to be an absolute relationship, but rather it was a way of showing order and predictability in drug effects. McKearney (1981) summarized the concept by saying rate-dependency is more of a theoretical law than it is a theory or hypothesis. It describes a predictable relationship between the control behavior and the effects of drugs. Viewed in this manner, it is not unlike the way the temperature of a tissue bath influences the response of a tissue to a drug. The temperature of the bath does not explain the action of the drug, but to consider the action of the drug without considering the bath temperature will lead to something that makes little sense. Thus, the rate of responding should be viewed not as the sole determinant of drug action, but, under the right conditions, it can assume a prime role in the determination of the response.

Although the issues and theories of the 1950s seem of little consequence today, the lessons learned need not be forgotten. For example, as we explore the role of genetics in the control of behavior and the response to drugs in newly developed animal strains, it must be remembered that ignoring the role of the control behavior in influencing drug effects is done at ones own peril.

Diagnostic precision is achieved using structured diagnostic interviews. In contrast, rating scales are not intended for diagnostic purposes. Their function is to measure the severity of a condition or symptom cluster after the diagnosis is made by independent means. Typically, in psychopharmacology research, patients are screened into studies using structured diagnostic interviews. The response to treatment over time is then assessed by measuring the severity of the primary and associated symptom clusters or domains of interest from baseline through treatment follow-up (American Psychiatric Association 2000).

Principles and Role in Psychopharmacology

Structured Diagnostic Interviews

Structured diagnostic interviews were developed to improve reliability in making psychiatric diagnoses for clinical and research purposes. Psychiatric diagnosis was very unreliable prior to the introduction of structured diagnostic interviews. Different criteria were used in different countries and within different schools of psychiatric thought. Within these groups, diagnosis varied based on the manner and on the amount of information elicited from patients. Information provided by patients was interpreted and assembled differently in reaching a diagnosis. The systems used to elicit information, to assemble this information, and to make diagnoses were too many, too varied, too inconsistent, and too divergent to permit accurate communication between large numbers of clinicians and to foster constructive and efficient international collaboration in research. The adoption of efficient and easily administered structured diagnostic interviews, that were translated into a large number of languages and used as consistent diagnostic criteria, has harnessed the energy of international research collaboration in pursuit of finding better treatments for, and understanding of, psychiatric disorders (Sheehan et al. 1998; Spitzer et al. 1992). Structured diagnostic interviews reduce variance in information gathering and reduce criterion variance in assembling this information to make a diagnosis. In this way, they improve both the reliability and quality of diagnostic decision-making.

Choice of Scales

A typical treatment-outcome study uses at least three scales: a scale to measure improvement in the symptom cluster of primary interest (Hamilton 1959, 1967; Montgomery and Asberg 1979); another scale to measure the functional impairment or disability (Endicott et al. 1993; Sheehan and Sheehan 2008); and a third scale to measure the global improvement (Guy 1976). In the past 2 years, the tracking of suicidality in psychiatric and neurological studies has also become routine and is now required by many regulatory agencies (Coric et al. 2009; Posner et al. 2007). Additional scales are frequently used to assess other secondary symptom clusters of interest, e.g., quality of sleep, ▶ cognitive impairment (Folstein et al. 1975), negative symptoms in ▶ schizophrenia (Kay 1990), anxiety symptoms in ▶ depression, or sexual symptoms. With the rise in managed care and increasing concern about cost containment, there is more inclusion of pharmaco-economic measures, especially on health care utilization and cost data. Since major drivers of costs in the management of many psychiatric disorders are poor adherence, increasing switch rates, and more augmentation with other medications, cost drivers are also increasingly tracked in long-term studies. A wide array of scales is available to assess adverse events. Examples include assessments of ▶ extrapyramidal side effects on ▶ antipsychotic medications (Barnes 1989), assessments of sexual side effects with ▶ antidepressants (Clayton et al. 1997), assessments of ▶ discontinuation withdrawal symptoms and of ▶ abuse liability, ▶ craving or "liking" with controlled substances (Selzer 1971).

Scale Metrics

Psychometric constructs may be measured in two major ways. Categorical classification (e.g., yes or no) qualitatively

assesses the presence of symptoms, signs, or attributes and is widely used in diagnostic assessment through structured diagnostic interviews. Continuous measures (e.g., height or weight) permit quantitative assessment of the severity, intensity, or frequency of symptoms, signs, or attributes. In between these two poles lie the ordinal scales that use an ordered set of categories (e.g., none, mild, moderate, and severe). Such ordinal scales are effectively treated and analyzed like continuous measures especially if they have 10 or more points. Continuous or ordinal scales that yield a total score may themselves be used for categorical classification. For example, a score of seven or less on the ▶ Hamilton Depression Rating Scale (Hamilton 1967) may be classified as a remission in depression.

A variety of scale structures or metrics are used in continuous or ordinal scales. The most common scale structure involves the use of a 5- or 10-point scale. Dichotomous categorical scales are less common and a few widely used scales have six or seven response options. Likert scaling is frequently used to measure change in symptoms in efficacy studies. Visual analog scales are popular in the assessment of pain. The DISCAN design metric is increasingly popular in scales designed to be sensitive to drug-placebo differences (Sheehan and Sheehan 2008). Although measures of frequency, e.g., of panic attacks, of seizures, or of ▶ tics are often used as outcome measures; in general, they disappoint in their ability to discriminate between active and ▶ placebo treatments. The main reason is that the frequency of most behaviors is of skewed distribution in nature. Nonparametric tests statistically punish sensitivity and this price makes them less able to discriminate drug from placebo and to be less sensitive to change.

Scale Testing

Scales and structured interviews in psychopharmacology must be subjected to proper reliability and validity testing. Validity tests the degree to which the scale or structured interview is consistent with a "gold standard" measure (e.g., how well a structured diagnostic interview maps the diagnostic classification or how a severity scale accurately reflects the severity of a disorder). The problem in psychiatry is that the "gold standard" is not really "gold." Three kinds of reliability testing are usually done on scales and structured interviews. These include inter-rater reliability, test-retest reliability, and internal consistency. Inter-rater reliability measures the agreement between two raters in rating the same subjects using the same scale or interview at the same time. It is most useful in assessing clinician-rated scales. Test-retest reliability measures the agreement between assessments done at two different points in time (e.g., the same scale done on consecutive days, but assessing the same time period). It has special value in assessing self-rated scales. Internal consistency measures the agreement among the items within a scale. It assesses the degree to which all the items measure a single dimension.

In spite of the limitations of these paper and pencil interview tests, they have performed well in guiding our search for and selection of effective treatments. Researchers in psychopharmacology continue to refine their precision and predictive value. Some day, they will be largely replaced by more precise laboratory tests.

Definition
Reboxetine (*R**,*R**)-2-[(2-ethoxyphenoxy)-phenyl-methyl]morpholine mesilate is an antidepressant that selectively inhibits the reuptake of norepinephrine (▶ SNRI). It is claimed to have mood-lightening effects in the elderly, but it is significantly less clinically effective against the acute phase of major depressive disorders, and less acceptable relative to other new antidepressants. It is also used in the treatment of panic disorder and ADHD.

The side effects of reboxetine derive from the anticholinergic effects of the compound, particularly antimuscarinic effects, and range from dry mouth, constipation, headache, drowsiness, dizziness, and excessive sweating to insomnia. Rare cases of seizures have been reported.

Receptor

Definition
A protein embedded in the cell membrane or the cytoplasm, which is sensitive to a drug or chemical neurotransmitter. It docks (binds) to the drug or neurotransmitter and then generates an electrical or chemical signal in the neuron in which it is located. A given substance can have more than one type of receptor.

Receptor Antagonist

Definition
A receptor antagonist is a type of receptor ligand or drug that does not provoke a biological response itself upon binding to a receptor, but blocks or dampens agonist-mediated responses. Antagonists mediate their effects by binding to the active site or to allosteric sites on receptors, or they may interact at unique binding sites not normally involved in the biological regulation of the receptor's activity. Antagonist activity may be reversible or irreversible depending on the longevity of the antagonist-receptor complex.

Definition

Receptor binding refers to a technique in which a labeled compound, a ligand, which binds to a receptor, is used to detect that receptor. Usually, the ligand is labeled by means of a radioactive isotope, such as ^{3}H, ^{125}I, ^{35}S, etc., but a fluorescent moiety is also possible. The receptor can be localized in a tissue that is homogenized or sliced or in cells in culture that either have an endogenous expression of the receptor or have been transfected with a cloned receptor gene. Tissue preparations are incubated with a labeled ligand that has a high binding affinity for the target receptor. The labeled ligand bound to tissue is then collected and detected using various techniques, such as filtration techniques combined with radioactivity counting, scintillation proximity analysis and autoradiography for radioactive ligands, and time resolved fluorescence resonance energy transfer (TR-FRET) or amplified luminescent proximity homogeneous assay (AlphaScreen) for ligands labeled with a fluorescent or a chemoluminescent probe, respectively. These techniques are applied in vitro or ex vivo. In vivo receptor binding can be investigated using positron emission tomography (PET) or single photon emission computerized tomography (SPECT) imaging.

Principles and Role in Psychopharmacology

Receptor binding techniques were first introduced in the 1970s (historic reviews: Lefkowitz 2004; Snyder and Pasternak 2003). It was the first tool enabling receptors to demonstrated in tissues using biochemical means. In the early years, one had no clue about the nature or structure of receptors. Extensive research throughout the 1980s led to the cloning of receptor genes and the identification of their structure. Today, three major classes of receptors that are located in cell membranes and one class of cytosolic receptors have been identified.

1. The ► G-protein coupled receptors (GPCRs), also called "7 Transmembrane (7 TM)" receptors, are integral membrane protein monomers. With 802 known and predicted human GPCRs, derived from the human genome, this is the largest receptor family and at least 50 of them have been identified as major drug targets (Lagerström and Schiöth 2008). Sequence comparison revealed five subfamilies, all of which have a central core domain in common, which consists of 7 TM helices connected by three intracellular and three extracellular loops. The protein has an extracellular N-terminal and an intracellular C-terminal, which can be of widely varying lengths. GPCRs have diverse natural ligands comprising of small molecules (amines, amino acids, nucleotides, nucleosides, prostaglandins, peptides, lipid-like molecules, etc.), light, Ca^{++}, odorants and pheromones, and proteins (for review of the GPCR classes, structures, features, and natural ligands, see Lagerström and Schiöth 2008). Upon activation, a GPCR associates with a G-protein that further activates effectors in the cell. Various different proteins can interact with GPCRs so that receptor complexes can exist in multiple states leading to possible complex kinetics for ligand binding (Christopoulos and Kenakin 2002).
2. Ligand-gated ion channels are multimeric, often pentameric, protein complexes that form a pore in the membrane. Members of this family are e.g., the nicotinic acetylcholine, $GABA_A$, $5\text{-}HT_3$, glycine, purinergic P2X, and the NMDA, AMPA and kainate subtypes of glutamate receptors, each of itself has several subtypes.

3. Receptors that are enzymes with a ligand-binding domain that couples to an intracellular membrane-anchored enzyme such as tyrosine kinase, tyrosine phosphatase, serine/threonine kinase, and guanylyl cyclase. Members of this class are e.g., growth factor receptors, neurotrophic factor receptors, and transforming growth factor β (TGFβ) receptors.
4. Cytosolic receptors regulate transcription in the cell nucleus. Members are steroid, retinoid, and tyrode hormone receptors.

Large numbers of members of each of these receptor classes as well as (neurotransmitter) transporters have been studied with receptor binding techniques and receptor binding assays, for hundreds of different molecular targets have been described. In this chapter, in vitro and ex vivo methods used for investigating membrane-bound receptors will be discussed.

Principles

Analytical Rules

Receptor binding assays require working according to analytical rules and procedures. Water must be of freshly double distilled or milliQ quality and all chemicals (salts, metal ions, organic solvents, etc.) of analytical grade. Labeled ligands must have a purity of >98% and purity must be checked regularly (radioligands, in particular with high specific activity, suffer from radiolysis). Stability of compounds must be checked and purified where necessary (e.g., catecholamines and indoleamines are very unstable and solutions need to be purified just prior to use). (Micro)-balances, pipettes (manual and automated) must be regularly gauged. Compounds must be solubilized and diluted according to their physicochemical properties. Lipophilic compounds are best solubilized and diluted in pure dimethyl sulfoxide (DMSO) and buffer should be used only for the last dilution step, or the organic solvent solution should be added directly into the incubation mixture. However, the organic solvent concentration in the assay mixture should not exceed 0.5%. Dilution in the organic solvent is indicated to avoid the loss of lipophylic compound due to adsorption to glass or plastic ware. Plastic tubing must be avoided when using robotic devices. Hydrophilic compounds must be solubilized and diluted in buffer or water. Sometimes protecting agents such as anti-oxidants must be added. Biological materials must be kept on ice in buffer of neutral pH until the start of the incubation. Buffer pH must be adjusted to the temperature of the incubation.

Law of Mass Action

Ligand – receptor binding experiments are usually analyzed according to the simple model of law of mass action:

$$[R] + [\mathrm{L}] \underset{k_{off}}{\overset{k_{on}}{\longleftrightarrow}} [\mathrm{RL}]$$

where [R], [L], and [RL] represent the free concentration of receptor, ligand, and receptor–ligand complex, respectively, and where it is assumed that the reaction components can freely diffuse within the medium. k_{on} and k_{off} are the rate constants for association and dissociation of the ligand–receptor complex. It is assumed that after dissociation, receptor and ligand are not altered.

Association and dissociation rates are temperature dependent. The reaction is driven by the concentration of the reacting agents. Equilibrium is reached when the rate at which ligand–receptor complexes are formed and dissociate are equal. At equilibrium, the following applies:

$$[R]\,[\mathrm{L}]\,k_{on} = [\mathrm{RL}]\,k_{off},$$

The equilibrium dissociation constant, K_d, a measure for binding affinity, is defined as

$$K_d = \frac{k_{off}}{k_{on}} = \frac{[\mathrm{L}]\,[\mathrm{R}]}{[\mathrm{RL}]}$$

The constants have the following units: k_{on}: $M^{-1}{\cdot}s^{-1}$; k_{off}: s^{-1}; K_d: M, where M stands for Molar or $mol{\cdot}L^{-1}$. When receptor binding experiments are performed, [R] usually is unknown (needs to be determined), [RL] is measured in the assay, and [L] usually is assumed to be equal to the applied ligand concentration. This implies, however, that only a minor fraction (<5%) of the total applied ligand should become bound (either by specific binding, nonspecific binding or adsorption to tissue and assay container) so that the free concentration is not significantly altered.

Criteria Required by the Law of Mass Action; Can They be Met?

It is important to realize that the reaction conditions never meet the required criteria. The reaction model itself is largely simplified, as receptors can occur in different states and ligands may bind to ► orthosteric and ► allosteric sites (see Christopoulos and Kenakin 2002). "Free in solution" and "freely moving in solution" does almost never apply to biological tissue, either as an homogenate or a membrane suspension and certainly not when tissue slices, whole cells or tissue fixed on a support are used. Membrane preparations consist of membrane vesicles of varying dimension, possibly with strips of membrane suspended in aqueous medium. Surface phenomena will

inevitably take place when ligands (hydrophobic or hydrophilic) approach the membrane vesicle. Examples of surface phenomena are electrostatic interactions of ionized compounds or surface excess of lipophilic compounds. Surface phenomena, which are difficult to measure or estimate, have received virtually no attention in receptor binding research. Yet, they are a matter of fact and, for ▶ haloperidol, a 1000 x surface excess was calculated to exist in the monolayer around a membrane vesicle as compared to the concentration in aqueous medium (Leysen and Gommeren 1981).

Furthermore, reaction temperature needs to be carefully controlled. A binding reaction is temperature dependent and tissue is temperature sensitive; the transition temperature of the lipid cell membrane (usually around 15°C) must be considered. Tissue and compounds may also behave differently according to pH, in particular when they have ionizable groups with an acid association constant, pKa, between 5 and 8. Therefore, it is advised never to consider experimentally measured values for e.g., K_d or K_i as "absolute," but refer to them as "apparent" under the conditions of a particular assay. Those conditions should always be fully reported.

Types of Binding

Labeled ligands show different types of binding, depending on their physicochemical and pharmacological properties. There is specific binding to the target receptor, which occurs in a concentration range of 2 log units around the K_d value. This binding is saturable, as the number of receptors present is limited. Binding to the target receptor should be reversible and can be inhibited by a compound (competitor) that has the same pharmacological property, related to the target receptor, as the labeled ligand. Full inhibition of receptor binding is obtained at 100 x K_i of the competitor (K_i, inhibition constant, see below), provided that the labeled ligand is used at concentrations around its K_d. A particular labeled ligand (or competitor) may bind to several different receptors within a narrow concentration range. In particular agonists or antagonists for various subtypes of dopamine, noradrenaline, serotonin, histamine, and acetylcholine GPCRs can show, what is called, a "broad receptor profile" (see Leysen 2002, 2004). Binding of a labeled ligand to several different receptors can be a problem, in particular when natural tissues are investigated (this is less of an issue when cultured cells transfected with a particular receptor gene are used and high receptor expression is obtained). If required, occluding agents can be added to prevent the labeling of nontargeted receptors. Labeled ligands also show "nonspecific" binding due to adsorption to tissue, this binding is linearly proportional with the labeled ligand concentration and non-saturable, i.e., non-displaceable. Nonspecific binding can be measured in an experiment where an appropriate competitor (with high ▶ affinity for the target receptor, but preferably of a different chemical structure than the labeled ligand) is added at a concentration 100–1,000 times its K_i and incubated together with the labeled ligand and the tissue. Resulting binding represents nonspecific binding. Labeled ligands may show an additional type of binding, apparently of high affinity and saturable, hence displaceable, but related to a particular moiety in its structure and apparently unrelated to binding to a known biological target (e.g., [^{3}H] spiperone, the 5-HT_{2A} and dopamine D2 receptor ligand, labels "spirodecanone sites"); this binding can be occluded by adding a structural analogue of the labeled ligand, but which does not bind to the target receptor. When studying receptor binding in natural tissues, the various possible types of binding should be carefully investigated (Leysen 1984).

Types of Experiments

Saturation Binding Experiments or "Labeled Ligand Concentration Binding Isotherms"

Aim: determination of K_d and ▶ B_{max} (maximum number of receptor binding sites in the tissue preparation) values.

These assays are performed using a constant amount of tissue at a particular temperature (preferably 37 °C, but sometimes lower temperatures are used) and pH (around 7.4) with increasing concentrations of labeled ligand. The specific binding isotherm, according to the simple law of mass action, follows the course of a hyperbola when the labeled ligand's free concentration on the abscissa and specific binding on the ordinate are plotted using linear scales. Half-maximal binding is reached at a concentration that equals the K_d value and maximal binding is approached at four times the K_d value. Applied labeled ligand concentrations should span a range from 0.2 to 8 times K_d in a series of at least 12 points covering the rising part and plateau of the hyperbola (e.g., for a labeled ligand with K_d=1 nM, appropriate test concentrations are 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 6.0, 8.0 nM). The "total binding" is measured in assays with the labeled ligand at its various concentrations, the tissue preparation and a solvent sample, the "nonspecific binding" is measured in assays with the labeled ligand (at each of its concentrations), the tissue preparation and a (non-labeled) competitor at a concentration of 100 times its K_i value. Specific binding is calculated by subtracting

nonspecific binding from total binding at each labeled ligand concentration. To date, binding isotherms are calculated by nonlinear regression analysis and computerized curve fitting, which provide the K_d and B_{max} values. In case a "one binding site model" does not fit the data, a "two binding site model" can be attempted. Curve fitting programs for labeled ligand binding are available commercially, e.g., GraphPad Prism (GraphPad Software, La Jolla, USA). The programs usually provide background on calculations with radioactivity, e.g., on converting bound radioactivity, measured in counts, into pmoles of bound labeled ligand. In the past, when computing power was not readily available, the hyperbola was transformed into a linear equation, e.g., a Scatchard plot.

Kinetic Binding Experiments

Aim: Determination of the association and dissociation rate constants.

Rate constants are relatively easy to measure for a labeled ligand.

To measure the association rate, a labeled ligand, at a given concentration (e.g., 3–4 x K_d), together with the tissue preparation, is incubated for various periods of time and for each time bound labeled ligand is measured. Association of ligands with nM affinity is fast and incubation times should be in the range from seconds up to 10 min. The maximal bound radioligand at equilibrium is usually reached within 2–4 min. Ligand–receptor association is a second-order reaction, involving two reaction partners: the free ligand and the free receptor. However, measured binding is the result of association and dissociation, and usually the free receptor concentration is small, and consequently the free ligand concentration drives the association. Therefore, the reaction proceeds according to pseudo first order kinetics. The plot of bound labeled ligand versus time is hyperbolic and can be transformed according to a pseudo first order rate equation, in a linear plot:

$$\ln\left(\frac{B_{eq}}{B_{eq}-b_t}\right) \text{versus time (s)},$$

B_{eq} and b_t are bound labeled ligand at equilibrium and at a given time. The pseudo first-order rate constant, k_{obs} (s^{-1}), is given by the slope of the line. For calculation of the association rate constant, k_{on} ($M^{-1}\cdot s^{-1}$), the dissociation rate constant, k_{off} (s^{-1}), is needed.

$$k_{on} = \frac{k_{obs} - k_{off}}{[L]}$$

The dissociation rate constant can be measured by incubating the tissue preparation with the labeled ligand at a given concentration (preferably not exceeding the K_d value) until equilibrium is reached and then either strongly diluting the reaction medium (more than 10 times) to favor dissociation and minimize re-association, or, more common, adding an excess of strong competitor to the reaction medium, which will induce displacement and hence dissociation of the labeled ligand. From that point onward a series of incubation samples is taken to measure remaining bound labeled ligand. The dissociation reaction is a first-order reaction, a semilogarithmic plot of log[bound labeled ligand] versus time is linear and the dissociation rate constant, k_{off}, is given by the slope of the line x 2.3 (transformation of $\log_{10}$ into ln). The half-life of dissociation is given by $t_{1/2}=0.693/k_{off}$. Measurement of the dissociation rate of an unlabeled competitor requires a more elaborate procedure. The approximate half-life of dissociation of an unlabeled competitor can be assessed by an indirect method. Tissue with competitor at a given concentration (not exceeding 2 x K_i) is incubated until equilibrium and filtered over a glass fiber filter. The tissue (with bound competitor) adsorbed on the filter is rinsed for various periods of time, followed by short incubation of the tissue on the filter with a labeled ligand. The amount of labeled ligand that becomes bound is then an indication of the amount of competitor that has dissociated. (Leysen and Gommeren 1986). Knowledge of the receptor dissociation rate of compounds has gained interest, in light of deriving information on factors that contribute to the duration of action of drugs and on the ease with which a drug bound to the receptor in vivo, can be displaced e.g., by the endogenous ligand for the receptor.

Competitive Binding Experiments

Aim: To determine the IC_{50} value (concentration producing 50% inhibition) of a competitor. Competitive binding experiments are used to compare different ligands acting at similar sites. The sigmoid curve obtained with a competitor should asymptotically approach the level of non-specific binding, without surpassing it. Nonlinear curve fitting programs can be used to estimate IC_{50} values. Curve fitting also yields a value for the slope (n) of the curve; $n = 1$, for competition at one binding site; $n > 1$ or $n < 1$ for multiple binding sites, binding of the competitor with different affinity to multiple states of the receptor, or involvement of cooperative binding. Curve fitting programs allow for the analysis of data for multiple binding site models. IC_{50} values are dependent on applied concentration and K_d of the labeled ligand. The Cheng Prusoff equation provides for the calculation of the equilibrium inhibition constant, K_i (equaling the

equilibrium dissociation constant), which is independent of the applied labeled ligand:

$$K_i = IC_{50}/(1 + [L]/K_d)$$

The Cheng Prusoff equation is derived from a simple model of competition at one and the same binding site; the same warnings of caution for the interpretation of K_i values as described earlier apply.

For further reading on different types of binding experiments, illustrations and details on analyses of receptor binding data, see: Keen and MacDermot 1993.

Antagonist Binding

For GPCRs and ligand-gated-ion-channels, the majority of studied labeled ligands and competitors are antagonists or ▶ Inverse Agonists. Antagonist binding to GPCRs, has appeared to be insensitive to the occurrence of the receptor in various states (e.g., G-protein coupled or uncoupled). Antagonist binding curves (labeled antagonist saturation binding and antagonist–antagonist competition) have often been found to obey apparent single site binding kinetics.

Agonist Binding

Agonist binding to GPCRs is sensitive to the state in which the receptor occurs. Agonists have substantially higher affinity for the G-protein coupled than for the uncoupled receptor. As a consequence, competition between a labeled antagonist and an unlabeled agonist often yields a shallow inhibition curve, pointing to multiple binding sites or binding to the receptor in multiple states. Inhibition curves of agonists can be influenced by additives in the incubation medium, in particular by agents that affect the coupling of the receptor to the G-Protein. Guanosine triphosphate (GTP), or a stable analogue thereof, uncouple the receptor-G-protein complex. Addition of GTP to the medium will shift an (shallow or biphasic) agonist inhibition curve to the right, make it mono-phasic, and decrease the slope to approach 1 (see Lefkowitz 2004). Agonist binding to GPCRs is also affected by divalent cations, in particular Mg^{++} or Mn^{++}, which may favor receptor-G-protein coupling and increase the agonist binding affinity. The effect of divalent cations on agonist binding should be experimentally investigated. A good example is the investigation of the effects of bivalent cations on the affinity states of the M1 ▶ muscarinic acetylcholine receptor (Potter et al. 1988). Labeled agonist concentration binding isotherms will similarly be influenced by additives in the incubation medium, and affect the measured apparent K_d and B_{max} values. When labeled agonist saturation curves are measured in a low concentration range, usually only the high affinity-binding constant of the agonist, K_H, will be detected. The B_{max} value measured with a labeled agonist may only represent the G-protein coupled portion of the receptor and, for the same tissue sample, usually will be lower than the B_{max} value measured with a labeled antagonist.

GPCRs for which labeled agonist binding hase been amply studied and for several of which agonists are used as therapeutic agents are μ−opiate, 5-HT_{1A}, 5-HT_{1B}, 5-HT_4, and various peptide receptors (e.g., NK1, NK2, NK3, CRF1). Examples of GPCRs that have been studied with both labeled agonists and antagonists are dopamine D_2, 5-HT_{2A}, 5-HT_{2C}, 5-HT_4, 5-HT_6 and muscarine M1ACh receptors, and β1-and β2-adrenoceptors.

Allosteric Competitors

The natural ligand or a synthetic agonist that binds to the orthosteric site and a compound that attaches to the ▶ allosteric binding site can concomitantly occupy the same receptor without mutual inhibition of binding. Positive ▶ allosteric modulators will enhance and negative allosteric modulators will reduce the activity/affinity of an orthosteric agonist. The allosteric receptor interaction of compounds usually is studied in functional, signal transduction assays (▶ Receptors: Functional Assays). Labeled ligand binding to an allosteric site may be used in competition binding assays to detect competitors that bind to the same allosteric site.

Ligand-gated ion channel receptors are known to have several different allosteric binding sites. The ▶ $GABA_A$ receptor was the first receptor for which the phenomenon was discovered with drugs that were in use as therapeutic agents, namely the ▶ benzodiazepines. GPCRs of family 3, the $GABA_B$ receptor, and the ▶ metabotropic glutamate receptor subtypes are amply studied for positive and negative allosteric modulators.

Methods for In Vitro Receptor Binding Using Tissue or Cell Homogenates or Membrane Preparations

Tissues and Preparation

Tissues used for receptor binding are e.g., dissected brain regions or organs, cultured cells (cell lines or primary cultures) or blood cells that express a particular receptor endogenously, or cultured cells with (abundant) expression of a particular receptor following the transfection of the cells with that receptor's cloned gene from a specific species (often human). Although, when conditions are appropriate, receptor binding can be performed on intact cells, in most cases the tissue is homogenized, and either

the whole homogenate or, more often, a membrane preparation is used for the assay. Used membrane preparations are the "total particulate fraction" (i.e., the total fraction of membranes spun down at high centrifugation speed following extensive homogenization of the tissue in buffer with a blender) or a membrane preparation from separated subcellular particles (e.g., heavy and light mitochondrial fractions, plasma membrane fraction) following careful homogenization of the tissue in 0.25 M sucrose followed by differential centrifugation (see Laduron et al. 1978). Membrane preparations are washed by re-suspension in medium and re-centrifugation. All tissue preparation steps are to be carried out at 0–4°C. Tissue preparations can be stored below −20°C.

Incubation in Tubes and Multi-Well Plates

Incubations can be performed in test tubes (volumes 0.5–2 mL) or 96 multi-well plates (0.1–0.2 mL). Incubation mixtures are composed of a sample of cells or membrane preparation suspended in buffer, an aliquot of labeled ligand to give a desired final concentration and, depending on the type of experiment, an aliquot of a competitor to give a desired final concentration (see types of experiments). The buffer has a particular pH (usually around 7.4) and can contain certain additives such as metal ions. Depending on the type of experiment, the incubation is run at a given temperature for a given time period (see types of experiments). For competition-binding experiments, the incubation time should be sufficiently long to reach binding equilibrium.

Filtration Methods

Labeled ligand, bound to the tissue preparation and free-labeled ligand, can be separated by filtration over glass fiber filters (filters are sometimes presoaked in polyethyleneimine to reduce absorption of the labeled ligand to the filters) under suction, followed by rapid rinsing with ice-cold buffer. For incubation in test tubes, a Brandel harvester (Brandel, Gaithersburg, USA) is used, for incubations in 96 multi-well plates, various harvesting devices are available (e.g., Micromate 196 and Mac II, Perkin Elmer, Waltham, USA; Brandel 96, Brandel, Gaithersburg, USA). The radioactivity of bound labeled ligand collected on the filters is counted; for β ray emitting isotopes e.g., ^{3}H-labeled ligands, the filters are dried, liquid scintillation fluid is added and radioactivity is counted in a liquid scintillation counter, for γ ray emitting isotopes (e.g., ^{125}I) radioactivity can be counted directly in a γ counter. For competition binding assays, 96 multiwell incubation, filtration, and counting methods and devices are appropriate; for saturation binding experiments with the determination of K_d and B_{max} values and the determination of ligand association and dissociation rates, incubation in test tubes and filtration over separate filters that are counted in vials in a calibrated liquid scintillation counter is advised.

Scintillation Proximity Assay (SPA)

SPA is a homogenous assay that avoids the filtration step. For SPA either poly-vinyl-toluene beads, filled with scintillant (GE Healthcare Life Sciences, Buckinghamshire, UK) or "Flashplates" or "Scintiplates" (Perkin Elmer, Waltham, USA), i.e., 96 multi-well plates with scintillant coated on the inner surface of the wells, are used. The beads or plates are coated with membrane preparation. Samples of coated beads added in 96 multi-well plates or wells of coated Flashplates are incubated with labeled ligand without or with competitor at desired concentration in buffer. Since the tissue is not "free in solution," several hours of incubation time are required to reach binding equilibrium. After incubation, the multi-well plates are counted directly in a Topcount NXT (Perkin Elmer, Waltham, USA). The scintillant will only detect radioactivity in its immediate vicinity, i.e., the radioactive ligand that is bound to the tissue coated on the beads or on the plates. The mix-and-read format technology is useful for high throughput screening, but long incubation times have to be taken into account.

Nonradioactive Proximity Assays

The burden on the environment and the inherent high cost for the removal of radioactive waste encouraged the development of nonradioactive techniques for receptor binding. TR-FRET, making use of fluorescent probes, and AlphaScreen™, which is based on chemoluminiscence, are examples that are mainly applied for high throughput competition binding assays. The technologies are based on the excitation of the "donor" probe (e.g., attached to the ligand), which triggers an energy transfer to the acceptor probe (e.g., attached to the receptor preparation) if they are within a given proximity. The acceptor probe in turn emits light of a given wave length, which is detected. The application of these techniques is limited, since it requires the development of ligands labeled with relatively large probes, resulting in a compound with a different chemical structure than the original ligand. The receptor binding characteristics of such fluorescent or chemoluminiscent ligands will be altered and need to be fully investigated. Development of apt fluorescent or chemoluminiscent ligands is a matter of trial and error.

Labeled Ligand Autoradiography

Autoradiography is a general technique allowing the visualization of the distribution of a radioactive ligand, bound to a molecular target in a tissue section. The radioactive ligand can be injected (iv) in an animal, followed by sacrifice of the animal, tissue dissection and sectioning. Otherwise, tissue sections can be incubated with radioactive ligand in vitro. Tissue (often brain) sections (20 µm thick), usually is cut with a cryostat, and mounted on a coated microscope glass support. Incubation is performed by overlaying the tissue section with a drop of incubation medium containing the radioactive ligand. After incubation, the tissue sections are quickly rinsed and dried. To "visualize" radioactive ligand bound to the tissue, different techniques have been used. The highest resolution, but requiring the longest exposure time (weeks up to several months), is obtained by exposing the tissue sections to a photographic emulsion. Shorter exposure times (several days up to one week) can be achieved by using a phosphor imager. The most recently developed device, the β-imager (Biospace Lab, Paris, France), can produce an image of the bound radioactivity, following over night counting and up to 15 microscope glass slides can be counted simultaneously. The images are analyzed and quantified by counting the number of β-particles emerging from the delineated brain areas by using the β–vision program (Biospace Lab, Paris, France).

For technical details on receptor autoradiography protocols, see: Wharton and Polak 1993.

Apart from neuroanatomical mapping, autoradiographic techniques can also be applied to measure receptor occupancy by non-labeled drugs (Schotte et al. 1993). A drug, at varying dosages, systemically is given to laboratory animals. The animals are sacrificed, tissue dissected and sectioned, and tissue sections are briefly incubated with a radioactive ligand for the target receptor. The difference in labeling in a defined area on matching tissue sections from drug-treated and non-treated animals is a measure for the occupancy of the receptor by the drug administered to the animal. This "ex vivo" incubation technique, is only applicable for drugs with a sufficiently slow dissociation rate from the receptor. Alternatively, the radioactive ligand can be injected iv to the animal that is systemically treated with the investigational drug; in this way, the competition for receptor binding between the drug and the radioactive ligand will take place in vivo. Subsequently, the animal is sacrificed, tissue dissected and sliced, followed by the quantification of the image. With the introduction of the highly sensitive β-imager in the 1990s, allowing images to be obtained in a few hours, receptor occupancy assays ex vivo, became a feasible and highly valuable drug screening technique (Langlois et al. 2001).

Application of Receptor Binding

Receptor binding data sometimes are scornfully looked at by pharmacologists with the view that binding does not say anything about function. Yet, receptor binding has contributed substantially to the field of pharmacology. It has demonstrated the existence of receptors at the molecular level. It has contributed to the isolation and purification of receptor proteins, leading to the cloning of the first receptor gene. It has allowed the study of the localization of receptors at anatomical and cellular levels and of receptor dynamics, such as receptor desensitization, receptor endo- and exocytosis, and transport of receptors along axons (see Lefkowitz 2004).

In terms of drug discovery and drug profiling, receptor binding has revolutionized the field. Drug screening with receptor binding started in the mid-1970s and soon led to high throughput, assay automation and super high throughput assays, allowing for screening thousands of compounds in one day at many different receptors with a minimum of personnel.

Receptor binding profiles of drugs have revealed that many of the drugs that were in clinical use, such as ▶ antidepressants and ▶ antipsychotics, bound to several different receptors within a narrow potency range, e.g., the antipsychotic ▶ clozapine was found to bind to more than 20 receptors with such potency, that all of them could be hit at a therapeutic dose (Leysen 2002; Leysen 2004). Receptor binding is the method of choice to investigate and demonstrate the selectivity of action versus the multiplicity of action of drugs. Measurement of receptor occupancy in the brain by drugs that are administered to animals, using ex vivo autoradiography, has become a key component of CNS drug discovery programs. It allows determination of the dose range within which central receptors become occupied and does not only provide information on the extent of receptor occupation, but also on the brain penetration of the drug.

Definition

Psychoactive drugs generally exert their effects by binding to a specific recognition site, whether that is associated with a receptor, a transporter, or an enzyme and thereby alter the function of that receptor, enzyme, or transporter. However, receptors are the predominant targets for psychoactive drugs (Grigoriadis et al. 2009) and these may be either ▶ G-protein-coupled receptors (GPCRs) or, to a lesser extent, ion channels (the latter of which may be either ligand- or voltage-gated).

Although the actual effect produced by drugs affecting GPCRs and ion channels are very different, their mechanisms of action follow similar principles. Hence, a drug acting at a GPCR or ion channel may block the effect of an endogenous ▶ Agonist (i.e., act as an ▶ Antagonist), mimic the effect of the endogenous activator (i.e., act as an agonist), or inhibit spontaneous (nonagonist-stimulated) receptor activation (i.e., act as an ▶ Inverse Agonist). In addition, a drug may bind to a recognition site that is physically distinct from the agonist-binding site and as a result, produce allosteric changes in receptor structure that enhance or reduce the effects of the endogenous agonist; such drugs are known as positive ▶ Allosteric Modulators (PAMs) and negative allosteric modulators (NAMs), respectively.

Stated simply, a drug binds to a receptor and then "does something." It is the purpose of functional assays to measure and quantitate that "something," with the choice and design of assay being highly dependent upon the type of receptor (i.e., GPCR or ion channel), as well as the effect being studied (agonism, antagonism, inverse agonism, or allosteric modulation).

Principles and Role in Psychopharmacology

Introduction

Drugs may exert their effects by specifically interacting with receptors, enzymes, or transporters, by interfering with DNA, RNA, or ribosomal processes, by exerting physicochemical effects, or in the case of monoclonal antibodies, by targeting a variety of different proteins. With regard to receptors, this classification includes GPCRs, ion channels, and nuclear receptors. Since the latter are primarily the therapeutic focus for obesity, diabetes, and cancer, the GPCR and ion-channel family represent the main receptor targets in psychopharmacology. As a therapeutic class, GPCRs are more successful than ion channels as measured in terms of FDA-approved drugs and hence, GPCRs appear to be more "drugable" targets. However, there is little doubt that ion channels have been generally underexploited, especially as targets for CNS disorders, especially when one considers that most of the neuropsychopharmacological ion channel drugs are ▶ $GABA_A$ modulators that were discovered prior to the revolution in molecular biology and genomics.

In the search for new psychopharmacological drugs, the identification of novel chemical structures that interact with the target of interest is arguably the most crucial step in the drug discovery process. Such compounds are usually identified in the screening of large chemical collections (ranging from hundreds of thousands to up to several million) in high-throughput screening (HTS) campaigns. Accordingly, the focus of this article will be the measurement of the functional effects of compounds at GPCRs and ion channels in such HTS formats.

Functional Assays: What to Measure?

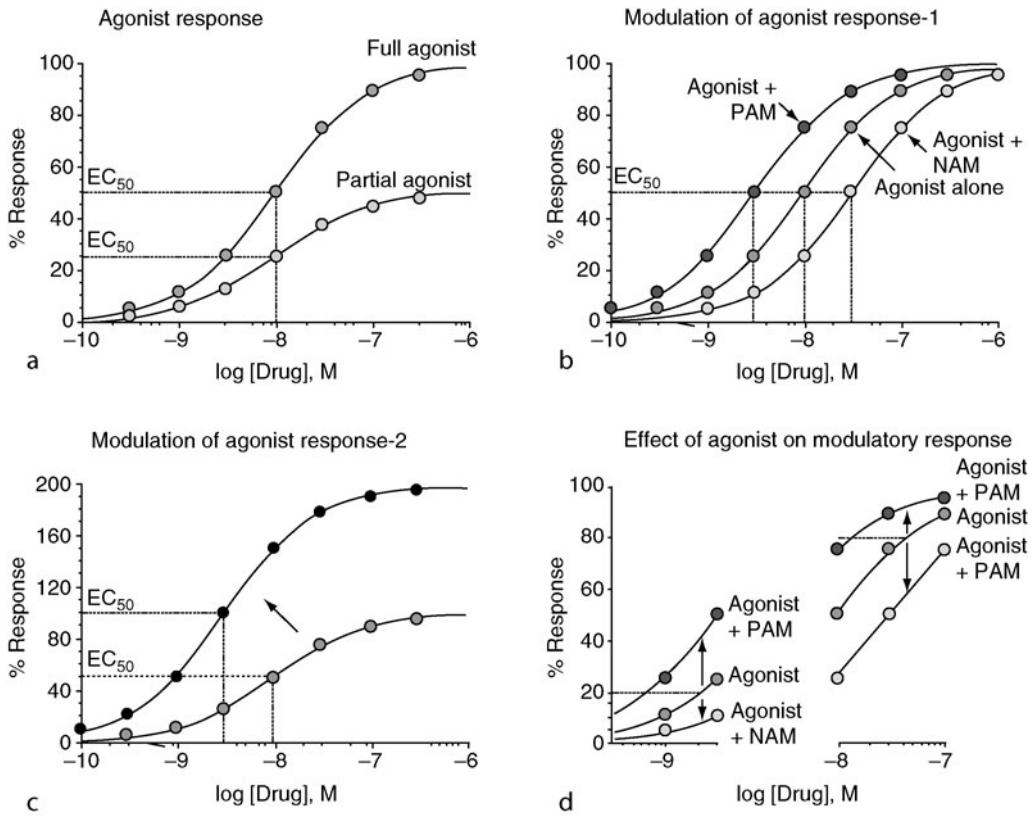
The design of an HTS-compatible functional assay is determined not only by the functional response being measured (i.e., change in ▶ second messenger or ion concentration or a downstream consequence of such changes), but also by the pharmacological profile – agonist, antagonist, and modulator – of the desired compound. The simplest type of assay is one in which the test compound is being evaluated for its agonist response. The ▶ potency of this effect is generally characterized in terms of the concentration at which a response that is 50% of the maximum (EC_{50}) is observed as well as the size of the maximum response. For instance, the response may either be of a magnitude comparable to the reference agonist or may produce a reduced response relative to the reference agonist (full and partial agonist, respectively; Fig. 1a). Compounds may also bind to the receptor and produce allosteric modulatory changes that might reduce or increase the EC_{50} (PAM or NAM, respectively) (Fig. 1b), as well as the maximal response (Fig. 1c). If an assay is being established in order to detect modulatory compounds, then the choice of agonist concentration should be picked according to whether a PAM or NAM is desired, in which case EC_{20}- or EC_{80}-equivalent agonist concentrations are usually employed (Fig. 1d). Although ▶ benzodiazepines represent a well-established class of ion-channel ($GABA_A$ receptor) PAMs, more recently allosteric modulators of GPCRs have attracted considerable attention as potential therapeutics (Conn et al. 2009).

As regards the shift toward the identification of allosteric modulators as drug targets, one of the attractive features of certain types of instrumentation is the ability to record data in real-time rather than producing just single, end-point readouts. This permits compounds to be assessed using two-addition, or sometimes even three-addition protocols. For example, in the absence of exogenous agonist, an initial addition of compound will detect direct agonist effects. If there is no direct agonist effect, then a second addition, this time of agonist, can detect a PAM (Fig. 2).

As regards antagonists, the ability of a compound to block an agonist-stimulated response is related to the functional affinity of the agonist as well as the affinity of the antagonist. For example, a low affinity antagonist will have difficulty in blocking the effects of a high affinity agonist. Although the potency of a competitive antagonist can be quantified in terms of the pA_2 derived from a Schild plot of the rightward shift of an agonist concentration-effect curve at increasing antagonist concentrations, such analyses are not suitable for an HTS screen. Accordingly, the choice of the reference agonist and the concentration and preincubation time of test compound, should be given consideration. In certain expression systems, some receptors demonstrate activity in the absence of an agonist and are therefore described as possessing ▶ constitutive activity. Compounds that block this constitutive activity are described as inverse agonists.

General Methodologies

The general principle of functional assays for receptors is that they should demonstrate that a compound binds



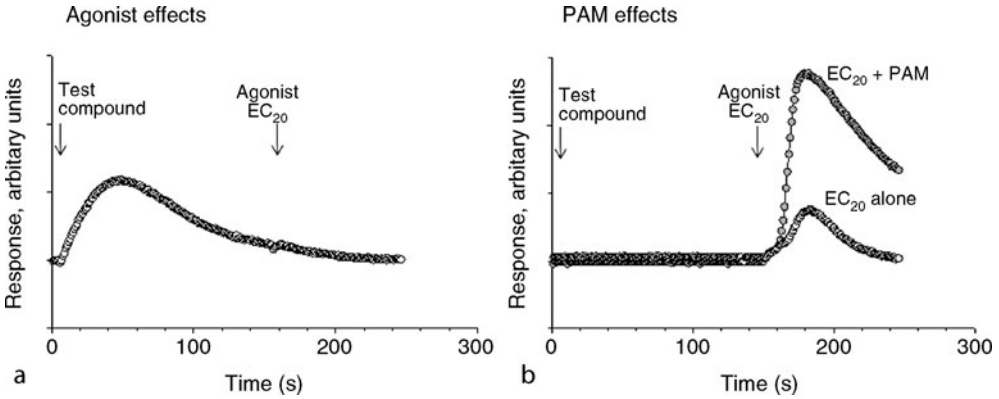
Receptors: Functional Assays. Fig. 1. Schematic representation of agonist-related responses. (**a**) Compounds may directly activate the receptor and produce a response that is comparable to or submaximal when compared with the endogenous ligand (full agonist and partial agonist, respectively). (**b**) Compound might produce a *leftward* or *rightward* shift in the agonist concentration–effect curve. Such compounds are designated positive or negative allosteric modulators (PAMs and NAMs, respectively). (**c**) In addition to shifting the EC_{50}, a compound may also have an effect on the maximal response (in this case increasing the maximum response). (**d**) An expanded view of parts of the concentration effect curves shown in Panel B illustrate how the absolute modulatory effects of PAMs and NAMs are a function of the agonist concentration. Hence, PAMs produce a proportionately greater potentiation of an EC_{20} when compared with EC_{80} response, whereas NAMs give a greater attenuation of an EC_{80} when compared with EC_{20} response.

to a receptor and "does something." Whether that "something" is direct activation, inhibition, or modulation of an agonist response, the key is being able to reliably demonstrate and quantitate a response. These methods most frequently rely upon a biosensor to detect that there has been an increase or a decrease in some component of an intracellular signaling pathway.

Some methods are unique to the class of receptor, for example [^{35}S]GTPγS is an hydrolysis-resistant analog of GTP (guanosine triphosphate). Its binding is specific for GPCRs in comparison to, for example, the measurement of ion flux which is specific for ion channels. However, some techniques are more generally applicable to the measurement of changes in intracellular molecules. These include, but are not limited to, techniques such as fluorescence resonance energy transfer (FRET) and the related technique of homogenous time-resolved fluorescence (HTRF), and bioluminescence resonance energy transfer (BRET).

Fluorescence and Bioluminescence Resonance Energy Transfer (FRET and BRET)

FRET refers to the process whereby energy is transferred from a fluorescent donor to a suitable energy acceptor, with the absorption spectrum of the acceptor overlapping the emission spectrum of the donor. Since the efficiency of this process is inversely proportional to the sixth power of the distance between the two molecules, then the acceptor



Receptors: Functional Assays. Fig. 2. Raw data traces from a real-time Ca^{2+} kinetic readout, showing the effect of a compound with (**a**) Agonist activity or (**b**) PAM activity. Ca^{2+} flux assays can be designed to identify compounds exhibiting agonist or PAM activity in one and the same assay well. Test compounds are added to cells loaded with a Ca^{2+} sensitive dye and incubated for 2.5 min. Thereafter, a submaximal (approximately EC_{20}) concentration of agonist is added. A compound displaying intrinsic agonist activity will increase the Ca^{2+} response in the first read (see *left-hand figure*), while PAMs will only show activity (i.e., a potentiation of the EC_{20} agonist effect) in the second read (see *right-hand figure*). The EC_{20} agonist effect after vehicle treatment, which was measured in a separate well of a 96-well plate, is indicated in the right panel in gray.

and donor molecules need to be in close proximity, in the region of 1–10 nm, for significant FRET to occur. The readout is a change in fluorescence emission of the acceptor, which may either increase or decrease as the proximity of the donor and acceptor also increases or decreases. The most common FRET acceptor–donor pair is the cyan fluorescent protein and yellow fluorescent protein, both of which are variants of green fluorescent protein. However, these proteins are not suitable for detecting ion-channel-mediated changes in membrane potential and therefore, special dyes are employed for this purpose (see below).

BRET is based on the same donor–acceptor energy transfer principle as FRET, with the difference being that in BRET the donor is a luminescent molecule, generally coelanterazine, which is excited by the enzyme Renilla luciferase (Rluc) rather than a fluorescent molecule; this avoids the need for the external illumination source required for FRET. The BRET-acceptor molecule can be a fluorescent protein such as green or yellow fluorescent protein.

Ca^{2+} Sensors

Fluorescent Ca^{2+}-sensitive probes linked to a fluorescence plate reader, such as the Fluorometric Imaging Plate Reader (FLIPR™, Molecular Devices, Corp.) or Functional Drug Screening System (FDSS, Hamamatsu), have become probably the gold standard for HTS of GPCRs. This is in part related to the combined liquid-handling and imaging capabilities of machines such as the FLIPR and FDSS as well as the properties of Ca^{2+}-sensitive dyes, such as organic fluorophores, fura-2, indo-1, fluo-3, fluo-4, and Calcium Green. In addition, Ca^{2+}-sensitive proteins may be used as Ca^{2+} sensors. Fluorescent proteins are generally engineered to contain the calcium-binding protein calmodulin as a molecular Ca^{2+}-sensing switch, which may be associated with either a single or two different fluorescent proteins, with the latter producing a FRET signal due to Ca^{2+} binding to calmodulin-producing conformational changes in the sensor.

Aequorin is a Ca^{2+}-activated bioluminescent photoprotein derived from the jellyfish *Aequoria victoria*, which emits luminescence as a result of the irreversible binding of Ca^{2+} ions. It comprises two components, the 22 kDa apoaequorin protein and a coelenterazine cofactor, and cells can be engineered to express apoaequorin, whereas coelenterazine needs to be added exogenously. When Ca^{2+} binds to the apoprotein, coelenterazine is oxidized to coelenteramide and this results in the emission of a blue light that is detected as luminescence.

Functional Assays for GPCRs

GPCRs activate intracellular signal transduction mechanism via either G-protein- or β-arrestin-mediated pathways, with examples of the various methodologies used to measure components of these pathways being presented in Table 1. With respect to the G-protein-mediated pathway, the binding of an agonist produces conformational changes in the GPCR which permit interaction between the C-terminal, intracellular receptor domain, and the heterotrimeric G-protein, which comprises an α, β, and γ subunit. This

Assay type	Comment
[^{35}S]GTPγS binding	Generic assay for studying interaction of G-proteins but $G\alpha_{i/o}$-linked receptors give best signal:noise ratio
cAMP measurement – direct (radioimmunoassay)	Radiometric assays not preferred for high-throughput screening (HTS)
cAMP measurement – direct (nonradiometric)[a]	High-affinity enzyme complementation (HitHunter™)
	Bioluminescence resonance energy transfer (BRET) (e.g., ALPHAscreen)
	Fluorescence resonance energy transfer (FRET) (e.g., LANCE™, PerkinElmer; HTRF®, CisBio)
	Fluorescence polarization (FP)
cAMP measurement – reporter gene assay	Reporter gene (e.g., β-galactosidase, β-lactamase, GFP, luciferase) linked to a cAMP-response element (CRE)
Ca^{2+} – direct measurement	Organic fluorophores (fura-2, fluo-3, fluo-4, etc.)
	Fluorescent proteins incorporating Ca^{2+} sensor (e.g., calmodulin)
	Bioluminescence – emission upon irreversible binding of Ca^{2+} to aequorin
Ca^{2+} – reporter gene assay	Reporter gene (e.g., β-galactosidase, β-lactamase, GFP, luciferase) linked to a calcium-sensitive element such as activator protein 1 (AP1) or nuclear factor of activated T-cells (NFAT)
β-arrestin	BRET
	FRET
	Enzyme fragment complementation (PathHunter™)
ERK phosphorylation	BRET (ALPHAscreen SureFire)
Electrical impedance or refractive index	Label-free cell-based assays (refractive index: EPIC; impedance: ECIS, RT-CES, CellKey)

results in the exchange of GDP for GTP associated with the Gα subunit, and in this activated state, the Gα subunit may, depending upon its subtype, stimulate or inhibit the production of cAMP ($G\alpha_s$ and $G\alpha_i$, respectively) or result in the $G\alpha_q$-mediated, phospholipase C (PLC)-dependent cleavage of phosphatidylinositol-4,5-bisphosphate to produce inositol trisphosphate and diacylglycerol, which mobilize intracellular Ca^{2+} stores and activate protein kinase C, respectively. These alterations in intracellular second messengers can in turn trigger cascades that result in changes in the gene expression.

Following agonist binding, GPCRs become substrates for G-protein-coupled receptor kinases (GRKs), and the resulting phosphorylated GPCRs are able to bind β-arrestins which causes the membrane trafficking machinery to internalize receptors away from the cell surface in clathrin-coated pits. In addition, the formation of the GPCR/β-arrestin complex can result in activation of the extracellular, signal-regulated (ERK)/mitogen-activated protein (MAP) kinase pathway.

[^{35}S]GTPγS Binding Assay

The nucleotide exchange process at G-proteins in cell membranes, resulting from agonist binding to GPCRs, can be measured by monitoring the binding of [^{35}S]GTPγS. The advantage of this assay is that it measures an early event in the signal transduction cascade and hence is less subject to amplification or regulation by more distal cellular processes that may compromise other functional measurements, such as reporter gene assays. The disadvantage of this assay is that it is generally more feasible for receptors coupled to the abundant G_i family of G-proteins, although several approaches have been introduced to extend its utility, such as use of immune-capture of [^{35}S]GTPγS-bound G-proteins of interest at the end of the assay, or the use of GPCR-G-protein fusion proteins (Milligan 2003).

cAMP Measurements

Historically, ► cAMP was measured based on radioisotopes using, for example, GE Healthcare SPA™ and Perkin

Elmer Flashplate™ cAMP assays; however, these methods are relatively expensive for screening large numbers of compounds, in addition to having issues with safety, and are therefore generally not the preferred option for HTS.

Alternatively, reporter gene assays are popular functional cell-based assays suitable for cAMP measurements. In order to monitor $G_{\alpha s/i}$-dependent changes in cAMP, the cAMP response element (CRE) can be used as the promoter for an easily detectable reporter gene, such as the firefly luciferase, β-galactosidase, β-lactamase, or GFP. Various detection methods are used to measure expressed reporter gene protein, including luminescence, absorbance, and fluorescence. CRE-luc assays are generally very sensitive given the low background signal and the amplification of the signal between GPCR activation and gene expression. They have the disadvantage of measuring downstream effects, and hence require a few hours of incubation to accumulate the reporter gene product in the cells. As a consequence, these assays are characterized by a high level of false positives.

Other HTS technologies for direct cAMP measurements rely on homogenous competitive immunoassays. TR-FRET combines HTRF and FRET principles and is based on the competition between an europium or terbium-labeled cAMP tracer and sample cAMP for binding sites on cAMP-specific antibodies labeled with a fluorescent dye. The formation of antibody-cAMP complex is inversely proportional to cAMP concentration in the sample. Several assay kits allowing cAMP detection based on this principle (e.g., LANCE™ and HTRF®) are commercially available.

The DiscoveRx technology platform HitHunter™ is based on high-affinity complementation of two separately inactive enzyme (β-galactosidase) fragments (enzyme donor and acceptor) to form a stable heteromeric enzyme complex capable of hydrolyzing substrates to produce a chemiluminescent or fluorescent signal. The analyte (cAMP) competes with an analyte-conjugated donor fragment for binding to an analyte-specific antibody. Upon antibody binding, the donor portion of the enzyme is incapable of association with the enzyme acceptor. Hence, the amount of cAMP-conjugated donor available for enzyme complementation is proportional to the concentration of cAMP in the sample.

Alternative assay kits include Alphascreen™, a highly sensitive bead-based chemiluminescent assay based on the competition between endogenous cAMP and exogenously added biotinylated cAMP, and fluorescence polarization (FP), which measures the parallel and perpendicular components of fluorescence emission generated by polarized light. The magnitude of the polarization signal is used to quantitatively determine the binding extent of a fluorescent cAMP tracer complex (Heilker et al. 2009; Thomsen et al. 2005).

Ca^{2+} Mobilization

If the GPCR of interest signals via PLC, then the most broadly used cell-based technique is the measurement of transient changes in intracellular Ca^{2+} concentrations using a fluorescent plate reader such as FLIPR™ or FDSS. In FLIPR-type assays, cells expressing a receptor of interest are usually incubated with a membrane-permeable fluorescent dye that after hydrolysis is converted to a Ca^{2+} sensitive, membrane-impermeable probe. Alternatively, Ca^{2+} generation can be measured with the use of Ca^{2+}-responsive luminescent photoproteins, such as aequorin. While Ca^{2+} fluxes traditionally could only be measured for G_q-coupled GPCRs, the coexpression of promiscuous G-proteins has extended the use of this technique to all GPCRs.

Reporter gene assays (using AP1 or NFAT response elements) can be used as an alternative method to measure Ca^{2+} mobilization (Heilker et al. 2009; Thomsen et al. 2005).

ERK Phosphorylation and β-Arrestin Signaling

GPCRs can generate diverse signals that activate the ERK MAP kinase pathway. Depending on the receptor and cell type, GPCR-mediated ERK activation may involve classical second messenger-dependent routes, utilize tyrosine protein phosphorylation, or involve β-arrestins as scaffolds for the MAP kinase module. A popular assay to measure ERK phosphorylation is the Alphascreen SureFire™ technology. Advantageously, ERK phosphorylation is independent of the type of G-protein linked to the receptor.

Signalling via the β-arrestin pathway is usually assessed by measuring β-arrestin translocation to receptors. This can be done via fluorescently tagged β-arrestins and either microscopic imaging of β-arrestin redistribution, or FRET or BRET assays to detect β-arrestin-receptor interactions. An HTS-suitable enzyme fragment complementation β-arrestin assay (PathHunter™) has been developed by DiscoveRx (Heilker et al. 2009).

Label-Free Functional Assays

Label-free technologies based on either electrical impedance or refractive index are novel tools for measuring cell-based, real-time, kinetic functional responses (Minor 2008).

While these assays eliminate the need for expensive and "artificial" tags, dyes, or specialized reagents, the downside of this technology is that one measures a response

"signature," and that it needs to be confirmed whether that is specific for the G-protein subtype to which the receptor is coupled. And although these systems can be configured in multiwell format, most of them lack on-board pipetting capabilities, and are therefore not yet equipped to support HTS campaigns (Table 1).

Functional Assays for Ion Channels

As their name suggests, ion channels are intramembrane proteins which when activated undergo a conformational change that results in the opening of a channel through which ions cross the cell membrane. Ion channels can be classified into two types: ligand-gated and voltage-activated ion channels, which are activated by the binding of a ligand or changes in the membrane potential, respectively, and representative technologies associated with measuring ion channel function are presented in Table 2. The relevance of ion channels as drug targets is highlighted by their pathological involvement in a variety of disorders (the so-called "channelopathies"), as well as the efficacy of drugs that target specific ion channels, most notably from a psychopharmacological view the ▶ benzodiazepines, which modulate $GABA_A$ receptor function, as well as antiepileptic drugs that target sodium and calcium channels (Camerino et al. 2007).

High-Throughput Electrophysiology

The flow of ions across the membrane is most precisely measured using electrophysiological methods, such as patch-clamp electrophysiology in mammalian cells or two-electrode voltage clamp in *Xenopus laevis* oocytes. While electrophysiology remains the gold standard for assessing ion-channel function, these methods are relatively low throughput and although higher throughput platforms have been developed, such as IonWorks (Molecular Devices), QPatch (Sophion Bioscience), Patchliner (Nanion Technologies), or PatchXpress (Axon Instuments), nonelectrophysiological, high-throughput cell-based assays using fluorescent dyes or ion flux have been widely used for HTS assays (Dunlop et al. 2008a,b).

Optical Methods: Membrane Potential Sensors

The changes in membrane potential that occur when ion channels are activated may be detected using dyes that are sensitive to membrane potential, such as the negatively charged oxonols, $DiSBAC_2(3)$ or $DiSBAC_4(3)$. These molecules are mobile and can move from the outer to inner face of the membrane according to the membrane potential. Hence, as the membrane potential changes, so does the partitioning of the oxonol across the plasma membrane. In the presence of a cell-impermeable fluorescence quencher, the dye will only produce a fluorescent signal when associated with the inner face of the membrane. FMP dyes operate on the same principle but have a faster response than the oxonol dyes.

Fluorescent probes may also be used to detect changes of membrane potential using FRET. One component, for example, a coumarin-labeled phospholipid, binds specifically to the exterior surface of the membrane whereas the other partner, typically $DiSBAC_2(3)$ or $DiSBAC_4(3)$, is mobile.

Receptors: Functional Assays. Table 2. Summary of methods available for assessing functional effects at ion-channel receptors.

Assay type	Comment
Electrophysiology	"Gold standard" for ion channel measurements. Labor intensive but recent technological advances (e.g., QPatch, IonWorks, PatchXpress) have markedly increased throughput
Optical probes – intracellular Ca^{2+}	Organic fluorophores (fura-2, fluo-3, fluo-4, etc.)
	Fluorescent proteins incorporating Ca^{2+} sensor (e.g., calmodulin)
	Bioluminescence – emission upon irreversible binding of Ca^{2+} to aequorin
Optical probes – other	Thallium-sensitive dyes as surrogate for K^+ (e.g., BTC-AM, ThalKal) MEQ for Cl^-
Optical probes – membrane potential	FRET-based – immobile donor (coumarin-linked phopholipid) mobile, voltage-sensitive oxonol acceptor (e.g., $DiSBAC_2(3)$, $DiSBAC_4(3)$)
	Fluorescence-based – voltage-sensitive oxonol or FMP dye plus quencher
Ion flux – radiometric	^{22}Na for sodium channels, ^{86}Rb for potassium channel, ^{45}Ca for calcium channels, ^{36}Cl or ^{125}I for chloride channels
Ion flux – atomic absorption spectroscopy	Lithium for Na channels; rubidium for potassium channels; chloride for chloride channels[a] (e.g., Ion Channel Reader from Aurora Biomed)

[a]Chloride ion measurement is indirect and involves precipitation with silver nitrate and measuring free-silver concentrations

Hence, as the membrane potential changes, so does the partitioning of the oxonol across the plasma membrane and as a result, the FRET between the membrane-bound donor and the mobile voltage-sensitive acceptor changes. Commercialization of this technology has resulted in the voltage-sensitive ion probe reader (VIPR; Aurora Biosciences Corp.) and the electronic-stimulation voltage ion probe reader (E-VIPR; Vertex Pharmaceuticals).

Optical Methods: Ion Flux Indicators

The use of detectors that are selective for particular ions provides a reliable means of detecting intracellular changes in ion concentrations in response to ion-channel activation. In this regard, methods for Ca^{2+}-permeable ion channels are the best established due to the wide range of well-characterized Ca^{2+}-sensitive organic fluorophores and Ca^{2+}-sensitive proteins. In contrast to Ca^{2+}, there are currently no generally accepted fluorescent indicators for K^+ suitable as primary functional assays for potassium channels, although thallium-sensitive indicators can be used as a surrogate since K^+-conducting ion channels are also permeable to other ions such as rubidium (for which no sensor currently exists) and thallium. As regards halide ions, the interaction of halide ions with 6-methoxy-*N*-ethylquinolinium iodide (MEQ) reduces the fluorescence of the latter, and this reduction in fluorescence can be used as an indicator of chloride channel-mediated Cl^- flux.

Ion Flux Indicators: Nonoptical

As an alternative to optical methods, the flux of ions through the channel may be measured either as an influx or efflux assay, depending upon the direction of ion flow. This might be using a radiometric assay in which, for example, $^{22}Na^+$ or ^{14}C-guanidinium may be used for sodium channels, $^{86}Rb^+$ for potassium channels, $^{45}Ca^{2+}$ for calcium channels, and $^{36}Cl^-$ or $^{125}I^-$ for chloride channels. However, such assays require a separation step in order to remove radioisotopes that have not been taken up into the cell and are therefore generally unsuitable for HTS. An additional factor that makes radiometric ion flux assays unattractive is that they often use high-energy radioisotopes. As an alternative, nonradioactive flux assays may be used in which highly sensitive flame atomic absorption spectrometers capable of measuring the ion content in small volumes are used to quantify ion flow (e.g., the Ion Channel Reader from Aurora Biosciences Corp.).

The disadvantages of flux methods, whether optical or nonoptical, include the possibility of large, nonspecific background fluxes or a rapid inactivation of the target ion channel. Moreover, although this latter aspect can be addressed by using mutated target proteins and/or pharmacological agents that prolong the channel open state or decrease the rate of channel inactivation, it is possible that some interactions may be missed or artifactually detected in such a modified system (Table 2).

Limitations and Other Considerations

The main caveat to most functional assays is that they are performed in artificial systems, generally using human receptors stably, or sometimes transiently, expressed in generally nonneuronal cell lines, such as Chinese hamster ovary (CHO) or human embryonic kidney (HEK) cells. Under such conditions, the functional effects of compounds can be influenced by the level of receptor expression and, in the case of GPCRs, by the efficiency of coupling to G-proteins. The level of receptor expression and G-protein coupling efficiency dictate the level of GPCR receptor reserve (i.e., the amount of "spare" receptors, in excess of those necessary to produce a maximum response when occupied by an agonist), and this may further complicate the interpretation of functional screening data. For example, a ► partial agonist in one tissue may appear to act as a full agonist in another tissue with a higher receptor reserve.

Consideration should also be given to the subunit composition of the particular receptor of interest, as well as the impact that auxiliary proteins may have upon the function of the receptor. For instance, ion channels may be heteromeric assemblies, the subunit composition of which is a key determinant of receptor pharmacology. Furthermore, an emerging area of GPCR research is that of heterodimerization of subunits which can also markedly influence the pharmacology (Waldhoer et al. 2005). However, since information concerning the physiological subunit composition and the relevance of ancillary proteins may well be absent, or at best poorly understood, a minimalistic approach is often adopted in which homomeric receptors are studied.

An emerging area of GPCR research is that of collateral efficacy, also known as biased agonism, ► functional selectivity and stimulus trafficking, in which different agonists can produce differential effects on different intracellular signaling pathways (in other words, all agonists for a particular GPCR do not necessarily produce the same effects on signaling pathways; Galandrin et al. 2007). The implication of this is that compounds that produce a functional response using a methodology based upon a GPCR-linked signaling pathway, for example, cAMP, may not necessarily produce a similar functional response in another pathway such as the β-arrestin-mediated pathway.

In summary, it is important to emphasize that there is no one-size-fits-all functional assay for GPCRs or ion channels. Hence, the choice of assay should be based upon practical considerations such as the number of compounds requiring testing, the instrumentation available, and the properties of the cell lines being used. As a result, a degree of trial-and-error evaluation of different assay formats is to be expected. Finally, while functional data obtained from recombinant model systems are crucial early on in the search for novel pharmaceuticals, it is critical that these functional effects of compounds are also evaluated at native receptors.

Definition

Recurrent brief depressive disorder (RBD) is a well-defined and prevalent mood disorder with an increased risk of suicidal behavior and significant clinical impairment. The syndrome is defined by depressive episodes that occur at least monthly and last only a few days. RBD represents a distinct and frequent clinical diagnosis in ▶ ICD-10. In contrast, ▶ DSM-IV classifies RBD into the subcategory of depressive disorders "Not Otherwise Specified (NOS)" for clinical purposes, with detailed operationalized diagnostic criteria offered in the appendix

of DSM-IV for scientific use only. In both diagnostic manuals, psychopathological symptoms required for the diagnosis of RBD are the same as for ▶ major depressive disorder (MDD). Hence, RBD is primarily diagnosed by its duration criterion (episode duration <14 days) and frequency criterion (approximately 1 episode/month). The average duration appears to be 3–4 days.

The longitudinal course of mood disorders is characterized by a substantial diagnostic overlap between different diagnostic groups. However, longitudinal epidemiological studies have demonstrated that RBD is neither a prodromal nor a residual state of MDD or any other psychiatric disorder. Sometimes, RBD symptomatology might be accompanied by recurrent brief hypomania.

The concept of RBD and its clinical significance have been further delineated by studies on the patterns and consequences of a lifetime co-occurrence of both RBD and MDD, called combined depression (CD). Epidemiological and clinical studies have demonstrated a dramatic increase in ▶ suicide attempt rates and measures of impairment in cases of CD in comparison to either RBD or MDD alone. Based on this data, it has been suggested that it is important to ascertain the existence of previous recurrent brief depressive episodes in patients with current MDD, because such information contributes to the assessment of suicidal behavior risk as well as drug response, which appear to be worse for CD in comparison to RBD patients.

The differential diagnosis of RBD and MDD is based on their distinct courses of depressive episodes (1–3 days vs. weeks or months). Other psychiatric disorders with short-lived syndromes have to be ruled out, such as: (1) panic disorder, characterized by recurrent unexpected panic attacks lasting for minutes up to a few hours; (2) premenstrual dysphoric disorder (PMDD), appearing exclusively in relation to the menstrual cycle; (3) borderline personality disorder (BPD), in which affective instability can be manifested by depressive mood fluctuations that usually last for hours but can persist for days as well (although clinical studies suggest low comorbidity of RBD with borderline personality disorder, as well as different endocrine response patterns); (4) rapid cycling (RC) (>4 episodes/year), ultra-RC (episodes in a weekly rhythm) or ultra-ultra-RC (ultradian episodes) bipolar disorders, which must show at least hypomanic (or manic) episodes according to DSM-IV; (5) other affective disorders, such as minor depression, ▶ bipolar disorder, and ▶ dysthymia, which can be easily distinguished from RBD by the criterion of duration of the depressive episode; (6) drug-induced depression, such as in cocaine withdrawal; and (7) various somatic diseases which might be accompanied by brief depressive episodes, such as postictal ▶ dysphoria or the so-called interictal dysphoric disorder in epilepsy, migraine plus aura, ▶ Parkinson's disease, Fabry disease, celiac disease, and Prader–Willi syndrome.

Role of Pharmacotherapy

Two-thirds of all RBD patients seek professional help in the course of their life. Of this group, one quarter consult a general practitioner, one quarter see a psychologist, and the remaining half consult a psychiatrist or neurologist. Epidemiological studies have shown that nearly all such patients receive treatment with psychotherapy. However, RBD patients hardly ever receive pharmacological treatment in community samples. Almost two decades after the concept of RBD was introduced, data from clinical trials are still limited.

However, there are a few placebo-controlled studies and several case reports, a single-case analysis, and one open trial assessing the drug treatment of patients with RBD. The most rigorous of these studies, which have used a classical ▶ double-blind placebo-controlled two-tailed design, have not been able to demonstrate successful drug treatment for RBD. It has been suggested that the negative results in ▶ placebo-controlled studies have been due to a study design that is inappropriate for this clinical phenomenon. This suggestion is mainly supported by reported treatment responses in double-blind placebo-controlled one-tailed single-case analyses with nimodipine, verapamil, and ▶ carbamazepine. Furthermore, the controlled studies were carried out with highly selected RBD patient samples, i.e., patients with repeated suicide attempts or ▶ comorbid borderline personality disorder or somatic diseases. This might have led to a bias reflecting treatment resistance. This view is supported by case reports or open trials demonstrating successful treatment of RBD with mirtazapine, reboxetine, fluoxetine, lithium, carbamazepine, lamotrigine, tranylcypromine, and olanzapine.

The optimal treatment regime for RBD remains an open question. The aggregate of available data and clinical experience suggest that second-generation antidepressants might be appropriate. As a second-line treatment, ▶ mood stabilizers can be considered. However, longer response rates (weeks to a few months) than in MDD are characteristic for this disorder, since symptoms are occurring less regularly than in MDD.

Because available study results remain unclear and contradictory, there is a great need for additional controlled clinical trials without the methodological limitations of previous studies. Early pessimism concerning the pharmacological treatment of RBD could be due to the false-negative study results and is probably not justified.

Re-Encoding

Definition

The fact or process whereby a memory item is again encoded after it has been retrieved. The resulting engram may or may not be identical to the one that preceded it.

Reference Electrode

Definition

Voltage potentials are only defined with respect to a reference: an arbitrarily chosen zero level. For each EEG recording, a reference electrode has to be selected in advance. Ideally, this electrode should be affected by ambient electrical activity in the same manner as all the other electrodes, such that this activity is subtracted out by the referencing procedure. In most studies, a reference on the head, but at some distance from the other recording electrodes is chosen. Such a reference can be the earlobes, the nose, or the mastoids (i.e., the bone behind the ears).

Reinforcement

Definition

A behavioral process whereby the probability of a response is increased because it previously produced a particular environmental consequence. Such consequences take the form of presentations of environmental stimuli, which are thereby defined operationally as reinforcers. Such stimuli can either be exteroceptive (e.g., a sweet-tasting substance) or interoceptive (e.g., an abused drug).

Reinforcement Disorders

Roy Wise
Behavioral Neuroscience Branch, NIDA IRP, Baltimore, MD, USA

Definition

Reinforcement refers to the process or constellation of processes that "stamp in" learned associations and response habits, processes that enhance or establish the transfer of immediate short-term memories to relatively permanent long-term memories. The mechanisms of reinforcement remain mysteries not yet fully understood, but a variety of animal models identify reinforcement closely with the consequences of the extracellular actions of the neurotransmitter dopamine. ► Dopamine is released from nerve terminals in response to various reinforcers – the prototypical reinforcer is food for a hungry animal – and, once the association is formed, in response to conditioned stimuli that reliably predict those rewards. The habit-forming and habit-sustaining effects of most positive reinforcers are lost in animal models when the receptors for dopamine are blocked pharmacologically.

Current Concepts and State of Knowledge

Until recently in our evolutionary history, the ability to learn associations and response habits leading to sweet and calorie-dense substances has had obvious adaptive value. By learning to identify the predictors and repeat the acts that bring them in contact with sweet taste, infants learn to find the mother's nipple efficiently and adults learn to find and eat ripe fruits and to save them for another day. When the food supply has been limited, this has served us well. However, in recent decades, people in industrial societies are increasingly exposed to more tasty and abundant energy rich foods than they need for simple subsistence, and the tendency to overindulge in sweet and fatty foods has resulted in an epidemic of obesity that can be seen as a disorder of reinforcement, of reinforcement gone awry. When we have easy access to tasty energy-laden foods, our reinforcement mechanisms prove to be *too* effective, encouraging maladaptive overeating.

In the last few thousand years we have learned to store and refine ▶ alcohol and inhale the smoke of tobacco and in the last few hundred years we have learned to refine and synthesize several addictive substances, substances that can themselves serve as positive reinforcers. Easy access to these substances and to effective ways to ingest them has given rise to a more immediately knotty problem of over-reinforcement: addiction. Drugs such as ▶ heroin, ▶ cocaine, and ▶ methamphetamine can elevate dopamine levels further and more rapidly than even the most palatable of foods, and can establish drug-taking habits that are arguably more compulsive than the eating habits of the clinically obese. The smoking of tobacco and the drinking of alcohol also elevate dopamine levels much more rapidly than does food, again, often leading to compulsive and maladaptive habits. Here, again is a disorder resulting from reinforcement that is too effective, from reinforcers that are too habit-forming. Also often viewed as disorders of over-effective reinforcement are compulsive gambling, compulsive video gaming, compulsive sexual habits, compulsive thrill seeking, and other learned compulsions. Our understanding that the mechanisms of reinforcement have gone awry derives in large part from studies of addictive drugs: substances that can act directly at the various sites of action of endogenous neurotransmitters.

Drug Addiction

Almost all addictive drugs share the ability to elevate extracellular dopamine levels. ▶ Amphetamines cause dopamine to be released from nerve terminals. Cocaine blocks the reuptake of dopamine when it has been released by neuronal activity. ▶ Nicotine stimulates dopamine neurons to fire and release dopamine. ▶ Opiates also cause dopamine neurons to fire, not by stimulating them but by inhibiting neighboring cells that usually limit dopamine cell firing. Ethyl alcohol and cannabis also – through yet other mechanisms – increase dopamine cell firing and extracellular dopamine release.

Moment-to-moment changes in dopamine levels have been monitored during periods of intravenous self-administration of cocaine and heroin. This is best seen in animals trained to earn intravenous injections by lever-pressing and given limited daily access to the drug. Experienced rats initiate a drug self-administration session by earning one or more injections causing rapid elevation of dopamine levels to three or four times the normal extracellular concentration. Once dopamine levels are elevated the animals cease lever-pressing until dopamine levels fall back to about twice normal. Then they make another response, again elevating dopamine levels and again waiting to respond further until the dopamine level again falls to about twice normal. This sequence is repeated until the session ends or until the animal is exhausted, with dopamine levels maintained above the trigger point of about twice normal elevations. If the animal is given an unpredictable sequence of sometimes small, sometimes medium, and sometimes large cocaine doses, the delay between successive lever-presses will be short, medium, or long, respectively.

The regular psychomotor stimulant intake seen when animals are limited to 1–4 h of daily drug access can escalate and become irregular when animals are given prolonged access to the drug. This can be seen with many weeks of access or with more than 6 h of daily access. A variety of neuroadaptations in the reward circuitry itself have been identified and hypothesized to contribute to the escalation of intake and the increasing compulsiveness of intake at a time when the subjective perception of drug reward is decreasing. The degree to which such neuroadaptations affect other compulsive behaviors remains unclear.

In the cases of cocaine and amphetamine – drugs that appear to rely entirely on dopamine as their reinforcement substrate – the pharmacological blockade of dopamine receptors eliminates the reinforcing effects of the drugs. Lesions of the terminals of the mesocorticolimbic dopamine system can have similar effects if the lesions are large enough and are correctly placed. It is not yet clear, however, what constitutes correct placement. Large lesions of the ventral striatum are effective, but they usually include damage to dopamine fibers terminating not only at ▶ nucleus accumbens, the intended lesion target, but also to dopamine fibers of passage to the olfactory tubercle and

the medial ▶ prefrontal cortex, two sites in which cocaine is known to have habit-forming actions. Small lesions tend to implicate the core but not the shell of nucleus accumbens as the site of cocaine reinforcement, but while rats will learn to work for cocaine microinjections into the shell of accumbens (and even more readily learn to work for injections into the underlying olfactory tubercle), they do not similarly learn to work for injections into the core of accumbens. Thus extracellular dopamine plays a necessary role in cocaine reinforcement, but it is not yet clear *where* dopamine plays this necessary role.

In the cases of opiates and ▶ phencyclidine, dopamine does not appear to play an essential role. The reinforcing effects of phencyclidine appear to be in the ventral striatum, but postsynaptic to the dopamine terminals that innervate the GABAergic ventral striatal output neurons. ▶ Morphine (like dopamine) inhibits these output neurons, and morphine appears to be reinforcing because of this ventral striatal action. Phencyclidine blocks the excitatory input of glutamatergic input to the GABAergic output neurons, an input that parallels and is thought to interact with the adjacent dopaminergic input to these neurons. Nicotine and dopamine may have additional inputs to reinforcement circuitry, inputs that are also "downstream" to the dopamine synapses of the mesocorticolimbic dopamine system. The effects of dopamine antagonists and dopaminergic lesions on the self-administration of other addictive drugs are more complex and less well understood.

Compulsive Eating

Foods are the prototypical reinforcers. The most powerful food reinforcers are sugars, particularly when taken in combination with lipids (which are also reinforcers in their own right); however, even untasted vitamins and minerals can serve as reinforcers. These are substances that, once encountered, are returned to because of their reinforcing effects. Sugars and lipids result in the release of dopamine from nerve terminals in many brain regions, elevating extracellular dopamine to as much as twice normal levels. If the receptors that normally respond to dopamine are pharmacologically blocked, food is no longer habit forming. Sweet foods appear to have a double reinforcing effect; sweet taste is naturally reinforcing to many species and the post-ingestional effects of natural sugars are also reinforcing.

While compulsive food habits are usually associated with sweet and fatty foods, compulsive food habits can be entrained by unpalatable foods. Calcium-deprived institutionalized orphans, for example, were reported to compulsively eat plaster off the walls, as do many birds, despite its lack of palatability. Sodium-deprived animals and humans develop compulsive cravings for salt. A variety of such "specific hungers" have been reported in animals lacking the nutrient provided by the craved substance. Most of these hungers are learned.

Other Learned Compulsions

Many other compulsions have been labeled and likened to addiction. Compulsive ▶ gambling, compulsive sexual behavior, and compulsive thrill seeking are examples. Several investigators are pursuing the hypothesis that the brain mechanisms subserving a variety of such behaviors are shared with the brain mechanisms of drug addiction and compulsive eating.

Reinforcement Leads to Craving

While some compulsive ingestion habits like salt intake in sodium deficient animals appears to be innate, most compulsive habits result from reinforcement-based learning. Most compulsive cravings are the result of experience. Some exceptions can be attributed to reflexes, such as the reflexive approach induced by sexual pheromones or the reflexive avoidance induced in some species by fox odor and in other species by putrid smell. Some human cravings can develop through communication by language; ▶ cravings for illicit drugs, for example, can be established by language. Most cravings, however, develop as a result of the reinforcing effects of contact with the substance or event in question. Once a compulsive habit has been established, it can be sustained for long periods in the absence of reinforcement. In this case, however, even sparse intermittent reinforcement can sustain an established habit.

Extinction

Once a compulsive habit is established, many repetitions of the habit in the absence of reinforcement are required before the habit is "extinguished." Indeed, there is strong evidence that a compulsive habit is never completely extinguished even after long periods of non-reinforcement; presumably extinguished habits can always be reestablished with less reinforcement than was required to establish them in the first place.

The rate of ▶ extinction of a response habit depends on several things. If reinforcement follows every response immediately during the learning period, extinction (never to zero but to some low probability) can be fairly rapid. If reinforcement is delayed or intermittent during training, a response habit can be very resistant to extinction.

Intermittent reinforcement is termed "partial" reinforcement, and the greater resistance to extinction after partial reinforcement training is known as the "partial reinforcement extinction effect." The partial reinforcement extinction effect has important implications for the treatment of compulsive habits. Each binge after an attempt to diet, for example, results in an intermittent reinforcement that makes subsequent extinction more difficult.

Thus it takes much less reinforcement to sustain a habit than it takes to establish one. Reinforcement can become less frequent or less intense and still maintain a compulsive response habit. Thus addicts report that even when, because of drug ▶ tolerance, their drug of choice no longer seems to bring the subjective pleasure that accompanied initial use, they still seek the drug and have compulsive thoughts about it. Clinicians refer to the persistence of drug habits despite reduced reinforcement as "chasing the remembered high." Whatever form the "remembered high" takes – whether it be a conscious memory or merely a residual memory trace in the nervous system, the consequences of reinforcement in the past are of great importance for the cravings and behaviors of the present.

Potential Medications

The fact that some degree of reinforcement is required to maintain reinforcement-based response habits suggests that drugs that block reinforcement should cause extinction of those habits. Much of the evidence that brain dopamine plays an important role in reinforcement, and, indeed, drugs that block the central actions of dopamine do cause extinction-like decreases in habitual responding. However, consistent with the fact that it takes less reinforcement to maintain a habit than it takes to establish one, dopamine antagonists do not block an established response habit right away, and must be given repeatedly to cause anything approaching complete extinction. Dopamine antagonists have not been found effective in treating reinforcement disorders. First, consistent with the view that brain dopamine is important for a wide range of reinforcers, these drugs attenuate the effectiveness of many of life's pleasures and are not pleasant to take. These drugs are used effectively to treat the (seemingly unrelated) symptoms of ▶ schizophrenia, and patients do not like them and often discontinue their use when given the chance. Moreover, schizophrenic substance abusers continue to seek and use cocaine and amphetamine despite treatment with dopamine antagonists. This may be, of course, because cocaine and amphetamine are antagonists for the dysphoric effects of the dopamine blockers. It is also the case that dopamine antagonists have little if any effect on the motivational impact of reward-predictive environmental cues that contribute to drug seeking and drug euphoria. In any case, dopamine antagonists have not proven useful for the treatment of reinforcement disorders.

Two classes of drugs that are currently under study as potential medications for reinforcement disorders are opioid antagonists and cannabinoid antagonists. Exogenous opiates and ▶ cannabinoids are drugs of abuse, but endogenous opioids and cannabinoids are found in the brain and serve neurotransmitters or neuromodulators that, like other addictive drugs, have actions in the reward circuitry of the brain. ▶ Opioid antagonists are known to block the reinforcing effects of opiates and also appear to attenuate cravings for alcohol and for nicotine. Cannabinoid antagonists block the reinforcing effects of cannabinoids (marijuana, hashish) and also attenuate heroin, cocaine, and food cravings. The fact that each drug appears to affect natural reinforcers as well as drug reinforcers strengthens the evidence that drug and natural reinforcers share a common reward mechanism in the brain, but makes the search for medications that can target a troublesome reinforcer without affecting others more challenging. Over most of the course of our evolutionary history, the substances our brain finds reinforcing have been the necessities of life.

Reinforcer

Definition

An event that maintains or strengthens a behavioral response that produces it. For example, cocaine can function as a reinforcer because when an animal is allowed to self-administer it by means of pressing a lever, the animal will continue to press the lever again and again. The act of pressing the lever was reinforced by cocaine.

Reinforcer Efficacy

► Subjective Value

Reinstatement

Definition

A procedure used to examine drug-seeking behavior, typically in rodents or nonhuman primates. Animals are first trained to self-administer drug (or other reinforcer) and then the response is extinguished by omitting the reinforcer. Following extinction, the animal receives a drug prime (typically by injection) or drug-associated cue and is allowed to respond, but without any contingent delivery of the reinforcer. Reinstatement is reflected as an increase in non-reinforced responding relative to the last day of extinction.

Definition

In the learning literature, the term "reinstatement" refers to the resumption of a learned response that occurs when a subject is exposed non-contingently to the unconditioned stimulus. In the addiction field, "reinstatement of drug self-administration" in experimental animals (typically termed "reinstatement of drug seeking") refers to the resumption of a previously drug-reinforced behavior by non-contingent exposure to drugs, different types of drug cues, or stressors after the ► extinction of the drug-reinforced behavior. The animal model that addiction researchers use to study the reinstatement of drug seeking is termed the "reinstatement model" (Shaham et al. 2003).

Impact of Psychoactive Drugs

Background

A major problem in the treatment of drug addiction is the high rate of relapse to drugs of abuse following a prolonged abstinence period. Results from studies in humans suggest that in drug-free individuals, relapse to drug use during periods of forced or voluntary abstinence can be triggered by acute exposure to the self-administered drug, stimuli previously associated with drug taking, or stressors. Acute exposure to the self-administered drug or related drugs, ► drug-associated cues, or ► stress also reinstates drug seeking in laboratory rats and monkeys (Shaham et al. 2003). Because of the similarities between the human condition and the laboratory animal model, many investigators currently use the reinstatement model to study mechanisms underlying relapse to drug use. Conceptual issues related to the validity of the reinstatement model as an animal model of relapse to drug use are discussed by Epstein et al. (2006).

Experimental Procedures

In the ► drug self-administration version of the reinstatement model, which is based on an ► operant-conditioning

procedure, laboratory animals (rats, mice, and monkeys) are initially trained to self-administer drugs by lever pressing (or another operant response such as nose-poking) for intravenous drug infusions (or for oral delivery of alcohol). Subsequently, the drug-reinforced behavior is extinguished by substituting the drug solutions with saline or by disconnecting the infusion pumps. After the extinction of the drug-reinforced behavior, the ability of acute noncontingent exposure to drugs (termed "drug-priming"), drug-associated cues, or stress to reinstate lever responding is measured under extinction conditions (Shaham et al. 2003). The non-reinforced responding on the "active lever" – the lever that previously delivered the drug – is interpreted to reflect the reinstatement of drug seeking. The responding on the "inactive lever" – the lever that has not been associated with drug injections – is often interpreted to reflect nonspecific activity, but it may also reflect response generalization.

In laboratory animals, the reinstatement of drug seeking has been studied using the "between-session," "within-session," and "between-within session" variations of the reinstatement model (Shalev et al. 2002). In the between-session procedure, training for drug self-administration, the extinction of the drug-reinforced behavior and tests for reinstatement are conducted on different daily sessions. In the within-session procedure, all three phases are conducted within a daily session. This daily session consists of 1–2 h of drug self-administration that is followed by 3–4 h of extinction of the drug-reinforced behavior; after extinction of lever responding, a test for reinstatement is conducted. In the between-within procedure, the laboratory animals are trained daily for drug self-administration; subsequently, the extinction of the drug-reinforced lever responding and tests for reinstatement are conducted on the same day. In addition, researchers also assess the reinstatement of drug seeking in variations of the reinstatement model that are based on the ► runway and ► conditioned place preference procedures. Shalev et al. (2002) provide a detailed description of the different procedural variations of the reinstatement model and discuss the advantages and disadvantages of using them for assessing the reinstatement of drug seeking.

Neuropharmacology of Reinstatement of Drug Seeking

In this section, we summarize the extant literature on the neuropharmacology of the reinstatement of drug seeking induced by exposure to the self-administered drug or related drugs (drug-priming), drug-associated cues, or stress. Due to space constraints, we often do not differentiate between results obtained from studies in which rats were trained to self-administer cocaine and other psychostimulants, heroin and morphine, or alcohol. A detailed description of the neuropharmacology of the reinstatement of drug seeking is provided by Shalev et al. (2002) and Bossert et al. (2005).

Drug-Priming-Induced Reinstatement

Results from studies on drug-priming-induced reinstatement of drug seeking indicate that this reinstatement is primarily mediated by dopaminergic and glutamatergic neurotransmission in the mesocorticolimbic system (Kalivas and McFarland 2003; Schmidt et al. 2005; Self 2004). This system consists of dopamine cell bodies in the ► ventral tegmental area (VTA) that project to limbic areas, including ► nucleus accumbens, ► amygdala, and bed nucleus of stria terminalis (BNST), and cortical areas, including medial ► prefrontal cortex (mPFC) and orbital frontal cortex (OFC).

Regarding dopamine, systemic injections of either D1-family dopamine receptor agonists or antagonists decrease cocaine-induced reinstatement; D1-family dopamine receptor antagonists also decrease heroin-priming-induced reinstatement. On the other hand, systemic injections of D2-family receptor antagonists decrease heroin- or cocaine-priming-induced reinstatement, while injections of D2-family receptor agonists reinstate drug seeking. The effect of cocaine priming on reinstatement is also attenuated by systemic injections of selective D3 receptor antagonists. Additionally, injections of D1-family or D2-family receptor antagonists into the dorsal mPFC, accumbens shell (but not core), and amygdala (both central and basolateral subregions) decrease cocaine-priming-induced reinstatement. Accumbens core injections of D1-family or D2-family receptor antagonists decrease heroin-priming-induced reinstatement. Finally, activation of VTA dopamine neurons by local injections of morphine reinstates heroin and cocaine seeking, while local inhibition of these neurons by a mixture of $GABA_A + GABA_B$ receptor agonists (muscimol+baclofen) decreases cocaine-priming- and heroin-priming-induced reinstatement.

Regarding ► glutamate, systemic injections of metabotropic glutamate receptor 5 antagonists or group II metabotropic glutamate agonists (which decrease evoked glutamate release via a presynaptic autoreceptor mechanism) decrease cocaine-priming-induced reinstatement. Additionally, local injections of nonselective ionotropic glutamate receptor antagonists into the VTA, selective ► AMPA receptor antagonists into the accumbens, or reversible inactivation of the glutamate projection from the dorsal mPFC to the accumbens decrease heroin or

cocaine-priming-induced reinstatement. Finally, there is evidence that cocaine self-administration and subsequent withdrawal leads to long-lasting neuroadaptations in glutamatergic transmission in the mPFC–accumbens pathway, and that the pharmacological reversal of these neuroadaptations prevents cocaine-priming-induced reinstatement.

Results from studies in which investigators used reversible inactivation manipulations (the sodium channel blocker tetrodotoxin or muscimol+baclofen) suggest a role of the ventral pallidum in cocaine- and heroin-priming-induced reinstatement. In the case of heroin-priming-induced reinstatement, there is also evidence for a role of the BNST (dorsal and ventral subregions), dorsal striatum, substantia nigra, and ventral mPFC. Additionally, there is evidence from pharmacological studies that other neurotransmitter systems, including ► endocannabinoids, ► serotonin, and ► GABA contribute to drug-priming-induced reinstatement. However, the brain sites involved in these effects are unknown. Finally, there is evidence for a role of accumbens protein kinase A and calcium–calmodulin dependent kinase II signaling pathways in cocaine-priming-induced reinstatement.

Cue-Induced Reinstatement

In humans, relapse-provoking drug-associated stimuli can be divided into two general categories: discrete drug cues (e.g., drug paraphernalia) that are associated with the acute rewarding effects of the drug, and contextual drug cues (e.g., a specific environment such as a local bar) that predict drug availability. In laboratory animals, procedures to assess cue-induced reinstatement of drug seeking are classified into three types according to the type of the conditioned cue: discrete-cue, discriminative-cue, and contextual-cue.

► Discrete-cue-induced reinstatement: Results from pharmacological studies suggest a role of several neurotransmitters and receptors in discrete-cue-induced reinstatement (Feltenstein and See 2008). Systemic injections of D1-family receptor antagonists, selective D3 receptor antagonists, nicotinic cholinergic antagonists, several serotonergic agents, group II metabotropic receptor agonists, cannabinoid 1 (CB1) receptor antagonists, and mu opiate receptor antagonists decrease the discrete-cue-induced reinstatement of drug seeking. In the case of D1-family receptors, two brain sites are critical for their effects: the amygdala (both central and basolateral subregions) and the accumbens core (but not shell). The brain sites involved in the modulation of the discrete-cue-induced reinstatement by the other neurotransmitter systems are unknown. Additionally, results from studies in which reversible inactivation manipulations were used suggest a role of the dorsal mPFC and dorsal striatum in the discrete-cue-induced reinstatement. In heroin-experienced rats, there is evidence that discrete-cue-induced reinstatement also involves the ventral mPFC, the dorsal BNST, the ventral pallidum, and the substantia nigra.

► Discriminative-cue-induced reinstatement: Results from pharmacological studies suggest a role of several neurotransmitter system in discriminative-cue-induced reinstatement (Weiss 2005). Systemic injections of D1-family and D2-family receptor antagonists, selective D3 receptor agonists, group II metabotropic receptor agonists, metabotropic glutamate receptor type 1 or type 5 antagonists, CB1 receptor antagonists, sigma 1 receptor antagonists, 5-HT2B/2C receptor agonists, and mu opioid receptor antagonists decrease the discriminative-cue-induced reinstatement. The discriminative-cue-induced reinstatement is also attenuated by ventricular injections of the opioid peptide nociceptin/orphanin FQ (the endogenous ligand for the opioid-like orphan receptor). In the case of CB1 receptor antagonists, two brain sites are critical for their effects: the mPFC and the accumbens. The brain sites involved in the modulation of discriminative-cue-induced reinstatement by the other neurotransmitter systems are unknown. However, in the case of dopamine receptor antagonists, likely brain sites are the amygdala, the accumbens, and the mPFC. Thus, exposure to cocaine discriminative cues increases dopamine release in the accumbens and amygdala. Additionally, discriminative-cue-induced Fos (a neuronal activity marker) expression in the basolateral amygdala and prefrontal cortex is decreased by systemic injections of a D1-family receptor antagonist.

► Context-induced reinstatement: Results from pharmacological studies suggest a role of several neurotransmitter systems in context-induced reinstatement (Crombag et al. 2008). Systemic injections of D1-family and D2-family receptor antagonists, group II metabotropic receptor agonists, CB1 receptor antagonists, and 5-HT2B/2C receptor agonists decrease context-induced reinstatement. In the case of D1-family receptors, a critical brain site is the accumbens shell. In the case of group II metabotropic receptors, the critical brain sites are the accumbens shell and VTA. The brain sites involved in the modulation of the context-induced reinstatement by the other neurotransmitter systems are unknown. Results from studies in which reversible inactivation methods were used suggest a role of the dorsal mPFC, the dorsal striatum, the basolateral amygdala and the dorsal hippocampus in context-induced reinstatement. Results from studies on the

effect of context-induced reinstatement testing on Fos expression in the brain suggest a role of the lateral hypothalamus in this reinstatement.

Stress-Induced Reinstatement

The phenomenon of stress-induced reinstatement of drug seeking was initially demonstrated in studies in which investigators used an intermittent footshock stressor. The effect of this stressor generalizes to certain other stressors, including swim stress, acute food deprivation, ► social defeat, and several pharmacological stressors: the stress neurohormone ► corticotropin-releasing factor (CRF), the anxiogenic drug ► yohimbine (an alpha-2 adrenoceptor antagonist), and agonists of the kappa opioid receptor.

Evidence from studies in which pharmacological agents were used suggests a role of several neurotransmitter systems in stress-induced reinstatement. The ► stressor used in most of the neuropharmacological studies is intermittent footshock. Systemic injections of nonselective CRF antagonists, selective CRF1 receptor antagonists, alpha-2 adrenoceptor agonists (which decrease ► noradrenaline cell firing and release), ► hypocretin 1 receptor antagonist, non-selective dopamine receptor antagonist, ► selective serotonin reuptake blockers (SSRIs), and $5HT_3$ receptor antagonists decrease stress-induced reinstatement. The stress-induced reinstatement of alcohol (but not cocaine) seeking is attenuated by ventricular injections of nociceptin/orphanin FQ.

The effect of CRF antagonists on stress-induced reinstatement is independent of the activity of the ► hypothalamic-pituitary-adrenal axis (HPA) and the effect of these antagonists on the stress hormone corticosterone. The critical extrahypothalamic brain sites and projections for CRF's role in footshock-induced reinstatement are the BNST, VTA, and a projection from the central amygdala to the BNST. Within the VTA, footshock causes local CRF release, which leads to increased glutamate transmission; this enhanced glutamate transmission is critical for stress-induced reinstatement, presumably via an activation of the mesocorticolimbic dopamine system. Support for this notion is provided by the findings that injections of D1-family receptor antagonists into the dorsal mPFC or OFC, or preferential D3 receptor antagonists into the accumbens decrease stress-induced reinstatement. The critical brain sites and projections for noradrenaline's role in footshock-induced reinstatement are the central amygdala and BNST, and the noradrenergic projection from the lateral tegmental nuclei to these brain sites.

Finally, results from studies in which reversible inactivation methods were used confirm the findings on the role of the dorsal mPFC, the BNST, the central amygdala, the accumbens, and the VTA in stress-induced reinstatement, and further suggest a role of the ventral pallidum in this reinstatement. Finally, as in the case of drug-priming-induced reinstatement, the glutamatergic projection from the mPFC to the accumbens plays an important role in stress-induced reinstatement.

Reinstatement of Drug-Taking Behavior

► Reinstatement of Drug Self-Administration

Reinstatement Procedure

Definition

In reinstatement procedures, the laboratory animals are trained to self-administer drugs and are then subjected to extinction training, during which lever presses are not reinforced with drugs. Reinstatement of extinguished lever responding (the operational measure of drug seeking) is determined after manipulations such as noncontingent ► priming injections of the drug, exposure to cues associated with drug intake, or exposure to different ► stressors. During testing for reinstatement, extinction conditions remain in effect (the drug is not available).

Relapse

Definition

In drug dependence, to regress back to a level of drug use at or comparable to use prior to a quit attempt following a period in which reduced use or abstinence was attained.

Relapse Prevention Studies

Definition

The standard approach to assessing the potential value of continued treatment in mood and anxiety disorders. Patients who have responded to open treatment are randomized to either continue with that compound, or to be switched to ► placebo, and followed up over 6–18 months, monitoring for signs of relapse, that is, the reappearance or significant worsening of symptoms. Efficacy is assessed through examining the mean time to relapse and the proportion of patients who relapse, in both groups.

Relapse Prevention Study Design

Definition

A study design that randomizes open-label responders to ongoing active or ► placebo treatment and follows them over several weeks under double-blind conditions to observe relapse rates.

Relative Validity

Synonyms

Degraded contingency; Partial reinforcement

Definition

A relative reduction in associative learning (compared with what would ordinarily be supported) arising because the reliability with which an ► unconditioned stimulus (UCS) is predicted depends on the level of contingency between the UCS and the preceding ► conditioned stimulus (CS) at issue. To the extent that this informational relationship or contingency is partial, associative learning to the nominal CS will be reduced and alternative available stimuli, including those provided by the context, are likely to gain associative strength. Relative validity is a term applied to classical (Pavlovian) conditioning and a constraint on the general importance of temporal coincidence as the sole determinant of new learning.

Release Probability

Definition

Quantal release probability refers to the likelihood of vesicular release events of quanta of neurotransmitter occurring in a population of nerve terminals or a single nerve terminal, usually during invasion of an action potential. Drugs that have presynaptic actions on nerve terminals either increase or decrease quantal release probability.

REM Sleep Behavior Disorder

Synonyms
RBD

Definition
In REM sleep behavior disorder, the paralysis that normally occurs during REM sleep is only partially present or may be absent altogether, thus enabling the affected individual to act out his/her dreams. Most frequently, the type of dreams that are acted out during RBD are vivid, intense, and violent. Examples include talking, yelling, punching, kicking, sitting, jumping out of bed, flailing arms about, and grabbing nearby objects, including the bed partner. A highly focused or acute form of RBD may occur during withdrawal from alcohol or sedative-hypnotic drugs.

Remission (From Depression)

Definition
Remission from depression is essentially the complete elimination of all symptoms for at least 6–12 months. In clinical trials, it may be defined according to the achievement of a particular score on a depression rating scale (e.g., a score of 7 or less on the Hamilton Depression (HAM-D) Rating Scale).

Cross-References

Remission (From Obsessive–Compulsive Disorder)

Definition
The concept of remission for OCD is debatable, and there is no universally accepted definition. It has been described as a brief period during which sufficient improvement has occurred so that the individual no longer suffers with OCD. Studies have chosen varying remission criteria based on the Y-BOCS scale. A score of 16 on Y-BOCS is generally considered too high to meaningfully represent true remission, and a score of 7 too low to be achieved by all but a very few cases. In a recent analysis, a Y-BOCS score of 7 did not discriminate between active and control treatments, whereas in two recent multicenter extended SSRI (SSRI and related compounds) studies a score of 10 did. Therefore, for the purposes of definition a reduction in OCD symptoms such that the individual no longer suffers with OCD and has a total score of 10 on the Y-BOCS is usually accepted as remission.

Reserpine

Definition

Reserpine is an indole alkaloid with antipsychotic and antihypertensive properties. It is currently not in clinical use for psychiatric conditions. Reserpine was isolated in 1952 from the dried root of *Rauwolfia serpentina* (Indian snakeroot), which was used in India for centuries to treat insanity and high blood pressure. Reserpine blocks the vesicular monoamine transporter, thereby acutely inhibiting the reuptake of the monoamines into the synaptic vesicles and increasing monoamine concentrations in the synaptic cleft, but eventually leading to depletion of vesicular monoamine stores in synaptic nerve endings upon chronic use, as the neurotransmitters that cannot reenter the vesicles will be degraded by monoamine oxidase. Chronic treatment can lead to ▶ depression, possibly due to depletion of these neurotransmitter stores. The drug can cause a range of additional side effects, for example, in the gastrointestinal tract (ulcerations, cramps, diarrhea) or the cardiovascular system (hypotension, bradycardia), all of which make it obsolete as an antipsychotic for today's treatment of ▶ schizophrenia or other psychoses. It was also used as a tool in experimental pharmacology, to deplete stored neurotransmitters and thus allow tests of their roles in pharmacological reactivity; this usage ended when more selective drugs became available.

Retaining Current

Definition

In neurophysiological studies, a current (either positive or negative) that reduces or blocks the spontaneous efflux of charged transmitters, drugs, or other compounds of interest from the iontophoretic pipette into the extracellular environment.

Retardation of Acquisition Test

Synonyms

Retardation test

Definition

The retardation of acquisition test is one of two widely accepted tests for whether a stimulus functions as a conditioned inhibitor (see summation test for the other). In the retardation test, a stimulus is first trained as a putative conditioned inhibitor. Once complete, the stimulus is then repeatedly paired with the unconditioned stimulus (US). If the stimulus functions as a conditioned inhibitor, acquisition of an excitatory

conditioned response should be impaired (retarded) relative to controls. Because alternative accounts remain for delayed acquisition, the strongest case for a stimulus functioning as a conditioned inhibitor also requires the use of the summation test.

Retention

Definition

The process that allows an engram (memory) to be retrieved over a protracted time span. Retention performance, which depends on memory recall, is influenced by the ability of the subject to retrieve contextual stimuli. Distinctions between a failure of retention and one of recall are difficult, especially in animal subjects. A dissociation may exist between memory and performance, since the subject may not be able to properly express a learned response.

Definition
Ribozymes are RNA molecules of viral, prokaryotic, or eukaryotic origin that possess catalytic activity. The term "ribozyme" was coined by Thomas R. Cech upon the discovery of a self-splicing intron in the ciliate protozoan *Tetrahymena thermophila*. Most commonly, ribozymes catalyze sequence-specific endonucleolytic cleavage, but also other catalytic activities, such as RNA polymerization, have been described. Similar to antisense oligonucleotides and siRNA, ribozymes find frequent application in the knockdown of expression of selected genes. There are several different classes of ribozymes, with the "hammerhead" ribozyme being the most widely studied, in recent years.

Risk Assessment (animals)

Synonyms
Stretched-attend posture

Definition
Risk assessment comprises a range of defensive behaviors displayed when animals are confronted with a novel and/or threatening stimulus. The biological function of these behaviors is to gather information about the potential threat by cautiously approaching it or by scanning the surrounding area. As rodents may display an increase in stretched-attend postures even when not avoiding an unprotected area, it has been advocated that risk assessment, thus representing the most enduring behavioral expression of anxiety, may even be more sensitive to anxiety-modulating drugs than avoidance behavior.

Definition

Substances, mainly plants that provoke an altered state of consciousness, have been used ritually for several thousand years throughout the globe in a wide variety of cultures. Their use has included religious, recreational, and healing aspects.

Current Concepts and State of Knowledge

Cultural anthropologists with interest in these substances document their important role in all continents among hunter/gatherers, incipient horticulturalists, advanced agricultural societies and pristine state societies as well as contemporary cultures. Over time, as societies became more complex, the use of plant ► hallucinogens changed from open access and widespread experiences to the usurpation of such use by elite segments of society. As societies became more complex, access to drug-induced altered states of consciousness became part of sumptuary laws, as fewer individuals were permitted entry to these states. This contrasts with societies of hunters/gatherers, for example, whereas many as one third of adult men might use plant psychedelics in ritual ceremonies for spiritual purposes. With cultural change, wars and conquest, much of our information about historical and prehistorical use of these substances was lost, only to be reformulated since the l960s. We can suppose that the abrogation of such drug access was related to the supposed power of the hallucinogenic state and the power believed to be conferred upon the user to control or harm others through magical means or witchcraft. There is a cultural evolutionary movement from exoteric rituals, open and accessible to all adults, to esoteric rituals, much like the Eleusinian mysteries of ancient Greece. Unauthorized drug use under these circumstances may have become a crime against the commonwealth. Cross-cultural studies of thematic materials linked to societies where these substances have been utilized and reported upon enable us to make a reasonable connection, however (Dobkin de Rios 1984). One illustrative example has been through the careful examination of ancient Mayan art, which has revealed that the water lily, found more frequently than the rain god, contained aporphine, which after causing heavy vomiting provided the user with a languid state conducive to visual ruminations, influencing the art and architecture of this ancient civilization.

Societies for which we have excellent data on the ritual use of plant hallucinogens include the Chumash Indians of Santa Barbara, the Tsogana Tsonga of East Africa and the Australian Aborigines (see Dobkin de Rios 1974; Dobkin de Rios and Kaz 1975; Mckenna et al. 1998; Siegel 1989). The examination of these tribal societies have identified that there existed managed altered states of consciousness where plant hallucinogens were given by elders to youth as part of an intensive short-term socialization for religious and pedagogical purposes. The use of hypersuggestibility as a cultural technique to "normalize" youth in these societies can be compared to the role of pathology of drug ingestion patterns among Euro-American adolescents (Dobkin de Rios and Smith 1977; Grob and Dobkin de Rios 1991).

In tribal societies for which we have good data, these plants have been used mainly as facilitators for religious ecstasy and to permit individuals to come into firsthand contact with spirit or divinity. In hunter/gatherer societies, male hunters used hallucinogens in shamanistic religious rituals to divine the future and to locate the animals they hunted. The chief focus in these societies was on power and its exercise by religious practitioners. These substances, however, have been viewed as a two-edged sword. On the one hand they have been utilized by different societies over time and space due to their perceived ability to access spiritual realms. The obverse is a faulty wiring hypothesis that argues that plant chemicals deceive and trick. These substances however have been seen by serious scholars as a psychotechnology that allow tribal elders to manage the altered states of consciousness of their adolescents through hypersuggestibility, utilizing the properties of the plant hallucinogens to decondition youth and to heighten religious experiences deemed important for social survival.

A major theme among traditional societies ritually utilizing plant hallucinogens is that of shape shifting. The transformation of human being into animals is found associated with plant drugs where the shamans, technicians of ecstasy, are metamorphosed into animal familiars. This action symbolized the power source of the individual who calls upon his animal familiar to do his bidding. The shaman is believed to be able to control and beckon a series of familiars for his own personal use in curing or bewitching. The concept of morphing, a phenomenon where one image remains in the mind's eye while a second is superimposed upon it, with the first then fading away, can be cited to explain this

common occurrence. Animal familiars are viewed as an empowering element. The religion of hunters and gatherers, shamanism, has a focus on personal ecstasy and direct knowledge of the preternatural. Human beings appear to be wired for the ability to experience ecstasy and the ability to have unordinary experiences to apprehend the divine, what psychiatrists call dissociative or potentially therapeutic transpersonal states. Hallucinogenic ingestion for purposes of religious ecstasy has been reported in all segments of human society.

Under the effects of the plant hallucinogens, perception of time changes. There is a circularity and reversible element of time, in which an eternal mythical present exists which is periodically reintegrated into the religious rites of tribal peoples. One of the characteristics of hallucinogenic drug use entails the perception of time which slows up almost to an imperceptible flow or else is experienced as indescribably fast.

A second theme deals with animals that appear to have played a vital role in teaching or revealing to human beings the properties of plant hallucinogens. Animals seek out psychotropic experiences and several societies that incorporate plant hallucinogens into their rituals report learning about drug plants from deer, reindeer or wild boars in their environment. Despite the apparent nonadaptive aspects of such animal behavior as they are likely to be placed in danger of predators, this is widespread and may point out the antiquity of hallucinogenic use in human society since hunters and gatherers are most likely to have been the ones to observe animal plant use most carefully and imitate this behavior.

The spiritual animation of hallucinogenic plants is another theme of interest. Many tribal groups believe that animated spirits of hallucinogenic plants exist that are either minuscule or gigantic in size, called micropsia or macropsia. Cultures across the world report this phenomenon.

Music is very important in ritual use of hallucinogens. Music is deemed by healers or sorcerers to evoke stereotypic visions. Music which is generally of a percussive nature, may be viewed as necessary for the individual to attain certain cultural goals, such as seeing an individual deemed responsible for bewitchment, to help in healing, to foresee the future, etc. Sudden access to the unconscious by means of hallucinogenic use, despite the esthetic and expressive dimensions, is a dangerous space for human beings to enter. Psychodynamically-oriented researchers stress the emotional response to such entry in terms of somatic stress registered by nausea, vomiting, diarrhea, tachycardia, and elevated blood pressure. The role of music with its implicit structure, may be to provide a substitute psychic structuring during periods of ego dissolution. Music does not simply create mood within the drug setting. Given the change in ego structure and the anxiety, fear and somatic discomfort attendant upon unexpected access to unconscious materials, the shaman guide also creates a corpus of music which some investigators have called the jungle gym in consciousness whose intrinsic structure provides the drug user with a series of paths and banisters to help him negotiate his way during the actual experience. Shamans themselves claim that the music created under their guidance provokes specific, highly valued patterned drug visions that permit their clients access to particular supernatural entities, to view the source of witchcraft, to permit contact with ancestor forces, etc. This goes along with death and resurrection themes reported in tribal societies where powerful hallucinogens are used in rituals. When used in adolescent rituals, the youth is seen to die in his social status of a child, and reborn and returned to social life as a new person with a new name, responsibilities and knowledge of the supernatural world. The psychedelic states heightened the learning of sacred knowledge and created a bonding among members of the cohort group.

Psychiatric/Psychological Implications

Cross-cultural research has shown is that at the most private and personal level of being – the hallucinogenic experience-cultural membership determines the nature of the visionary experience. Among ayahuasca users in the Peruvian Amazon (various *Banisteriopsis* sps.), beliefs hold that the mother spirit of the plant is a boa constrictor, which appears in visions overseen by the rural and urban healers. When Westerners take ayahuasca, they often report idiosyncratic visions that go along with the lack of hallucinogenic traditions in their own culture. These substances, drawing upon enhanced suggestibility, have a long history in the transformation of adolescent boys and girls into fully participating members of adult society. Legal constraints of use in Euro-American society contrast with the ritualistic use of such plant drugs in traditional tribal societies of the world. With indigenous traditions, we find managed altered states of consciousness where tribal elders provide a didactic experience to prepare youth for new adult roles. The psychedelic states heighten the learning of youthsand create a bonding among the cohort members so that individual psychic needs are subsumed to the needs of the social group. The youth may undergo austerities and rituals with painful activities such as genital mutilation, sleeplessness, and beatings. This results in an aboriginal boot camp where a youth would share and identify with his cohorts upon

whom survival success might often depend. Docility and bounded rationality is a mechanism for social selection and is implicated in the voluntary success of altruistic behavior. This docility – receptivity to social influence – contributes greatly to fitness in the human species. Plant hallucinogens used ritually create docility states in adolescents in tribal society for the purpose of maturity preparation and is widely found in the anthropological record.

Drug use patterns have also changed over time and some observers have documented controversies in recent years with foreigners seeking out ayahuasca experiences in the Peruvian rain forest, unfortunately with some abuses occurring on occasion with unscrupulous practitioners.

Modern Syncretic Religions and Ayahuasca

During the twentieth century, the use of ayahuasca was incorporated into a number of new syncretic churches in Brazil. By the late l980s, the Brazilian government sanctioned the use of this powerful Amazonian plant hallucinogenic decoction discovered from indigenous plant medicinal traditions for use as a ceremonial sacrament in the structure of modern religions. In 2006, the US Supreme Court also ruled, by unanimous vote, to protect the legal rights of the Brazilian syncretic church, Uniao do Vegetal, to practice its religion and ritual use of ayahuasca within the context of religious ceremony in the USA. Similar legal advances have been made in Europe by another Brazilian syncretic church, Santo Daime, allowing formal ayahuasca ceremonies. The origin of the Brazilian ayahuasca religions lie in the first half of the twentieth century when their respective founders, Maestre Gabriel of the Uniao and Maestre Irrianeu of the Daime churches, during expedition to the remote regions of the forest, encountered indigenous Amazonian people who used ceremonial ayahuasca for healing and divination. Bringing back knowledge of these ancient plants, they created the necessary religious doctrine and rituals for modern church structures that utilized this powerful psychoactive sacrament (Dobkin de Rios and Grob 2005).

A critical series of issues examined during proceedings to determine the legality of ayahuasca have focused on its effects on the health and safety of its users. After an extensive examination of the available evidence, all court rulings have accepted that there are safe parameters of ayahuasca use within the context of the groups studied. In the l980s, representatives of the Brazilian Confen (Narcotics Commission) tasked to investigate the use of ayahuasca by syncretic religions, conducted extensive examination of the Uniao do Vegetal in particular and determined that the responsible administration of ayahuasca in Uniao religious ceremonies caused no apparent harm to participants and should be provided legal status. The US Federal Courts investigation of ayahuasca also emphasized the importance of data provided by the medical section of the Uniao do Vegetal as well as published reports in the medical and neuroscience literature of an international multidisciplinary research investigation of the short and long-term effects of ayahuasca in subjects recruited in Manaus, Brazil in the early l990s (Grob et al. 1996).

Findings from these studies supported that the human use of ayahuasca, administered within the context of the Uniao do Vegetal, appears to be tolerated without evident negative consequence. Indeed, a number of subjects evaluated for this research investigation reported dramatic improvements in psychological and physical health, including most notably a number of cases of abolition of dangerous addictive and antisocial behaviors. Overall mood regulation, cognitive acuity, and responsible behavior all appeared to improve. An intriguing neuroscience finding from this project was the increased density of ▶ serotonin transporters in the blood ▶ platelets of long-term ayahuasca users compared to ayahuasca naïve controls, which may provide the biological substrate for the observed positive and potentially therapeutic outcomes (Callaway and Grob 1998). A cautionary note should be provided, however, regarding adverse interactions between ayahuasca and other biologically active prescription and non-prescription medicines. One example has been the reports of serious and potentially life threatening ▶ serotonin syndrome in individuals administered ayahuasca who were already taking selective ▶ serotonin re-uptake inhibitor (SSRI) antidepressants. Another concern is with individuals combining ▶ psychostimulants with ayahuasca. Given the ubiquity of stimulants in modern society, from legally prescribed Ritalin for attention deficit disorder to illegal cocaine and methamphetamine, there is a risk if combined with ayahuasca of causing serious cardiovascular problems as well as sustained adverse psychiatric reaction.

In the early 2000s, the Brazilian judiciary requested a formal research evaluation of the health and well-being of adolescents who participated with their parents in religious ceremonies of the Uniao do Vegetal. In collaboration with Brazilian psychological and psychiatric colleagues, an investigation was conducted of ayahuasca-exposed youth contrasted with a matched control group of young people without a history of ayahuasca use. Results included no differences between the two groups of neuropsychological function with ayahuasca-exposed adolescents demonstrating fewer psychiatric symptoms and less use of alcohol and other psychoactive recreational drugs. Indeed, one Brazilian medical authority of the Uniao do Vegetal, Glacus de Souza

Brito, has described the use of ayahuasca by young people within the Uniao as "prophylaxis against drug abuse" (Dobkin de Rios and Grob 2005).

In forming an understanding of the relative safety of ayahuasca within the context of the modern syncetic religion, Uniao do Vegetal, it is important to appreciate the contributions of both the psychobiological effects of the plant compound as well as the socio-cultural context within which it is taken. Ayahuasca, a decoction of native plants of the Amazon forest, *Banisteriopsis caapi* and *Psychotria viridis*, contain biologically active harmala alkaloids and dimethyltryptamine (DMT). When DMT is administered orally, its potent psychedelic effects are entirely neutralized by the monoamine oxidase (MAO) enzyme system in the gut. However, when the brew is infused with monamine oxidase inhibiting (MAOI) harmala alkaloids, the DMT is absorbed through the gut allowing for the intense activation of the central nervous system. Such precise knowledge of the native plant pharmacopeia of the Amazon forest was passed down over millennia from the earliest inhabitants through the indigenous tribal people to the founders of the syncretic religions (Callaway et al. 1994, 1996). The Uniao do Vegetal in particular has developed a scrupulous process of evaluating prospective participants in their ayahuasca ceremonies, screening for individuals with medical and psychiatric vulnerabilities. For those who pass the screening process, careful monitoring of their reaction to the ayahuasca experience is established. The relative care the Uniao takes with novice participants and vulnerable long-term members, along with the relative safety of ayahuasca when administered under ideal conditions, has led to a very low incidence of adverse health reaction. Indeed, the Brazilian syncretic ayahuasca religions represent an illustrative modern example of the value of ritual in establishing an essential structure that will minimize the potential adverse effects and maximize the therapeutic and positive transformative values of the psychedelic experience (Dobkin de Rios and Rumrrill 2008).

Conclusion

Two major themes emerge from a study of the ritual use of hallucinogens. The first is the reluctance of Western scholars to acknowledge the important role of plant hallucinogens in human history and expressive behavior. In the hallucinogens, hallucinophobic westerners see the forbidden and irrational. Yet in tribal societies, access to supernatural power and the unitive experience (so-called oceanic experience in psychoanalytic discourse) was highly valued. Psychedelic plants were used to enhance perception and intuition and played an important role in healing (Winkelman and Roberts 2008). The second area of interest is the enormous potential of these plants to create hypersuggestible states. These can reinforce religious and spiritual beliefs in their communities and can also be used to control and direct youth while contributing to the survivability of the social group.

Rivastigmine

Definition

Rivastigmine is an anti-dementia drug used for the treatment of mild to moderately severe ► Alzheimer's disease

as well as for dementia in ► Parkinson's disease. Clinical trials have indicated that it produces a very modest improvement in symptoms but appears to be particularly effective in patients with either type of dementia who suffer from hallucinations. Rivastigmine is a high-potency anticholinesterase (inhibiting both acetylcholinesterase and butyrylcholinesterase), the clinical effectiveness of which is based on its ability to enhance central cholinergic function by increasing the availability of ► acetylcholine. However, with the progression of the disease and further loss of functional cholinergic neurons, its effectiveness is reduced. The most common side effects of rivastigmine are nausea, vomiting, and diarrhea. However, recently developed transdermal rivastigmine patches reduce the incidence of unpleasant side effects without the loss of clinical effectiveness.

RNA Editing

Definition

RNA editing is a molecular process changing the information contained in the coding region of the primary RNA transcript. Editing can occur in tRNA, rRNA, and mRNA molecules of eukaryotes and takes place in the nucleus and in mitochondria. Mechanisms of RNA editing includes nucleoside modifications such as C to U and A to I deaminations but could also be non-templated nucleotide additions and deletions. RNA editing in neuronal iGluR transcripts is catalyzed by adenosine deaminase that recognizes partially double-stranded primary RNA transcripts, modifying adenosines to cause A to I, an editing process that results in this case in codon changes.

RNA Interference

Synonyms

RNAi

Definition

RNA interference (RNAi) is a surveillance system in most living eukaryotic cells that assists to regulate gene activity and to control expression of endogenous and parasitic genes, for example, viral genes or transposable elements. RNAi was discovered in 1998 by Andrew Z. Fire and Craig C. Mello in the nematode worm *Caenorhabditis elegans*. Mechanistically central to the RNAi system are small RNA molecules, such as siRNA (and also micro RNAs). Long double-stranded RNA, cleaved and processed by the RNase III family enzyme Dicer, are the typical precursors of siRNA molecules; shRNA (short- or small-hairpin RNA) introduced to cells by recombinant expression vectors is frequently used precursors in experimental gene-silencing studies (Fig. 2). One of the two strands of each siRNA fragment, known as the guide strand, gets incorporated into the multiprotein RNA-induced silencing complex (RISC). This complex specifically binds to and efficiently cleaves single-stranded RNA, for example, mRNA transcripts, which match the siRNA bound by RISC (Fig. 2B). Thus, RNAi represents a natural mechanism to knock down the expression of selected genes, which is more potent than conventional antisense oligonucleotides or ribozyme approaches because it is assisted by an efficient cellular defense machinery and also offers multiple turnovers. In addition, most eukaryotic cells possess RNAi-related pathways also recruited by siRNA (and micro RNA, to some extent), including activation of cellular antiviral defense mechanisms (e.g., the interferon response) or interference with the chromatin structure of the genome.

siRNA can also be used for pharmacological target validation by inhibiting target gene expression, thus representing an alternative strategy to pharmacological tools including antisense oligonucleotides, antagonists, and knockout mice.

siRNA can either be cellularly expressed by appropriate vectors or chemically synthesized and transfected into cells or whole animals, which is associated with technical challenges similar to the delivery of standard antisense oligonucleotides.

Definition

Rodent tests of cognition are behavioral means of assessing different components of cognition, including memory, learning, and attention, for evaluating the ability of drugs to remediate impaired cognitive functions or to produce cognitive enhancement.

Principles and Role in Psychopharmacology

Cognition is currently a much-employed term in psychopharmacology, referring to a collection of higher-order processes that intervene between sensory processing and motor output to produce behavior. Cognition is thus not a unitary construct and has to be carefully decomposed into its constituents, which can be modeled in terms of well-designed procedures that provide objective measures with good test–retest reliability. These constituents are derived from theories that provide operational definitions of constructs such as perception, attention, working memory, associative learning, and executive control. Further requirements are for tests that are validated in terms of their presumed psychological processes, neural basis, and sensitivity to drug effects. The ultimate requirement is to find procedures that can predict cognitive enhancing effects in humans with neurological or neuropsychiatric disorders. A secondary consideration is for the procedures to be sensitive to detrimental effects of certain drugs, neurotoxins, or other manipulations to provide models that can be remediated by appropriate drug treatments. The final, and perhaps key, consideration is that the tests have some translational validity for humans (McArthur and Borsini 2008a,b). The last is a contentious issue, as it is of course unclear to what extent cognitive functions in rodents might map onto functionally homologous processes in humans. Nevertheless, there has been an excellent degree of translatability thus far in certain domains, which bodes well for the further development of this discipline.

Although cognition can be segregated into its different aspects, it is important in any evaluation to measure a range of functions to be best able to define the functional selectivity of any drug effect; for example, is an effect on a memory or learning test in fact dependent on a perceptual or attentional effect of the drug? Moreover, one has to be certain that basic sensory, motor, motivational, or sedative actions are not in fact responsible for any behavioral change. This can be achieved by a battery approach, in which performance on several tests with different requirements are compared, or by the more elegant and economic method of incorporating "control" tests of such factors as motivation and sensorimotor capacity within a test of a cognitive construct such as attention or working memory.

Several examples of this will be provided later. The possibility of preclinical cognitive test "batteries" are currently popular in the wake of such approaches to measure cognition in clinical trials and experimental studies in humans, embodied, for example, by the ► MATRICS battery for schizophrenia and more generally by the ► CANTAB battery.

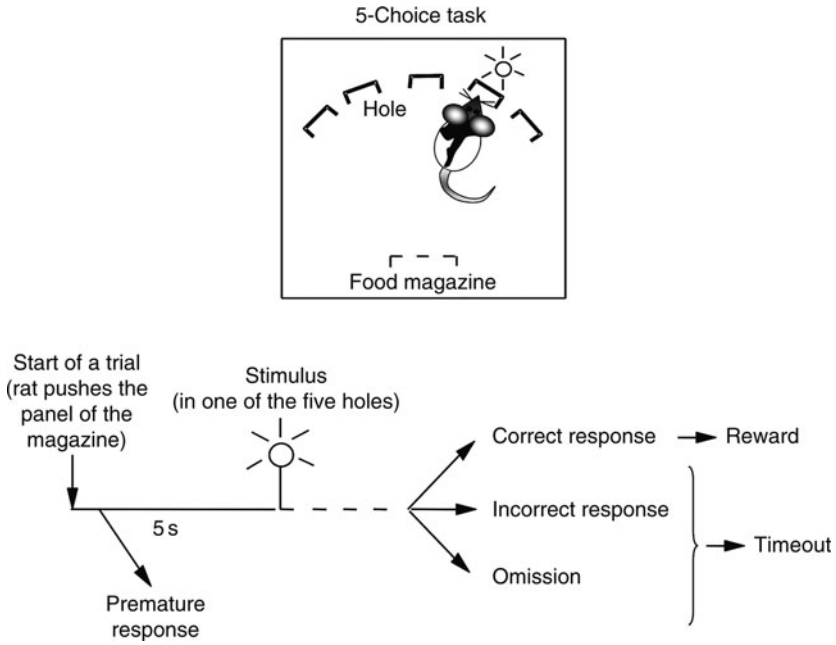
Perception

This is generally best tested by means of discrimination learning or performance, whereby responding in the presence of one stimulus is reinforced, whereas the other is not. The stimuli have to be presented randomly across two locations to avoid a confound by spatial factors. The test can be made more sensitive by varying the degree of similarity of the stimuli, and also using a titration method to determine the limits of discrimination (by which the stimuli are made more similar following a correct response and less so by an incorrect one). By this means, it may be feasible to determine a psychological ► threshold for detection. Of course, one has to rule out other factors such as motivation that might produce possible changes (often deficits) in perceptual function as a result of a drug effect. If a deficit, for example, occurs regardless of level or type of motivation, then a perceptual impairment is more likely. Comparison of different types of discrimination performance, for example, in the visual, auditory, or olfactory modalities will also serve to test the specificity of a perceptual explanation. Similarly, learning factors are also ruled out if the deficit occurs following training to asymptotic performance. It is quite difficult however to distinguish between an effect on perception or attention, unless special manipulations are used to influence the latter. A useful quantitative technique for separating sensory/perceptual from motivational or other response biasing factors is ► signal detection theory, which has been applied with success to determine whether drugs affect primarily perceptual/sensory factors (d') or response bias (ß) (Appel and Dykstra 1977). Finally, operant psychologists tend to avoid using such terms as "perception" in such tasks and prefer the more theoretically neutral term, "stimulus control." However, a loss of stimulus control is not necessarily due to perceptual factors.

Attention

There are many forms of human attention, including ► selective attention (focusing on one input or feature, while ignoring the rest), ► sustained attention (maintaining attention over a long period), vigilance (detecting rare inputs) and ► divided attention (maintaining attention to more than one input or task). Most, if not all, of these can be measured in experimental animals. Continuous performance tests measure the capacity to sustain attention and generally reveal impairments in disorders such as ► schizophrenia or ► attention deficit hyperactivity disorder. A simple analogue of this in experimental animals is the ► five-choice serial reaction time task (Robbins 2002), based on a paradigm once used to assess attention in human volunteers in a variety of experimental situations, including stress, distracting white noise, and following drug treatment. The five-choice task (Fig. 1) measures the accuracy (errors of commission) and latency of detecting visual targets, as well as errors of omission and impulsive responding (i.e., responding prior to target onset). The latency to collect food pellets provides a control measure of motivation. The difficulty of the task can be enhanced in various ways, including shortening of the duration of the visual target, varying its rate of presentation and temporal predictability, and also the occurrence of defined distractors, such as burst of white noise interpolated into the inter-trial interval. This task has now been widely used in rats, and more recently, mice to measure effects of drug, regional brain lesions, and manipulations of the central neurotransmitters or genetic mutations. Its major uses have been to reveal beneficial effects on response accuracy of some putative "cognitive enhancing" drugs such as dopamine D1 agonists, and also to characterize the neuropharmacology of impulsive behavior, which has also been shown to predict escalation of cocaine self-administration. There are several variants of this standard task, the main one of which requires the rat to make an observing response into a central location to detect a peripheral target, and has also been used to quantify the "attentional neglect" that can occur after unilateral manipulations of cortico-striatal brain regions. A rather different form of test requires the cross-modal integration of auditory and visual stimuli.

Some tests of rodent selective attention appear to mimic strongly specific tests in humans that are sensitive to frontal lobe damage, involving the formation and shifting of attentional "sets" and the capacity to avoid a prepotent response to one aspect of a stimulus in order to respond to another (Birrell and Brown 2000). The attentional set-shifting task is based on the use of compound visual stimuli (i.e., that vary in at least two perceptual dimensions). Humans or nonhuman primates are trained to attend to one dimension on the basis of reinforcement and to ignore the other one, including tests of reversal (where the two stimuli within a dimension have their reinforcement contingencies reversed), and intra-dimensional shifting (where novel stimuli are introduced, but the



Rodent Tests of Cognition. Fig. 1. Schematic of the rodent five-choice task (See Robbins 2002; Figure provided by courtesy of Dr. Christelle Baunez).

same dimension is reinforced). Finally, an extra-dimensional shift is arranged in which novel stimuli are again introduced, but now the previously irrelevant dimension is reinforced. This latter stage is analogous to the category shift on the ▶ Wisconsin Card Sort Test, which is much used to assess cognitive flexibility in human patient populations, especially those with presumed damage to the prefrontal cortex. In the rodent version (being available for mice as well as rats), the test is implemented using olfactory cues and texture in a "digging for food" test paradigm. Performance across the various stages is qualitatively comparable to that seen in primates; the extra-dimensional shift is the most sensitive stage to drug effects, performance at other stages usually being employed as internal controls. There are now various versions of these tests of "cognitive flexibility," which use similar logic for shifts between, for example, responding according to body turns or to space on a cross-maze, or alternatively attending to discrete (e.g., visual) cues versus contextual cues on a maze. These tests do not use different stimuli at each test and so are also confounded by any response to interference. However, they do exemplify the general requirements of tests of executive function (see below).

Another major source of tests of attention comes from animal learning theory, in which the repeated non-reinforced presentation of stimuli retards subsequent learning about them, a process called ▶ latent inhibition. One theory of latent inhibition ascribes the loss of salience of the preexposed stimuli to a loss of attention, although it is possible that an associative account might suffice. However, a particular advantage of latent inhibition paradigms, which are very sensitive to dopamine D2 receptor antagonists (i.e., ▶ antipsychotic drugs) is that impairments are indexed subsequently by successful learning, in drug-free state, thus controlling for many other explanations of impairment.

Learning (see Gluck et al. **2007**)

Both ▶ Pavlovian and ▶ instrumental conditioning are now considered to have cognitive aspects, given that the basis for the former is prediction and expectancy, and for the latter, cognitive control over environmental contingencies. The detection of instrumental contingency, in particular, can be thought of as a higher-order cognitive process, which plays an important component of our ability to make voluntary actions that form part of goal-directed behavior. Disruptions of aspects of Pavlovian and instrumental learning almost certainly underlie all of the major forms of neuropsychiatric disorder, including drug addiction. However, these forms of conditioning will be considered elsewhere in more detail under specific entries.

Learning is generally measured in simplified chambers or operant settings (especially for rats); however, maze learning is often employed when spatial cognition is the main subject of study, being especially compatible with the well-developed foraging tendencies of rodents.

Memory (see Gluck et al. 2007; Morris 2007)

This section serves to overview the many distinct forms of memory paradigms used in rodents, which are considered in greater detail under individual entries. Memory can be divided in many ways; a basic distinction is between relatively transient short-term memory and long-term or more permanent memory. Memory "traces" are thus hypothesized to be "consolidated" into long-term memory. Another distinction that has been made in human long-term memory by Tulving, ► "episodic" (generally autobiographical, the "what, where and when" of memory), versus ► semantic memory (memory for meaning) has not been exploited so far to any great extent in rodents.

Perhaps the greatest contribution made to the study of memory from rodent studies has been the post-trial or post-training paradigm popularized by McGaugh (McGaugh and Roozendaal 2009). Here, what is generally a single trial or training session is *followed* immediately by a drug treatment that can either be amnestic (e.g., protein synthesis inhibitors) or promnestic (e.g., amphetamine). ► Retention is tested on a subsequent trial, perhaps 24 h or 3d later. The post-training manipulation is thus designed to influence ► consolidation, either beneficially or adversely. The procedure most often used is of aversive memory; the rodent is punished for stepping down from a platform or through a door by presentation of electric foot-shock. Memory is expressed on the retention trial by a longer response latency to step down or through the door. The great advantage of this design is that the drug cannot be said to have affected memory indirectly by its actions on perceptual, attentional, or motivational mechanisms, as it is administered at a time when these no longer impinge on learning. It is necessary however to perform controls with longer post-trial treatments to check that the drug effects are not affecting retention proactively (i.e., by being active at the time of retention and affecting memory retrieval). Studies of the consolidation of appetitive memory are also feasible, but are used less often because of the unreliability of one trial appetitive learning. The post-trial paradigm has been employed for example to demonstrate the contribution of noradrenergic, opioidergic, and GABAergic mechanisms to emotional memories laid down in the ► amygdala.

Reference memory is a form of long-term memory, which refers to rodent task requirements that stay constant from trial to trial. This definition was originally applied by Olton to rats remembering the constant location of the food-baited arms in an eight-arm ► radial maze. However, it can also be applied to the ► Morris water maze, a notable assay of hippocampal function, in which rodents are required over a number of learning trials to learn the location of a hidden platform in order to escape from a vat of water (D'Hooge and De Deyn 2001; Morris 2007). The rodent is allowed to swim the maze beginning from different vantage points, and so successful learning depends on the construction of a "cognitive map" to navigate the environment. In contrast, the term ► "working memory" in the Olton maze refers to the requirements of another memory test procedure in which rodents are required to visit each of the eight arms once and once only in order to retrieve a maximum of eight pellets. So, the animals have to remember only where they have recently been, and this memory is irrelevant to performance on subsequent test days. It can be argued that this form of "working memory" is not quite the same as that defined by human memory theorists such as Baddeley, where there is a coordination of different, modality specific short-term memory buffers for use in various tasks such as planning, linguistic discourse, and logical reasoning. However, it does seem to overlap the human form of working memory in some important respects (see also Ko and Evenden 2009).

Olton's working memory tasks are strongly reminiscent of the tests of ► spatial delayed response and delayed alternation that have been used to establish the role of the primate ► prefrontal cortex in working memory. Delayed alternation in rodents is easily implemented in a maze or operant chamber, where it is often referred to as "delayed non-matching to position." Nonmatching is an easier task for rodents than matching because of their preexisting foraging tendency to alternate spatial choices. The operant versions of the task allow the systematic variation of delay intervals, which can extend from 0–60s. A "delay-dependent" effect in such a task is generally taken as evidence of a specific memory effect, independent for example, of attention. However, for that inference to be valid it is necessary for performance on the task at zero seconds to be shown not to be similarly susceptible when the perceptual difficulty of the task is enhanced. An additional artefact that is difficult to surmount in the operant task is that of mediating responses, by which the rodent adopts postures or positions that minimize the memory requirement of the task. One way of overcoming this

problem is to use sensitive touch screens to record responding and which can more precisely vary the spatial requirements of the memory tasks, as in the ▶ CANTAB battery for humans and nonhuman primates.

Recognition memory tasks have a superficial resemblance to those employed for working memory. A commonly used variant is that of object recognition (devised by Aggleton and others based on the paradigm of Delacour) in which a rodent explores a novel object during a sample trial, and is then given a choice between this familiar object and a novel object, in terms of the amount of time it allocates to exploring both objects. Lesser exploration of one object indicates greater familiarity and hence recognition of it (in some, restricted sense). The test can also be adapted to measure ▶ "social recognition" by using experimental animals as the "object." Recognition memory is generally manifested over long delays, up to 24 h, although it can be tested at much shorter intervals also and has been shown to depend on structures such as the rodent perirhinal cortex. What distinguishes such tasks from those used to test working memory, apart from the precise test material, is that recognition memory tasks generally employ stimuli only once, so that the test is "trial unique." If the same set of objects were to be used over many trials (as occurs in the spatial delayed alternation or delayed response task), this would produce considerable proactive interference, and the test therefore becomes one of recency memory (how *recently* the stimulus has been experienced) rather than one of recognition memory. In that case, the test also becomes one more of frontal rather than temporal lobe function.

Recognition memory is a less sensitive test of memory than either cued or free recall, in which the memory has to be generated from long-term memory store. Unlike recall, recognition is not particularly sensitive to hippocampal damage, and nor is it the earliest manifestation of ▶ Alzheimer's disease, where amnesia for episodic memories is more evident. Some human and primate data indicate that the hippocampus is implicated in forms of associative memory, particularly in animals involving space, for example, remembering the location of objects. Recent advances have begun to focus on these forms of associative memory, building on the classical Morris water maze. For example, recent touch-screen tests have been developed for mice and rats of their ability to remember the location of objects, and also to form associative memories of tastes with specific locations (Bussey et al. 2008).

Recognition and recall correspond to what Squire has denoted for humans as ▶ "declarative memory" as distinct from "procedural memory" (memory for "how," or for "skill"). We have not discussed procedural memory in any detail in this article, but it may readily be tested in rodents in motor-learning situations such as the rotor-rod test, or as memory for "habits," being part of the process of instrumental learning.

Executive Functions

In human cognitive neuropsychology, this term refers to that set of cognitive processes that serve to optimize performance. The term embraces a number of functions already described earlier, including cognitive flexibility (e.g., attentional set shifting), response inhibition, working memory, planning, ▶ decision making, and aspects of social cognition, some of which are difficult to test in rodents.

A recent development has been a rodent analogue of Logan's ▶ "stop-signal" task, which is much used in the testing of patients with ▶ Attention Deficit Hyperactivity Disorder, for assessing their impulsivity. The stop-signal task requires the cancellation or termination of a motor response that has already been initiated by a "Go" cue, by a less frequently occurring "Stop" cue. It is feasible to measure a stop signal reaction time, as well as a conventional (go) reaction time. The rodent stop signal task (Fig. 2), so far has shown a similar pharmacology to that of the human task, both being sensitive, for example, to the beneficial effects on stopping of the selective noradrenaline uptake blocker ▶ atomoxetine (Eagle et al. 2008). Intriguingly, the classical ▶ Go/No Go task, which has formal similarities with the Stop task, appears to be differentially sensitive to certain drug effects in a manner suggesting the mechanisms of stopping a motor response to be distinct from those of selecting it (Eagle et al. 2008).

Until recently, it was considered difficult to implement a version of the human Stroop task for rodents. The human Stroop requires subjects to resist responding to the dominant aspect of a colored word stimulus (the word itself) and to report the color. A similar conflict has been achieved in rats by training them on two different conditional discriminations with different rules for responding to each ▶ discriminative stimulus, and then placing the rat into conflict by presenting combinations of the discriminative stimuli that are either congruent (i.e., both stimuli indicate the same response or incongruent, both stimuli indicating opposing options) (Haddon and Killcross 2006).

Decision-making cognition has attracted considerable recent interest, in the context of both neuropsychological studies of human patients and in neuroeconomics. This

trend is followed in rodent studies by the provision of tests of important component processes, including the discounting of rewards over time, as well as time perception itself. Recently, rat analogues of the ► Iowa Gambling Task, as used to show deficits in patients with lesions of the ventromedial prefrontal cortex, have begun to be implemented, but there are, as yet, few pharmacological studies.

Rolipram

Definition

Rolipram is a PDE4 inhibitor. It is being widely researched as a possible alternative to current antidepressants. In addition, it might be beneficial to improve memory in patients with mild ► Alzheimer's disease either directly or via a neuroprotective mechanism. Like most PDE4 inhibitors, it also has anti-inflammatory properties. However, till now neither rolipram nor any other developed PDE4 inhibitor made it to the market due to emetic side effects.

Ropinirole

Definition

Ropinirole is a non-ergoline D2, D3, D4 dopamine agonist with preference for D3 receptor. It is approved for the treatment of ► Parkinson's disease (PD) and restless leg syndrome (RLS). Ropinirole can be used either as a monotherapy or as an adjunct to l-DOPA for PD. The mechanism for the treatment of PD is thought to be stimulation of the postsynaptic D2 receptor in the caudate-putamen. The mechanism for RLS is unknown. It is associated with rare side effects such as hypersexuality and compulsive gambling. Other side effects include hallucination, orthostatic hypotension, and somnolence, especially in Parkinson's disease patients.

Rotigotine

Definition

Rotigotine is a non-ergoline D3, D2, D1 dopamine agonist approved by the United States Food and Drug Administration for the treatment of ► Parkinson's disease. It comes as a transdermal delivery system designed for continuous release over 24 h period. Exact mechanism of action is unclear but is believed to result from its ability to stimulate D2 receptor in the brain. Major side effects include somnolence. Its availability in the USA ceased after April 2008.

Runway Procedure

Definition

In the form of these procedures used in connection with the ► Reinstatement of drug self-administration, the dependent measure is the *run time* from a *start box* to a *goal box* associated with a reward (e.g., food or drug). During daily training sessions, food-restricted rats are given food pellets when they reach the goal box, and over sessions they decrease their run time. During the subsequent extinction sessions, food is not available in the goal box, and over daily sessions the rats' run time progressively increases (reflecting extinction). A single exposure to

food pellets during extinction leads to a faster run time on the subsequent daily session; this decrease in run time is the operational measure of food-priming-induced reinstatement. A unique feature of the runway reinstatement procedure is that the effects of pharmacological manipulations are assessed on a subsequent, drug-free day. This helps rule out the possibility that any observed effects of pharmacological manipulations on reinstatement are due to locomotor activation or sedation during testing.

Saturation Binding Curve

Synonyms
Labeled ligand concentration binding isotherm

Definition
Isotherm: a line that connects points of equal temperature or points of measurements performed at equal temperature. The specific binding of the labeled ligand to tissue samples is measured at a given temperature at various concentrations of the labeled ligand. The values of the specific binding, on the ordinate, are plotted versus the labeled ligand's free concentration on the abscissa; connecting the points results in a curve with the form of a hyperbola. At a certain concentration of the labeled ligand, all available specific binding sites in the tissue sample will be occupied by the labeled ligand and specific binding will not further increase with increasing labeled ligand concentration; saturation of specific binding is reached.

Schizoaffective Disorder

Andreas Marneros
Martin Luther Universität Halle-Wittenberg, Klinik und Poliklinik für Psychiatrie, Psychotherapie und Psychosomatik, Halle, Germany

Definition

There is no agreement about how schizoaffective disorders could be defined. According to the World Health Organisation (WHO) and its International Classification of Mental and Behavioral Disorders (► ICD-10), schizoaffective disorders are "episodic disorders in which both affective and schizophrenic symptoms are prominent but which do not justify a diagnosis of either schizophrenia or depressive or manic episodes." The diagnostic criteria are the following:

G1	The disorder meets the criteria of one of the affective disorders (F30, F31, F32) of moderate or severe degree, as specified for each category.
G2	Symptoms from at least one of the groups listed below must be clearly present for most of the time during a period of at least 2 weeks: Thought echo, thought insertion or withdrawal, thought broadcasting. Delusions of control, influence or passivity, clearly referred to body or limb movements or specific thoughts, actions or sensations. Hallucinatory voices giving a running commentary on the patient's behavior or discussing the patient between themselves, or other types of hallucinatory voices coming from some part of the body. Persistent delusions of other kinds that are culturally inappropriate and completely impossible, but not merely grandiose or persecutory, e. g. has visited other worlds; can control the clouds by breathing in and out; can communicate with plants or animals without speaking. Grossly irrelevant or incoherent speech, or frequent use of neologisms. Intermittent but frequent appearance of some forms of catatonic behavior, such as posturing, waxy flexibility and negativism.
G3	Criteria G1 and G2 above must be met within the same episode of the disorder, and concurrently for at least part of the episode. Symptoms from both G1 and G2 must be prominent in the clinical picture.
G4	*Most commonly used exclusion clause.* The disorder is not attributable to organic mental disorder or to psychoactive substance-related intoxication, dependence or withdrawal.

ICD-10 defines three different types of schizoaffective disorders: manic type (F25.0), depressive type (F25.1) and mixed type (F25.2).

The American Psychiatric Association (APA) in the fourth revision of its Diagnostic and Statistical Manual of Mental Disorders (► *DSM-IV*) defines the following diagnostic criteria for schizoaffective disorder:

A	An uninterrupted period of illness during which, at some time, there is either a Major Depressive Episode, a Manic Episode, or a Mixed Episode concurrent with symptoms that meet Criterion A for Schizophrenia.
B	During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.
C	Symptoms that meet criteria for a mood episode are present for a substantial portion of the total duration of the active and residual periods of the illness.
D	The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

DSM-IV specifies two subtypes: bipolar type, if the disturbance includes a manic or a mixed episode (or a manic or a mixed episode and major depressive episodes), and depressive type, if the disturbance only includes major depressive episodes.

While the main problem with the ICD-10 definition of schizoaffective disorders is their ► longitudinal aspect, the problem with DSM-IV concerns both – ► cross-sectional and longitudinal aspects. The problem with the cross-sectional definition of DSM-IV concerns the time span indicated in criterion B (during the period of illness there have been ► delusions or ► hallucinations for at least 2 weeks in the absence of prominent mood symptoms). Obviously, that is an attempt of DSM-IV to separate schizoaffective disorders from psychotic ► mood disorders. The DSM-IV definition of mood disorders is broad, including even those with mood incongruent symptoms (even ► first-rank schizophrenic symptoms). The chronological criterion, however, is rather arbitrary (2 weeks of psychotic symptoms without mood disorders is schizoaffective; less than 2 weeks is psychotic mood disorder!). Yet, the beginning of a psychotic episode is hard to assess exactly. Every clinician knows that there is usually a gap of many days, weeks, or months between the beginning of a psychotic episode and admission to hospital. Reconstruction of the psychopathological picture, retrospectively, is fraught with difficulties. Given the likelihood that the psychotic period is underestimated, many patients who are really schizoaffective could be diagnosed as schizophrenic or as having psychotic mood disorder.

Furthermore, the intensity of both concurrent syndromes (mood and schizophrenic syndromes) can vary enormously during an episode; hence, it seems arbitrary to give chronological priority to the psychotic symptoms over the mood component. It is strange that DSM-IV rejected Jasper's hierarchical diagnostic principle, which suggested a diagnostic superiority of schizophrenic symptoms over affective symptoms, but, regarding the chronological criterion of the schizoaffective definition, obviously made an exception!

Considering what is known so far about schizoaffective disorders (see overviews in Marneros and Tsuang 1986, 1990), we suggest that the definition of

schizoaffective disorders should contain two components: a cross-sectional and a longitudinal aspect.

The *cross-sectional* definition should be the definition of an episode; while the longitudinal definition should be that of a disease or disorder. The cross-sectional definition of a schizoaffective episode should be based on the simultaneous occurrence of symptoms of a schizophrenic and a mood episode, independent of the chronological manifestation. Thus, we agree with the definition of ICD-10, which yields three types of schizoaffective episodes: schizodepressive, schizomanic and mixed ones.

The *longitudinal definition* of schizoaffective disorder should consider the sequential occurrence of mood and schizophrenic episodes during course. The longitudinal research demonstrates that the course of schizoaffective disorders can be very unstable because schizoaffective episodes, pure mood episodes, and pure schizophrenic episodes can each occur at different points in the patient's longitudinal course.

What are such disorders when viewed longitudinally? Are they considered to be mood disorders because of the pure mood episodes, or schizophrenic disorders because of some pure schizophrenic episodes, or schizoaffective disorders because of some schizoaffective episodes? Relevant to this question is the finding that there are no differences between patients who have only had schizoaffective episodes, and those in whom schizoaffective episodes occur along with pure mood and schizophrenic episodes. There are therefore no differences between the "*concurrent*" and the "*sequential*" type of schizoaffective disorder. Patients, who change from pure mood episodes to pure schizophrenic episodes and vice versa, do not differ from patients having schizoaffective episodes. In this sense, Marneros et al. suggest a longitudinal definition of schizoaffective disorders, including a concurrent and a sequential type, the "*concurrent type*" being characterized by the coincidence of schizophrenic and affective episodes and the "*sequential type*" being characterized by the longitudinal change from schizophrenic to affective episodes and vice versa (Marneros et al. 1989).

How essential it is to have a longitudinal definition of schizoaffective disorder is illustrated by the Halle Bipolarity Longitudinal Study (HABILOS), in which the investigators tried to allocate disorders with manic symptomatology to "pure mood disorders" or to "schizoaffective disorders" according to DSM-IV, ICD-10 and the "empirical definition" as described above. Applying the ICD-10 definition, only 8.3% of the 277 patients could longitudinally be allocated to schizoaffective bipolar disorder and 36.1% to affective bipolar disorder, while the majority of patients (55.6%) could not be allocated longitudinally due to the occurrence of different types of episodes (schizophrenic, schizoaffective, affective) at different times.

Using the empirical definition with its cross-sectional and sequential aspects, however, all patients can be allocated: 36.1%, as in the ICD-10 categorization, could be allocated to bipolar mood disorder, and 63.9% could be allocated to schizoaffective disorder.

Recent research has confirmed earlier assumptions that schizoaffective disorders occupy a position between affective and schizophrenic disorders with regard to relevant sociodemographic and premorbid features, as well as with regard to patterns of course, outcome, treatment response and prophylaxis (Marneros et al. 1988, 1989).

It seems certain that schizoaffective disorders are not simply a type of schizophrenic disorder, although in some cases that are ▶ schizo-dominant the relationship to schizophrenia is quite clear. With respect to the relationship between schizoaffective and mood disorders, the similarities are more compelling than the differences (Marneros and Tsuang 1986, 1990).

Role of Pharmacotherapy

Although the clinical relevance of schizoaffective disorders is - inspite of controversies - meanwhile well established their treatment has received less attention in pharmacological studies, especially ▶ double blind studies, than other psychotic or non-psychotic major mental disorders. One of the main reasons might be the problem of their definition and, most important for the pharmaceutical industry, the clinical fact that schizoaffective disorders usually need a combined treatment with more than one substance, for example, with ▶ antipsychotics, ▶ antidepressants and ▶ mood stabilizers. Pharmacological studies dealing with schizoaffective disorders mostly investigated them as a subgroup of schizophrenia and seldom as a subgroup of mood disorders. Pharmacological studies only on schizoaffective disorders are rare. Nevertheless it can be said that schizoaffective disorders are the domain of antipsychotics and mood stabilizers (Baethge 2003; Jäger et al. 2009; Levinson et al. 1999; McElroy et al. 1999; Mensink and Slooff 2004).

All antipsychotics seem to be efficient in the treatment of schizoaffective disorders, but some atypical antipsychotics like ▶ olanzapine, ▶ quetiapine, ▶ risperidone, or ▶ ziprasidone are superior or have some advantages in comparison to typical ones. The heterogeneity of the studies and the investigated populations do not permit a science-based statement on the topic. The clinical

effectiveness of mood stabilizers like ► lithium, ► carbamazepine or ► valproate was reported in some, however, heterogeneous studies. Clinical reality is compatible with such a conclusion.

Pharmacotherapy depends from the type of schizoaffective disorder. The official types of schizoaffective disorder registered in ICD-10 are: manic type, depressive type, mixed type, and those in DSM-IV are bipolar type and depressive type. Empirical work and longitudinal investigations considering a course of the disorder over many years, however, support some more subtypes:

(a) Schizo-dominant type
(b) ► Affective dominant type
(c) Bipolar type
(d) Unipolar type
(e) Sequential type

In the schizo-dominant type the main medication must be an antipsychotic one. In the affective dominant type mood stabilizers and antidepressants or antipsychotics are effective. The bipolar type is treated with antipsychotics combined with mood stabilizers, whereas the unipolar type needs to be treated with antipsychotics and antidepressants. The sequential type is totally ignored. The reasons are given at the beginning of this chapter. It is characterized by the occurrence of schizophreniform or mood episodes during course. The treatment focuses on the treatment of the particular disorder. The longitudinal treatment is a prophylactic one, mainly with mood stabilizers and antipsychotics (McElroy et al. 1999; Mensink and Slooff 2004).

Clinical studies reported also a positive effect of electroconvulsive treatment (Swoboda et al. 2001). Other treatments like augmentation with l-thyroxine found only small benefit (Bauer et al. 2002). The role of psychological treatment in schizoaffective disorders has not yet been systematically investigated.

Conclusions

Schizoaffective disorder is a very common diagnosis in clinical practice, but not sufficiently investigated, especially with regard to treatment.

Definition

Schizophrenia is a severe and persistent debilitating psychiatric disorder consisting of disturbances in thoughts, cognition, mood, perceptions, and relationships with others. According to ► DSM-IV-TR (American Psychiatric Association 2000), the patient must have experienced at least two of the following symptoms: delusions, hallucinations, disorganized speech, disorganized or catatonic behavior, or negative symptoms. Only one symptom is required if the delusions are bizarre or if auditory hallucinations occur in which the voices comment in an ongoing manner on the person's behavior, or if two or more voices are talking with each other. The patient must experience at least 1 month of symptoms during a six-month period, and social or occupational deterioration problems occur over a significant amount of time. These problems must not be attributable to another condition for the diagnosis of schizophrenia to be made.

By contrast, *schizophreniform disorder* is a short-term type of schizophrenia with the characteristic symptoms (including prodromal, active, and residual phases) being present for at least one month but not for the full six months required for the diagnosis of schizophrenia. In contrast to schizophrenia, the onset of schizophreniform disorder can be relatively rapid and the individual's level of functioning may or may not be affected. According to the American Psychiatric Association, about two-thirds of people with schizophreniform disorder do not recover and are subsequently diagnosed with schizophrenia.

Current Concepts and State of Knowledge

Historical Aspects

The clinical picture of schizophrenia was described for the first time by the German physician Emil Kraepelin who used the term "dementia praecox" to define a disorder with early beginning, a uniformly deteriorating course and a poor prognosis (Kraepelin 1893). Subsequently, Eugen Bleuler coined the term "schizophrenia" and distinguished between fundamental and accessory symptoms of the disease (Bleuler 1908, see Table 1). He believed that the fundamental symptoms were present in all patients and were unique to the disorder while the accessory symptoms could also occur in other disorders. Bleuler realized that the condition was not a single disease and referred to a whole "group of schizophrenias". Some decades later, Kurt Schneider established the differentiation between first- and second-rank symptoms (Schneider 1959, see Table 2), representing a preliminary stage of contemporary operationalized classification systems.

In 1980, Timothy Crow postulated two dimensions of pathology underlying schizophrenia. According to his concept, the type I syndrome is mainly characterized by positive symptoms, potentially neuroleptic-responsive and reversible while the type II syndrome is mainly characterized by negative and cognitive symptoms, sometimes progressive and relatively irreversible (Crow 1980, see Table 3).

The concepts described above have used a categorical approach, thereby indicating homogeneous, mutually exclusive subtypes of the disease. Essentially, schizophrenic disorders are heterogeneous and consequently, Peter Liddle has introduced a dimensional approach comprising three neuroanatomically classifiable syndrome clusters: psychomotor poverty, disorganization, and reality distortion (Liddle 1987, see Table 4).

Psychopathology

Disorders of Thinking and Speech

Basically, thought processes may be disordered in form and content. Common ► formal thought disorders observed in schizophrenia patients include ► incoherent thinking. The patient's thoughts are illogical and confused up to a defect in processing and organizing language

("schizophasia"). During *thought block* thinking is decelerated and stagnant, and the patient's language is sagging accordingly. Thought content may be diminished as well. On the other hand, the term *flight of ideas* describes excursive and uncontrollable thinking, associations become loose and mental activity is generally accelerated. Furthermore, *improper responding to questions*, ▶ perseverations, ▶ paralogism, ▶ neologisms, and ▶ concretism are commonly observed in schizophrenia patients.

Essentially, ▶ content-disordered thought processes are equivalent to delusions. They are characterized by abnormal, apparently unreasonable interpretations of one's own experiences and perceptions to which the person concerned adheres despite refutation by others (▶ Delusional disorder). According to Karl Jaspers, these interpretations fulfill three main criteria: certainty, incorrigibility, and impossibility (Jaspers 1913). The most frequently observed delusions in schizophrenia patients are delusions of reference, of persecution and guilt as well as megalomania, nihilism, and delusions with religious content.

Many patients experience prepsychotic states and prodromal symptoms before the first episode of schizophrenia is apparent. For example, this stage of the illness includes attenuated psychotic symptoms (APS) or brief limited intermittent positive symptoms (BLIPS) (▶ Prepsychotic states and prodromal symptoms).

Disorders of Affect and Mood

Schizophrenia is characterized by abnormalities of affect, emotional response, and mood. In this context, the profound disturbance of emotional rapport perceived in an intuitive way by an experienced psychiatrist interacting with a schizophrenia patient was named "praecox feeling." Due to fluctuations in attention and misinterpretation of stimuli, schizophrenia patients might be confused, depressed, and anxious. Sometimes, even situations of minimal novelty cause anxiety (novophobia), e.g., unfamiliar people, items, conversations. Common objects might take on undue significance and therefore scare patients. A further fundamental symptom of the schizophrenia-related affective disorder is parathymia, the inappropriateness of facial expression, gesture, and speech, which is contrary to the patient's real experience.

Affective flattening becomes manifest as a diminution of emotional response and indifference to events or topics that normally evoke such a response (Andreasen 1987, see Table 5).

Anhedonia refers to a pervasive and refractory reduction in the capacity to experience pleasure, which becomes apparent in reduced leisure activities or sexual interest.

Ambivalence is characterized by simultaneous, conflicting feelings toward a person or thing, e.g., love and hate or happiness and fear. These contradictory

impulses are usually unconscious and uninterpretable for other people.

Depressive symptoms can be found in up to 50% of schizophrenia patients. On the other hand, some patients develop ► manic conditions characterized by hyperactivity, a reduced ability to think critically and an overestimation of their own capabilities.

Hallucinations

► Hallucinations are conscious perceptions affecting the different senses in the absence of external stimuli. ► Auditory hallucinations are perceived as noise, words, sentences, whisper, or voices. They are apparent in about 70% of schizophrenia patients and mainly become manifest in thoughts becoming aloud as well as commenting, dialogic or imperative voices, respectively. ► Visual hallucinations occur relatively infrequently. ► Tactile hallucinations create the sensation of tactile sensory input and are perceived as touch, burning, or electrifying sensations. Coenesthesia is characterized by abnormal bodily sensations, e.g., parts of the body that are perceived as being changing their shape or size. ► Olfactory and gustatory hallucinations are quite uncommon in schizophrenia patients but can be associated with delusions of poisoning.

Disorders of the Ego

Patients with schizophrenia experience themselves in a disordered manner and often believe that they are affected by external forces. Accordingly, the term "disorders of the ego" comprises various symptoms. For example, patients experiencing thought diffusion are convinced that other people know their thoughts. Other symptoms belonging to this category are thought withdrawal, thought insertion, ► depersonalization, and ► derealization.

Disorders of Psychomotor Functioning

Many patients with schizophrenia experience psychomotor disturbances already at an early stage of the illness. Accordingly, changes in facial expressions, gestures, posture, voice, and speech are often observed. Everyday activities have to be reconsidered (loss of automatisms), which is why patients appear mannered.

Catatonic phenomena comprise disorders of movement, speech, and autonomic function. These motor disturbances consist of hyper- or hypokinesias (excitement and inhibition, respectively) and parakinesias (abnormal postures, mannerisms, grimacing, stereotypies). Catatonic speech disorders include perseveration, echolalia, mutism, et cetera. Characteristic autonomic signs are dilatation of pupils, seborrhea, sweating, and alterations in muscle tone (rigidity or hypotonia, respectively). Catatonic stupor and excited states represent the extreme ends of the spectrum.

Cognitive Symptoms

► Cognitive impairment is a cardinal feature of schizophrenia, which is found in 60–80% of patients. Generally, it is assumed that schizophrenia patients show deficits across a large number of neurocognitive domains including ► attention, ► executive functioning, memory, and fine motor skills. Performance has been reported to be two standard deviations below the mean of healthy control subjects. Cognitive variables have been related to the heterogeneity of functional outcomes, with difficulties in profiting from rehabilitation programs, and with quality of life. Evidence suggests that cognitive deficits may be of equal or greater importance in predicting functional outcome as positive or negative symptoms.

Such cognitive disturbances are present both in children who have a schizophrenic parent ("high risk children") and in first-degree relatives of patients, who do not suffer from a schizophrenic disorder. Furthermore, these deficits are apparent long before the onset of psychotic symptoms and they endure after a psychotic episode when patients are in remission. Therefore, cognitive deficits represent a possible trait marker of schizophrenia.

Next to neurocognitive impairment, schizophrenia has consistently been associated with deficits in the recognition, ► discrimination and experience of emotional stimuli. Impairments in affect perception have been demonstrated in chronic and first-episode patients and their unaffected siblings but not in high-risk individuals with initial prodromes, and it has been suggested that the initial psychotic episode represents a critical point for the emergence of emotion perception deficits in schizophrenia spectrum illnesses. Several studies have shown that these deficits in emotion recognition are associated with illness-related measures such as duration of illness, symptomatology, symptom severity, and cognitive

disturbances but are not influenced by age or antipsychotic treatment.

Other studies have shown significant and stable "theory of mind" (ToM) impairments in patients with schizophrenia. ToM refers to the ability to perceive other people's opinions, beliefs, and intents, and to establish a connection between these mental states and a person's behavior. These deficits are probably independent of neurocognitive dysfunctions and they might contribute to social and behavioral deviations in schizophrenia patients.

Subtypes

Depending on the combination of symptoms, different subtypes of schizophrenia have been defined:

► Paranoid schizophrenia is characterized by relatively stable, often paranoid delusions, usually accompanied by (auditory) hallucinations and perceptual disturbances. Disturbances of affect, volition and speech, and catatonic symptoms are not prominent.

Hebephrenic schizophrenia is dominated by affective changes with shallow and inappropriate moods. Thought is disorganized leading to incoherent and rambling speech, whereas delusions and hallucinations are fragmentary if present at all.

Catatonic schizophrenia is mainly determined by psychomotor disturbances with alterations between extremes such as hyperkinesias and stupor.

Undifferentiated schizophrenia meets the diagnostic criteria for schizophrenia but does not conform to any of the above subtypes or exhibits the features of more than one of them without a clear predominance of a particular set of diagnostic characteristics.

The diagnosis of ► post-schizophrenic depression (► Postpsychotic depressive disorder of schizophrenia) should be made if the patient has had a schizophrenic illness meeting the general criteria for schizophrenia within the past twelve months and some schizophrenic symptoms are still present. Depressive symptoms must be prominent and distressing, fulfilling at least the criteria for a depressive episode, and have been present for at least 2 weeks.

The term "residual schizophrenia" describes a chronic stage in the development of a schizophrenic disorder in which there has been a clear progression from an early stage (comprising one or more episodes with psychotic symptoms meeting the general criteria for schizophrenia described above) to a later stage characterized by long term, though not necessarily irreversible, negative symptoms, i.e., psychomotor slowing, underactivity, blunting of affect, passivity and lack of initiative, poverty of quantity or content of speech, poor nonverbal communication by facial expression, eye contact, voice modulation, posture, poor self-care, and social performance.

► Simple schizophrenia represents an uncommon disorder characterized by a slowly progressive development of negative symptoms without any history of hallucinations, delusions, or other manifestations of an earlier psychotic episode, and with significant changes in personal behavior, manifest as a marked loss of interest, idleness, and social withdrawal.

Epidemiology, Risk Factors, and Course of Symptoms

The incidence of schizophrenia in industrialized countries ranges from 10–70 new cases/100,000, whereas prevalence rates range from 1.6 to 12.1/1,000. The lifetime risk is 0.5–1%. Both "social drift" and environmental risk factors (e.g., drug abuse, migration) might account for an increased prevalence in the lower socioeconomic classes.

Epidemiological studies have shown gender differences in the age of onset of schizophrenia. The peak age of onset is 10–28 years for men and 26–32 years for women. However, there is a second peak of onsets in women after the menopause, resulting in an equal lifetime incidence for both genders. Affected men make contact with the psychiatric services at an average of five years earlier than women do.

Both twin and adoption studies indicate genetic effects in the liability to schizophrenia. Although the mode of transmission has not been clarified, several studies corroborate the so-called multifactorial polygenic model that involves an interaction between many contributing genes and environmental factors (obstetric complications, prenatal infection, neurodevelopmental abnormality, substance misuse, social and psychological factors).

Approximately 20% of patients with schizophrenia improve without relapse and 40% achieve a clinically stable residual state and are socially integrated, whereas approximately one-third of patients suffer from continuous psychotic symptoms and/or increasing social disability. Factors affecting prognosis are listed in Table 6.

Treatment Considerations

The discovery of ► chlorpromazine in the early 1950s introduced an era of effective pharmacological treatment for schizophrenia. Today, antipsychotics of different chemical structures, ranging from tricyclic ► phenothiazines to thioxanthenes, ► butyrophenones, dibenzazepines, substituted benzamides, benzioxazole derivatives, and chinolones are considered to form the backbone of treatment (► Antipsychotic drugs, ► First-generation

antipsychotics, ► Second-and third-generation antipsychotics, ► Future of antipsychotic medication). They shorten the length of an acute episode of the illness and reduce the risk of relapse. Clearly, modern concepts of schizophrenia management include psychosocial and rehabilitative measures, and pharmacotherapy should always be embedded in integrative treatment procedures.

Essentially, the prognosis of schizophrenia depends on when pharmacological treatment is started and on the number of psychotic episodes. Two-thirds of patients experiencing a first episode of the illness experience symptomatic remission within half a year if antipsychotic treatment is started immediately. In addition, consistent prophylaxis with antipsychotic medication results in a reduction of the one-year relapse rate from 75 to 20%. Since less than 50% of patients with schizophrenia in long-term treatment take their medication according to the physician's recommendations, interventions to enhance compliance should be implemented at the beginning of treatment (Fleischhacker et al. 2007).

The parenteral administration of rapid-acting antipsychotics should be confined to emergencies, where acute agitation and lack of insight lead to a high risk of patients harming themselves or others. In contrast, the administration of long acting depot antipsychotics is an important treatment option for the long-term management. The advantages of these injectable drugs include dose reduction due to avoidance of the first-pass-effect, the fact that patients do not need to take medication every day, and the facilitation of management due to certainty concerning compliance. The disadvantages of this type of treatment include the fact that some patients refuse intramuscular injections or develop irritations at the injection site. Another problem is that the dose of a depot antipsychotic cannot be reduced once administered.

Despite continuous new findings in the field of psychopharmacology, there are no reliable predictors for individual drug response/tolerability. Therefore, the choice of medication depends on an individual risk–benefit analysis. In patients who do not adequately respond to two antipsychotic drugs of different chemical classes, switching to ► clozapine is indicated. This compound has been shown to have unique efficacy in so far as it reduces symptoms in 30–60% of treatment refractory schizophrenia patients (Fleischhacker 1999) (► Antipsychotic drugs). However, although pharmacological agents have substantially advanced the treatment of schizophrenia and have had a significant impact on the lives of patients in terms of relapse prevention, ► quality of life, and resocialization there are still considerable unmet needs in the management of these patients.

Schizophrenia: Animal Models

Definition

Animal models for schizophrenia refer to animal preparations which attempt to mimic aspects of the human disorder, schizophrenia. In general, these animal models are subdivided into screening models, in which the therapeutic effects are modelled, and simulation models, in which the emphasis is on the symptoms of schizophrenia.

Current Concepts and State of Knowledge

Screening Models

In screening models, sometimes referred to as animal models for antipsychotic action, the focus is on the pharmacology of schizophrenia (Arnt 2000). The principal aim is to predict the therapeutic effects of novel drugs, based on the efficacy of antipsychotic drugs that have already been in clinical use. Such clinically successful drugs are often referred to as "gold standard." The development of a screening model therefore starts with the identification of an appropriate gold standard. In the early years, this gold standard was usually ▶ chlorpromazine or ▶ haloperidol. In more recent years, screening models often use two gold standards, a so-called classical (most often haloperidol) and an atypical antipsychotic drug (most often ▶ clozapine). The rationale behind this approach is that many clinical studies have shown differences between these two (classes of) antipsychotic drugs. Most notably, while classical antipsychotic drugs induce severe neurological (so-called extrapyramidal) side effects, ▶ atypical antipsychotic drugs do not, or to a much lesser extent. Having two gold standards might help identify which aspects of the screening models are more related to the therapeutic efficacy of antipsychotic drugs (i.e., those aspects in which both gold standards show similar effects) and those that are more related to the side effects (i.e., those aspects that are induced by the classical but not by the atypical gold standard).

After having selected the appropriate gold standard (or standards) the drug is given to an animal, usually a rat or a mouse. In many cases this is a normal, naïve, and untreated animal, but in some cases the animal is trained before hand (such as in the conditioned avoidance response) or treated with a specific drug (such as a dopamine agonist or a glutamate antagonist) to induce a specific behavioral response. Table 1 lists the most often used screening models for schizophrenia.

The effects of the gold standard are then evaluated in this behavioral setup and if a clear reproducible response

is obtained, the model can go into the next and most important phase of model development: the validation phase. In this most crucial phase of the model development, the validity of the model is established on the basis of clinical evidence. ► Antipsychotic drugs have been in clinical practice since the 1950s and therefore a vast knowledge about their clinical effects now exists. From this knowledge base, several criteria can be formulated that can be used to validate a screening model (Ellenbroek 1993). The two most obvious criteria are the absence of ► false negatives and ► false positives. False negatives are drugs that in the model do not resemble the gold standard but in clinical practice are effective antipsychotic drugs. False positives, on the other hand, are drugs that act like the gold standard in the model, but in clinical practice are not effective. Especially this criterion is difficult to test, since there are thousands of compounds available most of which have not been extensively tested in patients. Moreover, it was common practice that many pharmaceutical companies did not publish negative results from phase II or phase III studies, and in several instances contradictory data have been published. The evaluation of this criterion is therefore usually based on a selection based on similarity in chemical structure or drugs with a known influence on motor activity (such as ► diazepam or ► morphine), since such drugs can interfere with behavioral performance in general. Another general criterion is that there should be a correlation between the potency of the antipsychotic drugs in the clinic and in the model. Finally, several other criteria can be specifically deduced from the clinical literature on antipsychotic drugs. One of the most interesting criteria is the lack of effect of anticholinergic drugs. The rationale behind this criterion is that while anticholinergic drugs do not influence the therapeutic effect of antipsychotic drugs, they do diminish the extrapyramidal side effects. Thus, anticholinergic drugs can be useful to distinguish between parameters modelling the therapeutic and the unwanted side effects. The same holds true for chronic treatment with antipsychotic drugs. It is well known that the therapeutic effect usually increases with prolonged treatment, whereas the ► extrapyramidal side effects usually wane with repeated administration. Table 1 tries to summarize the vast literature on the validation of the screening models for schizophrenia (Ellenbroek 1993).

Once the validation phase has (satisfactorily) finished, the model goes into the final stage in which novel compounds can be evaluated and compared to the gold standard(s). Once a promising new drug candidate has been identified (that also shows a good ► pharmacokinetic and safety profile) it can then be tested in clinical trials.

Although most of the currently available treatments for schizophrenia have been developed using screening models, they have received much less attention in recent years. The principal reason for this is that such screening models, how predictive they may be, will always produce drugs similar to the gold standard (often referred to as a "me too" approach). Indeed, this probably explains why there are so few differences between the currently available drugs. However, in spite of this disadvantage, screening models are still being used because they are usually quick and easy, but also because they can help us to understand the mechanism of action of antipsychotic drugs and especially the differences between classical and atypical antipsychotic drugs.

Simulation Models

Since screening models will unlikely lead to a major breakthrough in the treatment of schizophrenia, attention has in recent years shifted more and more to simulation models. This shift was aided by the increasing clinical knowledge of the disease. In simulation models, one tries to mimic as many aspects of a disease as possible. In its simplest form, this requires two steps: (1) the induction of the disease and (2) the measurement of the symptoms. Unfortunately, both steps have proven to be very difficult in the case of schizophrenia. With respect to the symptoms, most of the cardinal symptoms (especially the so-called positive symptoms such as ► hallucinations and ► delusions) in humans can only be assessed in a psychiatric interview. Since such symptoms can not be modelled in animals, researchers have resorted to negative symptoms (such as anhedonia and social withdrawal) and symptoms within the cognitive domain (such as ► attention and ► (working) memory). In addition, much attention has recently been paid to so-called ► endophenotypes and potential biomarkers for schizophrenia. It is beyond the scope of this chapter to discuss all the aspects of endophenotypes, but in general, they are physiological or psychological phenomena that have a genetic basis and are associated with the specific disease. The idea behind such endophenotypes is that they may be more related to specific brain structures and neurotransmitter functions than the symptoms of the disease. Moreover, they are usually easier to model in animals. In the case of schizophrenia, several endophenotypes have been proposed, such as smooth eye pursuit movement, P_{50} sensory gating and ► prepulse inhibition. Especially the latter two can also quite easily be assessed in animals. Biomarkers are also increasingly considered to be of great value for diseases, although the traditional peripheral (for instance blood or urine) analyses may not be very relevant for

central nervous system disorder such as schizophrenia. However, with the advent of modern functional imaging new possibilities have occurred. For instance, using ► PET and ► SPECT scan analyses, it has been shown that psychotic patients have an increased basal as well as amphetamine-enhanced dopamine release in the basal ganglia. Using ► microdialysis techniques such changes in dopamine release can also be measured in freely moving animals. Thus, although the cardinal symptoms of schizophrenia seem to be beyond modelling in animals, other symptoms, biomarkers, and endophenotypes can be assessed in humans and animals often with more or less identical techniques and offer the possibility to assess vital aspects of schizophrenia in rats and mice.

However, even though we can measure social behavior, prepulse inhibition, dopamine release and other phenomena, the crucial step in animal modelling is to induce a disturbance in these phenomena that resemble the disturbance in the disease. There are several different approaches to achieve this and those approaches will be discussed in the following sections.

Spontaneous Models

One way of identifying a potentially interesting model is to compare different strains of rats or mice, to see whether certain strains have deficits in specific signs or symptoms of a disease. In the case of schizophrenia for instance, Brown Norway and Brattleboro rats show deficits in prepulse inhibition compared to Sprague Dawley and Lewis rats respectively. Interestingly, these animals also show other abnormalities related to schizophrenia and have thus been suggested to represent "spontaneous models" for schizophrenia.

An alternative to investigating different strains of animals is to investigate individual animals within one strain to identify extremes within a normal population. Once such individuals have been identified, the next step is usually to try to breed these extremes selectively in order to establish a colony of high and low responders to a specific situation. For instance, there have been several approaches to selectively breed animals with a poor performance in the prepulse inhibition. Many years ago, we started to select Wistar rats on the basis of their gnawing response to ► apomorphine. After only a few generations, there was an almost complete separation in susceptible (APO-SUS) and unsusceptible (APO-UNSUS) animals. Further experiments showed that the APO-SUS animals shared a large number of symptoms with schizophrenic patients (such as enhanced sensitivity to ► stress, enhanced dopamine release, reduced prepulse inhibition, etc.).

Thus, the spontaneous approach has led to several potentially interesting models. However, very few have been investigated in detail (for instance with respect to their validity) and the lack of a clear link (even if it is only theoretical) to the etiology of schizophrenia has limited the widespread use of them. In this respect, it is important to emphasize that none of the symptoms of schizophrenia are pathognomic, and that deficits in prepulse inhibition, for instance, occur in many diseases. Thus an animal with a deficit in prepulse inhibition does not immediately constitute an animal model for schizophrenia.

Pharmacological Models

It has long been known that certain drugs can induce symptoms resembling those seen in psychiatric or neurological disorders. Thus, ► antipsychotic drugs can induce a parkinsonian like ► rigidity and ► akinesia, and ► reserpine can induce depressive-like symptoms. Likewise, dopamine agonists such as ► amphetamine and NMDA antagonists such as ► phencyclidine can induce schizophrenia-like symptoms. Whereas amphetamine induces predominantly (positive) psychotic symptoms (though it can induce negative or cognitive deficits too), phencyclidine seems to be able to induce the full spectrum of schizophrenia. Such pharmacological tools have very often been used in animal modelling as well, and both drugs induce a large number of schizophrenia-like abnormalities in animals. Hence, amphetamine increases dopamine release, reduces prepulse inhibition, P_{50} gating and social behavior (especially in monkeys). Phencyclidine induces virtually the same symptoms as amphetamine, but several pharmacological studies have shown that this model is mediated via different mechanisms. For instance, all known antipsychotic drugs can reverse the amphetamine-induced deficits in prepulse inhibition, whereas most of these drugs do not reverse the phencyclidine-induced prepulse inhibition (Geyer et al. 2001). A more fundamental problem with these pharmacological models is that they induce only very short-lived symptoms, and the validity for the schizophrenic process (which is a chronic process probably already starting before birth, see below) is questionable. Indeed models such as the amphetamine or phencyclidine-induced deficit in prepulse inhibition are now often regarded more as screening models (similar to amphetamine-induced hyperactivity) than as simulation models (see also Table 1).

Etiological Models

The most interesting class of simulation models are those in which one tries to mimic the etiology of schizophrenia. Unfortunately, schizophrenia is a highly complex disorder

with a multifactorial etiology, in which genetic and environmental factors interact. Moreover, the nature of most of the genetic and environmental factors is still largely unknown. Fortunately, clinical genetic research is increasing rapidly and there is now more and more evidence for certain candidate genes associated with schizophrenia. It would go beyond the limits of this chapter to discuss the evidence in favor of each of these genes but the most often associated ones are DISC-1 (disrupted in schizophrenia-1), dystrobrevin, neuregulin-1and regulator of G-protein signalling-4 (Harrison and Weinberger 2005). Although such association studies have led to the development of specific transgenic mice, it should be noted that in different studies, different ► polymorphisms have been linked to schizophrenia and the functional consequence of these polymorphisms is in most cases still unknown, leading to intriguing results. For instance, whereas the heterozygous neuregulin knock-out mouse shows a reduction in prepulse inhibition, patients with the schizophrenia associated neuregulin ► haplotype seem to have increased mRNA and protein levels of neuregulin.

The search for specific environmental factors associated with schizophrenia is even more complicated than the search for genetic factors, since they often predate the onset of the disease by many years (if not decades) and are often only indirectly measurable, as an association between a specific event and the occurrence of the disease. For instance, several studies have reported that exposure to the 1958 influenza pandemic increased the risk of the schizophrenia in the offspring. However, whether this was due to the influenza virus, the medication, the stress of the situation, or other factors is impossible to deduce. Nonetheless, there is quite a large group of environmental factors that can increase the risk of developing schizophrenia. These include winter birth, migration, prenatal malnutrition, pre- and postnatal stressors, perinatal infection, and obstetric complications (Tandon et al. 2008). Some of these factors have also been modelled in animals, such as prenatal stress, prenatal protein restriction, Caesarean section, ► maternal deprivation, and ► isolation rearing (Carpenter and Koenig 2008). Although few of these models have been investigated in great detail, yet some of these manipulations seem to induce quite a variety of the schizophrenia-like signs and symptoms (see Table 2).

In addition to these etiologically based simulation models there are a few additional environmental models where one can argue whether they are really etiologically based, especially the ► early ventral hippocampal lesion model and the ► prenatal MAM model. Both models certainly aim to induce a neurodevelopmental disorder, but there is no evidence that patients with schizophrenia have an early hippocampal lesion nor that neurogenesis was blocked for some time during gestation. Nonetheless, both treatments induce a variety of schizophrenia like signs and symptoms.

The inspection of Table 2 shows several interesting points. Firstly, in contrast to clinical studies, much less data are available for the genetic models than for the environmental models. Secondly, of the signs and symptoms, most interest has focussed on prepulse inhibition, presumably because of the ease of measurement and the similarity to the clinical situation. In contrast, P_{50} gating and anhedonia have received much less attention.

Validation of Simulation Models

As with screening models, simulation models also have to be validated. Although this is often done using the same criteria used for screening models, it is important to note that there is much less clinical evidence that these criteria can be applied. For instance, most of the signs and symptoms in Table 2, including memory, social withdrawal, and anhedonia are related to the cognitive and negative symptoms of schizophrenia, i.e., domains that generally do not respond to antipsychotic drugs. Even with respect to prepulse inhibition, there is insufficient evidence from longitudinal studies whether (some or all) antipsychotic drugs improve this information-processing deficit. Thus, with a lack of clinical data on these signs and symptoms, the validity of simulation models is difficult to assess.

Gene – Environment Models

The models described earlier and in Table 2 are based on either genetic or environmental factors. However, there is a vast amount of evidence that schizophrenia results from an interaction between genetic and nongenetic factors (Van Os et al. 2008). So far, this interaction has received little attention in animal modelling. Some of the environmental manipulations have been performed in different strains of rats, such as early hippocampal lesions, isolation rearing, and maternal deprivation, but extensive gene – environment interactions still need to be performed. Nonetheless, some interesting findings have already been reported. Thus, compared to Sprague Dawley or Wistar rats, Lewis rats seem to be much less sensitive to early hippocampal lesioning, isolation rearing, and maternal deprivation (Ellenbroek and Cools 2000; Lipska and Weinberger 1995; Varty and Geyer 1998). This finding suggests that the genetic make-up of the Lewis rats may somehow be protective to these different manipulations. It would be of great interest to try to identify the underlying protective mechanism.

Summary

Schizophrenia is a severe psychiatric disorder with an unknown etiology and complex symptomatology. This has severely hindered the development of appropriate animal models. In the past, most therapeutic agents were developed using so-called screening models, in which novel compounds were compared to known therapeutic agents. Although these models are still in use nowadays, it is highly unlikely that they will lead to a major breakthrough in therapy. With the identification of specific signs and symptoms, including biomarkers and endophenotypes that could also be assessed in animals, the field of animal modelling obtained the boost it needed. Moreover, genetic and epidemiological studies have started to identify specific genes and environmental factors that contribute to the disorder. This has led to a wealth of novel simulation models in the last decade, most of which are still in a very early exploratory phase and have not yet been properly validated. The most important challenge for the coming years will be to merge the two types of etiologically based simulation models in order to investigate the gene – environmental interaction, which is crucial for the occurrence of schizophrenia.

Secobarbital

Synonyms
Secobarbitone

Definition
Secobarbital is an intermediate- to short-acting (half-life 15–40 h) barbiturate drug that is used primarily as a hypnotic agent to treat insomnia. It is also used as a premedication before surgery and for the emergency management of seizures. Secobarbital is an agonist at ► $GABA_A$ receptors thereby increasing inhibitory ► GABAergic transmission in the CNS. It binds to a distinct site upon the $GABA_A$ receptor ion channel complex increasing the duration of time for which the Cl^- channel is open. Secobarbital, like other barbiturate drugs, has a narrow therapeutic window, that is, a small difference between the minimum effective dose for sedation and maximum tolerated dose producing coma and death. Long-term use of this drug is

contraindicated because of its ability to produce tolerance and dependence, and abrupt withdrawal from chronic treatment precipitates a life-threatening withdrawal syndrome. It is used illicitly for the purposes of getting high, to reduce anxiety, to counteract the effects of stimulant drugs, for example, cocaine, ecstasy, and in suicide.

Second and Third Generation Antipsychotics

Gary Remington
Centre for Addiction and Mental Health, Department of Psychiatry, University of Toronto, ON, Canada

Synonyms

Atypical antipsychotics; Novel antipsychotics

Definition

This class of antipsychotics, with clozapine as the prototype, are distinguishable from their first generation counterparts by a lower liability for ► extrapyramidal symptoms (EPS) and claims of improved efficacy that extend to other domains beyond psychosis (e.g., cognition, negative symptoms). These drugs have been designated "atypical" when compared to the older "typical" or conventional antipsychotics like ► chlorpromazine, ► haloperidol, ► perphenazine and ► fluphenazine.

The distinction between second and third generation antipsychotics has been made based on mechanistic differences. Specifically, aripirpazole is the first approved antipsychotic that is a partial ► dopamine agonist and, as such, has been designated a ► third generation antipsychotic. This presumes that all other atypical compounds to this point, including clozapine, share some common attribute(s) pharmacologically that account for their unique clinical profile. However, beyond dopamine D_2 antagonism, which characterizes all antipsychotics including ► aripiprazole, this is not the case. For example, the ► serotonin 5-HT_2/dopamine D_2 model does not adequately represent all of these compounds (see *Atypicality: Mechanisms of Action*, below). Thus, as a partial dopamine agonist aripiprazole is unique amongst the atypical antipsychotics but the distinction between second and third generation agents may misrepresent the homogeneity of all other atypicals.

Pharmacological Properties

First Generation Antipsychotics and Limitations

Antipsychotics were introduced for clinical use in the 1950s. At the time, descriptive terminology included "► major tranquilizers" (because of their sedating/calming effect) and "► neuroleptics," literally meaning "to take the neuron" and reflective of their liability for motor side effects (i.e., EPS). They rapidly became the treatment of choice for psychotic conditions such as schizophrenia although it was initially unclear as to what aspect of their diverse pharmacology accounted for this effect. Within the next years, it was established that dopamine D_2 binding seemed critical to the antipsychotic effect and this generated an additional subgroup of these drugs characterized by high affinity for the dopamine D_2 receptor, drawing a distinction between low-potency (e.g., chlorpromazine) and high-potency (e.g., haloperidol) neuroleptics. A liability for EPS, both acute (e.g., parkinsonism) and chronic (e.g. ► tardive dyskinesia or TD) characterized all these drugs and represented a substantial burden to their use in the clinical setting.

Clozapine

Clozapine, developed in the 1960s, was notable for its antipsychotic efficacy in the face of minimal EPS at therapeutic doses. It was introduced for clinical use in the early 1970s but soon withdrawn in a number of countries because of a cluster of deaths, subsequently linked to its associated risk of agranulocytosis. Work in the late 1980s, though, underscored this drug's superiority in ► treatment resistant schizophrenia and suggested it might also have broader efficacy (i.e., negative as well as positive symptom improvement). By the 1990s it was reintroduced in different countries with the associated requirement of regular hematologic monitoring.

Atypicality

Atypicality has been defined as lack of EPS at therapeutic doses (Meltzer et al. 2003). At the time of clozapine's development, it was unique amongst existing antipsychotics in this regard, establishing it as the prototype of atypicality. Over time, a new class of antipsychotics

(second generation) was developed to mirror clozapine's clinical benefits while circumventing its adverse side effects, in particular risk of agranulocytosis. In this process, it was assumed that these drugs would also mirror clozapine in other regards (e.g., greater efficacy in treatment resistant schizophrenia, improvement in negative as well as positive symptoms). With a new class of antipsychotic available, the previous medications came to be designated "first generation" (vs. second generation), "typical" (vs. atypical) or "conventional" (vs. novel).

Atypicality: Mechanisms of Action

Several aspects of clozapine's diverse pharmacology were highlighted as possibly contributing to its unique clinical profile. These included its low binding affinity for the dopamine D_2 receptor in addition to comparatively high binding at the serotonin 5-HT_2 receptor. An elegant body of pre-clinical work led Meltzer et al. to postulate that the profile of greater serotonin 5-HT_2 versus dopamine D_2 binding accounted for clozapine's atypical features (Meltzer et al. 2003), a model that was rapidly embraced in drug development and one that describes most second generation antipsychotics including ▶ olanzapine, ▶ paliperdione, ▶ quetiapine, ▶ risperidone, ▶ sertindole, ▶ ziprasidone and ▶ zotepine. Critical to this model is the ratio of serotonin 5-HT_2 versus dopamine D_2 binding; earlier antipsychotics demonstrated combined serotonin 5-HT_2/dopamine D_2 antagonism but did not meet this identified ratio and were not seen as unique clinically.

Clozapine's low affinity for the dopamine D_2 receptor also called into question the longstanding argument that dopamine D_2 antagonism is absolutely critical for antipsychotic efficacy. This encouraged efforts to look at non-dopaminergic strategies and, following the importance this model ascribed to serotonin, led to work investigating the notion that serotonin 5-HT_2 antagonism alone might be sufficient (e.g., ritanserin, MDL-100907, fanaserin). While this was not substantiated, there continues to be interest in the pursuit of antipsychotic development that is not hinged on dopamine blockade.

Although the serotonin 5-HT_2/dopamine D_2 model was widely embraced, there was reason to pursue other explanatory models. In countries outside of North America, ▶ amisulpride and ▶ sulpiride (substituted benzamides) are accessible clinically and seen as atypical; however, their pharmacological profile precludes an explanation based on serotonin 5-HT_2/dopamine D_2 antagonism. At least two other models have since been posited to account for the atypical features of newer antipsychotics. The "low affinity-fast dissociation" model (Kapur and Seeman 2001) holds that clinical benefits such as decreased EPS, lack of prolactin elevation, and possible improvement in cognitive and negative symptoms may occur as a result of transient binding at the dopamine D_2 receptor, which mitigates against impairment of phasic dopamine release. Thus, while all drugs depress tonic dopamine release, those with more rapid dissociation (i.e., fast K_{off} drugs) are less likely to alter phasic dopamine release, essential for dopamine to exert its physiologic effects in the course of daily activities. There is, for example, abundant evidence linking dopamine to reward and goal-directed behaviors, as well as cognition (Berridge 2007). This line of thinking suggests there may be clinical gains through what these drugs *don't do* (i.e., sustained dopamine blockade) rather than by unique gains attributable to some other aspect of their rich receptor-binding profiles (e.g., concomitant serotonin 5-HT_2 binding).

A second hypothesis ascribes the clinical gains associated with atypicality to limbic selectivity (Bischoff 1992) and support for this comes from several lines of investigation (Remington and Kapur 2005). Looking at early gene expression (c-fos and c-jun) as a marker of synaptic activity, it has been noted that as a class the newer antipsychotics are associated with regional differences (e.g., increased c-fos expression in limbic versus striatal regions). Similarly, more recent opportunities to examine D_2 binding extrastriatally have provided evidence that atypical antipsychotics demonstrate preferential binding for extrastriatal structures, for example temporal cortex. This could account for the diminished risk of EPS and ▶ hyperprolactinemia, as well as a more direct effect on other brain regions. Of note, while the atypicals as a class are associated with decreased EPS and a diminished risk of hyperprolactinemia, this is variable; risperidone, paliperidone, and the substituted benzamides carry a greater liability. It has been suggested that the limbic selectivity model is, at least in part, a variation of the low affinity-fast dissociation hypothesis in that the decreased binding in striatal regions reflects competitive displacement by endogenous dopamine at dopamine D_2 receptors in dopamine-rich regions.

The distinction between aripiprazole and other atypical antipsychotics is, in contrast, clearer and draws upon a shift in thinking regarding dopamine's role in schizophrenia. For decades, the most widely held biochemical model for schizophrenia posited a disorder of hyperdopaminergic activity. However, by the 1980s a clearer distinction was drawn between positive and negative symptoms, and subsequently our conceptualization of schizophrenia has broadened even further to include other domains (e.g., cognition). In the context of these changes, dopamine's role has been reframed to accommodate its differential

involvement in this expanded model, suggesting more complex feedback loops involving various dopamine receptors and other neurochemical systems. For example, while limbic structures, dopamine D_2/D_3 receptors, and hyperdopaminergic activity have been implicated in the positive symptoms, cognitive and negative symptoms have been linked to prefrontal regions, a role for dopamine D_1 receptors, and hypodopaminergia.

In this context, drugs that affect dopamine differentially may have distinct clinical advantages and aripiprazole's proposed dual action on dopamine fits with this line of thinking. A partial dopamine agonist acting on postsynaptic D_2 receptors as well as presynaptic dopamine autoreceptors, its effects are linked to whether dopamine activity is high (i.e., mesolimbic) or low (i.e., mesocortical). Thus, through its antagonist properties it diminishes positive symptoms (mesolimbic), while its agonist profile results in improved negative and cognitive symptoms (directly at the mesocortical level and indirectly at the nigrostriatal level in the form of attenuated EPS).

The popularity of each of these models speaks to the importance of dopamine and serotonin in explaining the unique clinical benefits of the newer antipsychotics, but these drugs are characterized by diverse pharmacological profiles that impact a variety of receptors and systems (e.g., acetylcholine, norepinephrine, histamine, glutamate) (Remington and Kapur 2005). Although the currently available newer antipsychotics can each be characterized by one of the aforementioned models, the potential role (s) of these other systems remains a subject of investigation, both in terms of therapeutic efficacy as well as side effects. The involvement of other receptors and systems has taken on added interest with the growing body of evidence conceptualizing schizophrenia as a disorder of multiple symptom domains (e.g., positive, negative, cognitive, affective), paralleled by increased awareness regarding the clinical and functional importance of these other nonpsychotic features. The potential benefits of an effective antipsychotic without direct dopamine blockade remains alluring, ensuring the search for new antipsychotics focused on other systems thought to play an important role in schizophrenia.

Atypicality: Second/Third Generation Antipsychotics

While Meltzer et al. defined atypicality as absence of notable EPS at therapeutic doses (Meltzer et al. 2003), evidence clearly indicates that the newer antipsychotics are not the same in this regard. For example, risperidone has been identified as having a greater liability for EPS than many other atypical agents, a risk that is dose-dependent – this also distinguishes it from other atypicals such as clozapine and quetiapine. It must also be noted that the benefits of the atypical antipsychotics, particularly agents like risperidone, in terms of EPS have been challenged on methodological grounds; often comparator trials with first generation antipsychotics have used haloperidol, which has a notable propensity for EPS, and at doses in excess of what are currently recommended. It remains, though, that as a class the atypicals have been associated with diminished risk of EPS and it is this defining feature that best distinguishes atypical antipsychotics from their conventional counterparts.

Although classifying medications based on presence or absence of a particular side effect may seem misguided, it has occurred again more recently with the growing recognition that the newer antipsychotics, in particular agents like clozapine and olanzapine, demonstrate a substantially greater risk for weight gain and associated metabolic disturbances. At least some regulatory bodies have chosen to identify this as a class effect characterizing all atypicals although evidence clearly indicates that, as with EPS, there are marked differences between these drugs on this dimension. For example, at the other end of the continuum from olanzapine and clozapine are drugs like ziprasidone and aripirazole that are considered to be "weight neutral" (Newcomer 2007).

Other definitions, for example based on mechanism(s) of action, are even less homogeneous. While the serotonin 5-HT_2/dopamine D_2 hypothesis dominated initial efforts to replicate clozapine's clinical advantages, agents now classified as atypical cannot be collectively grouped within this model. Clozapine, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone and zotepine can be categorized as serotonin 5-HT_2/dopamine D_2 antagonists but this is not the case for amisulpride and sulpiride, where their benefits might best be explained by the low affinity-fast dissociation model. In fact, it has been argued that this same model could as readily explain the benefits of drugs that meet criteria for serotonin 5-HT_2/dopamine D_2 antagonists although this is the subject of ongoing debate. As a partial dopamine agonist, aripiprazole currently stands alone pharmacologically, which has led some to suggest that it represents a third generation antipsychotic. This is, of course, a misnomer if we are to use serotonin 5-HT_2/dopamine D_2 antagonism as the mechanism of action that categorizes all other newer antipsychotics (given the substituted benzamides). The low affinity-fast dissociation explanation might better capture other antipsychotics, but this debate itself speaks to the pitfall of classifying such diverse pharmacological agents on models that are hypothetical and singularly

focused. It is very likely that the clinical gains we are seeking to achieve can be attained through different pathways, and that benefits may be accrued through a combination of pharmacological manipulations.

Attempting to collectively group these agents based on clinical similarities faces similar challenges, (Tandon et al. 2008), made more difficult by the rapid expansion in purported benefits that occurred in parallel to the development of the different atypicals.

The fact that the atypical antipsychotics differ on various measures of efficacy and side effects, in combination with evidence that clinical differences between them and first generation antipsychotics may not be as prominent as once thought, has challenged the utility of terminology like "second generation" (Leucht et al. 2009). As an alternative, it has been argued that this "all or none" approach to categorization should give way to a strategy that allows individual drugs to be defined across a number of relevant measures (i.e., different clinical measures and side effects) (Waddington and O'Callaghan 1997).

Formulations

All atypical antipsychotics are available in oral preparations that call for once daily administration. There are examples where it is recommended that the dose be twice daily, based on shorter elimination half-life (e.g., quetiapine, ziprasidone), although extended-release oral formulations have been developed to address this (e.g., quetiapine). There is some question as to the value of establishing daily dosaging based on peripheral ► pharmacokinetics, as in vivo neuroimaging techniques such as positron emission tomography (► PET) have demonstrated that central kinetics do not necessarily mirror what is observed peripherally.

With certain atypical antipsychotics, variations in formulations have been marketed to ease administration and adherence. These include rapidly dissolving, oral formulations (e.g., risperidone, olanzapine), short-acting intramuscular for acute treatment (e.g., risperidone, olanzapine, ziprasidone), and longer-acting depot formulations for maintenance treatment (e.g., risperidone, administered every 2 weeks). At least some of the first generation antipsychotics had also developed shorter and longer acting injectable formulations, but the rapidly dissolving oral formulation is unique to the newer medications.

Pharmacokinetics

(see ► Antipsychotics)

Efficacy and Effectiveness

Central to antipsychotic development was the goal of more tolerable agents from the standpoint of EPS, but limitations in the efficacy of first generation antipsychotics also represented an impetus. As many as 25–30% of individuals treated with these drugs were designated treatment-resistant or refractory, with an additional subgroup deemed only partially responsive. Furthermore, these drugs, while at least reasonably effective in treating positive symptoms (e.g., ► delusions, ► hallucinations), were not particularly useful in controlling negative symptoms (e.g., amotivation, alogia).

With clozapine there was evidence that it was superior to first generation antipsychotics on both these domains, in addition to its improved EPS profile. Thus, implicit in the development of other antipsychotics that were intended to mirror clozapine was the assumption of similar clinical benefits. As the list of new agents expanded so too did the purported benefits though, with suggestions that these drugs demonstrated clinical superiority on other symptoms (e.g., cognitive, affective) and outcome measures (e.g., quality-of-life, adherence).

Initial efficacy trials generally demonstrated superiority of the different atypical agents versus a first generation antipsychotic on total clinical (e.g., Brief Psychiatric Rating Scale (BPRS), Positive and Negative Syndrome Scale (PANSS)) and positive symptoms scores, and frequently negative symptom scores as well. However, many of these efficacy studies were subsequently challenged methodologically; not only were the trials relatively short (i.e., 6–8 weeks), they often employed haloperidol as the comparator, a typical antipsychotic with notable propensity for EPS, at doses in excess of what are currently recommended.

Similarly, questions arose over claims of superior efficacy in other symptom domains. These followed two lines of thinking: (a) the magnitude of change and extent of difference between the atypical agents and first generation antipsychotics; and (b) factors underlying such changes. With regard to the former, claims regarding the extent of improvement on neuropsychological measures were tempered over time, with current thinking that at best these changes are modest and not of a magnitude that would translate to notable differences in ► functional outcome. For negative symptoms as well, subsequent evidence fostered a rethinking of how much different atypical antipsychotics were. In both cases, initial claims implicated unique aspects of these new drugs and their pharmacology (e.g., greater serotonin 5-HT_2 antagonism). However, an alternative explanation suggested that methodological issues, discussed earlier, favoring the atypicals could account for much of these differences. Further, the possibility was raised that gains could be explained, at least in part, not by what these drugs did through different receptors and systems compared to first generation antipsychotics, but by what they didn't do (i.e., invoke high and sustained

levels of dopamine D_2 binding). Evidence demonstrated that this was associated with various adverse effects beyond motor and endocrine problems (EPS and hyperprolactinemia), including dysphoria, amotivation, and cognitive impairment.

More recently, the research focus shifted from an assessment of atypical antipsychotics in the context of smaller and circumscribed efficacy trials to larger ▶ effectiveness studies thought to be more representative of "real world" clinical practice. Once again, results have suggested that differences between atypicals and first generation antipsychotics are notably smaller than once thought. They have also provided further evidence that clozapine is clinically superior, even amongst other atypicals, in treating treatment resistant schizophrenia. Of note, there is some suggestion that amongst other atypical antipsychotics there may be clinical differences, a position that has been supported through other larger scale approaches such as meta-analytic studies. As of yet, such differences are not well established, with methodological issues (e.g., dosing) making conclusions of this sort difficult (Leucht et al. 2009; Tandon et al. 2008).

Treatment Algorithms

Current guidelines advocate atypical antipsychotics as first-line treatment for schizophrenia and related psychotic conditions. There is a lack of evidence that these drugs are more effective in this population, although decreased liability for EPS, including TD, and hyperprolactinemia, in combination with improved tolerability represent advantages from the standpoint of side effects. However, the increased risk of weight gain and metabolic disturbances that can be observed with at least some of the atypicals, in conjunction with their higher cost and lack of clear clinical superiority, have more recently challenged this position.

Clozapine is generally advocated as treatment of choice following suboptimal response to two antipsychotic trials. This is in line with evidence that it is superior to all other antipsychotics in the treatment resistant population, and that treatment resistance can be seen quite soon after the illness' onset. There is no consistent evidence that combinations of antipsychotics, including those that include clozapine, offer superior clinical efficacy in individuals who have not responded to monotherapy (i.e., one antipsychotic).

Paralleling the increased number of atypical antipsychotics has been a rise in off-label use of these medications and efforts to expand their indications. Their efficacy in a variety of psychiatric disorders is being examined (e.g., ▶ pervasive developmental disorder; ▶ generalized anxiety disorder; psychotic depression), and as a result their approved indications has grown (e.g., ▶ autism; ▶ bipolar disorder, manic and mixed states), depending on agent and regulatory body.

Side Effects

As a class, the atypical antipsychotics continue to be seen as better from the standpoint of EPS, although such a distinction is less clear depending on a variety of factors that include specific agent, comparator first generation antipsychotic, and dose. Current evidence, albeit limited, does favor the atypicals as well in terms of TD risk (Correll and Schenk 2008), a significant clinical advantage should this finding hold true. There is also an indication that as a class the atypical antipsychotics might be better tolerated. While there was an expectation that such benefits would translate to improved adherence, this has not been confirmed, a reminder that non-adherence is complex and multi-factorial.

Atypical antipsychotics, to varying degrees, also share side effects that were identified with their first generation counterparts (e.g., sedation, postural hypotension). In general, the atypicals have a lower risk of hyperprolactinemia, although this is variable; risperidone, paliperidone, and the substituted benzamides carry a greater liability. There was anticipation that ▶ neuroleptic malignant syndrome (NMS), a potentially fatal adverse event that can occur with all first generation antipsychotics, would be diminished or even absent with the atypical agents; however, all of the newer drugs to date, including clozapine, appear to carry this risk and it is not yet clear as to whether the overall liability has been reduced.

Although the atypical antipsychotics appear superior from the standpoint of movement disorders, concern has been raised about their increased liability for weight gain and associated metabolic disturbances, including dyslipidemia and type 2 diabetes. This, in turn, translates to a greater risk of metabolic syndrome, cardiovascular risk and associated mortality. There is added concern because schizophrenia has already been associated with a shortened lifespan (independent of suicide) which may be related to various factors (e.g., economic, lifestyle, access to medical care). Moreover, there is some evidence to suggest that schizophrenia itself may be a risk factor for diabetes. As with EPS, the atypicals vary in risk of weight gain, with olanzapine and clozapine identified as carrying the greatest risk, while at the other end of the spectrum aripiprazole and ziprasidone have been identified as "weight neutral" (Newcomer 2007).

In the geriatric population, atypical antipsychotics have been associated with increased risk of death (in the range of 1.6 fold) from varied causes (e.g., cardiovascular, infectious). In fact, though, both typical and atypical

antipsychotics have been linked to increased mortality rates in schizophrenia (Weinmann et al. 2009). Data regarding safety and efficacy in the pediatric population are limited.

Conclusions

With clozapine as the prototype, a number of new antipsychotics have been developed. Collectively, they have been termed "atypical" and further distinguished as "second" or "third generation" antipsychotics. Atypical differentiates these drugs from their conventional counterparts based on clinical profile, specifically diminished risk of EPS, although this definition subsequently broadened to include a variety of other measures. The distinction between second and third generation antipsychotics is mechanistic, with aripiprazole (third generation) the only atypical antipsychotic to date that is a partial dopamine agonist.

The difference between these newer drugs and so-called typical antipsychotics may not be as notable as once thought, with the exception of clozapine's clinical superiority to all other antipsychotics in treatment resistant schizophrenia. Further, "atypical antipsychotics" implies a homogeneity amongst these newer drugs and separation from first generation antipsychotics that may be both misleading and confusing. There are differences between atypicals on a variety of clinical/biological measures, and even the distinction between second and third generation antipsychotics implies two distinct mechanisms of action. However, this belies the complexity of pharmacological features that may underlie clinical differences.

This said, the atypical antipsychotics represent a clinical advance and the first notable shift in schizophrenia's pharmacotherapy since chlorpromazine. Moreover, they have stimulated numerous lines of research that have substantially impacted our understanding and conceptualization of schizophrenia. The clear limitations of these medications as well in terms of clinical response and side effects, though, underscore the need for better drugs. The widespread claims of atypical antipsychotics were in keeping with a "magic bullet" approach, where a single drug could be effective across the multiple symptom domains now defining schizophrenia. However, it may well be that a multi-dimensional approach, premised on the notion that each domain reflects different pathophysiologic mechanisms, proves a more useful strategy.

Second-Order Schedules

Definition

In a second-order schedule of reinforcement, a contingency arrangement under which a series of responses under a schedule of conditioned reinforcement is treated as a unit response under a second schedule that is simultaneously in effect. For example, under a second-order fixed-ratio 10 schedule of food delivery with fixed-ratio 5 units, every fifth response produces a conditioned reinforcer (e.g., a visual stimulus) and the completion of the tenth fixed-ratio 5 units produces the conditioned reinforcer accompanied by food delivery.

Definition

Benzodiazepines are widely prescribed for sedative, hypnotic, and anxiolytic purposes. In this chapter, I focus on benzodiazepine dependence, although similar considerations may pertain to certain nonbenzodiazepine hypnotics (e.g., ► zolpidem, ► zopiclone), and even to ► alcohol dependence (although I will not discuss this here). Criteria for substance dependence are provided in the most recent editions of the *Diagnostic and Statistical Manual of Mental Disorders* (fourth edition-revised) (American Psychiatric Association 1994) and the *International Classification of Disease* (tenth edition) (World Health Organizaion 1992). These criteria include ► tolerance (as defined by either a need for markedly increased amounts of the substance to achieve the same clinical effect, or markedly diminished effect with continued use of the same amount of the substance), withdrawal (as defined by either the characteristic ► withdrawal syndrome for the substance, or by the same or similar substance taken to avoid withdrawal symptoms), escalation of dosage, and various features indicative of impairment (e.g., unsuccessful attempts to cut down or control substance use, time spent in activities necessary to obtain the substance, important activities are given up or reduced, continued use despite knowledge of having a problem).

Background

Benzodiazepines were introduced in the 1950s, and over subsequent decades, became widely prescribed for various psychiatric symptoms, including agitation, ► insomnia, and ► anxiety. There has long been a controversy about whether such widespread use of ► benzodiazepines is appropriate (Ashton 1989; Lader 1983). On the one hand, these agents appear to be effective for the short-term treatment of several anxiety disorders and insomnia, and are far safer than the older ► barbiturates. On the other hand, the benzodiazepines are not effective for all anxiety disorders, have important ► adverse effects, and may be difficult to withdraw. Although the nonbenzodiazepine hypnotics, or "z-drugs" (e.g., zolpidem, zopiclone) may have a more advantageous adverse event profile, similar concerns again arise (Lader 1997). The animal behavioral literature is consistent with the relevant clinical observations (Lader 1994).

Soon after the introduction of the ► selective serotonin reuptake inhibitors for depression, many of these agents received extensive study for the treatment of several anxiety disorders (► generalized anxiety disorder, ► obsessive-compulsive disorder, ► panic disorder, social phobia). These agents are effective for a broader range of anxiety disorders than are the benzodiazepines, and their robust antidepressant effects are valuable, given the high prevalence of comorbid depression in anxiety disorders. Further, they are relatively safe agents, and withdrawal is not typically problematic. Thus, they are widely advocated as the first line of pharmacotherapy for most anxiety disorders, for both acute symptoms, and for maintenance management (Bandelow et al. 2008).

Although there is clear support for the SSRIs in the treatment of anxiety disorders, there remains ongoing debate about the specific role of the benzodiazepines in these conditions. A number of studies indicate that when prescribed together with the SSRIs, the benzodiazepines may facilitate early ► efficacy and tolerability. However, by 6 or 8 weeks of treatment, no advantage is seen in patients initially co-prescribed benzodiazepines. Similarly, many clinicians would recommend benzodiazepines only in the short-term for patients with psychotic disorders, depression with anxiety, and other psychiatric disorders where acute sedation, hypnosis, or anxiolysis is useful. A number of treatment guidelines and consensus statements have emphasize that benzodiazepines should be reserved for short-term use in minimal dosage (Ashton 2005; Lader and Russell 1993).

The issue of whether medium-to-long term prescription of benzodiazepines can be appropriate under any

circumstances remains contentious. There are clinicians who argue that there is a role for long-term benzodiazepine prescription; not all patients respond to other agents such as the SSRIs. There is some evidence of the value of long-term treatment in disorders such as panic disorder, and certain features of dependence (e.g., dose escalation, tolerance) are rarely present. Although the benzodiazepines may not be highly robust antidepressants, they may have some antidepressant effects. However, some authors emphasize the significant adverse events associated with benzodiazepines (with no change over time in cognitive impairment or vulnerability to accidents), argue that long-term prescription inevitably leads to benzodiazepine dependence (with inefficacy and impairment), and conclude that there is rarely a place for such treatments.

Given the availability of the SSRIs for anxiety disorders, and of a range of treatment options for insomnia, it is reasonable to be cautious about medium-to-long-term prescription of benzodiazepines. Certainly, both clinicians and patients should be aware of the associated adverse effects, and the potential difficulties of withdrawal. Particular caution is required in certain populations (e.g., the elderly and those with a prior history of substance dependence). Although dose escalation is not very common, and although there are perhaps patients in whom long-term use of benzodiazepines is useful, given data that benzodiazepine discontinuation is associated with psychiatric and cognitive improvements, it may be useful to consider benzodiazepine withdrawal at regular intervals in those who are on longer-term treatment (Ashton 2005; Lader and Russell 1993).

Role of Pharmacotherapy

The pharmacological mechanisms underlying benzodiazepine tolerance and withdrawal have received considerable study, and may include both desensitization of inhibitory ► GABA receptors and sensitization of excitatory glutamatergic receptors. Benzodiazepine withdrawal symptoms include symptoms of anxiety states (e.g., anxiety, insomnia, ► dysphoria), as well as a range of other characteristic symptoms (e.g., perceptual distortions, depersonalization, confusion). Withdrawal symptoms may be somewhat different in younger patients, and relevant scales have been developed specifically for this population.

As above, some authors have emphasized that few patients on long-term dependence show tolerance, that not all meet criteria for dependence, and that, in some cases, long-term treatment is needed for chronic symptoms. Nevertheless, given data that reduction of benzodiazepines is accompanied by decreased psychiatric and cognitive symptoms, it also seems reasonable to consider benzodiazepine discontinuation in those who are taking it long-term. Certainly, tapering of benzodiazepines is indicated when there are concerns about cognitive impairment or other adverse effects of long-term benzodiazepines, when there is loss of efficacy, or where there is recreational abuse and dependence. Several strategies are useful for encouraging such benzodiazepine withdrawal.

First, gradual dose tapering is important. Rapid tapering can precipitate benzodiazepine withdrawal symptoms, including the more severe ones (e.g., convulsions, psychotic symptoms, ► delirium). A reasonable approach may be to decrease the dose by around one tenth every 1–2 weeks. There has been surprisingly little work comparing different withdrawal regimens (Lader et al. 2009). Thus, a reasonable approach is to individualize the withdrawal regimen; while some patients may be able to discontinue benzodiazepines over 6–8 weeks, others may require many months.

Second, switching to a benzodiazepine with a longer half-life prior to tapering may be useful. This may be particularly necessary in patients using high potency benzodiazepines (e.g., ► lorazepam, ► alprazolam), where trials indicate a higher drop-out rate during attempts at discontinuation (Voshaar et al. 2006). Diazepam, for example, has a slow elimination, allowing a gradual fall in blood concentration. Furthermore, it is available in low dosage forms, including liquid formulations, which allows gradual tapering. Equivalent doses of diazepam can be determined for each of the benzodiazepines.

Third, psychological support can be useful. A range of simple interventions, including clinical audit, information sheets, letter from the GP, reminder cards, or brief consultations have been shown to be effective in controlled studies (Lader et al. 2009). Similarly, elements of cognitive-behavioral therapy, such as psychoeducation and providing support, appear important. Furthermore, CBT may address comorbid disorders, and may be particularly useful in preventing relapse. Patients with high-dose benzodiazepine abuse may require more intensive management, including hospitalization.

Fourth, treatment with concurrent psychotropics may be considered. ► Anticonvulsants, ► antidepressants, ► beta-blockers, ► buspirone, ► flumazenil, and ► gabapentin have all been investigated. A Cochrane review suggested that only ► carbamazepine was useful in assisting in benzodiazepine discontinuation (Denis et al. 2006). However, the available data are insufficient to suggest routine

administration of this agent in benzodiazepine withdrawal. Antidepressants may be useful for pre-existing or emergent comorbid depression.

In general, a stepped approach, beginning with simple interventions, and then proceeding to more intensive ones is appropriate when attempting benzodiazepine discontinuation (Lader et al. 2009). There is a growing database of information about predictors of response to attempts to discontinue benzodiazepines, which may be useful in guiding future interventions (Mol et al. 2007). In the interim, however, it is reassuring to note the relative success of benzodiazepine discontinuation, and the positive effects that this has for many patients.

Selective Association

Definition

Selective association refers to the fact that not all classically conditioned associations can be acquired. Specifically, animals appear better able to associate specific stimuli, for example, tastes and toxicosis, than others, for example, audiovisual cues and toxicosis. These selective associations are thought to be shaped by evolution and to prepare animals for the acquisition of stimulus associations important for survival.

Selective Attention

Definition

Selective Breeding

Definition

Selective breeding occurs when individual animals with specific behavioral (or anatomical or physiologic) traits are bred with animals with similar characteristics. The traits selected are extremes (such as high responders or low responders in a specified task) and are determined by some criterion of deviation from the group mean (e.g., behaviors that are two standard deviations above or below the mean).

Definition

Selective serotonin reuptake inhibitors (SSRIs) are a group of antidepressants that selectively inhibit the reuptake of serotonin into the presynaptic cell. This leads to an increased concentration of serotonin available to bind to postsynaptic receptors. Before the introduction of the SSRIs, the pharmacologic treatment of depression was mainly based on ► tricyclic antidepressants that inhibit the reuptake of serotonin and noradrenaline into the presynaptic cell.

Definition

Selegiline or L-deprenyl is a phenylethylamine, specifically (*R*)-*N*-methyl-*N*-(1-phenylpropan-2-yl)prop-2-yn-1-amine. It is an antidepressant that selectively inhibits the enzyme monoamine oxidase (MAO), preferentially the type B isoenzyme in the recommended low doses. Unlike other MAOIs, selegiline is less likely to interact adversely with the consumption of tyramine-containing food, the so-called cheese reaction. In 2006, the FDA approved this compound for the treatment of major depression in the form of a transdermal patch (Emsam Patch). It is most often used in the treatment of ► Parkinson's disease in interaction with L-DOPA.

The side effects of selegiline are similar to those of amphetamine-like stimulants and may comprise cardiovascular, respiratory, motor, and perceptual problems.

Self-Administration of Drugs

Synonyms

Drug seeking; Drug taking; Self-injection

Definition

"Self-administration" is an experimental technique which gives subjects, to some extent, control over the ingestion of a drug. In essence, the method is an ► operant conditioning procedure in which drug delivery is made contingent on a particular response emitted by the subject. A variety of species have been tested in self-administration procedures including human; however, the vast majority of published self-administration studies have examined oral or intravenous drug intake in rats or nonhuman primates. Self-administration techniques are used to study the reinforcing effects and underlying neurobiology of different classes of reinforcing drugs, to evaluate ► abuse liability of specific agents and to model the addiction process.

Impact of Psychoactive Drugs

History

There was a time when human intelligence was considered an essential requirement for the voluntary ingestion of drugs of abuse, such as ► heroin or ► cocaine. Given this bias, it was considered unlikely that any animal would self-administer psychoactive drugs.

In one of the earliest reports to challenge the prevailing dogma that drug addiction was exclusively a human condition. Spragg (1940) reported that chimpanzees would "work intentionally" to receive a ► morphine injection. The chimps received daily injections of morphine until there was clear evidence that ► physical dependence had developed (i.e., the appearance of withdrawal signs when the drug was withheld). Spragg then showed that chimps would engage in a sequence of responses that resulted in a morphine injection. If the animal were drug deprived, it would select the correct "key" (a colored wooden stick), turn, walk to a particular box, open it with the key, remove a syringe containing morphine and hand it to the investigator who would deliver an intramuscular injection of morphine. When not drug-deprived the

chimp would select a different key which provided access to food inside a different box.

Spragg wrote

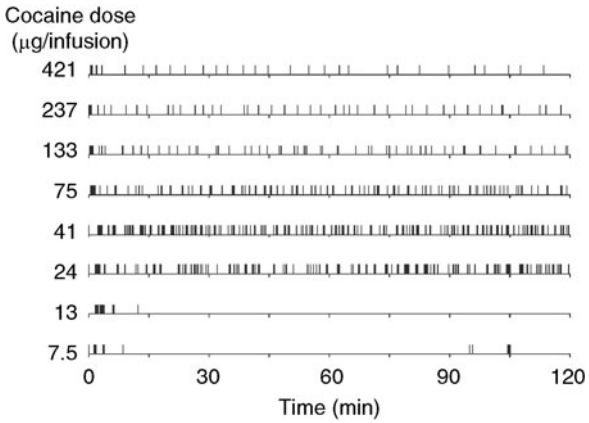
> ...since morphine addiction seems to depend essentially upon forming an association between the administration of the drug and the alleviation of withdrawal symptoms, and since this sequence involves a time lag of 10–15 min or more, the value of using subjects high enough in the phyletic scale to be able to make a delayed association of this nature is obvious. By this token, animals such as the rat, for example, could probably never become addicted to morphine, simply because they are not capable of forming associations of this order... (p 126)

The quote illustrates two important presumptions of the early literature. The first is the notion that drug taking is phylogenetically biased toward primates and the second is that ► physical dependence is a necessary precondition of drug self-administration in animals. These assumptions went unchallenged for two decades.

Weeks (1962) of the Upjohn Company published a seminal paper which marked the beginning of modern self-administration studies. By combining operant conditioning techniques, a pump mechanism that delivered precise amount of drug and a chronically indwelling jugular catheter that allowed animals to move freely within a cage, Weeks demonstrated that rats learned to respond on a lever which resulted in the delivery of an intravenous injection of morphine. Clearly rats were capable of making the correct associations and were able to self-administer morphine. Weeks' initial demonstration used animals that were first made physically dependent. Later, however, it was shown that physical dependence was not a necessary precondition for drug self-administration. Readers are referred to the 1978 NIDA Monograph No. 20, Self-Administration of Abused Substances: Methods for Study (http://www.drugabuse.gov/pdf/monographs/20.pdf) for a collection of reviews which summarize the foundational work in the field.

Patterns of Intake

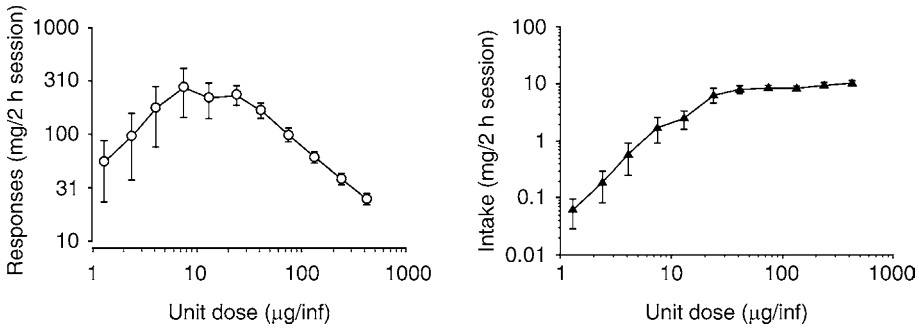
The pattern of drug self-administration depends on the pharmacological class of the drug as well as experimental factors such as dose, price, and availability. Figure 1 shows the pattern of ► cocaine self-administration in a rat using the most basic schedule, a ► Fixed Ratio 1 (FR1). Note the brief burst of responding in the first few minutes of the session; for the remainder of the session the interval between each injection is relatively consistent. As the unit dose is reduced, the number of self-administered injections increase within the 2-h session until, at some point, the dose no longer supports sustained responding (bottom two event records). This dose–response relationship for a group of animals is shown in Fig. 2 (*left*). The gradual ascending limb apparent to the left of the apex is an artifact of averaging across a group of animals and does not reflect the fact that the behavior of an individual animal shows an abrupt change from a non-reinforcing to a threshold reinforcing dose (see Fig. 1). To the right of the apex is a descending limb with a very small variance surrounding the mean rate at each dose. Figure 2 (*right*) shows the same data plotted according to total drug intake during the session. This graph illustrates that above some threshold dose animals tend to self-administer similar amounts or show a slight increase in intake at each supra-threshold doses.



Self-Administration of Drugs. Fig. 1. Examples of a rat self-administering various doses of cocaine on an FR1 schedule. Each line is an event record of a daily 2 h session with each injection indicated by an *upward* tick. The unit dose for each daily session is indicated to the *left*. The figure illustrates that (above some threshold) lower doses are self-administered more frequently.

Appetitive Versus Consummatory Responses

It is important to distinguish between two related concepts in drug self-administration: appetitive versus consummatory responses. A consummatory response is determined by the route of administration. For example, the consummatory response for ► alcohol might involve opening a bottle and drinking from it. For smoking tobacco or ► crack cocaine, it is the act of preparing and lighting a cigarette or pipe and inhaling the smoke. For intravenous drug use, it is filling the syringe and injecting the drug into a vein. Such consummatory behaviors can become extremely ritualistic and powerful habits.



Self-Administration of Drugs. Fig. 2. The effect of manipulating dose on rate of responding (*left*) and total intake (*right*) for a group of rats. Each rat in the group was implanted with an IV catheter and trained to self-administer cocaine. Each animal was then tested using a descending series of doses as illustrated in Fig. 1. The graph on the *left* illustrates that above a mean threshold dose (apex) the rate of self-administration deceases as the unit injection dose is increased. The graph on the *right* illustrates that in spite of the decrease in the number of injections self-administered, the amount consumed within a session increased gradually with dose (Oleson and Roberts 2009).

By contrast, appetitive responses serve to make the drug available. In humans, appetitive responses might involve working for money to buy the alcohol, tobacco product, or drug; in a laboratory situation it could be pressing on a lever and completing a response requirement. The difference between appetitive and consummatory responses is relatively straightforward in humans; however, the distinction becomes blurred in animals receiving drug via intravenous catheters. The appetitive response is obvious – animals can be shown to work quite hard to receive an injection. But since the drug is infused automatically via a catheter the consummatory act is harder to define. It might be argued the consummatory act is the last response on the lever prior to the injection. With that being the case, the single operant response on an FR1 schedule is both appetitive and consummatory.

Schedules will be reviewed below which attempt to address separately the appetitive and motivational factors which influence drug seeking. For the moment it is assumed that responding on an FR1 is largely consummatory and that the rate and pattern of responding reflects the preferred level of consumption.

Factors Affecting Drug Consumption

The pattern shown in Fig. 1 has been taken as evidence that animals regulate (or titrate) their intake around some preferred blood or brain level. The early burst is a "loading phase," during which blood levels of cocaine increase presumably to a preferred plateau. The subsequent regular pattern reflects a maintenance phase with each post-infusion pause determined by the ► half-life of the unit injection dose. Longer acting drugs, such as ► amphetamine, produce longer post-infusion pauses.

Independent variables such as session length and timeout periods can dramatically affect the daily pattern and rates of consumption. An examination of these factors illustrates the qualitative differences between stimulant and opiate drug use. Subjects given 24 h/day access to cocaine or other stimulant drugs on an FR1 schedule tend to "► binge" for many hours or days. It is unclear what actually terminates a binge; however, animals generally do not eat or sleep during this period so that a deterioration of their physical health probably contributes. A drug binge inevitably resumes after some recuperative drug-abstinence period. Unlimited access to stimulant drugs, therefore, results in a series of binge–abstinence cycles. Toxic effects can accumulate with repeated cycles resulting in an increased likelihood of convulsions. The probability of lethal overdose is extremely high virtually for all psychostimulants tested including cocaine, amphetamine, and ► methamphetamine. This is true for every species tested. By contrast, unlimited access to ► opiates results in a very different outcome. Heroin and morphine intake is relatively circadian rather than binge-like. Drug intake increases gradually over days as ► tolerance and physical dependence develops. The danger of lethal overdose is far less for opiates than for stimulants. Instead, a severe withdrawal reaction during experimenter-imposed opiate deprivation becomes a concern.

Any examination of extended access to stimulant drugs must necessarily limit intake in some fashion to avoid toxicity. The majority of cocaine and amphetamine studies constrain intake by restricting the daily session to 1 or 2 h a day. This produces a very consistent pattern of intake from day to day. Longer sessions (6 h) have been shown to produce an escalation of intake across days

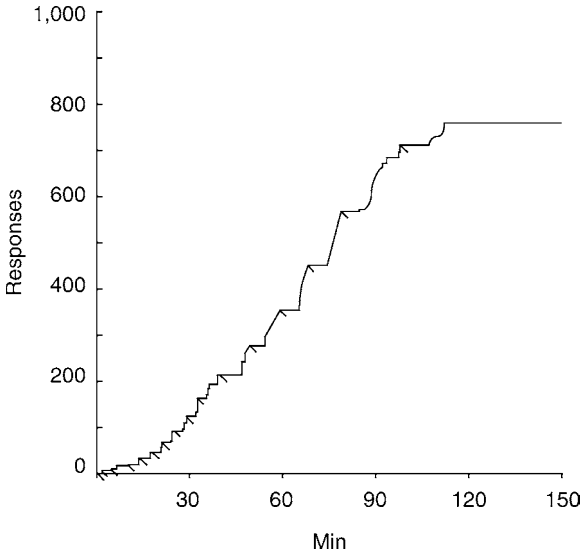
(Ahmed and Koob 1998), modeling an important aspect of the addiction process. Another method of constraining daily drug intake is to restrict the number of injections offered each hour. For example, four discrete trials per hour effectively restrict hourly intake (and the danger of drug overdose or toxicity), while permitting round-the-clock access to drug. When the number of trials and the dose is chosen so as to cap cocaine intake at 3 mg/kg/h, self-administration generally becomes restricted to the active part of the light–dark cycle and will remain circadian over many weeks (Roberts et al. 2002). Binge–abstinence cycles (without lethality) are engendered by higher hourly access (7.5 mg/kg/h).

Factors Influencing Appetitive Responding

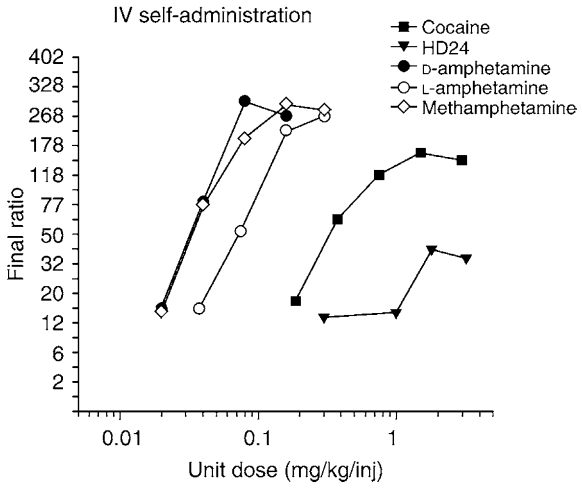
A variety of ► schedules of reinforcement have been used in order to directly address appetitive responding. It is important to recognize that different drug classes can have potent direct effects on rates of responding; therefore, once the first injection is delivered the response rates are "contaminated" by having the drug on board. ► Second order schedules have provided a useful method to circumvent this problem. A second order schedule, for example [FR5 (FR10:S)], might have an initial component wherein every tenth response results in the delivery of a stimulus light; completion of five of these components results in the delivery of the stimulus light and a drug injection. Relatively high rates of responding over prolonged periods can be maintained prior to the delivery of the first drug injection. Second order schedules have demonstrated that stimuli associated with drug injections can become potent ► conditioned reinforcers and brief presentations of these stimuli can effectively maintain drug seeking behavior. Second order schedules have been particularly useful in evaluating pharmacological treatments for drug addictions in nonhuman primates and for evaluating the neural mechanism in rats (Schindler et al. 2002). There has been a recent trend for an appetitive and consummatory phase to be formally incorporated into an experimental design. A second order schedule might be used in the initial phase of the session. Completion of the second order requirement then results in access to drugs, perhaps on an FR1. The two phases are designed to assess "drug seeking" versus "drug taking."

Choice procedures offer another way of assessing reinforcing efficacy of a drug. Typically, a subject is offered a choice between a particular dose of drug and a nondrug reinforcer such as food. Such methods, together with an assessment using ► drug discrimination techniques, have been used to evaluate abuse liability. Drugs that are abused by humans are almost invariably self-administered by rats and nonhuman primates, indicating self-administration procedures provide a good predictor of abuse liability for new therapeutic agents being considered for the clinical market (Bergman and Paronis 2006).

The ► progressive ratio (PR) schedule has been used extensively to assess the reinforcing strength of a variety of drugs. The distinguishing feature of the PR schedule is that the response requirements increase following the delivery of each reinforcement. In a typical self-administration study in rats, the first injection "costs" only one response, but with each injection the response requirement escalates through an exponential series (1, 2, 4, 6, 9, 12, 15, 20, 32, 40, 50, 62, 77, 95, 118, 145, 178, 219, 268, 328, 226 402, 492, 603). Studies in nonhuman primates have used the same or similar series except that the initial ratio often begins at 50. Figure 3 shows a cumulative record from a session in which a rat was self-administering cocaine on a PR schedule. Note that at some point in the session responding ceases. The last completed ratio (termed a ► breakpoint) is considered an index of the reinforcing value.



Self-Administration of Drugs. Fig. 3. A cumulative record illustrating the response pattern of a rat self-administering cocaine on a progressive ratio schedule. *Upward* movements of the record represent responses; *downward* angle ticks indicate a drug injection. The first response resulted in an injection. The response requirements for subsequent injections escalated through an exponential series. In this case, the animal self-administered 16 injections. The final ratio was 145.



Self-Administration of Drugs. Fig. 4. Graph shows the dose–response relationship in rats for a variety of drugs self-administered on a PR schedule. Groups of rats were first trained to self-administer cocaine. Various doses of test drug were then evaluated. The dependent measure was the final ratio (or breakpoint). HD24 is an experimental tropane compound synthesized by Dr. H. M. L. Davies. Note that the selected drugs have a range of reinforcing efficacies and potencies.

Figure 4 shows the dose–response curves for several different stimulant drugs. Higher unit doses are associated with higher breakpoints. The large range of breakpoints across various drugs suggests a wide spectrum of reinforcing efficacies.

Whether responding is measured while drug is on board is a critical theoretical issue. In some cases, it is imperative that drug seeking be measured in a drug-free state. However, it has become clear that blood levels of drug can greatly affect responding and in fact may be one of the most important factors which drives further drug taking once it has started. In this context, it is important to emphasize that the breakpoint on a PR schedule measures the motivation to continue a binge and not necessarily the motivation to start a binge.

In the past decade there has been a pronounced increase in the number of studies examining "relapse" to drug taking. In relapse experiments, animals are tested either in a drug-free state or under the influence of an experimenter delivered drug. Typically rats are trained to self-administer (e.g., cocaine or heroin) and in many cases, responding is then extinguished. The effect of a ▶ priming drug injection or ▶ conditioned stimuli are then assessed on lever responding. The term relapse is perhaps a misnomer, since animals do not self-administer during these test sessions; however, the procedure has provided a robust model to examine important influences on drug seeking. It has been shown that conditioned stimuli, ▶ stress, or a priming injection of drug can reinstate responding (Shaham et al. 2003).

Another important trend in the self-administration literature has been the application of behavioral economic principles. The theoretical constructs of supply, demand, consumption, and price have been usefully applied to the analysis of drug intake. Price can be manipulated by changing the response requirement for a fixed unit dose of drug. Alternatively, the response ratio can be fixed (e.g., FR1) and the unit injection dose reduced as might occur in an assessment of threshold (illustrated in Fig. 1). Either way the theoretical issues are the same. A behavioral economic analysis of the relationship between consumption and price offers a relatively new way of assessing reinforcing strength (Hursh 2000).

As stated previously, the majority of self-administration studies have used the intravenous route of administration. Studies of alcohol intake have quite naturally used the oral route. Rodents are generally reluctant to drink alcohol without some encouragement. ▶ Schedule-induced polydipsia has been used to induce higher levels of alcohol intake. Similarly, intake can be increased by sweetening the alcohol solutions. After a reasonable intake level has been established then the sweetener is faded out over days. The neurobiology of both appetitive and consummatory aspects of alcohol intake is currently being assessed in rodent studies through analysis of different strains, knockout mice, and through ▶ selective breeding programs for alcohol preferring animals.

Intragastric, inhalation, intraventricular, and intracerebral routes have all been used in self-administration experiments. The ▶ pharmacokinetics of each route is different; the rate of drug delivery to the brain necessarily affects the reinforcing efficacy.

Self-administration by the intracrerebral route is a special case which offers a unique perspective on brain circuitry involved in drug reinforcement. Since the first report by Olds et al. (1964) there have been about 50 papers describing self-administration of drugs into various brain regions. Interestingly, nondrugs of abuse have been reported to support operant responding. Because drugs are introduced directly into circumscribed brain regions, they can have a purely local effect which is quite different from a systemic injection. For example, Liu and Ikemoto (2007) have shown that muscimol (a $GABA_A$ agonist which would produce local inhibition) is self-administered into the median raphe nucleus. By contrast, picrotoxin (a $GABA_A$ antagonist which would produce neuronal

disinhibition) is self-administered into the ▶ ventral tegmental area. Thus, the brain region (and presumably the local circuit) determines whether a drug has a reinforcing effect. Note that, neither muscimol nor picrotoxin is self-administered when offered systemically.

Definition

Sensitization, in relation to ▶ Pavlovian conditioning, is an incremental change in the response to a stimulus in the absence of any associated contingency. In psychopharmacology, sensitization is more frequently used as the name

for the progressive enhancement of an ► unconditioned response to a drug when it is administered on two or more occasions. It regularly occurs with ► psychostimulant and ► opioid drugs and is believed to involve enhanced function of dopaminergic neurons projecting from the ► ventral tegmental area to the ► nucleus accumbens.

Definition

The word "sensitization" is used to refer to a number of different, but related effects. For example, in immunology, sensitization refers to the hypersensitivity to an antigen (often an allergen) that can develop upon repeated exposure to the antigen. In the study of learning, sensitization refers to a form of nonassociative learning whereby exposure to a stimulus (an ► unconditional stimulus, US) increases subsequent responsiveness to the same or other stimuli, even though they were not explicitly paired. Similarly, in pharmacology, the word sensitization has come to refer to an increase in a drug effect upon successive exposures to a drug, or, hypersensitivity to a drug in animals that were exposed to the drug in the past (Fig. 1). For example, one unconditional effect of drugs such as ► amphetamine or ► cocaine is to produce *psychomotor activation*, often measured as an increase in forward locomotion. Under some circumstances, the repeated administration of ► psychostimulant drugs results in a progressive increase in this drug effect, whereby successive injections of the same dose produce greater and greater psychomotor activation. Furthermore, exposure to one drug (e.g., amphetamine) can also render animals hypersensitive to the locomotor activating effects of other drugs (e.g., cocaine or ► morphine). When exposure to one drug (or another stimulus, such as ► stress) renders an animal hypersensitive to another drug or stimulus, this is called "cross-sensitization" (Kalivas and Barnes 1988; Robinson and Becker 1986; Stewart and Badiani 1993).

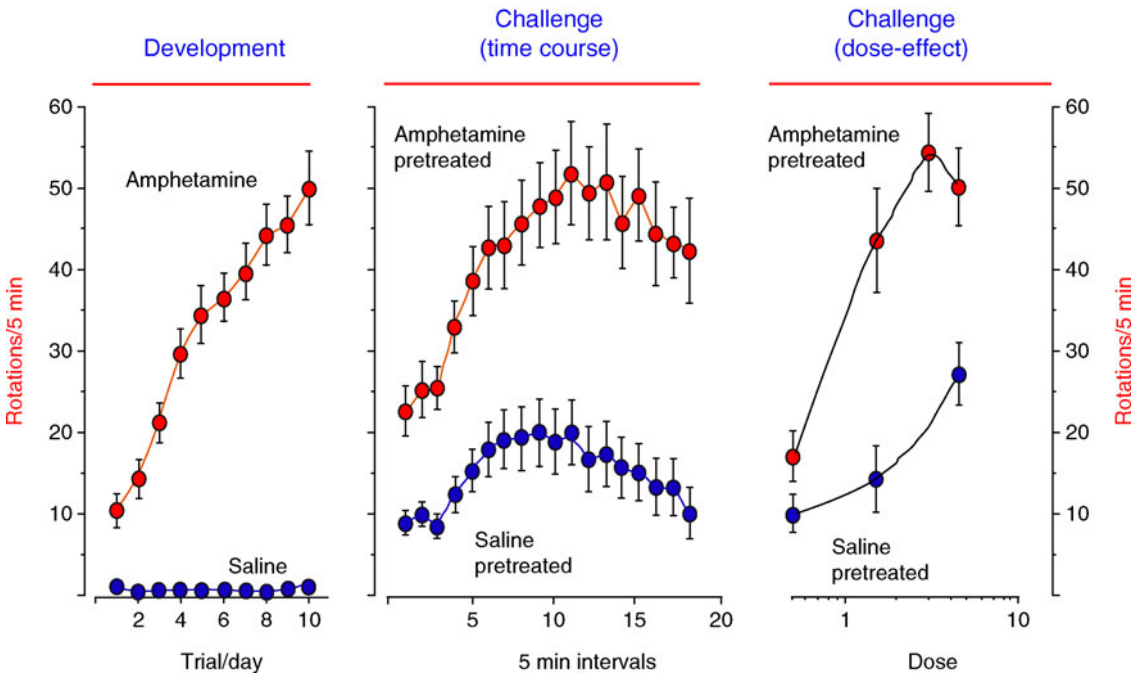
Impact of Psychoactive Drugs

Behavioral Sensitization

By itself, with no adjective, the word sensitization provides no information about the nature of the drug effect that is changed or about the underlying mechanisms. Indeed, it is not very useful to refer to "drug sensitization" or to just say an animal is "sensitized," because sensitization (or tolerance) does not develop to the drug itself. Specific drug *effects* show sensitization or tolerance. Drugs produce many different effects, and with repeated administration some effects may show sensitization while at the same time other effects show ► tolerance and yet others do not change. In fact, the same drug effect may show tolerance or sensitization depending on the conditions under which the drug is administered (e.g., if it is given continuously or intermittently – intermittent injections favor sensitization). Thus, an animal that is "sensitized" may also be "tolerant" – depending on which drug effect is under consideration.

It is important to ask, therefore, which effects of drugs tend to show sensitization, and under what conditions is sensitization induced and expressed. Most studies on sensitization involve some behavioral measure, and if a behavioral effect of a drug increases with repeated drug administration, this may be called *behavioral sensitization* (Fig. 1). In other studies, a neurobiological effect of a drug may be measured, and if increased by prior drug exposure, this may be referred to as *neural sensitization*, although again, these terms provide no information about the exact effect that is changed. Therefore, unless one wants to just refer to the general phenomenon, it is best to use terms that convey information about the specific drug effect under study, because most of them are dissociable.

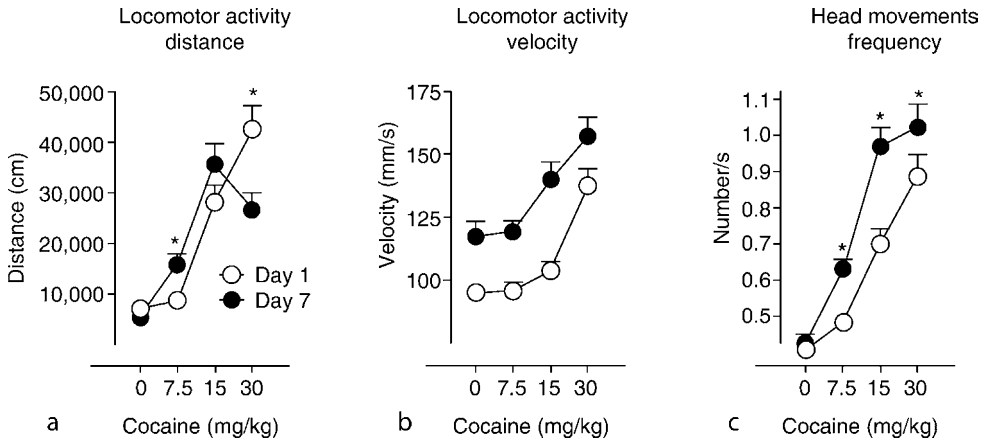
In many studies of behavioral sensitization, the drug effect measured is a psychomotor effect (*psychomotor sensitization*; Fig. 1 and 2). But the psychomotor-activating effects of drugs represent a very complex set of different behaviors, and they can compete with one another, making the accurate assessment of psychomotor effects a complicated endeavor (Flagel and Robinson 2007; Robinson and Becker 1986). The most frequent psychomotor effect studied involves some measure of locomotor activity (e.g., beam breaks, crossovers, distance traveled, etc.). To the extent that locomotor activity increases with repeated drug administration, this can be called *locomotor* sensitization. But drugs can produce many other psychomotor effects, including complex patterns of repetitive motor actions (stereotyped behaviors), including rearing, head movements, limb movements, sniffing, oral



Sensitization to Drugs. Fig. 1. An illustration of the different ways of viewing psychomotor sensitization. The specific behavior quantified is amphetamine-induced rotational behavior in rats with a unilateral 6-OHDA lesion. The dose-effect function for this behavior is linear over a much wider range of doses than for locomotor activity (see Fig. 2). *Left panel: a within-subjects* measure of sensitization, in which rats were given an injection of 3 mg/kg of D-amphetamine (or saline) once every 3–4 days for a total of ten injections. Amphetamine produced more and more rotational behavior ("psychomotor activation") with successive injections, whereas the response to saline did not change. The increase in behavioral effect is called behavioral or psychomotor sensitization. *Middle panel: a between-subjects* measure of sensitization, in which rats that were previously treated with saline or amphetamine both received a challenge injection of amphetamine (1.5 mg/kg). The behavioral response in rats that previously received ten injections of amphetamine (left panel) is much greater than in those that previously received saline, and the magnitude of the group difference indicates the degree of sensitization. *Right panel: dose-effect analysis*, in which rats previously treated as in the left panel received a challenge injection with different doses of amphetamine. In this case the degree of sensitization is indicated by the magnitude of the shift to the left in the dose-effect function. (Data are from Anagnostaras S, Robinson TE (1996) Sensitization to the psychomotor stimulant effects of amphetamine: modulation by associative learning. Behav Neurosci 110:1397–1414).

movements (licking and biting), rotational behavior, etc. Which psychomotor effect dominates behavior depends on many factors, including the drug, dose, the test environment, the time after drug administration, and many others. For example, in animals previously exposed to amphetamine a subsequent injection may initially increase locomotor activity, which then decreases and is replaced by complex patterns of stereotyped behaviors performed "in place," and then this followed by the re-emergence of locomotor hyperactivity ("post-stereotypy hyperactivity"). What is critical to realize is that each of these different psychomotor effects can be dissociated, and they do not all change uniformly as a function of repeated drug treatment (see Fig. 2). Repeated drug administration does not have the same effect on each of these behaviors, presumably in part because they are mediated by different neural systems that are changing in different ways, and in part because of the competitive relationship between different behaviors.

For this reason, negative findings can be very difficult to interpret in studies of sensitization. If a given manipulation is reported to not produce, or to prevent the expression of "sensitization" – one must immediately ask – by what measure? It could be that the manipulation influenced the induction or expression of locomotor sensitization, but had no effect on some other measure of psychomotor sensitization, or on other psychological processes that undergo sensitization (see below). Or, it could



Sensitization to Drugs. Fig. 2. Different measures of psychomotor activation in a within-subjects study of behavioral sensitization. On the first day of treatment, rats were given three injections of cocaine in ascending doses (0, 7.5, 15, and 30 mg/kg), with 45 min between each treatment. For the next 6 days, they received one injection of 15 mg/kg each day. Then, on the seventh day they again received multiple doses, as on day 1. The graph show three different behavioral measures on day 1 and day 7 of testing, obtained from video. *Panel A* shows a measure of locomotion (distance traveled in cm). Between day 1 and 7 the animals showed an increase in locomotor activity when given 7.5 mg/kg, no change when given 15 mg/kg, and a decrease in locomotor activity when given 30 mg/kg. This highlights the complexity of the dose-effect function when using locomotor activity as a measure of psychomotor activation (compare with Fig. 1). For example, under the conditions of this study, if only a dose of 15 mg/kg were used, one would conclude that the animals did not sensitize. However, other measures of psychomotor activation reveal robust sensitization. *Panel B* shows the average velocity of each bout of locomotion, and there is a large effect of repeated drug treatment on this measure (the effect at a dose of zero also reveals a conditioned effect not evident in the distance traveled). *Panel C* shows the average frequency of head movements, and again this measure reveals robust psychomotor sensitization, at all doses. These data illustrate the importance of using multiple measures of psychomotor activity in studies of sensitization, especially if negative findings are obtained. (Data are from Flagel and Robinson 2007).

be that the measure of locomotion was not the most appropriate measure under the conditions of the study. For example, repeated exposure to cocaine may have no influence on one measure of locomotion, such as distance traveled, while at the same time dramatically increasing the velocity of each individual bout of locomotion and the frequency of stereotyped head movements (Flagel and Robinson 2007; Fig. 2). Thus, the apparent absence of locomotor sensitization may not allow one to conclude no effect on "sensitization," but only on one behavioral measure. Unfortunately, in many studies only one measure is provided making it nearly impossible to interpret negative results.

It is also important to remember that many other behavioral effects of drugs can sensitize, besides just psychomotor effects. Other behaviors that have been reported to sensitize include acoustic ▶ startle, drinking behavior, lick rate, discriminative effects, and the disrupting effect of amphetamine on ▶ latent inhibition and ▶ selective attention, to name a few (Badiani and Robinson 2009; Kalivas and Barnes 1988; Robinson and Becker 1986; Stewart and Badiani 1993). In humans the psychotomimetic effects of psychostimulant drugs also sensitize (Featherstone et al. 2007; Robinson and Becker 1986). In addition, there is considerable evidence that repeated exposure to a variety of drugs of abuse increases some aspect of their rewarding or incentive motivational effects (Vezina and Leyton 2009). Repeated exposure to a number of potentially addictive drugs facilitates the later acquisition of ▶ drug self-administration behavior and a ▶ conditioned place preference, facilitates the learning of S-R habits, increases motivation for drug based on performance on a ▶ progressive ratio schedule and running in an alley, and increases the incentive salience attributed to stimuli associated with drug and nondrug rewards. This latter form of sensitization – *incentive sensitization* – may be especially important in the development of addiction because it may result in people being maladaptively attracted to drugs and cues associated with drugs, thus instigating and maintaining drug-seeking behavior even when there is a desire to remain abstinent (Robinson and Berridge 2008).

Neural Sensitization

Presumably the reason that so many different behaviors and psychological functions can be sensitized by repeated exposure to drugs is that drugs change many different neural systems, neural systems that mediate the behaviors and psychological functions that sensitize (Thomas et al. 2008). Many studies of neural sensitization have focused on ► mesotelencephalic dopamine systems, and a number of sensitization-related changes in dopamine systems have been described, including an increase in stimulated dopamine release and striatal D2 receptors (Robinson and Becker 1986; Robinson and Berridge 2008). However, sensitization-related changes have been described in nearly every neurotransmitter system within the relevant mesencephalic-striatal-amygdala-cortical circuitry, including glutamate, GABA, serotonin, acetylcholine, norepinephrine, etc. systems, and in a host of intracellular ► signaling cascades. Indeed, sensitization has been associated with changes in patterns of synaptic connectivity in these circuits, suggesting a level of reorganization that may fundamentally and persistently change their operation. Despite considerable research on neural sensitization, cause-effect relations are not well understood. What changes in what neural systems are causally-related to what changes in behavior and psychological function remains a topic of active investigation.

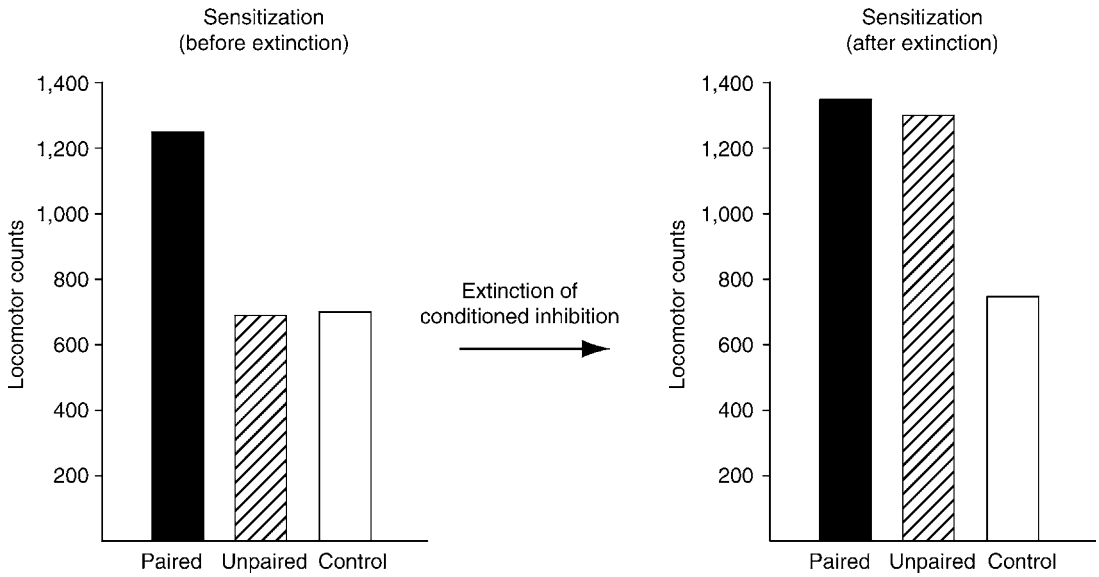
The Induction Versus the Expression of Sensitization

Most major drugs of abuse are capable of inducing sensitization, including psychostimulants (amphetamine, cocaine, ► MDMA, cathinone, fencamfamine, ► methylphenidate, phenylethylamine, etc.), opiates, ► phencyclidine, ► alcohol, and ► nicotine. Direct agonists that act on the D2 receptor also produce robust psychomotor sensitization, although it is not clear the mechanism is the same as with ► drugs of abuse, which influence dopaminergic activity indirectly. In addition, repeated intermittent exposure to stress can produce cross-sensitization to drugs, and vice versa (Kalivas and Barnes 1988; Stewart and Badiani 1993).

For some drugs it is thought that an action at the level of dopamine cell bodies in the midbrain is necessary to induce sensitization. However, once induced, sensitization may be expressed by drug actions in structures that receive dopaminergic inputs (Vezina and Leyton 2009). Whatever the case, one remarkable feature of sensitization is that, once induced, it can persist for very long periods of time in the absence of any further exposure to the drug – for weeks, months, or years. The persistence of sensitization depends on many factors, including the drug, the dose, the number of exposures, and the pattern of exposure. Furthermore, sensitization can be induced when a drug is administered by an experimenter, or when it is self-administered, including when it is self-administered under conditions that promote the development of symptoms of addiction (i.e., under extended access conditions).

Modulation of Induction and Expression

Although the repeated, intermittent administration of a number of drugs of abuse may produce sensitization, it is important to emphasize that there are a host of factors that modulate both the induction and expression of sensitization. Whether a given dose of a drug *induces* sensitization, or how robust the effect, is dependent on many factors beside dose and the treatment regimen, including, the strain of the animal, its sex (females generally sensitize more), hormonal status, past experience with ► stress, age, the rate of drug delivery (faster rates produce greater sensitization), and the context in which the drug is administered, amongst others (Badiani and Robinson 2009; Kalivas and Barnes 1988). Indeed, there are large individual differences in susceptibility to sensitization. After neural sensitization is induced there are also a number of factors that determine if it is *expressed* in behavior at any particular place or time. For example, when an animal that has developed psychomotor sensitization is re-exposed to drug in a context where it has never before experienced drug, sensitization may not be expressed in behavior (this is so-called context-specific sensitization; Fig. 3). Exactly, how contextual factors modulate the expression of sensitization is not well understood. The available data suggest that contexts *not* associated with drugs may act to actively inhibit expression, perhaps through a kind of inhibitory ► occasion-setting type mechanism. This is because specific ► extinction procedures and ECS can "release" this inhibition so that sensitization is now expressed in a nondrug context (Stewart and Badiani 1993; Vezina and Leyton 2009; Fig. 3). Of course, drug-associated contexts can also elicit drug-like conditioned responses that may add to sensitization effects, but this kind of conditioned response appears to be a different process than contextual modulation of sensitization. Indeed, it may be misleading to speak of "context-specific sensitization" versus "context-independent sensitization" as if they represent two different forms of sensitization. It appears there is one form of sensitization, a nonassociative increase in responsiveness to various stimuli because of changes in the relevant neural systems. However, the *expression* of sensitization can be powerfully modulated by associative learning, and if it is,



Sensitization to Drugs. Fig. 3. Context-specificity of sensitization (adapted from Vezina and Leyton 2009). Paired rats received amphetamine in the test environment on one day and saline in the home cage (or somewhere else) the following day. Unpaired animals were subjected to the opposite configuration while Control animals received saline in both environments. After repeated treatments, all animals were then administered a challenge injection of the drug in the test environment to assess the expression of sensitization. The results on the left illustrate that sensitization was only expressed in Paired animals. Rats that received the same number of drug injections but explicitly Unpaired with the test environment showed levels of responding similar to animals receiving the drug for the first time (controls). Evidence that this is due to Conditioned Inhibition of the expression of sensitization in Unpaired rats comes from the finding that after these rats were subjected to a procedure known to extinguish Conditioned Inhibition (but spare conditioned excitation), they now expressed sensitization (right panel). This suggests that the failure of unpaired animals to express sensitization in the first test was due to some form of conditioned inhibition (see Vezina and Leyton 2009 for further discussion).

sensitization may be expressed only under specific conditions. How contextual factors (and other stimuli) modulate the expression of sensitization is an important (but little investigated) topic, because of the potential importance of such factors in relapse. Addicts are much more prone to ► relapse in contexts associated with drugs than in other contexts. This may be related not only to the ability of drug-associated contexts to evoke conditioned responses, which is well-documented, but also because context can gate the expression of sensitization. Thus, conditions that promote the expression of neural sensitization in behavior may also promote relapse, whereas conditions that inhibit the expression of sensitization may inhibit the propensity to relapse. For this reason a better understanding of factors that modulate the induction and expression of sensitization (especially incentive sensitization) may prove useful in developing treatments for addiction (Robinson and Berridge 2008; Stewart and Badiani 1993; Vezina and Leyton 2009).

Sensitization in Humans

By necessity, most research on sensitization has involved preclinical studies in nonhuman animals. However, it is worth noting that similar effects have been described in humans (Leyton 2007). As mentioned above, it has long been recognized that the psychotomimetic effects of psychostimulant drugs sensitize, as does their ability to produce complex stereotyped behavioral patterns (in humans this is called "punding"). Indeed, sensitization of psychotomimetic effects has been interpreted as involving sensitization of incentive salience, whereby otherwise innocuous stimuli in the environment acquire pathological importance (Featherstone et al. 2007). In addition, there are now a number of reports that repeated exposure to amphetamine induces both behavioral sensitization (e.g., increased eye-blink responses, vigor, and energy ratings), and neural sensitization (e.g., an increase in evoked dopamine "release" as indicated by raclopride displacement). Finally, as in nonhuman animals, the expression of

sensitization in humans appears to be highly modulated by the context under which drugs are experienced (Leyton 2007; Robinson and Berridge 2008; Vezina and Leyton 2009).

In conclusion, the sensitization produced by repeated exposure to many drugs of abuse turns out to be a very complex form of neurobehavioral plasticity that can alter many different neural systems, and thus be manifest as a change in many different behaviors and psychological processes. Some of these changes may be related to why, in addicts, drugs and drug-associated stimuli come to acquire such inordinate control over behavior (Robinson and Berridge 2008).

Definition

A monoamine (► indoleamine) neurotransmitter found in the brain, ► platelets, and the gastrointestinal tract. Serotonin is synthesized from the amino acid ► tryptophan, and is involved in a wide range of behavioral, physiological, and cognitive functions, including mood, emotion, appetite, sleep, memory, temperature

regulation, platelet aggregation, vascular tone, intestinal secretion, peristalsis, and bone metabolism. Serotonin is well known for its role in psychiatric and behavioral disorders such as ► depression, ► anxiety, ► obsessive compulsive disorders, ► eating disorders, and ► addiction. This neurotransmitter may also be involved in physiological disorders such as irritable bowel syndrome and cardiac arrhythmias. The actions of serotonin (5-HT) are mediated through at least 16 receptor subtypes grouped into seven families (5-HT_1–5-HT_7) according to their structural and functional characteristics, and include 13 distinct ► G-protein-coupled receptors, coupled to various effector systems, and three ligand-gated ion channels (the 5-HT_3 receptors). The drugs targeting the 5-HT system that are in the widest clinical are the selective serotonin reuptake inhibitors that are used for the treatment of depression and other disorders.

Definition

Sertindole is a second-generation antipsychotic that acts as a dopamine D2 and serotonin 5-HT_{2A} antagonist. A phenylindole derivative, sertindole has been reintroduced as a second-line drug treatment after it had been voluntary withdrawn from the market because of concerns over cardiac arrhythmias and sudden deaths. However, the risk for cardiovascular mortality was found not to differ from that by other atypical antipsychotics, while it may be useful for patients in whom other antipsychotics have failed. Sertindole also lacks the sedative properties inherent to many other antipsychotic drugs. However, ECG monitoring is required before and during the treatment.

Sertraline

Definition

Sertraline is a naphthalenamine derivative and acts as a ► selective serotonin reuptake inhibitor (SSRI) that is used as an antidepressant. Its effects are mostly typical for the class of SSRIs, sharing their therapeutic effects and side-effects although some studies have found a particularly favorable balance between benefits, acceptability, and cost. A recent systematic review and meta-analysis found evidence favoring sertraline over several other antidepressants for the acute phase treatment of ► major depression. Among side effects, there was a higher rate of diarrhea with sertraline than some other SSRIs. It is absorbed slowly after oral administration and there are several metabolites including N-desmethyl-sertraline, which has weak pharmacological activity. The elimination half-life is in the range of 22–36 h. Sertraline has little inhibitory effect on the ► cytochrome P450 enzymes, with the result that interactions with other drugs are less likely than with some other SSRIs.

Definition

In the 2001 National Academy of Sciences report (Exploring the Biological Contributions to Human Health: Does Sex Matter?) *sex* is defined as "the classification of living things, generally as male or female according to their reproductive organs and functions assigned by their chromosomal complement, and *gender* as a person's self-representation as male or female, or how that person is responded to by social institutions on the basis of the individual's gender presentation." The term "sex differences" is used to explain biological differences between males and females while "gender differences" imply differential effects of social and cultural milieu on males and females; in other words, gender can be considered as a psychosocial construct. In nonhuman animal research, "sex differences" is the preferred term. Because of the complex interplay between biological and environmental factors, it is hard to define a clear-cut distinction between sex- or gender-based differences between males and females. Furthermore, recent findings from ► epigenetic research show that the biological factors are influenced by the environment. In either case, there is a variation in the characteristic associated with either the male or female sex. Morphological characteristics or features that are different in males and females of the same species are referred to as "sexual dimorphism" (two forms).

Sex differences are not limited to reproductive function and endocrine systems, but are also observed in brain and behavior. As a result of these distinctive features between males and females, their biological responses to drugs are not the same.

Current Concepts and State of Knowledge

Until recently, women were excluded from many experiments with drugs, and, therefore, information about appropriate treatment of diseases and reactions to drug therapy was based on studies conducted only on men. Without systematic research, it was assumed that sex

differences in responses to drugs might be attributed to differences in height, weight and hormones. The exclusion of women from drug trials was, in part, the result of the thalidomide tragedy of the 1950s. Subsequently, in 1977 FDA recommended that women of childbearing potential be excluded from drug research. It was assumed that studies conducted in adult males could be extrapolated to other patient populations, including women, children, and the elderly. For example, a 1989 study, excluding women, suggested the use of aspirin as the first-line treatment of cardiovascular disease, but in 1992 two studies showed that the benefits of aspirin were greater in men than in women. In 1993, the FDA withdrew the rule against including women of childbearing potential in clinical trials and went forward to ensure that women were included in all future drug research. The newer studies reveal that drug researchers are showing increased awareness of gender specific responses to drugs and are including more women in clinical trials.

The chemical structure and dose of a drug are important factors in producing the expected effects, but the actual amount of drug which binds to its target sites, in other words ▶ bioavailability, is critical. The primary target site for ▶ psychoactive drugs is the brain. Dynamic factors (e.g., absorption, distribution, metabolism, and excretion) that determine the bioavailability of a drug (▶ pharmacokinetics) are not the same in males and females. Gastric acid secretion and gastrointestinal blood flow are lower and gastric emptying time is longer in women; on average, women weigh less and have a higher percentage of body fat; activity of enzymes that metabolize drugs are sexually dimorphic; women have a lower glomerular filtration rate and a lower creatinine clearance compared with men.

The composition of the body, more specifically the ratio of fat and water, is an important factor in determining the plasma levels of a drug and in females the adipose tissue is more and the water content is less than in males. Therefore, as the proportion of water is smaller in females than males, the same dose of a drug would be expected to result in a higher blood level in females than males; subsequently, more concentrated drug levels would result in greater effects in females, even if the dose was corrected for body weight. On the other hand, because there is more adipose tissue in a women's body (approximately 25%) and most of the ▶ antipsychotic drugs are ▶ lipophilic, some antipsychotic drugs may accumulate in the adipose tissue and result in extended bioavailability in women. The endocrine milieu of women is much more variable than that of men; the gonadal (▶ Gonad) hormones fluctuate during the menstrual cycle, pregnancy, postpartum period, lactation, menopause, and while using oral contraceptives. Ovarian hormones have substantial modulatory roles on central neurotransmission. In case of a challenge such as an epileptic seizure, the permeability of the ▶ blood brain barrier is slightly elevated in females compared to males. This difference may impact the rate of drug entry to the brain and result in a stronger effect. Drug metabolism is another factor where sex differences are observed. Liver is the major site of drug inactivation and sexual dimorphisms in the liver may partly account for different metabolism of drugs in women and men. Sex-specific differences in enzyme activity can lead to sex differences in drug response. For example, women wake from general anesthesia several minutes before a man, given an equivalent dose. Gastric enzymes which metabolize ▶ alcohol before it reaches the bloodstream are weaker in women than men, thereby after ingesting similar amount of alcohol, women will have higher blood concentrations than men. Several ▶ cytochrome P450 isoenzymes are responsible for the metabolism of many drugs. For example, certain cytochromes which break down ▶ nicotine to its inactive metabolites are significantly higher in women than men and higher metabolism is related to nicotine dependence.

Although the ▶ activational effects of ▶ sex hormones cannot fully account for all sex differences observed in the adult brain, and though many sex differences persist in the absence of these hormones, they have a substantial impact on brain, behavior, and response to drugs. Ovarian hormones affect ▶ pharmacokinetics properties of a variety of drugs. Changes in the menstrual cycle are related to differential ▶ absorption and bioavailability of certain drugs. Gastric emptying is slower during the luteal phase of the menstrual cycle compared to the follicular phase. Gastrointestinal transit time is prolonged during the luteal phase compared to the follicular phase, allowing for greater drug absorption. Sodium retention, water content, and urinary volume may also vary with the menstrual cycle in women and influence the distribution of drugs.

Overall, rates of side effects to most drugs are reported to be higher in women than in men and sex differences in drug metabolism may be involved in these adverse reactions. Additionally, increasing age, polypharmacy, liver and renal disease may have sexually dimorphic impacts on side effects.

Dopaminergic System

Central dopaminergic systems are the target of many psychoactive drugs, including abused substances. Males and females differ in the functioning of the dopaminergic system and therefore, sex differences are observed in response to drugs which act primarily through this system.

► Dopamine neurotransmission mediates the reinforcing effects (reward system) of ► drugs of abuse and may underlie neuropsychiatric disorders such as ► schizophrenia, ► Parkinson's disease, and ► attention deficit disorder, where sex differences have been reported in incidence, prevalence, clinical course, and treatment outcome. Addiction to some abused ► psychostimulants such as ► cocaine and nicotine is more severe in women, the age of onset of schizophrenia is later in women than men and the prevalence of Parkinson's disease is lower in women than men. Sex differences in the baseline activity of the dopaminergic system may underlie these observed differences as well as responses to dopaminergic drugs.

Dopamine release and uptake rates, which regulate extracellular dopamine levels, are higher in females than males in some brain regions such as the striatum. Women have higher levels of ► dopamine transporters in the striatum, lower striatal dopamine D2 receptor affinity and higher dopamine 2 (D2) receptor levels in the frontal cortex compared to men; this may result in elevated levels of dopamine in these brain regions in women. In fact, postmortem and neuroimaging studies in human subjects suggest that dopamine release in women is higher relative to men. In human subjects, d-amphetamine-induced dopamine release in striatal and extrastriatal regions is higher in women suggesting sex differences in cognitive function and sensation-seeking behavior. The decline observed in DA receptor levels with age is also slower in women than men. In rats, indirect dopamine agonists like ► cocaine, which block the dopamine transporter, induce greater behavioral and neuroendocrine effects in females than males. Female rats acquire self-administration of cocaine faster than males. Responses to direct acting dopamine D2 ligands display sex differences with females being more sensitive than males.

Ovarian hormones underlie some, but not all sex differences observed in drug abuse, suggesting qualitative and quantitative sexual dimorphisms in neural systems. Estrogen enhances the response to the psychomotor stimulants ► amphetamine or cocaine; this effect is observed both during estrogen replacement following ovariectomy and during the estrus phase of the estrus cycle in rats.

In studies on rodents, estrogen is reported to increase dopamine synthesis, and baseline dopamine release in the striatum, and to increase neuronal firing in substantia nigra. Estrogen inhibits gamma-aminobutyrate (► GABA) neurons in the striatum and accumbens, which subsequently increase dopaminergic activity. Another established effect of estrogens is the down regulation of dopamine receptors. Dopaminergic transmission varies with estrous cycle phase. For example, amphetamine-stimulated dopamine release is greatest during the estrus phase of the cycle, a time when the behavioral response is also greatest. Estrogen plays an important role in modulating sex differences in neurochemical responses to ► psychomotor stimulants.

► Stress, negative mood, and exposure to drug-related cues predict relapse in cocaine dependence. The effect of stress is more significantly associated with relapse in women and drug cues in men. Estrogen and progesterone have opposite effects on behavioral responses to cocaine, while the former increases the effects, the latter decrease it and the effects are more pronounced in females than males. Stress and cocaine enhance the stress response, mainly through the ► corticotrophin releasing factor (CRF) and central noradrenergic pathways, both of which activate the mesolimbic dopaminergic systems involved in the rewarding effects of cocaine. Progesterone also plays a key role in stress regulation and D2 receptor function, which results in an increase of DA release. On the other hand, in male rats, the density of dopamine D1 receptors is higher than in female rats in the ► nucleus accumbens, a brain region implicated in reward.

Sex differences observed in behavioral responses to one drug cannot be generalized to all behaviors because neurobiological mechanisms controlling different behaviors can be dissociated. For example, in rats, while the locomotor responses to amphetamine and ► methamphetamine show sex differences with females being more sensitive than males, no sex differences are reported for conditioned place preference. Alternatively, sex differences are observed in responses to nicotine both in locomotor activity and in ► conditioned place preference, albeit in different directions: The effect of nicotine on locomotion is more pronounced in females, but unlike males, females do not show nicotine induced place preference. Similar to nicotine, ► LSD induces place preference in male but not in female rats. On the other hand, female rats are reported to be more sensitive to the conditioning effect of cocaine.

► Sensitization of behaviors such as rotation, stereotyped grooming, head bobs, and forelimb movements observed following chronic exposure to ► psychostimulants is greater in female rats than in males.

Methamphetamine, another abused drug like cocaine, increases dopamine levels in some brain regions but through different mechanisms: while cocaine blocks reuptake, methamphetamine induces release from nerve terminals. The sex differences observed in the effects of methamphetamine are similar to cocaine: Females are more sensitive to the locomotor activating effects, but the effect gradually declines with repeated treatment in rats.

Drug Abuse

Until recently, preclinical (► Addictive disorder: animal models) and clinical research on drug abuse has been conducted mainly on male subjects. Drug abuse was generally accepted as a male problem and males were thought to be more vulnerable to drug abuse (► abuse liability evaluation). However, this view did not take into consideration the opportunity for use. There is growing evidence that points to sex differences the effects of abused drugs. Biological and environmental predictors of drug use such as ► depression, conduct disorder, physical and sexual abuse, prenatal drug exposure, and family dysfunction affect males and females differently. Therefore, treatment strategies that are effective in one sex may not be equally successful in the other. Sex differences in sensitivity to abused drugs and in drug self-administration is also observed in laboratory animals, and during different stages of the addiction process (i.e., acquisition, maintenance, and relapse). Females appear to be more vulnerable than males to the reinforcing effects of psychostimulants, ► opiates, and nicotine as revealed by their behavioral, neurological, and pharmacological responses to these drugs. Women take less time to progress to dependence (tobacco, ► caffeine, alcohol, ► cannabinoids, opiates, ► sedatives, cocaine, inhalants, amphetamine, ► hallucinogens, and ► phencyclidine) than men. Furthermore, in many cases, women appear to be more sensitive to the adverse health effects of drugs than men, pointing to the importance of developing gender-specific prevention and treatment programs in drug-related health problems. Methamphetamine (► amphetamine derivative) abuse may be an exception. It is reported that women begin to use methamphetamine at their earlier ages, and appear to be more dependent, but also they also respond better to treatment than men do. In women, use of methamphetamine is associated with depression, suggesting a type of self-medication.

Epidemiological studies indicate that during adulthood, men outnumber women in using illicit substances (except prescription medications), alcohol and tobacco, and that men are more likely to have a ► drug abuse/dependence disorder or an alcohol use disorder than women. However, this gender difference in prevalence is not observed among adolescents; in fact, some studies point to a slightly higher prevalence of smoking among girls than boys. Nonetheless, ► alcohol abuse and dependence is higher in males than females at all age groups.

Women are more sensitive to the physiological effects of alcohol than men, have higher blood levels following similar doses of alcohol and report feeling more intoxicated. However, negative mood-induced craving for alcohol is greater in women than men.

Following different routes of cocaine intake, women detect the subjective effects of cocaine later than men and report less euphoria and dysphoria, but feel more "nervous" compared to men. Women show greater reactivity than men to cocaine-related cues and the ► craving during abstinence is significantly higher in women.

Women have greater vulnerability for smoking-related diseases (specifically myocardial infarction and lung cancer) than men, but are less successful in quitting smoking. Men benefit from nicotine replacement therapy more than women. Studies on rodents point to similar sex differences, suggesting the involvement of underlying sexual dimorphisms in biology. Females may take a shorter time to become dependent than males, they make fewer quit attempts and can stay abstinent for shorter periods than males; the rate of relapse is higher in females than males. Sexually dimorphic pharmacokinetics that causes variance in blood/brain levels of nicotine or the effects of gonadal hormones may underlie some of the sex differences observed in nicotine/tobacco addiction.

There are established sex-dependent differences in ► opiate reward. Female rats are more sensitive to the rewarding effects of ► morphine, and work more than males to self-administer morphine, and acquire conditioned place preference at lower doses than males. Additionally, there are also sex-related differences in the effect of morphine on locomotor activity, cardiovascular system, temperature, stimulus discrimination, ► physical dependence, and analgesia.

The cyto-architecture of male and female brains is not the same; for example, the dendritic arborization in the anterior cingulate cortex, implicated in craving, is greater in male rats than in females. ► Psychoactive drugs modify the action of various neurotransmitter systems at the cellular and molecular levels and impact synaptic structure and function. There are clearly established sex differences in the action of neurotransmitters, with specific characteristic. The organizational and ► activational effects of ► gonadal hormones underlie some of the sex differences in brain and behavior. Since sex steroids, and especially estrogens, modify the binding of ligands to their receptor sites, sex differences in the action of pharmaceuticals deserve attention.

Antipsychotics

The response and end-organ sensitivity to antipsychotic treatment, similar to other drugs, are influenced by genetics, age, height, weight, lean–fat ratio, diet, exercise, concurrent disease, smoking and alcohol, and the

administration of concomitant drugs. There are sex differences in all of these factors and taken together, these factors are estimated to contribute to a tenfold variability in responses to medication.

Sex differences in response to ► antipsychotic agents have been reported in both animals and humans. In drug-naive subjects, response to antipsychotic drugs is reported to be superior in women. In chronically ill patients with ► schizophrenia or related psychoses, men require twice as high a dose as women for effective maintenance. Recommendations for prescribing antipsychotic medication to women include using lower doses for women than men, longer intervals for women when depot doses are used, and careful modulation of drug dose in aging women. In general, schizophrenic women have higher degree of symptom improvement, but also of ► extrapyramidal symptoms.

Until recently, women have been underrepresented in clinical trials of ► second generation antipsychotics, and therefore, there are limited data on possible sex differences in drug efficacy and side effects. A main reason for this underrepresentation was the fear of potential ► teratogenicity. Currently, sex-specific analysis of efficacy and safety data is a requirement and therefore an increasing number of studies are now available concerning sex differences in pharmacokinetics or ► pharmacodynamics of second generation antipsychotics.

There are reported sex differences in pharmacokinetics for second generation antipsychotics ► clozapine, ► olanzapine and ► sertindole, and CYP1A2 activity has been implicated in these differences. Women have higher plasma levels of all these second generation antipsychotics than men. On the other hand, no sex differences were observed for ► quetiapine. However, as the studies involve relatively small number of patients, larger samples are required before generalizations can be made on sex differences in responses to novel antipsychotics.

Recent reports suggest that women on olanzapine have a significantly better treatment response than men, and premenopausal women have a better treatment response than postmenopausal women. Overall, schizophrenic women under 40 years of age require lower antipsychotic doses than men regarding both acute response and maintenance.

Because of important side effects of antipsychotic medication, regular monitoring of weight gain and body mass index, plasma glucose level, lipid profiles, signs of prolactin elevation and ► hyperprolactinemia, or sexual dysfunction are recommended. Cardiac side effects and extrapyramidal symptoms should be considered as well. However, despite established sex differences in response to antipsychotic medication, these effects do not receive much emphasis in prescribing these drugs to men or women. Women, perhaps because of the influence of sex hormones, have a lower risk of sudden cardiac death, but a higher risk of acquired ► long QT syndrome from antiarrhythmic drugs. Estrogens may facilitate bradycardia-induced prolongation of the QT interval. Patent antipsychotic drugs were likely to block cardiac voltage-gated potassium channels, prolong the QT interval, and result in ventricular arrhythmias. Subsequently, women may be at a higher risk of cardiac side effects of antipsychotic medication. Older antipsychotics like ► butyrophenone and ► phenothiazine derivatives, and some of the second generation antipsychotics elevate prolactin levels (hyperprolactinemia) and result in sexual dysfunction, which in turn results in non-compliance with treatment, particularly in men. In the long run, hyperprolactinemia also causes galactorrhoea, amenorrhea, breast engorgement, and osteoporosis. In women, the elevation of prolactin concentrations is generally noted to be higher than in men. On the other hand, ► aripiprazole which has a different profile from second generation antipsychotics by being a partial D2 receptor agonist is reported to lower prolactin levels.

Antidepressants

Although, the prevelance of major depression is twice as much in women than men, sex differences observed in ► antidepressant medication is not overwhelming. Women experience more vegetative and atypical symptoms, ► anxiety, and anger than men, and report higher severity of depression on self-report measures; however, no significant sex differences are observed in the course of the illness and treatment response. The efficacy of ► bupropion and ► selective serotonin reuptake inhibitors (► SSRI), appear to be equally effective in treating depression, anxious/somatic symptoms, and ► insomnia; there is a slight sex difference as greater improvement was seen in women during SSRI treatment regarding anxious/somatic symptoms of depression. Additionally, the efficacy of antidepressants is more pronounced in younger patients. On the other hand, a recent study suggests that women with ► generalized anxiety disorder, particularly those with a later age of onset, may have a poorer response to the SSRI ► fluoxetine compared to men. Although women have higher plasma levels than men, no sex differences are reported in response to ► tricyclic antidepressants.

Analgesics

Pain management by pharmacotherapy is another important medical problem where sex differences are noted. Furthermore, there may be gender differences in pain

tolerance. Women report suffering from migraine and arthritis, more intensely than men do. Men have a better response to non-steroidal anti-inflammatory analgesics (NSAIDS) than women, and women benefit more from narcotics than men do. Therefore, over-the-counter analgesics do not help women as much as men, and lower doses of narcotics which are effective on women are not as effective on men.

Males and females respond differently to drugs acting at ▶ opioid receptors; these quantitative and qualitative differences are not restricted to the ▶ analgesic and antinociceptive properties of opioids, but are also present in opioid-induced side effects (i.e., effects on respiration, locomotor activity, learning/memory, addiction, and cardiovascular system). However, the direction and magnitude of sex differences regarding the potency of opioids depend on the interacting variables which are specific to the drug (i.e., dose, pharmacokinetics and pharmacodynamics, route and time of administration) or to the subject (i.e., species, type of pain, genetics, age, gonadal/hormonal status, and psychological factors). The differential organizational and/or ▶ activational effects of gonadal steroid hormones in males versus females have received emphasis in explaining sex differences in opioid antinociception. There are sex differences in response to drugs acting on ▶ kappa-opioid receptors: Women respond more robustly than men to ▶ kappa-opioid agonists and antagonists with analgesic and hyperalgesic properties, respectively. When drugs acting at different receptors are compared, women have better pain scores with kappa-opioid agonists (butorphanol) than mu-opioid agonists (morphine). However, rodent data from laboratory pain models contrast with human data.

Conclusion

Recent studies on both animals and humans clearly indicate that many normal physiological and pathological functions are influenced by sex-based differences in biology, either directly or indirectly. Males and females are not only different regarding reproductive function, but sex differences exist in brain and behavior, including emotion, memory, vision, hearing, processing faces, pain perception, navigation, neurotransmitter levels, stress hormone action on the brain, and disease states. Sexual dimorphisms are observed in many neurotransmitter systems, including monoamines, serotonin, GABA (gama-aminobutyric acid), acetylcholine, vasopressin, and opioids. Furthermore, dynamic factors that influence the bioavailability of drugs, body composition, gastrointestinal, renal and liver function, hormonal status, and activity of enzymes involved in drug metabolism, are not the same in males and females. Subsequently, it is clear that there are sex and gender differences in response to neuropsychopharmacological treatments. Sex is an important variable that should be considered when designing and analyzing studies in all areas of biomedical and health related research.

Gonadal hormones

Definition

The brains of mammals are sexually dimorphic due to the actions of testosterone and estradiol during sensitive periods of development. Additionally, males and females produce different sex ► hormones, so the circulating hormonal milieu is also sexually dimorphic. The ► gonadal hormones act in the brain at both intracellular and membrane receptors to induce changes in brain and behavior. One of the things that the ovarian hormones, estradiol and progesterone, do is modulate the response to cocaine and amphetamine by acting at membrane receptors in the striatum and nucleus accumbens. These effects of the ovarian hormones result in sex differences in the behavioral responses to these drugs. While ► androgens are reinforcing in their own right, they do not seem to modulate the behavioral response to cocaine or amphetamine.

Pharmacological Properties

Background

The brains of mammals undergo sexual differentiation during sensitive periods of development. In rodents, this occurs during the perinatal period and again during the peripubertal period. In humans, this occurs during the second trimester and, then again, during the peripubertal period. Exposure to testosterone (which is converted to estradiol in some areas of the brain) during early brain development influences neuronal survival, differentiation, and connectivity. During the peripubertal period, less is known about the extent of hormonal influences, but neuronal and dendritic pruning, as well as neuronal reorganization, are thought to occur when the brain is exposed to ovarian or testicular hormones at the onset of puberty. As a result of these periods of hormone exposure, the brains of adult males and females are sexually dimorphic (Becker et al. 2005, 2008).

In concert with the sexual dimorphisms caused by the processes involved in sexual differentiation, there may also be sex differences in brain function produced in response to exposure to gonadal hormones in the adult. This second type of sex difference can be either due to the effects of gonadal hormones acting on sexually dimorphic brain regions or as a result of the different effects induced by ovarian versus testicular hormones, which in some neural regions may decrease differences between the sexes.

Gonadal hormones are by definition sexually dimorphic, since males have testes that produce androgens and females have ovaries that produce ► estrogens and ► progestins. They are also dimorphic in their patterns of secretion. Testicular hormones are secreted in a tonic pattern, and feedback of testosterone to the brain maintains the rate of pituitary hormone secretion that sustains a constant rate of spermatogeneisis in the testes. Ovarian hormones are released in a cyclic manner. First, estradiol is released gradually during the development of the follicle that nourishes the development of the egg (follicular phase). Then, a rapid increase in estradiol induces the hormonal trigger to induce ovulation (periovulatory phase). Finally, in some species, estradiol and progesterone are released to prepare the womb for implantation of a fertilized egg (luteal phase) (Becker et al. 2005, 2008).

Unlike many pharmacological agents, in general, gonadal hormones do not activate or inhibit specific behaviors; instead, they prepare an individual to be able to engage in a particular behavior should the appropriate conditions arise (e.g., sexual behavior) or modulate the behavior that is exhibited (e.g., the behavioral response to ► amphetamine in females). One exception to this rule is the anxiolytic effects of progesterone and its 5α-reductase-derived metabolites, which are produced in the brain and are known as ► neurosteroids.

Mechanisms of Action

Gonadal hormones are steroidal in chemical structure, so they are lipophillic and act at both intracellular and membrane-associated receptors. The primary intracellular receptors have been well characterized. When bound to the ligand the receptor-ligand complex dimerizes and then binds to the DNA to initiate transcription. Activation of this receptor mechanism requires hours to days for a response to be observed. There are two forms of the

estradiol receptor (ER), known as ERα and ERβ. One of the products of ER activation is the progesterone receptor (PR) which has two isoforms, PR-A and PR-B (Mani 2008). Only one form of the intracellular androgen receptor (AR) has been identified to date. Males and females tend to express intracellular ER, PR, and AR in the same brain regions, but there are sex differences in the number of receptors expressed, with females expressing more ER and PR than males, and males expressing more AR than females.

Membrane receptors for the gonadal hormones have been identified only recently. In the case of progesterone, a novel receptor with seven transmembrane domains that activates a G-protein-mediated intracellular signaling pathway has been identified in vertebrates with two isoforms. The nuclear PRs are also thought to be found at the cell membrane after palmitylation, which anchors the nuclear receptor to the membrane. The nuclear PRs at the membrane also activate G-protein-mediated intracellular signaling pathways, but the exact nature of the interaction is not yet known (Mani 2008). For estradiol, two novel membrane receptors have been identified, GPR30 and Gq-mER; both activate G-protein-mediated, intracellular signaling pathways. As was seen with progesterone, nuclear ERs are also found at the cell membrane to activate G-protein-mediated intracellular signaling pathways. In the case of the ERs, palmitylation may also be involved, and the ERs are thought to associate with caveolin-1 and/or caveolin-3 as well to maintain their position in association with the membrane (Boulware et al. 2007; Micevych et al. 2009). It is not yet clear how the nuclear ERs (or PRs) are positioned relative to the membrane so that the ligand can be bound and intracellular pathways activated. In some brain regions, it is thought that ERs associate with ► metabotropic glutamate receptors to gain access to intracellular signaling pathways (Boulware et al. 2005). The rapid actions of androgens have been well documented in the brain and other tissues. The nuclear AR is implicated in many of these effects, and it is likely that there are also novel membrane ARs yet to be discovered.

Gonadal Hormone Modulation of Drug Effects in the Brain

Stimulant Drugs

In both rats and humans the behavioral effects of ► drugs of abuse, and the ► psychomotor stimulants in particular, are both sexually dimorphic and modulated by the gonadal steroid hormones. With repeated intermittent exposure to ► cocaine or ► amphetamine, the behavioral response exhibited is enhanced with each drug exposure. This is referred to as behavioral ► sensitization, is different in males and females, and is differentially affected by gonadal steroid hormones. For example, intact females exhibit more robust sensitization than do intact males. Following ovariectomy (OVX) of female rats, the expression of sensitization to amphetamine is attenuated or suppressed altogether relative to intact female rats. Estradiol treatments in OVX rats enhance sensitization of locomotor activity induced by amphetamine or cocaine (Becker and Hu 2008; Carroll et al. 2004).

These effects of gonadal hormones are relevant to addiction, where sex differences have been reported during all phases of the addiction process. Women tend to become addicted to drugs more rapidly than men and to escalate drug use at a greater rate. In animal models, when a low dose of a drug is used, female rats acquire cocaine ► self-administration at a faster rate than do males. The role of gonadal hormones can be seen when estradiol is given just before a self-administration session, as estradiol treatment enhances acquisition of cocaine self-administration in OVX female rats and treatment with the estradiol antagonist, tamoxifen, inhibits acquisition in intact females. In male rats, estradiol does not enhance acquisition or cocaine intake, so the brains of males and females are sexually dimorphic in this regard (Becker and Hu 2008; Carroll et al. 2004; Walker et al. 2006).

During maintenance conditions, when given a choice between two doses of cocaine, female rats in estrus preferred higher doses of cocaine when compared with females in other phases of the estrous cycle or male rats. When the role of estradiol in "binge" cocaine intake and subsequent motivational changes is examined, estradiol treatment increases the initial binge length and total levels of cocaine self-administration. Another way to assess motivation is to use a ► schedule of reinforcement in which the number of responses required to obtain a cocaine infusion progressively increases with each dose received. Under this "► progressive ratio schedule," intact female rats reach much higher final ratios than do males, indicating that females are more motivated to obtain cocaine. Females also work harder for access to cocaine during the phase of the estrous cycle when estradiol is elevated, indicating that ovarian hormones modulate the motivation to obtain cocaine. In fact, estradiol treatment enhances responding for cocaine on a progressive ratio schedule. These results show that estradiol influences acquisition of cocaine self-administration, and that there are motivational effects of estradiol on cocaine intake (Becker and Hu 2008).

In contrast to estradiol, progesterone treatment given concurrently with estradiol counteracts the effect of estradiol on acquisition of cocaine self-administration behavior. We have recently confirmed this finding and

understand that progesterone not only affects cocaine self-administration, but also enhances cocaine intake in estradiol-primed OVX rats. Taken together, ovarian hormones contribute to sex differences in cocaine self-administration, and estradiol in particular is a key factor influencing the reinforcing effects of cocaine in female rats. So, over the course of the estrous cycle, there are peaks and valleys during which females are more or less susceptible to the reinforcing properties of cocaine and other drugs of abuse.

As discussed above, our understanding of the mechanisms mediating the effects of estradiol and progesterone in the areas of the brain that mediate the response to drugs of abuse is evolving rapidly. For the most part, we believe that the effect of drugs of abuse on the ascending ► mesotelencephalic dopamine (DA) system is necessary for the addictive and motivational properties of these drugs. The acute administration of estradiol to OVX rats induces a rapid increase in amphetamine- or cocaine-induced DA release in ► nucleus accumbens or striatum. Estradiol also induces an increase in striatal DA turnover and downregulates D2-class DA receptors. These effects have been shown to be due to the direct effect of estradiol on the striatum and nucleus accumbens, presumably at membrane receptors for estradiol. Finally, estradiol induces an increase in PRs in the striatum, and progesterone also acts directly on the estradiol-primed striatum to modulate DA release (Becker and Hu 2008; Walker et al. 2006).

In terms of androgens, castration (CAST) of males has been reported to enhance sensitization of amphetamine- or cocaine-induced psychomotor behavior, although this result has not been found consistently. It has been hypothesized that if CAST enhances the induction and/or expression of behavioral sensitization, that testosterone treatment should reverse this effect. This is not the case, however, as testosterone treatment has not been found to affect behavioral sensitization in CAST males. Furthermore, there is no effect of CAST on acquisition of cocaine self-administration behavior, and a dose of estradiol that enhances self-administration in female rats has no effect on cocaine self-administration behavior in males. So, it does not seem that androgens play a role in modulating the motivational effects of drugs of abuse, even though hamsters, rats, and humans self-administer testosterone and other anabolic steroids all by themselves (Becker and Hu 2008).

Other Psychoactive Drugs

Gonadal hormones can also affect the response to drugs other than the stimulants, but the mechanisms mediating the effects are not as well worked out as for the psychomotor stimulants. Nevertheless, menstrual cycle effects and sex differences in the effectiveness of antidepressants and analgesics suggest that the gonadal hormones can modulate a wide variety of drug effects. In addition, the effects of gonadal hormones on the pharmacokinetics and pharmacodynamics of a drug's action must always be considered (Becker and Meisel 2007).

Conclusion

In summary, the gonadal hormones act in the brain at both intracellular and membrane receptors to induce changes in brain and behavior. The ovarian hormones, estradiol and progesterone, modulate the response to cocaine and amphetamine by acting at membrane receptors in the striatum and nucleus accumbens. These effects of the ovarian hormones result in sex differences in the behavioral responses to these drugs.

Synonyms

Mating behavior; Reproductive behavior

Definition

Anaphrodisiac; any compound reducing the intensity of sexual behavior.

Aphrodisiac; any compound enhancing the intensity of sexual behavior or the pleasure derived from such behavior. The term is sometimes used to designate anything that increases sexual urges, like in "visual aphrodisiacs," referring to sexually exciting pictures or movies.

Lordosis; a concave dorsiflexion associated with lifted rump and the tail moved to one side. This posture exposes the vaginal orifice, and is the basic female copulatory posture in many mammals. The ease by which lordosis is activated is frequently called receptivity.

Proceptive behavior; stereotyped motor patterns, in rodents mainly ear wiggling and hop-darting, typical of many female mammals and supposed to indicate a high propensity to engage in copulatory behavior.

Sexual behavior; any action leading to sexual reward. Sexual reward is a state of positive affect activated by the physical stimulation of the genitalia or mental representations of such stimulation.

Sexual motivation; a concept referring to a set of central nervous processes determining the likelihood of display of sexual behaviors, and their intensity if displayed.

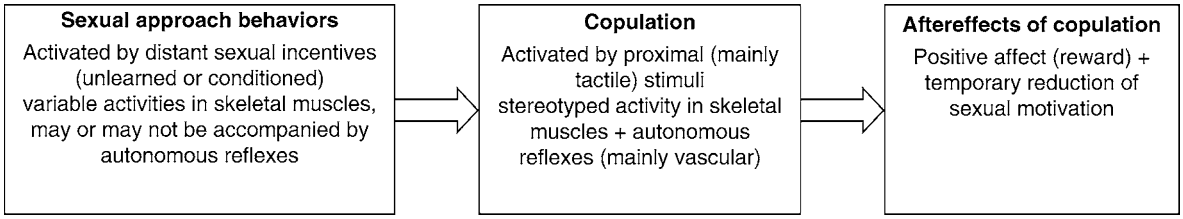
Impact of Psychoactive Drugs

A Long Tradition

The human seems to have been interested in manipulating sexual urges through pharmacological means since the dawn of history. There is anecdotal mention of plants and herbs purportedly stimulating or reducing the interest in sexual activities in many ancient sources. The search for and use of aphrodisiacs have attracted much attention, but there has also been made efforts to find ways to diminish sexual desire. In the classical Chinese Empires, this was achieved by a simple procedure modifying the availability of androgens through castration. Eunuchs were favored as high state officials during many centuries. Likewise, some men of faith, like the Egyptian theologian Origen, castrated themselves in order to be relieved from sexual temptations. During the Dark Ages, castration was no longer an approved practice, but monks are said to have prepared and consumed extracts of a plant, the common rue (*Ruta graveloens*), supposed to inhibit sexual desire. Despite the existence of occasional efforts to reduce sexual behavior, it can safely be stated that the main interest has been directed toward ways to enhance it. Unfortunately, none of the many suggested aphrodisiacs has been shown to have any reliable effect, although most of them have never been subjected to clinical or experimental tests. This, by the way, is also the case for the vast majority of anaphrodisiacs. However, it is conceivable that plants causing a strong sensation of ill-being, as *Ruta graveloens*, temporarily reduce or eliminate interest in sexual activity. Nevertheless, it is only with the advent of modern pharmacology that scientifically sound studies of the effects of xenobiotics on sexual functions have been performed (see Riley et al. 1993; Crenshaw and Goldberg 1996, for classical reviews of the pharmacology of human sexual behavior).

Essential Notions About Sexual Behavior

Any discussion of drug actions on sexual behavior becomes difficult without having some basic notions about this behavior. A schematic representation of the basic elements of sexual behavior is found in Fig. 1. Prominent among these is copulation. In all nonhuman animals, copulation is highly stereotyped. Some would even maintain that the copulatory acts basically are a series of somatic reflexes. However, copulation requires at least two individuals in



Sexual Behavior. Fig. 1. The elements of sexual behavior. Distant sexual incentive stimuli, emitted by a potential mate, activate approach behaviors. The specific motor patterns involved are determined by the context. If successful, the approach behaviors will lead to the establishment of physical contact with the potential mate. Eventually a sequence of stereotyped copulatory motor patterns (such as mounting and lordosis in rodents) may be activated. These motor patterns will bring the male genitals in contact with the female genitals and normally continue until the deposit of sperm in the female reproductive tract has been accomplished. Sperm deposit (ejaculation in the male) is followed by a state of positive affect. Every part of this sequence may be modified by drugs. The reactivity to sexual incentives may be enhanced or reduced, having as consequence increased or decreased likelihood for the display of sexual approach behaviors. Even the incentive properties of an individual may be altered through pharmacological means. However, very little is known about this. The stereotyped copulatory motor patterns themselves are rarely affected by drug treatments, but their frequency or number may be affected. Finally, the hedonic consequences of sexual activity may be enhanced or reduced by drugs. There are few experimental studies of drug-induced modifications of postcopulatory affective states. However, the opioid antagonist ► naloxone has been shown to block the postcopulatory hedonic state in male and female rats. See Ågmo (2007) for an extensive discussion of the sequence of sexual behaviors.

physical proximity. In fact, behaviors leading to approach to a potential mate always precede the execution of copulatory behaviors. Approach behaviors are extremely variable, and determined by the prevailing context. The intensity of approach to a potential sexual partner is an exquisite indicator of the intensity of the urge to engage in sexual activities, or sexual motivation. In nonhuman animals, the display of copulatory reflexes is as dependent on sexual motivation as sexual approach and proceptive behaviors are. However, the human may engage in copulatory behaviors because she/he is forced to do so (the term for most such activities is rape), or as part of a business arrangement (often called prostitution), even in the absence of sexual motivation. It is not entirely clear whether nonhuman animals also may engage in sexual behaviors without an active sexual motivation. In the case of rodents, all available data suggest that sexual motivation is a requisite for the display of sexual behaviors. With these rare exceptions, the intensity of sexual motivation determines the likelihood of display of sexual approach behaviors and their intensity as well as the likelihood of display of copulatory acts and their intensity. It can be maintained that all drug actions on sexual behaviors are, in fact, actions on motivation. It must be noted that different neurobiological processes underlie different aspects of sexual behavior. The neural systems crucial for sexual approach may be different from those controlling seminal emission and ejaculation, for example (Ågmo 2007). This means that a drug may affect the latter without modifying the former. No effort will be made to present a comprehensive list of drugs that may affect sexual behaviors. The following brief review is limited to compounds that has attracted more than occasional attention, and for which reasonably consistent and sound experimental data are available. A short summary of the effects of manipulations of the most studied neurotransmitters is found in Table 1.

Drugs Enhancing Sexual Motivation

Any increase in sexual motivation leads to an increase in one or more of the sexual behaviors. However, not all increases in the intensity of sexual behaviors should be attributed to an increment of sexual motivation. In males, including men, penile erection is a requisite for sexual behavior in the form of penile–vaginal intercourse and for some other forms of penetrative sex. Thus, the frequency of copulation is by necessity low in males suffering from ► erectile dysfunction. Such males will display more sexual behavior when using ► sildenafil, tadalafil, or some other of the phosphodiesterase-5 inhibitors than when treated with ► placebo. This is also the case for men using intra-penile treatments or centrally acting, erection-enhancing drugs such as ► apomorphine. Nevertheless, drugs facilitating erection, regardless of their site of action, are usually not considered as stimulating sexual motivation. This also holds for treatments promoting vaginal lubrication, although such treatments well may

Only the most consistently reported effects are mentioned. Facilitation includes enhanced receptivity and/or increased proceptivity in females, and reduced latencies to mount, intromit, or ejaculate in males. Inhibition includes reduced receptivity and/or reduced proceptivity in females and enhanced latencies to mount, intromit, or ejaculate in males. Many other effects on subtle details of sexual behaviors have been described in addition to those mentioned, but they are ignored here (see Argiolas 1999; Paredes and Ågmo 2004; Hull and Dominguez 2006, for reviews). Several additional transmitters/modulators have been shown to modify sexual behaviors, but our knowledge about these is at a very preliminary stage, making it too adventurous to summarize their actions

enhance the frequency of intercourse. A drug considered as stimulating sexual motivation should not render sexual activity possible. Instead, it should enhance the urge to engage in sexual activity and/or improve the performance of copulatory acts.

► *Acetylcholine*. It has been reported that muscarinic agonists facilitate ejaculatory mechanisms in male rats. The number of intromissions necessary to trigger ejaculation has repeatedly been found to be reduced after treatment with oxotremorine. Muscarinic agonists have also been found to facilitate lordosis in females injected with a low dose of estradiol, by itself producing a low level of sexual behavior.

► *Dopamine*. Agonists reliably facilitate copulatory behavior in males with a low baseline level of sexual activity, but their effect in males with a normal activity level is highly variable from one study to another, and frequently it is none. A few studies have evaluated the intensity of sexual approach behaviors in male and female rats after treatment with drugs facilitating dopaminergic neurotransmission, such as ► amphetamine or apomorphine, usually without finding any consistent effect. To the contrary, dopamine antagonists have been found to facilitate lordosis in female rats. Strangely enough, apomorphine administered directly into the ventromedial nucleus of the hypothalamus has been found to facilitate lordosis in estrogen primed, ovariectomized females.

► *Noradrenaline*. Adrenergic α_2 antagonists such as ► yohimbine and atipamezole have been reported to facilitate copulation and sexual approach in male rats, but these studies needs to be extended before a firm conclusion can be proposed. There are also some data showing facilitated sexual behavior in both male and female stump-tail macaques after treatment with atipamezole.

Peptides. Among the peptide neurotransmitters, ► oxytocin stands out as producing the most reliable stimulatory effects on male and female sexual behavior. In the case of the female, it is known that estrogens enhance the expression of the oxytocin receptor gene as well as the oxytocin gene at brain sites relevant for female sexual behavior. This has led to the hypothesis that oxytocin is involved in the physiological control of female sexual behaviors. There are also data from male rats suggesting that oxytocin may enhance sexual behavior.

Several other peptides, such as ► orexin, ► leptin, and galanin-like peptide, have been reported to facilitate different aspects of copulation in rats after intracerebroventricular or intracerebral administration, but the number of studies is still too low for any firm conclusion. A melanocortin-4 agonist, bremelanotide, has been reported to stimulate some aspects of copulatory behavior in female rats. The compound was also subjected to clinical trials in the human as a treatment for ► sexual dysfunctions, but these trials have now been abandoned.

► *Serotonin*. Drugs reducing serotonergic neurotransmission generally stimulate copulatory behavior in both males and females. In male rats, a particularly consistent effect has been reported after treatment with 5-HT_{1A} agonists. The numbers of preejaculatory intromissions and of the time needed to achieve ejaculation are much reduced after such diverse drugs as ► buspirone, lisuride, and 8-OH-DPAT. These effects are usually explained as a consequence of actions at serotonergic autoreceptors within the raphé nucleus, leading to reduced serotonin release in the forebrain. Despite the clear-cut effects of the agonists, a 5-HT_{1A} antagonist failed to modify copulatory behavior although it reliably blocked the effects of agonists. This observation suggests that there is no tonic inhibitory activity at 5-HT_{1A} receptors in male rats. A 5-HT_{1A} agonist/5-HT_{2A} antagonist, flibanserin (BLMT-17), is currently being tested as a treatment for hypoactive sexual desire disorder in the human female. In vivo data suggest that the compound is mainly acting as an agonist at the 5-HT_{1A} receptor. The possible effects of other receptor subtype specific 5-HT agonists are less clear. Some data suggest that an agonist ((+/−)-1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane, DOI) acting at the 5-$HT_{2A/2C}$ receptor may facilitate both lordosis and proceptive behaviors in female rats.

Drugs Reducing Sexual Motivation

In contrast to the mostly failed efforts to enhance sexual motivation with drugs, many compounds reliably inhibit it. In fact, almost any drug will inhibit sexual motivation if the dose is large enough. Sedation, gross motor disturbances, stereotypies, or other drug actions will eventually interfere with sexual behaviors. Therefore, the present discussion is limited to drugs that appear to reduce sexual functions without having dramatic effects on other behaviors.

Acetylcholine. ► Muscarinic antagonists have generally an inhibitory action on male and female copulatory behavior. There are also some data showing that ► scopolamine reduces sexual approach behaviors in female rats and proceptive behaviors in monkeys.

Dopamine. Antagonists reduce copulatory behavior in males. Whether the inhibitory effects in males are specific to sex behavior or consequences of a generally reduced arousal is a matter of debate. Agonists are known to inhibit lordosis in females when given in high doses. The role of dopamine-dependent activation of competing behaviors, in any case, should not be ignored. In moderate doses, dopamine agonists have no effect in fully receptive females.

► *GABA*. Systemic treatment with GABA agonists are always inhibitory in both males and females, but the doses needed are almost always of such a magnitude that motor functions are compromised, and effects on sexual behavior may be secondary to motor effects. The intracerebral administration of GABAergic compounds has variable effects, again depending on the site of infusion. It is most likely so that GABA agonists will reduce nervous activity at the site of infusion, while the antagonists will have an excitatory effect. Indeed, the effects of locally infused GABA agonists are similar to those of a lesion, and GABA antagonists have effects similar to those of electrical stimulation.

► *Opioids*. Chronic use of opiates is known to reduce sexual behaviors in human males, and acute as well as chronic treatment reduces it in male rats. Since opiates inhibit gonadotropin release, it is possible that the deleterious effects of chronic opiate use are caused by reduced testosterone availability. In male rats, acute treatment with an opiate agonist that does not penetrate the ► blood-brain barrier blocks sexual behavior as efficiently as morphine, suggesting that peripheral actions may be of importance. However, the intracerebral administration of large doses of opioid receptor agonists also reduces male sexual behavior. In females, studies employing the intracerebral infusion of compounds acting at opioid receptors have provided evidence for both facilitation and inhibition of lordosis. Facilitation was observed after infusion into the ventromedial nucleus of the hypothalamus while inhibition was observed when drugs were infused into the medial preoptic area. Both effects may be mediated by the δ opioid receptor.

Peptides. Oxytocin receptor antagonists or ► antisense oligonucleotides directed against the oxytocin receptor consistently reduce lordosis. ► Neuropeptide Y has also been reported to inhibit sexual behavior in male and female rats.

► *Serotonin*. Compounds facilitating serotonergic neurotransmission inhibit copulatory behavior and sexual approach behaviors in rodents. These effects do not seem to be secondary to drug actions on other behaviors. Efficient drugs range from the serotonin precursor

5-hydroxytryptophan (5-HTP) through the ► selective serotonin reuptake inhibitors (SSRIs) to several receptor agonists. Lordosis is consistently inhibited by 5-HT_{1A} agonists. It should be observed that the effects of 5-HT_{1A} agonists are completely different in males and females. 5-$HT1_A$ antagonists usually fail to facilitate lordosis , suggesting that there is no tonic inhibitory activity at 5-HT_{1A} receptors. The inhibitory effects of serotonin agonists are not limited to rodents. In the clinical use of the SSRI antidepressants, one of the main adverse effects is reduced sexual function, both in men and women. The specific serotonin receptor involved in this effect is unknown. However, in male rats a 5-HT_{1B} antagonist blocks the inhibitory effect of 5-HTP, suggesting that the 5-HT_{1B} receptor is crucial for the inhibitory actions. Other serotonin receptors may also inhibit sexual behavior. For example, a selective 5-HT_{2C} antagonist has been found to reduce sexual motivation in female rats tested in a procedure similar to the natural mating situation. There is also some evidence suggesting that DOI inhibits copulatory behavior in male rats through actions on the 5-HT_{2A} receptor. It should be noted that DOI facilitates female copulatory behavior. Here we might have another example of the opposite actions of serotonergic drugs in males and females.

Conclusion

It is certainly too simplistic to imagine that a complex behavior like sex is controlled by a single neurotransmitter. This proposal holds both for sexual approach behaviors and for the copulatory reflexes. As well it is probably too simplistic to imagine that a particular aspect of sexual behavior, for example, lordosis, is controlled by a single transmitter. Likewise, although the medial preoptic area is required for the performance of all elements of male sexual behavior and the ventromedial nucleus of the hypothalamus is necessary for all aspects of female sexual behavior, it is too simplistic to believe that drug actions within these structures can explain the effects observed after systemic drug treatments. Manipulations of one transmitter system will certainly modify the activity of a host of other transmitter systems, and alterations within a particular structure will alter the activity of other structures. Finally, receptor agonists may have actions that the endogenous ligand never has, because of a mismatch between receptor localization and sites of endogenous transmitter release. All these facts make it extremely risky to try to elucidate the physiological control of the sexual behaviors through pharmacological means. However, if we are interested in finding compounds that can enhance or reduce some particular aspect of the sexual behaviors, then there is no need to consider whether the drug's action is part of the physiological control of sex behaviors or not. A pure description of drug effects is sufficient and interesting by itself.

Sexual Disorders

Vera Astreika, Robert Segraves
Department of Psychiatry, MetroHealth Medical Center, Cleveland, OH, USA

Definition

Sexual disorders are common in the general population and have a high prevalence in certain psychiatric populations. The Diagnostic and Statistical Manual of Mental Disorders, fourth edition (► DSM-IV-TR), divided sexual disorders into two groups: (1) sexual dysfunctions, defined as psychophysiological impairment of sexual desire and/or

of sexual response cycle and (2) paraphilias, defined as recurrent, intense sexual urges or behaviors that cause marked distress and involve unusual objects or activities.

Sexual Dysfunctions

Sexual dysfunction is best understood by having knowledge of the stages of the normal sexual response, which vary with age and physical status. The five-step model of Masters and Johnson has been elaborated into phases of excitement (arousal), plateau (maximum arousal prior to orgasm), orgasm (involving muscular contractions at 0.8 s intervals), resolution (return to baseline), and refractory period (a recovery stage during which another orgasm is not possible; in men this stage increases with age, whereas women have no refractory period). The triphasic model of Kaplan includes desire, excitement (arousal, a vascular phenomenon, mediated by innervation of the parasympathetic nervous system, specifically the second, third, and fourth sacral segments of the spinal cord), and orgasm (a muscular reaction, mediated by innervation of the sympathetic nervous system, whose reflex center is in the lumbar cord).

Changes in sexual response are associated with aging. In females, having decreased levels of estrogen leads to less vaginal lubrication and narrowing of the vagina. Males are slower to achieve an erection and need more direct stimulation of the penis to achieve an erection. Sexual dysfunction can be primary (life-long) or secondary (acquired), and it may be generalized (occurring in all circumstances) or situational (limited to certain types of stimulation, situations, or partners). Medications, ► drugs of abuse, diseases, injuries, and psychological conditions can affect the sexual response in any of its component phases and can lead to different dysfunctional syndromes. The emphasis on biological treatment in this chapter is not intended to minimize the importance of psychological interventions.

In DSM-IV-TR, sexual dysfunctions are categorized as follows:

1. Desire phase disorders in males and females
   - *Hypoactive sexual desire disorder* denotes persistently deficient sexual fantasies and an infrequent desire for sexual activity.
   - *Sexual aversion disorder* reflects a persistent and extreme aversion to, and avoidance of, all or almost all genital sexual contact with the sexual partner.
2. Arousal phase disorders
   - *Female sexual arousal disorder* involves a persistent inability to attain or maintain the lubrication/swelling response of sexual excitement until completion of the sexual act.
   - *Male erectile disorder* consists of the inability to attain or maintain a satisfactory erection until completion of sexual activity.
3. Orgasm phase disorders
   - *Female orgasmic disorder* is a condition in which there is a persistent delay in, or absence of, orgasm following normal excitement.
   - *Male orgasmic disorder* involves a persistent delay in, or absence of, orgasm following a normal sexual excitement phase. It is infrequent and usually restricted to failure to reach orgasm in the vagina during intercourse, although orgasm can occur with masturbation and/or with a partner's manual or oral stimulation (retarded ejaculation). This condition must be differentiated from retrograde ejaculation, where the bladder neck does not close off properly during orgasm, causing semen to spurt backward into the bladder, which can cause infertility.
   - *Premature ejaculation* is comprised of persistent ejaculation with minimal stimulation before or after penetration and before the person wishes it. It is the most common male sexual disorder.
4. Sexual pain disorders
   - *Dyspareunia* involves persistent genital pain before, during, or after sexual intercourse in either the male or the female. If the pain is caused solely by vaginismus or a lack of lubrication, the diagnosis of dyspareunia is not made.
   - *Vaginismus* denotes persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with intercourse. It can be life-long with an abrupt onset following the first attempt at penetration, or occur suddenly following a sexual trauma or a medical condition.

Paraphilias

DSM-IV-TR delineates eight categories of paraphilias, all involving recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors occurring over a period of at least 6 months:

1. *Exhibitionism* involves exposure of one's genitals to an unsuspecting stranger.
2. *Fetishism* denotes the use of nonliving objects.
3. *Frotteurism* consists of touching and rubbing against a nonconsenting person.
4. *Pedophilia* describes sexual activity with prepubescent children.

5. *Sexual masochism* reflects the act of being humiliated, beaten bound, or otherwise made to suffer.
6. *Sexual sadism* denotes acts in which the psychological or physical suffering of the victim is exciting to the person.
7. *Transvestic* fetishism consists of cross-dressing.
8. Voyeurism involves the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.

Role of Pharmacotherapy

Treatment of Sexual Dysfunction in Women

When education, lifestyle, communication, and behavioral changes do not achieve the desired level of success, pharmacological therapy can be utilized to treat sexual dysfunction in women.

Estrogen

Estrogen replacement therapy (ERT) may positively affect sexual function in a number of ways. Estrogens rapidly restore the superficial cell layer of the vaginal epithelium, reestablish elasticity, restore the balance in vaginal pH, improve mood, and increase blood flow to enhance lubrication. Short-term studies of estrogen replacement therapy have confirmed a benefit in some postmenopausal women with sexual dysfunction. However, not all studies have demonstrated positive results, possibly because women most likely to respond are those with symptoms of hypoestrogenism. Any short-term positive effect of oral estrogen may diminish in long-term use because of increasing sex hormone binding globulin (SHBG) levels, which lead to reduced estrogen and androgen bioavailability, and consequent decreased desire and activity. The increase in SHBG appears to be less significant in women who use non-oral delivery system for ERT. Vaginal estrogen is highly effective for treating genitourinary atrophy symptoms, in particular, the vaginal dryness and dyspareunia. Water-soluble lubricants are also helpful for continued sexual activity.

Progestin

Progestin agents downregulate the estrogen receptor, a desired result in the endometrium, but potentially undesirable in the brain, heart, bone, and genitalia. Progestins generally have an overall negative effect in the central nervous system (CNS) with respect to depression and mood, and have been shown to decrease sexual desire and diminish vaginal blood flow. Available options include micronized progesterone (MP) and 19-nortestosterone derivatives, norethindrone acetate (NA), and norgestimate (NGM). When estrogen is given with progestin, the effect on SHBG depends upon the type of progestin used. 19-nortestosterone-derived progestins decrease the SHBG levels. Newer studies in progress with more modern combinations of progestin with estrogen and androgens will provide better insight into the progestational effects on sexuality.

Androgens

Androgens play an important role in physiologic aspects of the female sexual response. However, the effect of androgen therapy on sexual function in women is controversial. Some studies have reported improvements in libido, sexual arousal, and the frequency of sexual fantasies with testosterone therapy in a variety of forms. The observation that testosterone therapy may result in improvement in mood and well-being is felt by some researchers to be most important. The central sex steroid's effect on mood may be what underlies sexual function in both women and men. Potential side effects of androgens include a decline in serum high-density lipoprotein (HDL) cholesterol with oral preparations and mild cosmetic side effect such as hirsutism and acne. Testosterone preparations include creams, gels, and tablets that can be taken orally or used sublingually. They are not approved in the US FDA, but one product approved in Europe for postmenopausal women is a transdermal testosterone patch. Many clinicians have tried creams that are used for vulvar dystrophies made up with 2% testosterone propionate. Others have tapered down the potency using micronized testosterone 0.5% up to 1%, and rarely 2%. Creams were applied first on the inside of the forearms or thighs, while later paraclitoral use became common. The creams seemed to work better paraclitorally in patients with sexual arousal disorder than in those with hypoactive sexual desire disorder. Studies on the use of dehydroepiandosterone (DHEA) have shown an increase in energy level, well-being, sexual satisfaction, and sexual function only in women with primary and secondary adrenal insufficiency. There are no receptors for DHEA and side effects occur due to conversion to testosterone and then to estrogen. Combination therapy with oral estrogen and methyltestosterone also improved sexual interest/desire in postmenopausal women who were experiencing hypoactive sexual desire. The data that androgen therapy significantly improves sexual functioning are suggestive, but not conclusive. No guidelines for androgen therapy for female sexual dysfunction are available. Women most likely to benefit from androgen therapy are probably

those who have undergone bilateral oophorectomy with hysterectomy. Women with hepatic disease, a history of breast cancer, uncontrolled hyperlipidemia, acne, or hirsutism should not be treated. Baseline free and total testosterone levels, liver function tests, and lipid profile should be obtained prior to initiating therapy. Liver function tests and lipids should be monitored every 6 months during therapy. Women should be current on cervical and breast screening.

Herbal Therapies

► Yohimbine has been reported to enhance desire, arousal, and orgasm in women with sexual dysfunction secondary to ► selective serotonin inhibitors (SSRIs), but results are inconclusive. Side effects of yohimbine can be serious and include dizziness, anxiety, hyperstimulation, nausea, renal failure, and seizures. Yohimbine should not be taken together with ► tricyclic antidepressants, ► phenothiazines, clonidine, or other drugs or supplements for lowering blood pressure.

L-arginine, an amino acid, has been touted as the natural sildenafil due to the claimed ability to release nitric oxide, causing increased vasoconstriction in the genitalia of both sexes. It causes side effects such as hypotension, dizziness, headache, and nausea.

Future Therapies

Tibolone is a synthetic hormone, currently available in Europe and Australia. Tibolone is used in women to relieve symptoms of menopause and to prevent osteoporosis. It has not been approved by the US FDA. Its metabolites have estrogenic, androgenic, and progestational effects. Oral tibolone is found to increase vaginal lubrication, arousability, and sexual desire.

► Sildenafil, a phosphodiesterase-5 inhibitor, in preliminary findings demonstrated positive effects in the areas of sexual arousal and orgasm in appropriately selected women, but several large studies have yielded inconclusive results. It has been reported to reverse anorgasmia associated with SSRIs.

► Apomorphine SL, a non-ergoline dopamine agonist, has been reported to improve sexual desire and function in premenopausal women with hypoactive sexual desire. Apomorphine SL is not FDA approved for this indication. Its side effects include hypotension, dizziness, bradycardia, headache, sedation, and nausea.

Treatment of Sexual Dysfunction in Men

The three major forms of male sexual dysfunction are erectile dysfunction, ejaculatory dysfunction, and decreased libido.

Erectile Dysfunction

Therapy in men with ► erectile dysfunction is aimed at restoration of the two vital sexual functions: the capacity to acquire and sustain penile erection and to reactivate libido. Erectile dysfunction can also be a side effect of antidepressant and antipsychotic therapy. Optimal treatment varies with the cause of the erectile dysfunction.

For first-line therapy, the ► phosphodiesterase-5 (PDE-5) inhibitors are recommended because of their efficacy, ease of use, and favorable side effect profile. The three ► PDE-5 inhibitors, sildenafil, vardenafil, and tadalafil, appear to be equally effective, but tadalafil has a longer duration of action. The rationale for the use of PDE-5 inhibitors is based upon the role of nitric oxide-induced vasodilatation. Nitric oxide release triggers the production of cyclic guanosine monophosphate (cGMP), which leads to decreased intracellular calcium, smooth muscle relaxation, and penile erection. All available PDE-5 inhibitors work by inhibiting the degradation of cGMP. They are highly specific, vary somewhat in selectivity for other phosphodiesterase enzyme types, and differ in duration of action. Common side effects include dyspepsia, flushing, rhinitis, and headache. The use of PDE-5 inhibitors with nitrates is contraindicated by the risk of severe hypotension. PDE-5 inhibitors should be used cautiously with alpha-blockers (because of the risk of hypotension) and in men with aortic stenosis, recent myocardial infarction, unstable angina, heart failure, arrhythmias, degenerative retinal disease, or poorly controlled hypertension. The rare possibility of priapism exists, and patients should be instructed to seek emergent medical attention if erection persists for more than 4 h without sexual stimulation. Cases of sudden loss of vision or hearing have been associated with PDE-5 inhibitors. Sildenafil also causes blue vision in 3% of men. This effect usually lasts for 2–3 h and disappears spontaneously. For maximum effectiveness, sildenafil should be taken orally about 1 h before a planned sexual encounter. The initial dose should be 50 mg, reduced to 25 mg if side effects occur. If the drug is well tolerated but the erectile response is not fully satisfactory, the dose can be increased to 100 mg. The duration of action is approximately 4 h. Vardenafil shares a similar structure, onset of duration of action and side effect profile with sildenafil. It is available as 10 and 20 mg doses. Tadalafil differs in chemical structure, has an equally rapid onset but longer duration (24–36 h) and does not cause blue vision, but otherwise shares a similar side-effect profile with the other two PDE-5 inhibitors. The recommended starting dose for as-needed use is 10 mg, increasing to 20 mg if necessary. Lower

doses of tadalafil (2.5 mg, 5 mg) are available for once daily administration. This approach appears to be as effective as taking higher doses on an as-needed basis. Sildenafil and vardenafil must be taken on an empty stomach, while tadalafil can be taken without regard to food.

Intrapenile injection therapy with alprostadil (prostaglandin E), papaverine, and phentolamine has been used to induce erection. Since the advent of PDE-5 inhibitors, these approaches are rarely used. In the early days of penile self-injection therapy, papaverine proved to be more reliable than phentolamine in producing an erection. Papaverine is a parenteral vasodilator with marginal efficacy in peripheral vascular disease, while phentolamine is an alpha-adrenergic blocker. Alprostadil and papaverine are still used in monotherapy, and all three drugs can be given together. Intrapenile injection is recommended 10–20 min before intercourse and may require additional penile stimulation. Limitations of these agents include penile pain, lack of efficacy and need for self-injection. Priapism occurs in 6% of men who use intrapenile alprostadil and about 11% of those who use intrapenile papaverine.

Intraurethral alprostadil provides a less invasive alternative to intrapenile injection. After insertion of the alprostadil into the urethra 5–10 min before intercourse, the penis should be massaged for up to 1 min to ensure equal distribution in the corpora cavernosae. The drug can be used twice daily. It is not recommended with pregnant partners. Systemic effects are uncommon and complications such as priapism and penile fibrosis are less common than after alprostadil given by penile injection.

Off-label use of some other agents may be moderately effective in treating erectile dysfunction in men who do not respond adequately to PDE-5 inhibitors. Efficacy has been reported for ► cabergoline, a dopamine D2 receptor agonist used to treat hyperprolactinemia and ► Parkinson's disease; valvular heart disease has been observed at higher doses of this drug. Yohimbine, a presynaptic alpha 2-adrenergic blocking agent, has been used for men with psychogenic erectile dysfunction. Treatment is considered only in those who respond and also tolerate the drug's side effects, which include dizziness, flushing, nausea, headache, anxiety, insomnia, hypertension, and seizures. Melanocortin receptor agonists, which act on the CNS rather than on the vascular system, are being developed as a possible new therapy for erectile dysfunction. PT-141, an intranasal preparation, appears to be effective as monotherapy or in combination with PDE-5 inhibitors. However, significant side effects, including flushing and nausea, may limit its clinical utility. This agent is not commercially available.

Premature Ejaculation

Locally applied anesthetic creams, such as prilocaine/lidocaine mixtures, have been found to increase ejaculatory latency by approximately 7–10 min. Their major side effect is penile hypoanesthesia. The man also must use a condom or wash off the cream before vaginal penetration to minimize vaginal absorption.

Although no medications are FDA-approved for this indication, case reports have described the use of ► monoamine oxidase inhibitors, ► tricyclic antidepressants, and ► antipsychotics for this off-label use. ► Clomipramine, a tricyclic antidepressant with strong serotonergic activity, has been shown in ► double-blind trials to be effective in treating premature ejaculation on an as-needed basis. Clomipramine usually is taken 4–6 h before coitus in doses of 25–50 mg. Common side effects are dry mouth, nausea and fatigue. The SSRIs ► paroxetine, ► sertraline, and ► fluoxetine also delay ejaculation. Most trials have found that the dose needed to delay ejaculation is similar to the dose necessary to treat depressive disorders. SSRIs require chronic dosing to be effective. Among the SSRIs, paroxetine appears to have the greatest effect on ejaculatory latency. Paroxetine 20 mg daily can be started as initial treatment. Low-doses (0.5– 1 mg) of the benzodiazepine ► lorazepam, taken 30 min before coitus, also can be effective in some men. Lorazepam has the common side effect of sedation.

Decreased Libido

For men with sexual dysfunction and low serum testosterone levels, testosterone replacement therapy should be the initial treatment. If sexual dysfunction is associated with testosterone deficiency, testosterone therapy to restore normal-range testosterone levels can be achieved with transdermal gels, patches, or injections. Current recommendations are to attempt to restore serum testosterone to mid-normal range. A variety of therapeutic approaches are possible. These include 75–100 mg of testosterone enanthate or cyproate administered weekly, one to two 5 mg patches nightly, 5–10 mg of testosterone gel applied daily, or a 30 mg bioadhesive buccal testosterone tablet applied every 12 h. Potential side effects of testosterone replacement therapy include prostatic hypertrophy, increased erythropoiesis, worsened sleep apnea, gynecomastia, and fluid retention possibly worsening hypertension and cardiac failure. Follow-up care should include routine prostatic specific antigen (PSA), hematocrit and serum testosterone levels.

Pharmacological Treatment of Paraphilias

Pharmacological interventions for paraphilias are symptom-focused and directed toward ameliorating or managing comorbid conditions. The number of medications used to treat paraphilias has been steadily increasing. Pharmacological interventions fall into three primary categories: antiandrogens (testosterone-lowering agents), antidepressants, and neuroleptics and other agents.

Antiandrogens or Testosterone-Lowering Agents

Use of these drugs in treating paraphilias usually must be long-term. Relapse is common upon cessation of the medication. Testosterone-lowering agents are the gold standard for treating any paraphilic disorder in which sex-drive reduction is a desirable component.

Medroxyprogesterone acetate (MPA) is the most commonly used hormonal agent for the reduction of sex drive. It reduces levels of testosterone by inducing hepatic testosterone reductase. The goal of this strategy is to reduce baseline testosterone to 50% of initial value. Common dosages are 50–300 mg orally or 300–400 mg weekly via intramuscular injections. Depot preparations of MPA are also available.

Cyproterone acetate (CPA) blocks androgen receptors, directly decreasing the biological effect of testosterone. CPA can be given orally 100 mg daily or 200 mg every other week via intramuscular injections. CPA is not available in the USA.

Side effects of treatment with MPA and CPA include reduced sexual drive and erectile ability, fatigue, depression, liver dysfunction, gynecomastia, weight gain, hyperglycemia due to an exaggerated insulin response to a glucose load, headaches, and increased risk of deep vein thrombosis.

Leuprolide and triptoreline are long-acting luteinizing hormone-releasing hormone (LHRH) agonists. LHRH agonists suppress testosterone by decreasing the number of pituitary LHRH receptors and testicular receptors, thereby desensitizing the testes to luteinizing hormone (LH). As a result of their depleting effects, levels of circulating testosterone and dihydrotestosterone decrease to prepubertal levels. LHRH agonists more completely suppress androgen than MPA or CPA. Leuprolide and triptoreline are given intramuscularly in doses of 3.75 or 7.5 mg monthly. They can cause a surge in gonadotropin secretion in the first 2–4 weeks of treatment. Because of this effect, patients receiving treatment with LHRH agonists should temporarily be prescribed an androgen receptor blocker, such as flutamide. The typical flutamide oral dosage is 250 mg three times a day. It can be discontinued after 2–4 weeks. Side effects of LHRH agonists are related to hypoestrogenic states and consist of erectile failure, hot flashes, and decreased bone mineral density.

Antidepressants

SSRIs have been proposed for alleviating paraphilic symptoms because of their adverse side effects of diminished sexual desire and arousability. A study comparing the effectiveness of ▶ fluvoxamine, ▶ fluoxetine, and ▶ sertraline in paraphilics found all three effective in reducing the severity of fantasies and no significant differences in overall efficacy. It is unclear whether the SSRIs are selectively useful in individuals with a clear obsessive-compulsive disorder component, comorbid anxiety, or depressive disorder underlying the paraphilia or, rather, whether they have a more generalized usefulness for the paraphilias. The SSRIs and other antidepressants are highly variable in the degree to which they cause the sexual side effects that might be beneficial in managing paraphilias.

Neuroleptics and Other Agents

▶ Neuroleptic agents have been reported to diminish paraphilic behavior and fantasies. ▶ Lithium and ▶ anticonvulsants have been reported to be useful in treating sexual impulsivity. However, the successful use of neuroleptics and mood stabilizers in treating paraphilias may reflect their efficacy for the comorbid ▶ mania or other psychotic states that are often associated with paraphilia.

Short-Term and Working Memory in Animals

Yogita Chudasama
Department of Psychology, McGill University, Montreal, QC, Canada

Definition

Short-term memory refers to a storage mechanism that retains information for a limited period of time. In animals, working memory (WM) is conceptualized as a form of short-term memory that encompasses both storage and processing functions. In WM, information is not only held transiently in mind but also actively manipulated; items may be monitored, compared and/or associated to other items and incoming information as they are recalled. Information in WM is active on the time scale of several seconds, and is sensitive to attentional distraction. The main role of WM is to keep track of relevant information, continuously update it, and use it to shape behavior in the present. In animals, the prefrontal cortex plays a central role in WM, and disruption to its intrinsic circuitry or its connectivity with other brain regions leads to several cognitive deficits. In animals, a wide range of psychoactive agents affect WM.

Impact of Psychoactive Drugs

Recently, much attention has been focused on the psychopharmacology of WM. Two main developments have converged to create this interest. First, there have been significant advances in our understanding of the anatomy and organization of the neurotransmitter pathways in the mammalian brain. These pathways include the major monoaminergic (dopamine, serotonin and norepinephrine) and cholinergic projections, which innervate diverse forebrain regions that have discrete psychological functions. This has refined our understanding of the neurochemical basis of pathophysiological conditions such as ► Parkinson's disease, ► Alzheimer's disease, and ► schizophrenia, which are characterized by memory loss and cognitive disorganization. Second, research has linked poor psychosocial functioning to persistent cognitive deficits, including WM, which fail to improve with current pharmacotherapies. Consequently, there has been an important need to identify pharmacological compounds intended to improve cognitive deficits in psychiatric illness and dementia (see ► cognitive enhancers), and WM impairments have become important targets for treatment.

In animals, WM is assessed using the spatial delayed response task, which evaluates the animal's capacity to act on the basis of stored information rather than information available in the environment. Typically, a monkey is shown the location of a food morsel. The food morsel is then hidden from view. After a delay of several seconds, the monkey is required to choose one of the two locations. To be rewarded, the animal must remember where the food was located prior to the delay period. In a variation of the task, ► spatial delayed alternation, the monkey is required to alternate between left and right food wells in successive trials that are separated by delay periods. In this latter version, the monkey is not permitted to observe the experimenter baiting the food well. Therefore, to be correct on any given trial the monkey must remember which response was made last. In rats, spatial delayed alternation is a commonly used ► rodent test of cognition which exploits the ease with which rats can remember different locations and hence, have used spatial stimuli as in the

T-Maze and ▶ radial arm maze (Dudchenko 2004). The ▶ delayed (non)-match to sample is another test of WM, but it is used more commonly in monkeys than rats (see ▶ primate models of cognition). Lesions of the dorsolateral prefrontal cortex in monkeys and medial prefrontal cortex in rats profoundly impair WM performance in these tasks (Dalley et al. 2004; Goldman-Rakic 1987). This finding has proven to be extremely useful in the study of the psychopharmacology of WM; the prefrontal cortex is highly sensitive to its neurochemical environment and small changes in the degree of prefrontal monoamine and acetylcholine neurotransmission contributes significantly to prefrontal WM function.

Dopaminergic Drugs

The work of Brozoski et al. (1979) was the first to demonstrate that ▶ catecholamines played a critical role in the modulation of spatial WM function in the prefrontal cortex. Large catecholamine depletions of the prefrontal cortex using ▶ 6-hydroxydopamine (6-OHDA) in monkeys, impairs performance in spatial WM tasks to the same degree as large prefrontal lesions, and can be pharmacologically reversed with dopamine (DA) agonists such as levadopa (▶ L-DOPA) and ▶ apomorphine. Spatial WM deficits can be mimicked in rats and monkeys by acute, local infusions of DA D_1 receptor antagonists into the ▶ prefrontal cortex, and similar cognitive impairments can be observed following systemic administration of ▶ haloperidol.

In addition to the detrimental effects of reducing DA transmission in the prefrontal cortex, increased DA turnover in the prefrontal cortex impairs spatial WM as well. This is because WM relies on an optimal level of mesocortical DA, which functions according to an inverted 'U-shaped' relationship between DA and cognitive performance (Arnsten 1998). This means that "too much or too little DA" is associated with impaired WM performance. For example, in animals, mild stressors such as ▶ conditioned fear or a weak footshock preferentially increase DA turnover in the prefrontal cortex compared with other DA terminal fields. Mild stress exposure to monkeys or rats produce WM deficits that can be blocked with low pre-treatment doses of DA D_1 receptor antagonists such as SCH 23390, typical ▶ antipsychotics such as haloperidol, or atypical ones such as ▶ clozapine. This stress-induced WM deficit can be mimicked in rats by infusing DA D_1 agonists (e.g., SKF 81297) directly into the prefrontal cortex which can be blocked with a pretreatment dose of a DA D_1 receptor antagonist. Relative to the pretreatment effects of DA antagonists, however, the β adrenergic antagonist ▶ propanolol, or the ▶ SSRI fluoxetine, are not effective in reversing stress-induced WM deficits, illustrating the importance of dopaminergic mechanisms of WM in the prefrontal cortex.

Research has now established the importance of the DA D_1 receptor family in the regulation of prefrontal WM function. Selective antagonists that work on the D_2 receptor in the prefrontal cortex are mostly ineffective. Overall selective D_1/D_5, but not D_2/D_3 receptor antagonist infusion in the prefrontal cortex impairs WM in rats and monkeys. However, although D_2/D_3 antagonists have little effect on WM when infused in the prefrontal cortex, systemic treatment of these drugs improves WM in monkeys and humans (see ▶ short-term and working memory in humans). More research is needed to establish where in the brain the actions of these drugs are taking place.

Disruptions in delayed response tasks are not necessarily indicative of a specific impairment in WM. WM relies not just on holding information online but also overlapping mechanisms of attention which enable the active maintenance of information within a WM system. Recent research indicates that different levels of prefrontal DA activity may be required for different cognitive processes so that DA D_1 receptor stimulation sufficient to improve one cognitive function may serve to impair another. Thus, although treatments with ▶ psychostimulants such as ▶ amphetamine facilitate mechanisms of arousal (or attention), they disrupt WM, and enhance ▶ long-term memory. This has led to the idea that arousing conditions in animals such as white noise or highly emotional contexts can impair short-term recall (i.e., WM) but benefit long-term retention, and suggest the existence of independent memory systems in animals, including rats.

Adrenergic Drugs

While antipsychotic medications exert their benefits primarily by modulating the DA neurotransmitter, they also affect ▶ norepinephrine (NE) receptors. Recent studies in animals have shown that NE has just as powerful an influence on the prefrontal cortex as DA. In the prefrontal cortex, NE has opposing actions at α_2- and α_1- adrenoreceptors (AR) with respect to WM function. Thus, while NE enhances WM via α_2-AR stimulation, it impairs WM via α_1-AR stimulation. For example, α_2-AR agonists such as clonidine guanfacine, or medetomidine administered systemically improve WM in rats and monkeys (including aged monkeys), which can be blocked with α_2-AR antagonists such as ▶ yohimbine. Yohimbine alone is sufficient to impair WM performance. The improved WM effect of α_2-AR agonists is pronounced in monkeys with large catecholamine depletions and under conditions of high interference or distraction, conditions that require

prefrontal function. Performance of tasks that do not depend on the prefrontal cortex is not improved by treatment with α_2-AR agonists (Arnsten 1998).

NE has a lower affinity for α_1-AR than α_2-AR, which means a high level of NE release is necessary to engage α_1-AR in the prefrontal cortex. In addition to increasing DA, exposure to ▶ stress preferentially increase NE in the prefrontal cortex. Hence, α_1-AR antagonists infused into the prefrontal cortex have little effect on WM under nonstressed conditions. By contrast, rats and monkeys exposed to uncontrollable stress, which causes NE activation at α_1-AR markedly impairs WM function. Infusing phenylephrine, a highly selective α_1-AR agonist, directly into the prefrontal cortex, mimics the detrimental effect of stress on WM. This impairment can be reversed by coinfusion of the α_1-AR antagonists, urapidil. Together, these findings suggest not only that the therapeutic effects of antipsychotic medication may be due in part to α_1-AR blockade, but also that α_2-AR agonists such as clonidine may serve to protect prefrontal function, and therefore WM from the detrimental effects of stress.

Cholinergic Drugs

▶ Atypical antipsychotics such as ▶ clozapine and ▶ risperidone, in addition to increasing DA release in the prefrontal cortex, also increase ▶ acetylcholine (ACh) release in the prefrontal cortex. It is thought, therefore, that ACh release in the prefrontal cortex may also contribute to the ability of atypical antipsychotics to improve cognitive symptoms of WM. In rats, for example, local prefrontal infusions of the cholinergic muscarinic receptor antagonist ▶ scopolamine produce spatial WM deficits in delayed match to sample tasks. These deficits can be ameliorated with cholinergic treatments such as ▶ physostigmine, an acetylcholinesterase inhibitor. However, it is now apparent that cortically projecting cholinergic neurons play a crucial role in attentional processing, and failures in ▶ attention may contribute to an overall WM deficit (McGaughy et al. 2000). Thus, ▶ delay-independent deficits in delayed match to sample tasks following prefrontal cholinergic manipulations are thought to reflect impairments in attention, rather than mnemonic processing *per se*. Nevertheless, more research is needed to fully appreciate the role of prefrontal ACh in cognitive function, especially WM. Recent observations suggest that the function of prefrontal ACh is to distribute attentional capacity in tasks that require effortful processing such as holding a stimulus online in WM.

Unlike the muscarinic ACh receptor, nicotinic cholinergic receptors have received much less attention. Recently however, the effects of ▶ nicotine as a ▶ cognitive enhancer have made it particularly attractive for clinical use. Both acute and chronic ▶ nicotine treatments significantly improve WM performance in rats using the radial arm maze. Chronic treatment with nicotine agonists has been shown to improve memory performance in other tasks such as ▶ passive avoidance, and in other species including monkeys, mice, and zebrafish (Levin et al. 2006). In addition to enhancing WM performance, nicotine also improves ▶ attention. Chronic nicotine infusion diminishes the impairing effects of antipsychotics such as ▶ haloperidol, risperidone, and clozapine on attention, whereas ▶ mecamylamine, a nicotinic antagonist used sometimes as an anti-addictive drug, decreases attentional performance, and WM. The cognitive impairing effects of mecamylamine have reduced its clinical utility for smoking cessation.

The temporal lobe structures such as the ▶ hippocampus and perirhinal cortex, also receive a dense cholinergic input from the medial septal (MS) nucleus and the vertical limb of the diagonal band of Broca (VDB). Although the hippocampus and related structures are known to be critical for certain memory functions (see ▶ short-term memory and ▶ long-term memory), robust WM impairments following manipulations to the cholinergic septo-hippocampal pathways have been difficult to demonstrate.

Serotonergic Drugs

One characteristic feature of atypical antipsychotic drugs is their high affinity for various serotonin 5-HT receptors, especially 5-HT_{1A} and 5-HT_{2A}, which are densely localized within the limbic cortex of humans and animals. These 5-HT receptors received much attention because they are involved in the action of ▶ hallucinogens such as lysergic acid diethylamide (LSD) and psilocybin, but there is growing evidence from animal experiments indicating a role for serotonin in modulating cognitive functions. While there is considerable evidence connecting the serotonergic system to cognitive functions of ▶ behavioral inhibition, its modulatory role in WM has not been well characterized. Much of the earlier work on the role of 5-HT in WM used nonselective global strategies in which the entire 5-HT system was manipulated by increasing or reducing central 5-HT transmission. Thus, in rats, global 5-HT depletion using 5, 7-dihyroxytrptamine (5, 7-DHT) or *p*-chlorophenylalanine (PCPA) had little effect on delayed nonmatch to position tests of WM. By contrast, 5-HT ligands with varying degrees of receptor specificity have been shown to disrupt WM performance, and in some cases improve it. Importantly, although the prefrontal cortex is substantially innervated by serotonergic fibres

from the raphe nuclei in monkeys and rats, 5-HT depletions in the prefrontal cortex does not impair WM performance. In addition, although the 5-HT_{2A} receptor is abundant on the dendrites of prefrontal pyramidal cells implicating a role for it in WM function, there is no direct evidence linking 5-HT_{2A} receptor activation (or deactivation) with changes in spatial WM. Furthermore, the physiological evidence for the apparent deleterious effects of prefrontal 5-HT_{2A} blockade on WM stands in contrast to the proposed benefit of 5-HT_{2A} properties of atypical antipsychotics such as clozapine, olanzapine, and risperidone; these drugs share potent 5-HT_{2A} and relatively weaker DA D_2 receptor antagonism. While it is thought that the clinical efficacy of atypical antipsychotics might be due to increased prefrontal DA release, further experiments are needed to evaluate the impact of pharmacological treatments targeted to alter both DA and 5HT signalling on WM performance (Meltzer et al. 2003).

Other Neurotransmitters and Psychoactive Drugs

► GABA receptors are the major targets for ► benzodiazepines and related ► anxiolytics. ► Alcohol and benzodiazepine such as ► diazepam, both potentiate actions at $GABA_A$ receptors, and both impair WM performance in rats. In monkeys, WM performance depends on appropriate GABA transmission in the dorsolateral prefrontal cortex.

► Dissociative anesthetics such as ► phencyclidine (PCP) and ► ketamine work primarily as ► NMDA receptor antagonists and produce WM deficits in rats performing spatial delayed alternation or delayed match to position tasks. Low doses of AMPA/kainate antagonists produce delay-dependent WM impairments. In addition, potential ► anxiolytics such as LY-354740, which act as $mGLU_{2/3}$ receptor agonists, autoregulate ► glutamate release in the prefrontal cortex and reverse WM deficits caused by NMDA antagonist treatment.

Conclusion

The prefrontal cortex is critical for guiding behavior using WM. In WM tasks, animals can code and recall constantly changing locations or stimuli as in delayed response and delayed alternation tasks. Animals can also track in WM their recent choices from a set of stimuli, and update relevant information in order to respond on a moment-to-moment basis. As in humans, a disruption to WM in animals prevents the execution of effective organized behavior, a behavioral deficit that is evident in patients with dementia and psychiatric illnesses. While improvements in WM predict favorable behavioral outcomes, the neurochemical basis of WM is not yet fully understood. Animal studies have demonstrated convincingly, that catecholamines (DA and NE) are involved in WM function but there is also evidence that pro-cholinergic drugs can ameliorate WM deficits. Although there is little evidence for a direct role for serotonin in WM, serotonin receptors are used as targets for antipsychotic drug development. That existing antipsychotic drugs possess many pharmacological profiles, it is likely that any therapeutic action on WM will involve interacting receptor mechanisms.

Short-Term and Working Memory in Humans

Roshan Cools
Centre for Cognitive Neuroimaging, Donders Institute for Brain, Cognition and Behaviour, Department of Psychiatry, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Definition

The term short-term memory is considered to refer to just one component of working memory and is generally used only to describe a range of tasks that focus explicitly on short-term storage, e.g., digit span tests. Working memory refers to a broader set of processes that facilitate the ability to encode, maintain, store, hold on-line and retrieve representations of information for further processing or recall (Baddeley 2007). Working memory processes are active temporarily for a short period of time, on the order of seconds. These processes include short-term storage of information, but also executive processes that operate on the stored material. Working memory is mediated by a widely distributed neural system in the human brain, including (not exclusively) the prefrontal cortex (PFC), the striatum, the posterior parietal cortex and the inferotemporal cortex.

Impact of Psychoactive Drugs

Evidence indicates that the major ascending neuromodulators, in particular dopamine, but also noradrenaline, acetylcholine and serotonin can influence working memory performance in humans. However, the effects of drugs that affect these neuromodulators depend on (1) the particular task demands under study, i.e., the stage (encoding, delay, probe) and type (e.g., spatial vs. non-spatial) of working memory, (2) the neural region that is targeted by the drug (e.g., the striatum or the ▶ prefrontal cortex), (3) the baseline neurochemical state of the system and (4) the receptor-specificity of the drug. Accordingly, drugs that are known as ▶ cognitive enhancers can induce impairments on some tasks and in some individuals. Similarly drugs that are known as cognitive inhibitors can induce improvements on some tasks and in some individuals.

A variety of paradigms are used to study working memory in humans. Examples of tasks in behavioral psychopharmacological studies include the self-ordered spatial working memory task from the Cambridge neuropsychological test automated battery (▶ CANTAB), which requires self-ordered searching through a set of boxes to locate hidden tokens, tests of digit span and *the* ▶ *delayed match-to-sample* (DMTS) *test*. Although the ▶ *Wisconsin Card Sorting Test* (WCST) and related tests were not designed to test working memory (▶ behavioral flexibility), adequate performance also critically relies on intact working memory, in particular its executive components. Neuroimaging studies which employ positron emission tomography (▶ PET imaging) or functional magnetic resonance imaging (▶ magnetic resonance imaging (functional)) have often employed blocked versions of *the* ▶ *n-back task*, which do not directly allow the disentangling of its different components (e.g., maintenance during delay vs. flexible updating during encoding). Other neuroimaging studies have used variants of the DMTS paradigm, or adaptations, which do allow such decomposition.

Dopaminergic Drugs

Best studied are the effects of dopaminergic drugs on working memory. Acute administration of single low doses of dopamine receptor agonists, such as ▶ bromocriptine or ▶ pergolide, affects working memory performance on DMTS tests as well as tests measuring the executive components of working memory (n-back, WCST). Low doses seem more beneficial than high doses, which might induce sedative side effects. Beneficial effects of bromocriptine and other dopamine-enhancing drugs like levodopa have been observed in patients with ▶ Parkinson's disease and traumatic brain injury. These effects are most pronounced on tests measuring the executive, flexible updating components of working memory (e.g., n-back, self-ordered searching, WCST, DMTS with stimulus-reordering requirements), but not on tests measuring only the maintenance component of working memory (e.g., DMTS). Non-specific catecholamine enhancers like ▶ amphetamine and methylphenidate, which affect both dopamine and noradrenaline (▶ methylphenidate and related compounds), can also improve working memory performance on the more executive working memory tasks (i.e., n-back, self-ordered searching, WCST) in healthy volunteers, as can the COMT

inhibitor tolcapone. Improvements after methylphenidate, amphetamine and ▶ tolcapone in young healthy volunteers and after levodopa in Parkinson's disease are accompanied by, and correlated with reductions in activity in fronto-parietal brain regions, possibly reflecting enhanced processing efficiency and higher signal to noise ratio. Conversely agents that block dopamine D2 receptors, like ▶ sulpiride, can impair working memory. However paradoxical improvements have also been observed following sulpiride administration in some individuals, perhaps reflecting predominant action at self-regulating autoreceptors. Effects of acute tyrosine depletion are less consistent, questioning the reliability of tyrosine depletion as a modulator of dopamine function.

Some data have suggested that spatial variants of the DMTS and self-ordered search tests are more sensitive to manipulations of dopamine than are tests of non-spatial working memory. However, a number of prominent caveats have been highlighted (Mehta and Riedel 2006). For example, the spatial variants of the DMTS test often loaded on movement preparation to a greater extent than did the non-spatial variants, thus confounding modality-dependency with dependency on movement preparation.

The direction of the effects of dopaminergic drugs depends on baseline working memory capacity, as measured for example, with the *listening span test*: Dopamine D2 receptor agonists like bromocriptine and ▶ cabergoline, as well as D2 receptor antagonists like ▶ haloperidol have opposite effects in subjects with high and low working memory capacity. Similar dependency on baseline working memory capacity has been observed for the non-specific catecholamine enhancers methylphenidate and amphetamine. For example, low-span subjects with low working memory capacity benefit from bromocriptine in terms of set-shifting performance on the WCST, while high-span subjects with high working memory capacity are impaired by bromocriptine. The direction of drug effects, however, cannot be predicted from working memory capacity alone; rather the type of working memory test must also be taken into account. Thus while benefiting in terms of flexible set-shifting on the WCST, low-span subjects are actually impaired by bromocriptine on the DMTS test, which loads more highly on the robust maintenance rather than on the flexible updating of current representations.

The dependency of these dopaminergic drug effects on baseline working memory capacity has been hypothesized to reflect dependency on baseline levels of dopamine. Evidence for this hypothesis comes from neurochemical PET studies showing that working memory capacity, as measured with the listening span, correlates positively with baseline dopamine synthesis capacity in the striatum. Higher working memory capacity is associated with higher dopamine synthesis capacity (Cools and D'Esposito 2009). The implication of these data is that subjects with low baseline levels of dopamine benefit from dopamine-enhancing drugs, at least in terms of the flexible updating component of working memory, while subjects with already optimized levels of dopamine are impaired by the same dopamine-enhancing drugs. This is consistent with the existence of an "Inverted U" shaped relationship between dopamine and cognitive performance (▶ short-term and working memory in animals).

Individual variability in baseline dopamine levels might reflect individual variation in genetic predisposition. Opposite effects of amphetamine, which increases both dopamine and noradrenaline transmission, as well as tolcapone are seen on PFC activity during n-back performance as a function of genetic variation in COMT (catechol-*O*-methyltransferase). Amphetamine and tolcapone increase the efficiency of PFC processing during n-back performance in subjects homozygous for the val allele of the COMT gene polymorphism, who have hypothetically reduced PFC dopamine function. By contrast, amphetamine and tolcapone reduce efficiency of PFC processing in subjects homozygous for the met allele, who have hypothetically enhanced PFC dopamine function (e.g., Mattay et al. 2003).

Theoretical models and preliminary results suggest that the effects of dopaminergic drugs on working memory will depend also on the neural locus of drug action. For example, bromocriptine, which stimulates dopamine receptors, modulated the flexible updating of information during encoding of a DMTS test and these effects are accompanied by modulation of neural activity in the striatum. Conversely, bromocriptine modulated activity in the PFC during (the resistance to distraction in) the delay period of a DMTS test (Cools and D'Esposito 2009). Further study is necessary to identify the neural loci of dopaminergic drug action during component processes of working memory.

Research with experimental animals and computational modeling work has suggested a particularly important role for D1 receptor stimulation in the on-line maintenance of information in working memory (short-term and working memory in animals). However, agonists used in human research so far (i.e., bromocriptine, pergolide) have affinity for both D1 and D2 receptors. The lack of selective D1 receptor agents available for human research has limited the ability to investigate the supposed D1 receptor selectivity of dopaminergic drug effects on working memory. Future study should address this issue,

for example, by making use of receptor-selective ▶ genetic polymorphisms or neurochemical PET imaging with receptor-selective ligands.

Similar lack of methods available for human research prevents the study, in human volunteers, of another current hypothesis, which states that effects of dopamine depend on the mode of transmission affected. Specifically, phasic and tonic modes of dopamine transmission might influence different (updating vs. maintenance) component processes of working memory.

Noradrenergic Drugs

Although much work with experimental animals has focused on a role of ▶ noradrenaline (in particular the alpha-adrenergic system) in (the maintenance components of) working memory (▶ short-term and working memory in animals), work with humans has concentrated more often on long-term and emotional memory. Nevertheless, empirical studies using selective noradrenergic manipulations in human volunteers have revealed a role for, in particular, the beta-adrenergic system in modulating (executive components of) working memory, perhaps via their well-accepted modulation of (selective and sustained) attentional processes (▶ attention). Specifically working memory performance is consistently impaired by the beta-blocker ▶ propranolol, which penetrates the blood-brain barrier easily, but generally not by ▶ oxprenolol and atenolol, which have more limited central activity. The α_2 adrenoceptor agonist clonidine also generally impairs working memory, possibly via a presynaptic mechanism of action. However, dose-dependent effects of clonidine as well as effects of other α_2 adrenoceptor agonists (like guanfacine), α_2 adrenoceptor antagonists (like ▶ yohimbine) and acute noradrenaline potentiation with ▶ reboxetine are less consistent (Barch 2003; Chamberlain et al. 2006; Ellis and Nathan 2001).

Cholinergic Drugs

Cholinergic drugs are known to affect working memory performance. Specifically, working memory performance benefits from agents that enhance cholinergic function, such as ▶ physostigmine, while being impaired by agents that block cholinergic function, such as ▶ scopolamine (Barch 2003; Ellis and Nathan 2001). The effects might be receptor-specific, with muscarinic and nicotinic receptors mediating distinct (spatial and non-spatial) types of working memory. Cholinergic effects are particularly pronounced in the presence of distraction.

Consistent with the well-known link between acetylcholine and stimulus detection (or vigilance), cholinergic effects in working memory are hypothesized to reflect changes in the selectivity of attentional processing during encoding, thus simplifying demands during maintenance and retrieval. In keeping with this hypothesis are findings that cholinergic antagonists, like scopolamine which is sometimes referred to as a "memory-inhibitor," impair the encoding but not the maintenance or the retrieval of new information. Furthermore, the anticholinesterase inhibitor physostigmine, sometimes referred to as a "memory-enhancer" improved accuracy on a task that maximized demands for ▶ attention, while leaving unaffected accuracy on a matched working memory task. Neuroimaging results from studies with physostigmine have substantiated hypotheses from work with experimental animals that acetylcholine promotes stimulus-driven shifts in attention by enhancing encoding- and attention-related activity in the posterior sensory cortex (Bentley et al. 2004).

Serotoninergic Drugs

Although manipulations of the indolamine ▶ serotonin (5-HT, 5-hydroxytryptamine) have been shown to alter performance on tasks involving long-term (verbal) memory ▶ consolidation and affective components of impulse control processing, it remains unclear whether serotonin is involved in working memory. Effects on memory of the most common procedure to manipulate central serotonin in humans, the dietary ▶ acute tryptophan depletion (ATD) procedure are generally restricted to delayed recall, not extending to immediate recall. ATD also does not affect spatial working memory, consistent with a lack of effect of PFC 5-HT loss on spatial working memory performance in monkeys (▶ short-term and working memory in animals). Furthermore, ATD administered an hour after word learning left delayed recall unaffected. These data suggested that ATD affects memory consolidation rather than the encoding or retrieval of information. Few studies have examined effects of selective serotonin receptor agents on working memory. One study revealed that ▶ fenfluramine impaired performance on a spatial working memory task in a delay-dependent manner. Effects of ketanserin, a $5HT_{2A}$ receptor blocker, on spatial working memory tasks are inconsistent. It is not unlikely that any effects of $5HT_2$ receptor stimulation or blockade reflect indirect effects on dopamine transmission. Further work is required to investigate interactions between 5-HT and dopamine as well as acetylcholine, and the possible receptor selectivity of any effects (there are at least 17 serotonin receptors which may serve different functions).

Other Psychoactive Drugs

The ▶ benzodiazepine sleeping pills and tranquillizers (e.g., ▶ triazolam, ▶ diazepam [trade name Valium],

►lorazepam) are some of the best known drugs to cause memory impairment and facilitate the transmission of the major inhibitory neurotransmitter ►GABA (γ-aminobutyric acid). However, like the so-called memory-enhancing (anti-dementia) drugs, which enhance cholinergic transmission, these benzodiazepines are thought to act primarily on processes other than those affecting qualitative aspects of working memory. These processes include episodic memory (►long-term memory humans) and/or processing speed (Curran and Weingartner 2002).

The NMDA receptor antagonist ►ketamine, which affects the transmission of the major excitatory neurotransmitter ►glutamate, produces impairments on manipulation in working memory as well as other so-called frontal tests, known to rely on the executive components of working memory (Curran and Weingartner 2002).

The wake-promoting agent ►modafinil, which affects the catecholamine, glutamatergic, GABAergic, orexin and histamine systems in the brain, while having little abuse potential, has been shown to improve working memory in a number of studies in healthy volunteers (with or without sleep-deprivation), with some evidence for dependency on baseline performance. Improved working memory following modafinil has also been observed in patients with ADHD, schizophrenia and depression and might reflect primary modulation of the catecholamines (Minzenberg and Carter 2008).

Notes of Caution

Psychoactive drugs modulate the effects of neurotransmitter systems that are diffuse and widespread, innervating large undifferentiated parts of cortex (and subcortical structures). Receptors of the different neurotransmitters are often co-localized on the same cells. Therefore, despite clear evidence for distinct functions, the different systems must interact to determine optimal working memory. Further, drugs with preferential effects on one system (e.g., serotonin, glutamate) might exert secondary effects on other systems (e.g., dopamine). In addition, most drugs are not selective for one particular system. For example, propranolol also exhibits affinity for serotonin receptors.

Conclusion

Working memory is disturbed in a range of neurological and psychiatric disorders, including schizophrenia, Parkinson's disease, attention deficit hyperactivity disorder and traumatic brain injury. The treatment of these cognitive deficits will benefit from a better understanding of the psychopharmacology of human working memory. Consistent with the observation that all these disorders implicate abnormal dopamine neurotransmission is the conclusion that human working is most sensitive to drugs that affect dopamine neurotransmission. Particularly pronounced are effects of dopaminergic drugs on tests measuring executive and flexible updating components of working memory. This might reflect the fact that compounds used for human research all act at D2 receptors.

The direction and extent of these drug effects vary greatly between different tasks and between different individuals. Factors that contribute to this variability include task demands and baseline dopamine levels in underlying brain regions. Further work is required to establish the regional selectivity of working memory processes and dopaminergic drug effects. Drugs affecting acetylcholine also modulate performance on working memory tests, probably via altering attentional processes. Working memory is less consistently sensitive to drugs affecting serotonin neurotransmission. Further research is necessary to elucidate the role of noradrenaline, glutamate and GABA in human working memory.

siRNA

Synonyms
Short interfering RNA; Silencing RNA; Small interfering RNA

Definition
siRNA stands for small interfering RNA, also known as silencing or short interfering RNA. In contrast to classical antisense oligonucleotides, siRNA is a class of double-stranded RNA molecules, 19–25 nucleotides in length,

with 2-nucleotides 3′ overhangs on either end and a phosphate group at each 5′ end (Fig. 1A). siRNA can efficiently knock down expression of target genes via the RNA interference (RNAi) pathway, which was first described in the nematode worm *Caenorhabditis elegans* in 1998 by Andrew Z. Fire and Craig C. Mello. Any gene of interest with known sequence can be targeted by siRNA that match the mRNA sequence. siRNA may also recruit RNAi-related pathways, including activation of cellular antiviral mechanisms (e.g., the interferon response) or interference with the chromatin structure of the genome.

Synonyms
Serotonin-norepinephrine reuptake inhibitors

Definition
The serotonin-norepinephrine reuptake inhibitors (SNRIs) are a class of ► antidepressants that simultaneously inhibit the reuptake of both ► serotonin and ► norepinephrine. SNRIs are primarily used to treat ► major depressive disorder (MDD).

Following the development of the tricyclic antidepressants (TCAs), the monoamine oxidase inhibitors (MAOIs), the selective serotonin reuptake inhibitors (SSRIs), and the norepinephrine-dopamine reuptake inhibitors (NDRIs), SNRIs are one of the most recent classes of antidepressants

approved for the treatment of MDD. Many TCAs, such as ▶ clomipramine, ▶ imipramine, and ▶ amitriptyline, also inhibit the reuptake of serotonin and norepinephrine. However, the SNRIs differ from the TCAs in two major ways: (1) they do not possess a tricyclic-like structure and (2) they do not have a clinically-relevant affinity for any monoaminergic, histaminergic, or cholinergic receptors or for the sodium channel. As a result, they are safer (i.e., have a lower risk of arrhythmia and seizures) and better-tolerated (i.e., have a lower risk of sedation, somnolence, and weight gain).

Pharmacological Properties

Four SNRIs have been developed and marketed to date: ▶ venlafaxine, ▶ desvenlafaxine, ▶ duloxetine, and ▶ milnacipran. First introduced in the early 1990s, venlafaxine is the prototypical agent of this class. Milnacipran was introduced as an antidepressant in the late 1990s in Europe, and received approval in 2009 for the treatment of fibromyalgia in the United States. Duloxetine was first marketed in 2004 in the United States. Desvenlafaxine, the newest SNRI, is an active metabolite of venlafaxine.

The efficacy of all four SNRIs in the treatment of MDD in adults has been well established in multiple randomized, double-blind, placebo-controlled trials (Montgomery and Anderson 2006; Papakostas and Fava 2007; Perahia et al. 2006; Ricknes et al. 2004). In addition to their use as antidepressants, some SNRIs have been approved by the United States Food and Drug Administration (FDA) for the treatment of other Axis I disorders in adults, including ▶ generalized anxiety disorder (venlafaxine, duloxetine), ▶ panic disorder (venlafaxine), ▶ social anxiety disorder (venlafaxine), and fibromyalgia (duloxetine, milnacipran).

It has been proposed that SNRIs may be more effective in the treatment of MDD than the SSRIs, perhaps due to their simultaneous action on both serotonin and norepinephrine transporters (Papakostas et al. 2007). However, whether this difference is clinically relevant (Papakostas et al. 2007), and whether it applies to all SSRIs remains unclear (Montgomery and Anderson 2006; Lam et al. 2008).

The efficacy and safety of the SNRIs have not been established for children, adolescents, or the elderly. The United States FDA placed a "▶ black box warning" (signifying the possibility of severe adverse events) on the labeling for all four SNRIs based on pooled analysis of data for nine antidepressants (SSRIs and others) describing an increased risk of suicidal ideation and/or suicide gestures in a pediatric population. Therefore, close monitoring is required when prescribing SNRIs or other antidepressants for MDD, especially in vulnerable populations.

Pharmacokinetics

All four SNRIs are well absorbed after oral ingestion and show modest to excellent bioavailability; they are primarily metabolized in the liver and eliminated by the kidney.

The ▶ bioavailability of venlafaxine extended-release capsule formulation is about 45%, while for the immediate release tablet it is 100% (relative to an oral solution). Approximately 27% is protein-bound. Venlafaxine is metabolized extensively by the hepatic ▶ cytochrome P450 (CYP) isozyme 2D6; O-desmethylvenlafaxine is its active metabolite. Approximately 87% of a dose of venlafaxine is excreted by the kidneys, 82% as metabolites and 5% remaining unchanged. The ▶ elimination half-life for venlafaxine and O-desmethylvenlafaxine are about 5 h and 11 h respectively, but they are prolonged in patients with hepatic and/or renal impairment.

After oral administration, desvenlafaxine has a bioavailability of approximately 80%, and 30% is protein-bound. It is metabolized primarily by the liver via conjugation, and to a lesser extent via the hepatic cytochrome P450 CYP 3A4. Forty-five percent of desvenlafaxine is excreted via the kidneys in an unchanged form. The elimination half-life of desvenlafaxine is 10 to 11 h, but it is prolonged in patients with impaired liver function.

Duloxetine is well absorbed after oral administration; its bioavailability ranges between 50% and 80% (decreased among smokers). It is more than 90% protein-bound. Duloxetine is metabolized by the hepatic cytochromes P450 CYP 2D6 and 1A2, and it is ultimately eliminated in the urine (70%) and feces (20%). Its half-life is approximately 12 h.

Milnacipran is well absorbed after oral use. Its bioavailability is about 85%. Protein-binding is low (approximately 13%), and it is nonsaturable. The drug is metabolized by the liver to an unknown extent, primarily via glucuronidation, and it does not appear to be metabolized via the hepatic cytochrome P450 system, suggesting that it might have some pharmacokinetic advantages (including a low drug-drug interaction potential). Milnacipran has no active metabolites. The excretion of milnacipran is mainly (90%) through the kidneys, and its half-life is 8 h (Puozzo et al. 2002).

Social Anxiety Disorder

Avoidant personality disorder; Social phobia

Definition

Social anxiety disorder (SAD) is recognized as a highly prevalent (up to 13.3% lifetime prevalence rate) as well as a chronic disorder with onset during the teenage years (Kasper 1998). Although the disorder is associated with significant disability, which includes educational and occupational capabilities that has a negative impact on the ▶ quality of life, it is highly underdiagnosed and undertreated. SAD is recognized as a serious medical condition that is accompanied by significant disability since it starts in early life and therefore impairs the otherwise occurring socialization including the development of coping skills. This view has been strengthened by data showing that SAD cannot simply be equated with shyness or with avoidant personality traits, and by evidence that this disorder is a discrete entity associated with distinct psychobiological dysfunctions (Lanzenberger et al. 2007) and responsive to specific pharmacotherapeutic interventions (Kasper et al. 2003).

Within SAD, patients have been divided into those with generalized and non-generalized (discrete, specific, circumscribed, and performance anxiety) symptoms. Whereas generalized SAD affects the individual in more than one social situation, non-generalized SAD is specific and circumscribed and may be for instance performance anxiety with pure speaking fears. Pharmacotherapeutic dissection of different SAD subtypes may be possible and it emerged that clear ▶ placebo differences can only be achieved with generalized SAD. For performance anxiety beta-blockers are useful but demonstrated to be ineffective in generalized SAD.

Role of Pharmacotherapy

Most pharmacotherapeutic studies, specifically the systematic ones with ▶ selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (▶ SNRIs) have been carried out in patients suffering from generalized SAD. The most commonly used primary efficacy scale in medication studies of SAD is the Liebowitz social anxiety scale (LSAS) (Liebowitz 1987), which enables also the comparativeness of the studies.

Early work demonstrated that irreversible ▶ monoamine oxidase inhibitors (MAOIs; e.g., ▶ phenelzine) are effective in the treatment of SAD, but these agents are limited by their side effect profile, the need for dietary precautions, and drug interactions (Versiani 2000). Studies with the reversible MAOI ▶ moclobemide indicated effectiveness in earlier but not later development program studies and have therefore not been granted indication status by health regulatory authorities (Brunello et al. 2000). More recent work has established the efficacy of several SSRIs (Montgomery et al. 2004), and these agents have been recommended as first-line pharmacotherapy agents.

The available ▶ placebo-controlled studies have been carried out for acute as well as long-term efficacy, including relapse prevention (see Table 1). Interestingly, the question if psychological treatment is able to enhance the pharmacotherapy has only been addressed in one study and there are no placebo-controlled studies to

guide the clinicians which treatment to administer after treatment-nonresponse, an approach which is available for the indication of depression. The main group of medications which has been studied is SSRIs and interestingly there are no studies with ▶ tricyclic antidepressants (TCA) which indicates that pharmacotherapy of SAD was developed after the introduction of SSRIs for the indication of depression. A few studies with ▶ benzodiazepines and SNRIS as well as ▶ pregabaline have been conducted. Pregabaline is not a benzodiazepine as may be suggested by the name. It differs insofar from the other available medications used since it binds with high specificity to the α_2-δ subunit of P/Q-type voltage-gated Ca^{++} channels, thereby reducing the influx of Ca^{++} at nerve endings and attenuating the release of excitatory neurotransmitters such as norepinephrine, glutamate, aspartate, substance P, and calcitonin gene-related peptide.

In addition to pharmacotherapeutic approaches, cognitive behavioral psychotherapy has been studied in a placebo-controlled design indicating superior efficacy to placebo, however, no medication control group has been assigned in these treatment trials.

Cross-Reference

There is a high rate of ▶ comorbidity (up to 60%) between depression and anxiety disorders as well as between anxiety disorders themselves and antidepressants have been used and granted indication by health authorities for both depression and anxiety disorders. It is apparent, that both SSRIs and SNRIs work in depression as well as in different forms of anxiety disorders, including SAD, and for SAD additionally benzodiazepines (▶ clonazepam) as well as to a lower extent pregabaline have been studied (Zohar et al. 2002).

Social Anxiety Disorder. Fig. 1. Algorithm for the pharmacotherapy of social anxiety disorder in primary practice (After: Stein et al. 2001).

An algorithm for the pharmacotherapy of SAD in primary practice has been developed by Stein et al. (2001) and divided into different steps as outlined in Fig. 1. Firstly, this algorithm indicates the necessity to establish

a diagnosis and to clarify if certain complications may have an impact on the choice of medication to be used, like comorbid severe depression or suicidality which requires specific therapeutic regimens. If this can be ruled out SSRIs could be initiated and if patients are responsive a maintenance therapy can be continued with the same dosage of medication with which remission has been achieved. Interestingly, the same dosages are used for SAD as for depression. Whereas in depression a clear response might be observed already after 2–3 weeks' time this usually takes at least 6–8 weeks in SAD, since patients need to experience the social situation in which the symptoms appeared before. If intolerable side effects are emerging, the switch to another SSRI or SNRI can be considered, although there are no placebo controlled studies to justify this approach. Thereafter an optimization of the dosage (most likely an increase) as well as the duration of treatment (over 8 weeks) needs to be taken into account before a treatment response can be expected. If this regime does not lead to remission a reassessment as well as a switch to another type of medication, like pregabaline, can be considered. However, it needs to be noted that pregabaline does not have the indication for SAD, and that this approach is also not substantiated by placebo-controlled switch studies.

Conclusion

SAD is not a mild form of mental disorder but a clinical meaningful medical illness with an established pathophysiology which deserves early diagnosis and distinct treatment. Since SAD starts early in life and may result in a disabling disorder, the treatment of selected pharmacotherapeutic and psychotherapeutic interventions need to be initiated early in the course of the illness. Our continued progress in understanding and managing SAD will result in a progress in delineating the subtypes and treatment responses to this condition.

Social Behavior

Definition

Social behavior is behavior between members of the same species. However, depending upon the context, it may more specifically signify nonaggressive, nonterritorial, nonsexual behavioral interactions between members of the same species.

Impact of Psychoactive Drugs

Social Behavior

Social behavior is in its broadest sense behavior taking place between members of the same species. It can therefore include territorial, parental and sexual behavior

as well. However, individuals living in groups have a special need to communicate because they have to share resources, coordinate activities such as hunting or foraging, defend the territory against intruders and protect the group against predators. Social species such as humans, monkeys and rats have therefore developed communication systems and internal organizational structures that allow them to live in proximity without having to engage in frequent fights over resources. Fighting may cause injury and can jeopardize the welfare of the individual and of the group, and it is therefore something that must be avoided if possible.

Drug effects in animals are typically studied to predict how the drugs may affect human behavior and the relevance of studying drug effects on social behavior in animals such as rats, mice, and monkeys may seem rather distant to the complexity of human social behavior and structure. However, humans are also a social species that has a highly hierarchical organization and are very territorial, and while the exact details will differ between species, the more general responses can be comparable. We often view human behavior to be fundamentally different from animals, but a very obvious example of human territorial behavior is how we define countries and borders and the vigor with which we defend our territory. Another more mundane example is how we feel if someone sits in "our chair" in a classroom. The social hierarchy is similarly very obvious in many work situations and when observing an interaction between two individuals with different status in an organization: from body posture and movements it can easily be understood, which of the individuals has the higher status. The military is an example of an organization where this hierarchy has been practiced to its fullest extent.

In this essay, social behavior will be used to indicate nonaggressive, nonterritorial and nonsexual social behaviors between members of a species that live in social structures. It is therefore the normal behavior we express when interacting with other people in a daily-life situation. This type of social behavior is disturbed in many diseases such as ► depression, ► anxiety, social phobias, ► schizophrenia, and ► autism; it may be affected by drug side effects, e.g., corticosterone, and it may be changed as a result of another condition, e.g., chronic pain.

In relation to psychopharmacology, social behavior represents a very interesting group of behaviors. They are important aspect of human behavior with a clear biological function, they are disrupted in many diseases, they are complex behaviors that must be normalized by a treatment, and because it is a set of complex active behaviors it is relatively easy to dissociate the nonspecific, e.g., sedation from specific drug effects.

Social species usually have a rich repertoire of communication signals, but typically for other species than our own we are only able to observe and record a fraction of these. For example, rats and mice rely to a great extent on olfactory signals and ► ultrasound in their communications and presumably also use very discrete facial and body postures that we do not recognize, and the level of information that we are able to extract from an encounter between two individuals is therefore very limited. This therefore does not mean that their communication systems and social organization are simple and primitive, but rather that we are not able to record and interpret the true level of complexity. For example, most studies on social behavior between pairs of rats record time spent investigating, following, and grooming the other individual as an index of the level of social behavior. These measures are very crude and probably disregard 95% of the true communication that exist between the rats. However, for the purpose of studying drugs that interfere with the social structure, this may be sufficient – it should just be realized that it does not represent the true level of communication.

A number of factors need to be considered, when studying social behavior. One factor is, as mentioned above, that each species will use different routes of communication, e.g., visual, auditory, olfactory, and postures and movements. Humans have, compared to most animals, a rather inferior olfactory sense and we will rarely be able to monitor communication using this channel. Similarly, we will rarely be sensitive to small discrete postures and movements in a different species than our own, and for auditory signals, we cannot perceive signals above 15 kHz unless we use special equipment. A second factor is strain differences in the chosen species. There are considerable differences between different lines of rats and mice in terms of their level of ► aggression and anxiety, and this will affect the study. A third factor is the influence of other behavioral categories on the observed social behavior. ► Sex differences and estrus cycle will affect the level of sexual behaviors in an experimental situation and repeated exposure to a particular arena may prompt the appearance of strong territorial behaviors, thus increasing the level of aggressive behaviors. A fourth factor is that diseases, just as for humans, will affect the behavior of an animal and particularly for transgenic animals or aged animals, this can be a concern. It has for example been reported that some of the transgenic lines of mice carrying an Alzheimer's disease mutation have inferior vision and reduced level of hearing. Also, in case a drug

causes pain or induces, e.g., nausea, this will affect behavior as well.

A final factor is that experimental conditions and handling will affect the outcome of an experiment. A stressed animal or an animal placed in an aversive experimental situation will necessarily exhibit a different behavior compared to a nonstressed or a nonanxious animal. These factors need to be controlled and what may constitute an aversive stimulus for that particular species needs to be considered. However, it is also possible to use aversive stimuli to control the types of behavior that the animals express and that are studied. For example, the light level in an arena will have considerable impact upon the behavior of a rat. High-light conditions will produce an anxiogenic state in the rat, which will reduce the level of active behaviors, whereas a low-light condition will increase the level of natural behaviors, e.g., explorative and social behaviors (Whishaw and Kolb 2005). The olfactory level in the arena and the number of repeated visits to the arena will affect the speed with which the animal begins to perceive the arena as a part of its territory and thereby the level of aggressive behaviors it expresses in order to defend its territory, if confronted with a conspecific. The level of aggressive behavior is also affected by the housing condition of the animals, e.g., in rats single housing will increase the aggression level. Light/dark cycle will affect the sensitivity of the animals to drugs. If animals are tested during their normally active period, i.e., during the night for a rat, it will be more sensitive to drug effects compared to testing conducted in the day time, i.e., the rats inactive period. Finally, handling can have unexpectedly strong effects on behavior, e.g., handling a rat by the tail can stress it so much that it becomes impossible to study social interations, and the presence of a computer in the experimental room can affect behavior because the rats may be able to hear it.

Standard Test Paradigms

Social behavior can in principle be studied in any situation that involves two or more members of the same species. Complex situations involving many members living in a stable structure is likely to provide more detailed information on the effects of drugs on normal behavior or on behavioral abnormalities in animals carrying a disease, but it can be very difficult to standardize a test of this type to allow comparison of different drugs and the amount of time required to study drug effects may become so demanding that it in practice becomes impossible to compare drug series. For these reasons a number of simplified, standardized behavioral tests have been developed that allow the experimental observation of some aspects of social behavior thought to be relevant to human behaviors.

One of the most routinely used tests for social behavior is the ▶ social interaction test where two rats or mice are placed simultaneously into an arena and where their level of social behavior is recorded for 7–10 min (File and Seth 2003). The animals may be familiar with the arena and to each other. The test is usually performed in a high-light and a low-light configuration. For the high-light configuration, the arena is brightly illuminated and this will create an aversive environment since rats and mice in general avoid open, brightly lit areas. Their natural tendency will be to avoid the center of the arena and to stay in the periphery of the arena, where they usually remain inactive. Using this design, it has been shown by many researchers that anxiolytic drugs such as the ▶ benzodiazepines, ▶ diazepam and ▶ chlordiazepoxide, will increase the level of social interaction, indicating a reduced level of anxiety in the animals, whereas drugs that lack ▶ anxiolytic effects are inactive. However, it should be noted that the avoidance of open spaces is a biologically appropriate response for a rat and a mouse, and the test therefore studies drug effects on natural behaviors and not on pathological anxiety, which is the type we seek to treat in human patients.

In the low-light configuration, the arena is only illuminated by dim red light to simulate a night-time situation, which is non-aversive to rats and mice, and they will typically explore the entire arena and engage in frequent social interactions, e.g., rats will typically investigate the novel area together. Under these conditions it is possible to evaluate manipulations that disrupt social behavior, e.g. to model a disease condition, or to determine if a drug causes side effects that affect normal behavior. An example of a disease model is phencyclidine-induced social isolation (Ellenbroek and Cools 2000). ▶ Phencyclidine (PCP) is an NMDA-antagonist that often is abused by humans and it has frequently been observed that PCP will induce a type of symptomatology, which resemble the negative symptoms of ▶ schizophrenia, i.e., the inability to engage in normal social relations. PCP will potently disrupt social behavior in rats, and this disruption can be reversed by ▶ antipsychotic drugs that in patients have an effect on the negative symptoms, e.g., ▶ clozapine and ▶ risperidone, whereas drugs that only affect the positive symptoms, e.g., ▶ haloperidol or that are not effective in the treatment of schizophrenia, e.g., ▶ citalopram and diazepam, are ineffective.

A different test paradigm is the ▶ social recognition test, which typically is performed in rats, where the level

of social behavior or social interest is used as a measure of recognition. In this test, an adult rat is allowed, e.g., 5 min, to investigate a juvenile rat. The juvenile is removed and after a certain time period, e.g., 30 min, 2 h or 24 h, either the same juvenile or a different juvenile is presented to the adult rat. If the adult rat recognizes the juvenile it will spend less time investigating it compared to the situation where it is a novel juvenile. Drug studies have shown that ► nicotine, which is known to improve memory in humans, can prolong the time period in which the adult rat recognizes the juvenile, whereas ► scopolamine, which interferes with memory, reduces the time period. The social recognition test is typically used in two configurations with either a long delay or a short delay until the re-introduction of the juvenile. The purpose of using a long delay is to identify drugs that can enhance memory, e.g., for symptomatic treatment of memory deficits in ► Alzheimer's disease, by demonstrating that a drug extends the time period in which the adult animal recognizes the juvenile. The purpose of using a short delay at which normal animals will recognize the juvenile is to determine whether a drug inhibits normal memory processes, e.g., caused by side effects, or to determine if animals display memory deficits, e.g., in connection with disease models, and whether drugs are able to reverse these deficits. Examples of the latter are scopolamine-induced memory deficits and cognitive deficits in disease-models of e.g., Alzheimer's disease, schizophrenia, and ► stroke. Finally, it is possible to administer the investigative drug at different time points in the testing sequence to determine which aspects of the memory process it affects, e.g. administering it after the first presentation of the juvenile to determine if it affects the ► consolidation of memory.

Social defeat

Definition

Social defeat is a procedure in which a smaller "intruder" rodent (rat or mouse) is introduced into the cage of a larger and aggressive "resident" rodent. The resident rat usually attacks the intruder rodent until it manifests a submissive posture. Additionally, the mere presence of the resident rodent (a threat condition) is sufficient to provoke physiological and behavioral stress responses in the intruder rodent that are similar to those obtained after the physical confrontation (Miczek et al., 2008).

Social Impairment

Definition

Individuals with ► pervasive developmental disorders (PDDs) have core social impairments that are persistent and severe. These impairments can be seen through deficits in multiple different behavioral and relationship realms. Core social impairment seen through nonverbal behavior can consist of deficits in eye contact, facial expression, and gestures that are used to help regulate social interaction. Often there is a failure to develop age-appropriate friendships. Core social impairments can consist of a lack of spontaneous seeking to share achievements or interests with other individuals. They are also commonly exhibited by a deficit in social reciprocity with individuals having a decreased awareness of others. They

can be exhibited by a lack of empathy and awareness of the needs of others.

Social Interaction Test

Definition

Two animals, typically rats or mice, are placed into an arena and their interactions, for example, investigation, following, and grooming, are recorded for a period of time, usually 5 to 10 min. Social behaviors such as following, adjacent lying, and anogenital sniffing are recorded by an observer or via automated image analysis. Many drugs modulate behavior on the social interaction test: benzodiazepines, MDMA, and oxytocin tend to increase social interaction while amphetamines, cannabinoids, NMDA antagonists, and withdrawal from various ► drugs of abuse tend to decrease social interaction. In the high-light version of the then test, the arena is brightly illuminated and this creates an aversive situation for the animals, which results in low levels of social interaction. In this configuration, it is possible to identify drugs or manipulations that reduce the inferred level of anxiety in the animals, that is, they result in an increased level of social interaction. In the low-light version, the arena is only illuminated with low, typically red light in order to minimize aversive cues. In this configuration, the level of interaction will be maximal and it is possible to test drugs or manipulations that reduce the normal level of social interactions. In addition to light level, which is the strongest experimental factor, the animals' familiarity with the arena can be varied, for example, by having been introduced to the arena prior to the testing session, and whether the animals know each other prior to the testing session. Familiarity with the arena will reduce the level of aversive cues, but will also increase the level of territorial behavior, resulting in more fighting between the animals. Familiarity between the animals being tested can reduce the level of aversive cues during the testing situation and the level of fighting, because a hierarchy does not have to be established, but it may also increase variability in the data, because the animals will have a preestablished rank that not will be present if they are unfamiliar to each other.

Social Recognition Test

Definition

The test uses social memory, that is, remembering having seen another individual before, as a measure of cognitive function. A juvenile is introduced to an adult animal, typically rats are used, for 5–7 min and the level of investigative behavior performed by the adult animal toward the juvenile is recorded. After a delay of typically 30 min, 2 h or 24 h, either the same juvenile or a novel juvenile is introduced to the same adult animal and the level of investigative behavior is recorded. If the adult animal recognizes the juvenile, the level of social investigation will be lower compared to the situation, where the adult male does not recognize the juvenile or it is a novel juvenile. In a variant of this test, an object is used instead of a juvenile animal. When the test is conducted using short delays between the two testing sessions, it is possible to identify drugs or manipulations that interfere with memory and learning, whereas for longtime delays it is possible to identify drugs or manipulations that enhance cognition.

Social challenge

Definition

In most general terms, social stress refers to the immediate response to a change in the social life of an individual, either in response to separation or confrontation. If the social stress persists, pathological consequences become evident in suppressed reproductive, immune, and metabolic functions and in social intercourse; many cardinal symptoms of psychosis, depression, and drug abuse, such as anhedonia-like responses, dysregulated circadian rhythms, weight, and movements, emerge in vulnerable individuals.

Impact of Psychoactive Drugs

Types of Social Stress

In the definition of social stress and the response to ► stress, pressures, loads, and strains, as characterized in the physical, engineering, and military sciences, serve as metaphors for physiological, cellular, and molecular events. In biological systems, the concepts of homeostasis and allostasis are important in the definition of stress – the former defining a set point surrounded by minimal and maximal limits and the latter referring to constantly changing boundaries. Like many other stressors, maternal separation stress and stress arising from social conflict in adulthood incorporate the rapid sympathetic and slower hypothalamic–pituitary–adrenal (HPA) responses. In addition to these changes in the autonomic nervous system, many physiological and neurobiological features are unique to the specific social stress.

Social Isolation, Crowding, and Instability

Most primate species and other socially cohesive species, such as rats, require social contact, and deprivation of this contact constitutes a type of social stress that eventually results in behavioral, physiological, and neurochemical pathologies (*social isolation*). In contrast, in animal species that disperse after puberty, single housing mimicks the life of males who mark, patrol, and defend their territory and exclude other males. The opposite type of social stress is represented by *crowding*, which in most cases leads to lethargy and eventual increased mortality. High population density profoundly alters the toxicity to drug action as demonstrated earlier by increased amphetamine toxicity in crowded mice. In species with well-defined social hierarchies, the establishment of social stratification by *instability* can be stressful. Experimentally, the constant rearrangement of social groups of laboratory animals has been used to induce constant social instability, although with questionable validity.

Maternal Separation Distress

Two types of *maternal social separation* stress have been identified with behavioral and neurobiological consequences that continue into adulthood and that are particularly relevant to drug abuse and affective disorders. Experimental studies in rodents have identified a critical developmental period in rodents, starting about 3–4 days after birth, during which individuals are hyporesponsive to stress in terms of glucocorticoid activation. Brief separations of pups from the dam (ca. 15 min/day) during this period render the individual more resistant to stress in adulthood, possibly related to anxiety-like responses. In contrast, prolonged separations from the dam (ca. 180 min/day) enhance the hypothalamic–pituitary response to stress in adulthood, possibly relevant to anhedonia, a core symptom of affective disorders.

The amount of play and its intensity during adolescence determine how individuals cope with stress later on as adults. Some adolescents appear to be particularly vulnerable to social defeat stress, and these episodes of stress can impair neural maturation. Of particular concern is the impact of social stress during adolescence on the later acquisition of compulsive drug taking.

Social Defeat Stress

Social stress in adulthood is experienced most often in aggressive confrontations, typically during the formation of dominance hierarchies and during the breeding season. The *socially defeated* animal rapidly learns to display the species-typical defensive and submissive postures, acts, and signals. The physiological and behavioral consequences manifest themselves by impaired social interactions, particularly reproductive activities, reduced exploration, disrupted foraging, less feeding, and drinking. Even a single episode of ► social defeat stress impairs circadian activity, nociception, and motor activity, and activates cellular activity in mesencephalic and corticolimbic nuclei. Repeated episodes of social defeat stress amplify these neurobiological and behavioral consequences over a long term. These enduring neuroadaptive changes lead to sensitized stimulant responses, similar to those after intermittent stimulant drug treatment. Repeated social defeat stress engenders also deficits in memory that relies on intact hippocampal activity.

Social Subordination Stress

When social stress is continuous rather than episodic such as in *subordinate* animals that are continuously exposed to the presence of higher ranking individuals, its behavioral repertoire and physiological functions are severely

compromised, in extreme cases leading to a morbid course. Subordinate animals are characterized by scars and wounds, inactivity, immunosuppression, elevated ACTH and glucocorticoid activity, lower androgens, eventual testicular regression, and adrenal hypertrophy. The persistent behavioral, immunological, and endocrine characteristics of a subordinate animal lead to lowered success in transmitting genes into the next generation and ensuring the survival of its offspring.

Neurobiology and Psychopharmacology of Maternal Separation Stress

GABAergic, glutamatergic, monoaminergic, and opioid peptidergic mechanisms are activated during the separation stress of an infant from the dam. In most myomorph rodents, maternal separation stress is evident behaviorally by the emission of loud and frequent ► ultrasonic vocalizations during the first 2 weeks after birth. Similar distress vocalizations are emitted in avian and primate species. These vocalizations are sensitive to the suppressive effects of agonists at the 5-HT_1 receptor family, positive modulators of the ► $GABA_A$ receptors, and $mGluR_{2/3}$ receptor agonists. Drugs which are clinically effective as ► anxiolytics (e.g., ► benzodiazepines, ► buspirone) and ► antidepressants (e.g., SSRIs, SNRIs) effectively reduce the ultrasonic distress vocalizations by rodent pups that are separated from the dam and litter mates. These vocalizations may be expressions of affective distress and serve primarily the immediate purpose to prompt retrieval by the dam and, during prolonged separations, thermoregulatory functions may become relevant. While the GABAergic, glutamatergic, monoaminergic, and opioid receptor systems continue to undergo significant maturation during the first weeks of life of rodents, the pharmacological manipulations of these targets may result in effects on affective vocal responses that differ from those in the mature adult.

Repeated maternal separation stress in the first 2 weeks after birth results in profound and long-lasting changes in the expression of the message for ► GABA, ► glutamate, and ► neuropeptides such as CRF and opioid peptides and their receptors. A key variable is the duration of the maternal separation; for example, prolonged daily maternal separations resulted in increased mRNA for CRF in hippocampal cells relative to the lower mRNA levels of CRF after short separations (180 vs. 15 min/day). Two types of long-term consequences are significant from a psychopharmacological perspective. First, rodent pups that are repeatedly separated from the dam and littermates can show depressive-like behavioral and neural phenotypes, and antidepressant treatment can prevent some of these changes. Secondly, of particular significance are the large and persistent increases in ► alcohol and stimulant self-administration and in sensitized responses to stimulant challenge in adults that were exposed during the stress hyporesponsive period to repeated long episodes of uncontrollable maternal separation stress, although these increases are limited to specific experimental conditions.

In addition to the hyporesponsiveness to psychomotor stimulants during adolescence, social defeat stress during this developmental period renders adolescents far less sensitive to the psychomotor stimulant effects of amphetamine or cocaine relative to adults in several rodent models. Repeated exposure to social defeat stress or to cocaine activates adolescent neural circuits in a remarkably similar manner suggesting shared mechanisms of emerging resilience and vulnerability.

Neurobiology and Psychopharmacology of Social Defeat and Subordination Stress

In adulthood, even a single episode of social defeat stress may increase the release of DA in mesolimbic, but not striatal structures as assessed by in vivo ► microdialysis and fast-scan voltametry, complementing earlier evidence for noradrenergic activation in both the perpetrator and victim during social confrontations. Stimulant-evoked DA rises in the ► prefrontal cortex, and ► nucleus accumbens are very large after the intruder rat has experienced several episodes of social defeat providing evidence for neural sensitization. This stress-sensitized release of cortical and accumbal DA needs to be integrated with the often reiterated hypothesis of DA's special role in reward processes.

Increased serotonergic impulse flow characterizes socially stressed tree shrews and mice, as is evident in the activity of raphé cells as well as in the terminals in the ► hippocampus. Chronic social subordination stress results also in reduced affinity and message for receptors of the 5-HT_1 family in several animal species. Persistent changes in cellular activity after repeated social defeat stress are evident not only in the raphé cells, but also in the VTA (► ventral tegmental area), prefrontal cortex, and ► amygdala.

The study of brief social defeat stress and of continuous subordination stress represents a promising source of information on account of anxiety- and depressive-like physiological and behavioral profiles in several animal models. Social defeat can engender features indicative of profound emotion, ranging from anhedonia to intense fear. The loss of social initiatives and the lack of

experiencing pleasure ("anhedonia"), most often assessed by the preference for sweet tastes, in animals that were exposed to uncontrollable, unpredictable, and chronic social defeat stress, can be attenuated by ► tricyclic antidepressants and ► SSRIs. In parallel, antidepressants can reverse the social subordination and stress-induced suppression of neurogenesis in the hippocampus. Endogenous ► brain-derived nerve growth factor (BDNF) is profoundly suppressed by continuous social subordination stress, and increased BDNF activity is detected in the VTA in animals exposed to intermittent episodes of brief social defeat stress suggesting an important role of this factor in the contrasting neuroadaptations after brief versus continuous social stress.

In anticipation of an imminent episode of social defeat stress, animals become hyperthermic and start to emit distress calls; these physiological and behavioral indices are interpreted to reflect intense emotional states. In fact, clinically effective ► anxiolytic drugs which act as positive modulators at $GABA_A$ receptors or at 5-HT_{1A} receptors attenuate these anxiety-like responses. These anxiolytic-like effects of benzodiazepines, ► buspirone, and also alcohol of the anticipatory hyperthermia and ► distress vocalizations contrast with the absence of ameliorative effects on defensive responses in reaction to social stress.

In laboratory rodent models, similar to other mild stressors such as tail pinch or foot-shock pulses, intermittent defeat stress induces a persistent, sensitized, psychomotor stimulant response upon challenge with a moderate dose of ► cocaine, ► amphetamine, ► morphine, or ethanol. As little as one defeat experience is sufficient to induce a sensitized locomotor activation to a challenge with D-amphetamine, and this effect grows in magnitude and extends in time after repeated episodes of social defeat stress. Blockade of ► glutamate receptors in the VTA prior to each stress episode can prevent the sensitizing effect of stress, and this protective effect critically depends on BDNF and phosphorylation of ERK and CREB. Behavioral and neural ► sensitization have been hypothesized to contribute to the neuroadaptations that escalate drug seeking and taking.

The long-postulated facilitative effects of social stress on drug abuse are more directly examined under experimental conditions that quantify the rate, amount, and persistence of drug intake as a result of exposure to discrete episodes of social stress. Similar to other types of intermittent stress, brief episodes of social defeat stress in laboratory rats and nonhuman primates can facilitate the acquisition of stimulant and possibly alcohol self-administration, increase the rate of regular daily drug intake, and especially increase the amount and duration of cocaine self-administration under unlimited access conditions ("binging"). Mechanistic studies have begun to delineate the glutamatergic, GABAergic, and peptidergic modulation of DA in the VTA–accumbens–prefrontal cortex–amygdala neural circuit as being critical for social defeat stress to escalate psychomotor stimulant intake.

In contrast to the intense and prolonged cocaine taking after episodic social defeat stress, continuously threatened subordinate rats responded less to a stimulant challenge in terms of locomotor hyperactivity and accumbal DA release, and they ceased self-administering intravenous cocaine sooner when given unlimited access relative to controls. There is indication that BDNF in the VTA, prefrontal cortex, and amygdala is suppressed as a result of chronic subordination stress. The divergent adaptations in BDNF cells after episodic relative to continuous social stress appear, characteristic of escalated versus suppressed cocaine taking that follow different types of stress. To which extent the controllability of stress determines the BDNF activation in the prefrontal cortex remains to be determined.

In sum, considerable evidence points to different kinds of social stress as risk factors for initiating, escalating, and resuming ► drug abuse in vulnerable individuals. The hyperdefensive behavior, weight dysregulation, signs of anhedonia, altered sleep, and activity patterns, and the profile of HPA activity in subordinate animals bear similarities to cardinal signs of depressed patients. Other signs in the physiological and behavioral repertoire of socially stressed animals may reflect anxiety-like responses. Understanding the intracellular cascade of events in mesocorticolimbic circuits for the transition from episodic to continuous, inescapable social stress in infancy and adulthood promises to provide insight into basic reward processes that are relevant for addictive and affective disorders.

Definition

Pharmacologic agents have long been recognized as potentially helpful for patients with somatic symptoms such as insomnia and neuropathic pain. However, there have been very few well-controlled studies on the pharmacologic treatment of specific somatoform disorders as defined by DSM-III-R and ► DSM-IV. This section will summarize what is known, based on well-controlled studies on the pharmacologic treatment of three somatoform disorders – hypochondriasis, somatization disorder, and body dysmorphic disorder (BDD).

Role of Pharmacotherapy

Pharmacotherapy of Hypochondriasis

The advent of the ► selective serotonin reuptake inhibitors (SSRIs) in the early 1990s led to a series of case reports suggesting efficacy for various depressive and anxiety disorders. Of particular relevance was the superior efficacy profile of the SSRIs, compared to primarily noradrenergic agents, in ► obsessive–compulsive disorders. Perhaps because of the favorable side effect profile and the striking efficacy for obsessional disorders proffered by the SSRIs, case reports and small series appeared, suggesting that agents with serotonergic activity might be particularly beneficial in helping patients with hypochondriasis as noted by Fallon and Feinstein (2001), with positive findings reported for clomipramine, fluvoxamine, fluoxetine, citalopram, paroxetine, nefazodone, and imipramine. Responder rates were high in the small (10–18 subjects) uncontrolled series for treatment completers, ranging from 70 to 89%. Clinicians were advised to treat patients for 8–12 weeks for optimal efficacy.

Controlled data on the use of medication in the treatment of hypochondriasis, however, is limited to two ► randomized trials. In 2008, Fallon et al. (2008) conducted a ► placebo-controlled study of ► fluoxetine for

hypochondriasis among 45 randomized patients. At the primary end-point of week 12, the proportion of clinician-rated global improvement responders to fluoxetine compared to placebo was significant for the completer and minimum treatment samples and at the margin of significance ($p = 05$) for the intent-to-treat (ITT) sample. The responder rate for the ITT sample at week 12 was nearly twice as great for those patients randomized to fluoxetine (62.5%) as compared to placebo (33.3%). Because this pattern of improvement was also seen at week 8, it was suggested that a treatment duration of 8 weeks of medication might be sufficient to test efficacy. When a conservative imputation method was used in which all patients not rated were categorized as nonresponders, the ITT responder rate at week 12 was 14/24 (58.3%) for fluoxetine vs. 4/21 (19.0%) for placebo ($p = 007$). The degree of improvement in hypochondriasis at week 12 was moderate on average, but improvement appeared to increase over time. Fluoxetine was generally well-tolerated, as demonstrated by the comparable rates of study withdrawal for the fluoxetine-treated and placebo-treated groups. Although the sample size was small, these results support the conclusions that fluoxetine treatment is effective, durable, and well tolerated.

In 2007, Greeven et al. (2007) conducted a randomized controlled trial among 112 patients comparing the efficacy of cognitive behavior therapy (CBT), ▶ paroxetine, and a ▶ placebo (administered in a ▶ double-blind fashion) in the treatment of hypochondriasis.

Patients were randomly assigned to one of the three treatments for 16 weeks. The main outcome measure was the Whiteley Index. The authors considered subjects who scored at least one standard deviation below the mean pretest score on the Whiteley Index as responders. For the ITT and completer cohorts, pooled CBT and paroxetine were significantly superior to placebo, but did not differ significantly from each other. The responder rates for the ITT and completer cohorts were 45 and 54% for CBT, 30 and 38% for paroxetine, and 14 and 12% for placebo. For the ITT analysis, only CBT differed significantly from placebo. In the completer analysis, both paroxetine and CBT differed significantly from placebo. This study supported the authors' conclusion that paroxetine and CBT are each helpful short-term treatment options for patients with hypochondriasis.

Patients with no insight into the irrationality of their illness concerns are often diagnosed as having ▶ delusional disorder, somatic subtype. Case reports and small series have reported the efficacy of typical and atypical antipsychotics in the treatment of delusional parasitosis in particular, with marked improvement in two-thirds of cases. The antipsychotic ▶ pimozide was reported as effective for delusional parasitosis in two small placebo-controlled trials with ON–OFF–ON designs, but the use of pimozide remains a concern because of the increased risk of torsades de pointes and sudden death resulting from the drug's tendency to prolong the electrocardiographic QT interval. Two meta-analyses of controlled studies of patients with delusional parasitosis, including one by Lepping et al. 2007, have supported the benefits of typical and atypical antipsychotics. Whether SSRIs may play a role in the treatment of psychotic forms of health anxiety has not yet been adequately studied.

Pharmacotherapy of Somatization Disorder

Pharmacologic studies of somatization disorder are few. This reflects the stringency of the diagnostic criteria and the consequent rarity of the full-blown syndrome, which makes clinical trials extremely difficult. To circumvent this problem and to examine therapies for the much larger population of patients who frequent primary care doctor's offices, researchers have conducted studies of patients who meet criteria for a spectrum of somatization conditions, primarily abridged somatization, which requires meeting fewer somatic criteria for diagnosis. There have also been meta-analyses, such as by Kroenke (2007), of studies conducted in patients who would meet the even more encompassing umbrella category of medically unexplained symptoms (MUS). Prior research suggests that roughly half of patients with MUS have a concomitant mood or anxiety disorder and that about one-third would meet criteria for a somatoform disorder.

A meta-analysis by O'Mallay et al. (1999) identified studies of MUS, mainly representing headache, fibromyalgia, functional gastrointestinal disturbances, idiopathic pain, tinnitus, and chronic fatigue. Ninety-four randomized controlled trials (RCTs) were found that compared different ▶ antidepressant medications, including tricyclics and SSRIs; of these, 69% of the studies documented favorable outcome on either a pain score, a global assessment score or a summary symptom index. Of concern is that high withdrawal rates were seen in almost two-thirds of the studies. Of further concern is that only 37% of the studies reported the side-effect profiles from the antidepressant medications.

St. John's wort was reported as efficacious in two 6-week's duration placebo-controlled treatment studies of MUS. The earlier study had 149 subjects, of whom 108 met criteria for either somatization disorder or abridged somatization disorder. More recently, Muller et al. (2004) studied 173 subjects, of whom 67 met criteria for somatization or abridged somatization disorder. Improvement

was reported in both studies for symptoms and psychological status.

► Venlafaxine was studied in 112 patients with "multi-somatoform disorder" in a randomized double-blind controlled trial by Kroenke et al. (2006). Although pain improved, no change was noted in total somatic symptom score.

In the RCT of fluoxetine for hypochondriasis conducted by Fallon et al. (2008), although improvement in hypochondriasis was noted, there was no significant difference between drug and placebo in improvement in total quantity of somatic symptoms.

Opipramol, a tricyclic ► anxiolytic with high affinity for sigma receptors, was studied in a placebo-controlled trial in 200 patients with mixed somatoform disorders (primarily somatization, abridged somatization, and an autonomic dysfunction syndrome). Although a reduction in total somatic symptoms and psychological symptoms was noted, the effect size was small.

Overall, these studies suggest that antidepressants may have a beneficial role in the treatment of some of the MUS disorders known as "functional somatic syndromes" – fibromyalgia, irritable bowel, and headache. Data supporting the benefit of pharmacologic agents for abridged or full somatization disorder is weaker. Although studies suggest a benefit for agents such as St. John's wort, the effect size is not very large. Further study is needed to identify better treatments for this particularly troubled group of patients.

Pharmacotherapy of Body Dysmorphic Disorder

Following the advent of the SRIs, open treatment studies of patients with BDD suggested beneficial effects of clomipramine, fluoxetine, and fluvoxamine, which was further confirmed by a 16-week double-blind crossover-design study of 29 subjects using ► clomipramine vs. desipramine conducted by Hollander et al. (1999). This crossover study showed clomipramine, a tricyclic with potent ► serotonin and ► norepinephrine reuptake inhibition, to be superior to desipramine, a tricyclic with predominant norepinephrine reuptake inhibition, on all primary outcome measures of BDD, including patients' obsessive preoccupation with perceived body defects, repetitive behaviors in response to this preoccupation, and global ratings of symptom severity. Additionally, a placebo-controlled study in 2002 by Phillips and colleagues of fluoxetine ($n = 67$ randomized, 59 completed) showed preferential response to fluoxetine at weeks 8 and 12 for treating the symptoms of BDD and for improving functional outcome.

While different SRIs have not been compared directly in the treatment of BDD, initial studies showed a variety of them to have efficacy and tolerability. Several open-label studies have been done, including two with ► fluvoxamine ($n = 15$ and $n = 30$ and one with ► citalopram ($n = 15$). Additionally, in an open label study of ► escitalopram with 15 subjects with BDD, 73.3% ($n = 11$) reported significant symptom improvement, with 33% much improved and 46% very much improved at 4.7 ± 3.7 weeks. Comparison studies, assessing the degree of response and time to response, are needed. One study, which examined the quality of pharmacotherapy for BDD among 151 individuals in a convenience sample found that, while many had been tried on an SRI (65.6%), only 12.9% of SRI trials were considered optimal and only 21.5% were considered minimally adequate. Optimal treatment is often considered a minimum of 12 weeks in duration, with at least 2–4 weeks at the highest dose tolerated by the patient.

While SRIs are certainly effective for BDD, 25–50% of patients do not respond to current pharmacotherapies and; even among responders, the degree of improvement is often only partial. While the data are limited, augmentation with another psychiatric agent, such as ► buspirone, may be helpful once the SRI has been optimized. Nonpsychiatric medical treatments, including the most commonly topical dermatologic treatments or creams, do not appear effective for the treatment of BDD.

Review by Philips (2004) suggested there is no convincing evidence supporting the use of ► antipsychotic medications in BDD. Although initial case reports suggested that delusional BDD responded to pimozide, a small ($n = 28$) placebo-controlled, double-blind study of pimozide augmentation of fluoxetine in BDD by Phillips in 2005 showed it to be no more effective than placebo (18.3% responding to pimozide and 17.6% responding to placebo), even in more delusional patients. Contrary to expectations, the delusional variant of BDD appears to respond to SRIs alone, with similar findings in adolescents with BDD. In the 1999 study of Hollander et al. (1999), clomipramine was surprisingly more effective for delusional patients than nondelusional patients, whereas the study of Philips et al. 2002 showed an equivalent BDD symptom response to fluoxetine (50 vs. 55%). Of note, in the latter study, delusional BDD patients were significantly less likely to respond to placebo than nondelusional patients.

Definition

Somatostatin (somatotropin release-inhibiting factor, SRIF) is a cyclic peptide widely expressed throughout the central nervous system (CNS), in endocrine tissues, and in the gastrointestinal tract (GIT). The 14 amino acid peptide, somatostatin (SRIF-14), was first identified and isolated from ovine hypothalamic extracts by Guillemin and collaborators (Brazeau et al. 1973) during their search of GHRH hormone/growth hormone (GH) releasing hormone, instead they identified SRIF as a potent inhibitor of growth hormone release from the pituitary. Subsequently, a longer N-terminally extended form (SRIF-28) was identified in the periphery, both deriving from the same prepropeptide.

Pharmacological Properties

Introduction

About 20 years later, a rat ▶ neuropeptide with strong homology to SRIF was identified, cloned, and named ▶ cortistatin (CST) due to its supposed brain selective expression; however, CST is also present in the periphery. In rodents, CST is a tetradecapeptide (CST-14), sharing up to 11 amino acids with SRIF, whereas the human homolog is a heptadecapeptide (CST-17). Similar to SRIF, a longer isoform of CST has also been identified, i.e., CST-29. Both peptides (SRIF and CST) are produced as prepropeptides, which are then processed to the final forms by peptide cleavage; it is strongly suggested that SRIF and CST are the products of gene duplication (De Lecea 2008; Hoyer et al. 1995). Finally, neuronostatin, a somatostatin-gene derived peptide isolated from gut, has recently been mentioned to be expressed in some brain regions, but activation of SRIF receptors does not seem to mediate its reported neuroendocrine effects.

SRIF exerts a wide range of biological actions, including inhibition of secretion of growth hormone, insulin, glucagon, and gastrin as well as other hormones secreted by the pituitary and the GIT. SRIF also acts as a neuromodulator in the CNS and, in addition, has marked antiproliferative effects on a wide range of cancer cells (Viollet et al. 2008). Although various physiological parameters, including transitions between sleep phases, ▶ consolidation of short- and long-term memory, and locomotor activity, respond in an apparently peptide-specific manner to SRIF and CST, both peptides in the short and long forms have nanomolar affinity for each known SRIF receptor subtype (sst_1–sst_5). The existence of specific CST receptors has not been demonstrated so far in spite of major efforts (Siehler et al. 2008). Clinically, SRIF receptor modulation is targeted primarily in the endocrine and gastrointestinal sphere, especially in a number of gastroenteropancreatic (GEP) cancers, although preclinical evidence points at a number of other diseases, such as inflammation, pain, migraine, epilepsy, additional cancers,

and neuropsychiatric disorders such as ► depression and ► Alzheimer's disease (Viollet et al. 2008).

SRIF and CST Receptors

SRIF and CST act via a family of ► G-protein-coupled receptors (GPCRs); it was suggested initially that there are two receptors, based on pharmacology and distribution studies; receptors were distinguished by their high affinity or low affinity for ► octreotide (SMS-201–995); however, in the early 1990s, at least five receptors (sst_1–sst_5) have been cloned and characterized from various species. Sequence homology is 39–57% among the five subtypes, each being highly conserved across species. Based on structural and operational features, they are divided into two groups: SRIF-1 (sst_2, sst_3 and sst_5 receptors) and SRIF-2 (sst_1 and sst_4 receptors), distinguished by high affinity for small analogs such as octreotide, seglitide (MK-678), and ► lanreotide (BIM-23014) for the SRIF-1 group. They have nanomolar affinities for SRIF and CST, and will be generically referred to as SRIF receptors here. In humans, SRIF receptors are encoded by five nonallelic genes, located on chromosomes 14, 17, 22, 20, and 16, respectively. Genes coding for sst_1, sst_3, sst_4, and sst_5 are intronless, whereas in rodents the sst_2 gene contains three introns, which result in the generation of two receptor splice variants, sst_{2A}, and sst_{2B} (Hoyer et al. 1995).

Studies utilizing subtype selective SRIF analogs in both in vivo and in vitro experiments, demonstrate that sst_2 receptors are the major player in the SRIF receptor family with broad inhibitory effects on the endocrine secretion e.g., growth hormone, insulin, glucagon, gastrin, ► cholecystokinin, vasoactive intestinal peptide, and secretin, as well as the exocrine secretion, e.g., gastric acid, intestinal fluid, and pancreatic enzymes. sst_2 receptors also seem to play a major role in various forms of GEP cancers, in epilepsy and pain. The sst_1 receptor may function as an autoreceptor in the basal ganglia, the ► hypothalamus, and the eye and possibly in the ► hippocampus. It is also involved in regulating insulin secretion (Thermos et al. 2006). sst_3 receptors are enigmatically localized to neuronal cilia, and sst_3 antagonists have marked behavioral effects (Viollet et al. 2008). sst_4 receptors are highly expressed in the cortex and the hippocampus and in the lung, where their role still remains to be defined; in the mouse they modulate epileptic activity whereas in the rat it seems that this effect is largely assigned to sst_2 receptors (Moneta et al. 2002). Hippocampal sst_4 have been recently shown to be involved in the selection of memory strategies, switching from the use of hippocampus-based multiple associations to the use of simple dorsal striatum-based behavioral responses (Gastambide et al. 2009). sst_5 receptors mediate the inhibition of insulin release from the pancreatic β-cells in addition to regulating growth hormone release (Viollet et al. 2008).

Currently, octreotide and lanreotide are in clinical use for the treatment of acromegaly, diarrhea, and various GEP tumors, whereas [^{111}In] penteotride is used for whole body tumor imaging. Other SRIF receptor agonists are in development for additional indications, such as Cushing's disease.

CST and SRIF appear to produce different effects both in the brain and in the periphery, especially in the immune system. Due to these differences, the existence of CST-specific receptors has been suggested: MgrX2 and GHS-R1a are two unrelated orphan receptors reported to have affinity for CST; however, these reports have not received positive confirmation. On the other hand, there is convincing evidence for CST and SRIF to act with similar high affinity and efficacy at the known sst_1–sst_5 receptors (De Lecea 2008; Siehler et al. 2008). Since the existence of specific CST receptors is still an open question, thus we will generically refer to SRIF receptors here.

SRIF and SRIF Receptors in the Brain

Two types of somatostatinergic neurons exist in the CNS: long-projecting neurons and short GABAergic interneurons. SRIF neurons are primarily located in the hypothalamus, hippocampus, striatum, cerebral cortex, ► amygdala, preoptic area, olfactory bulb, and brainstem. Concerning receptor mapping, data from receptor autoradiography, RT-PCR, in situ hybridization and immunocytochemistry studies and receptor knockout/LacZ knockin use allow to state the following: all five SRIF receptors are present in the brain, sst_2 being the most prominent whereas sst_5 shows the lowest expression levels. sst_2 is often coexpressed with other given subtypes in a tissue-specific way, and the functional meaning of such differential expression repertoires is currently under study. In rodents and humans, the olfactory bulb expresses sst_2, sst_3, and sst_4, when the anterior olfactory nucleus does express primarily sst_2, the neocortex, sst_2 and sst_4; in the hippocampus, DG and CA3 region express sst_2 whereas the CA1 region displays both sst_2 and sst_4; in the amygdala and locus coeruleus, sst_2 expression is largely predominant, whereas the hypothalamus expresses sst_1 and sst_2 receptors. sst_5 receptors are very scarce in the brain. The sst_3 receptor is peculiar, as its mRNA is highly detected in several brain regions; however, the sst_3 protein does not distribute in a somatodendritc fashion, as the other receptors, but is restricted to somatic neuronal cilia, whose function remains elusive (see Viollet et al. 2008).

Somatostatin and its receptors (sst_1, sst_2, and sst_3) are also transiently expressed concomitantly during early sensory and brain development, suggesting that they may participate in ontogenetic processes.

The Somatostatin System in Health and Disease

Beside its neuroendocrine functions, somatostatin and its receptors have neuromodulatory roles, influencing motor activity, sleep, sensory processes, and cognitive functions. SRIF and its receptors are altered in affective and neurological disorders, e.g., depression, migraine, pain, epilepsy, and Alzheimer's disease. SRIF acts as a neuromodulator, e.g., of gamma-aminobutyric acid (► GABA), ► glutamate, and ► acetylcholine, and has both pro- and anticonvulsant activity, that are potentially relevant to the neurobiology of affective disorders. A consistent alteration observed in depression is the state-dependent decrease of CSF SRIF (Roca et al. 1999). However, such a decrease is seen also in other patient populations where cognition is or may be impaired, such as ► schizophrenia, Alzheimer's dementia, drug refractory epilepsy, and multiple sclerosis. The SRIF decrease in affective illness and active multiple sclerosis has been considered state dependent, in that levels normalize with recovery from the acute episode. On the other hand, increased SRIF levels have been reported in psychiatric illness where cognition is accelerated, as in ► mania and ruminative or ► obsessive-compulsive disorder (Viollet et al. 2008). Finally, acromegalic patients treated with somatostatin agonists are largely devoid of migraine attacks.

Which Role for the Various SRIF Receptors?

sst_2 receptors: Somatostatin induces an inwardly rectifying K^+ current in almost all projection neurons of the lateral amygdala: these effects are blocked by an sst_2 antagonist or mimicked by a sst_2 agonist. A role for sst_1, sst_3, or sst_4 receptors was ruled out since selective agonists were ineffective. Preclinical data suggest a role of somatostatin neurons in the central nucleus of the amygdala in rats on fear, since octreotide applied locally on caudal pontine reticular nucleus neurons blocks fear potentiation. These cellular effects support ► anxiolytic as well as ► anticonvulsant and antiepileptogenic actions of somatostatin or analogs in the amygdala (Fendt et al. 1996). Somatostatin also plays a critical role in the acquisition of ► contextual fear memory, but not does not tone fear learning, which supports a role for SRIF in hippocampal synaptic plasticity in processing contextual information. These data are in line with an anxiety phenotype presented by the sst_2 KO mouse, which is also impaired with respect to memory. SRIF modulates ► glutamate release in the striatum, an effect that is abolished in sst_2 receptor KOs. The sst_2 receptor modulates neprilysin, which affects $A\beta_{42}$ metabolism. SRIF KO mice have higher concentrations of the $A\beta_{42}$ peptide, accumulation of which leads to late-onset sporadic Alzheimer's disease. sst_2 and sst_4 receptors also seem to interact positively on the phosphorylation of ► Tau proteins at the Ser 262 site, a site modified in Alzheimer's disease. On the other hand, 3 and 6 h after middle cerebral artery occlusion (MCAO) in the rat, sst_2 receptors were internalized excessively in cerebrocortical neurons adjacent to the infarct and sst_2-deficient mice exhibit a 40% reduction of infarct size after permanent distal MCAO and a 63% reduction after transient proximal MCAO as compared to wild type animals. Thus, the activation of sst_2 receptors by an endogenous ligand after focal ischemia may contribute to increased sst_2 gene expression and postischemic neurodegeneration (see Viollet et al. 2008).

sst_1 receptors: sst_1 receptors are present in the brain, retina, neuroendocrine cells, endothelial cells, and various human tumors. They are involved in the intrahypothalamic regulation of growth hormone (GH) secretion and modulate somatostatin release in basal ganglia. We have proposed an autoreceptor role for sst_1 receptors located on somatostatin neurons in the hypothalamus, basal ganglia, retina, and possibly hippocampus. Thus, sst_1-selective analogs may play a role in various diseases, such as retinal and endocrine dysfunctions, cancer, and neuropsychiatric disorders. We have reported NVP-SRA880, an sst_1 antagonist to promote social interactions, reduce aggressive behavior, and stimulate learning. SRA880 reduced contextual/fear conditioning without affecting cue-elicited freezing in rats (Thermos et al. 2006). Further, sst_1-selective analogs have been shown to mimic the inhibitory effect of SRIF on GH secreting pituitary tumors; in medullary thyroid carcinoma, calcitonin secretion/gene expression is inhibited by sst_1-selective agonists. Finally, sst_1-selective agonists inhibit endothelial activities, suggesting utility for sst_1-selective agonists in angiogenesis.

sst_3 receptors: A potential role for sst_3 has been proposed in hippocampal dependent memory. sst_3 null mutant mice showed a severe impairment in their ability to recall previously learned spatial information. NVP-ACQ090, an orally active somatostatin sst_3 receptor antagonist has marked sociotropic effects in intruder mice, shows sociotropic effects in aggressive resident mice, and increases the social exploration of an intruder toward a non-aggressive resident rat. ACQ090 has anxiolytic-like activity in stress-induced hyperthermia and pronounced antidepressant-like effects in both the modified rat forced swim test and in olfactory bulbectomized rats. Thus, sst_3

receptor blockade has profound central effects in animal models for neurological and psychiatric disorders.

sst_4 receptors: There is evidence in the mouse that the main role in mediating the antiepileptic effects of SRIF is by the sst_4 in conjunction with sst_2 receptor, whereas in the rat only sst_2 is involved. Unprovoked seizures are observed in the sst_4 KO. The sst_4 receptor couples to the K^+ M-current (I_M, Kv7), which is an important regulator of cortical excitability; mutations in these channels cause a seizure disorder in humans. SRIF augments I_M in hippocampal CA1 pyramidal neurons. When seizures were induced by a systemic injection of kainate, only sst_4 knockouts showed an increase in seizure sensitivity. sst_2 and sst_4 appear to mediate the majority of SRIF inhibition of epileptiform activity in CA1. sst_4 receptors could therefore be an important novel target for developing new antiepileptic and antiepileptogenic drugs, but it remains to be seen that this applies to humans. sst_4 and sst_2 receptors can interact in a cooperative or in a competitive manner. Thus, when applied in the hippocampus, L-803087, a selective sst_4 receptor agonist, doubled seizure activity and facilitated AMPA-mediated synaptic responses in wild-type mice on average and this effect was blocked by octreotide. However, the sst_4 agonist was no longer active in sst_2 KO mice.

sst_5 receptors: Little is known about sst_5 receptors in the brain, which seem to express very low sst_5 levels, although the LacZ expression of the sst_5 KO looks very high in the hippocampus. Brain penetrant selective ligands are essentially missing or have not produced any remarkable central effect. Peripherally, sst_5 receptors modulate insulin release and various other endocrine effects appear to be mediated by hypothalamic sst_5 receptors.

Outlook

The involvement of SRIF and its receptors in neurological and psychiatric disorders is still largely circumstantial, primarily since selective and brain penetrating ligands have not reached the market yet. However, preclinical evidence as well as changes in SRIF and receptor levels in various diseases strongly suggest that modulating SRIF receptor activity will have clinical relevance in neuropsychiatric diseases.

Definition

Five SRIF receptors (sst_1–sst_5) have been cloned from various species. Sequence homology is 39–57% among the five subtypes; each is highly conserved across species. They have nanomolar affinity for SRIF and CST. Human SRIF receptors are encoded by five nonallelic genes, located on chromosomes 14, 17, 22, 20, and 16, respectively. Genes coding for sst_1, sst_3, sst_4, and sst_5 are intronless, whereas in rodents the gene for sst_2 contains three introns, which result in the generation of two receptor splice variants, sst_{2A} and sst_{2B}. SRIF receptors are GPCRs; they couple to G_0/G_i proteins and modulate cyclic AMP production and other transduction pathways.

Definition

Source localization techniques refer to a set of mathematical techniques for identifying the locus or loci of neural activity that give rise to a particular ERP voltage distribution measured on the surface of the scalp. By making assumptions about the physical properties of the skull, brain, and underlying active neural populations, these methods attempt to constrain the number of possible source configurations that can explain the observed scalp distribution. Preexisting knowledge about the brain and further assumptions, for example, about the number of active sources, are needed to arrive at a plausible solution. An important shortcoming of source localization techniques is that there is no means of quantifying the likelihood that a solution is correct.

Spatial Delayed Alternation

Definition

Classical paradigm for measuring short-term (often called "working") memory in rodents generally employing a T-maze and basing the measure of memory on the well--known tendency of rats spontaneously to alternate their spatial choices. The memory load can be increased by lengthening the delay between the first and second trials. Analogous but not equivalent to spatial delayed response task in nonhuman primates.

Spatial Learning in Animals

Definition

Spatial learning refers to the process through which animals encode information about their environment to facilitate navigation through space and recall the location of motivationally relevant stimuli. This form of learning is critically dependent on the integrity of the ► hippocampus, although surrounding regions of the temporal cortex and certain forebrain structures also play a role in these processes. It is generally believed that spatial learning entails encoding of the locations of cues relative to the position of other cues in a particular environment that leads to the formation of a cognitive map of an individual's surroundings. Thus, during spatial learning, animals use allocentric spatial cues to navigate in space, keeping track of their position relative to other distal stimuli. Support for this notion comes from the finding of place cells in the hippocampus, where different groups of neurons in this region display consistent changes in firing when an animal is oriented in a particular location in space. Moreover, changing the arrangement of distal spatial cues in an arena reorganizes the patterns of activity in these place cells to match the new orientation of stimuli in the environment. In rodents, one of the most common means for assessing spatial learning is with different types of maze tasks, where rats or mice use allocentric cues to guide an escape response (e.g., finding a hidden platform in a ► water maze task) or to locate food (e.g., on a ► radial arm maze). The majority of studies that have investigated the psychopharmacology of spatial learning have used these types of tasks. An important caveat is that drugs that alter performance of these tasks do not appear to exert a selective influence on spatial learning and

memory, as they typically can affect other forms of learning independent of the hippocampus. As such, preclinical tests of spatial learning in rodents, either in intact animals or those subjected to treatments that impair spatial learning, are often used as an initial assay to investigate the effects of potential cognition enhancing drugs.

Impact of Psychoactive Drugs

Excitatory Amino Acids

Drugs with interference from glutamatergic transmission, particularly those which block the n-methyl-D-aspartate ► (NMDA) receptor subtype, severely interfere with spatial learning. The systemic administration of either competitive (e.g., CPP) or noncompetitive (MK-801, ► phencyclidine) NMDA antagonists impair learning of spatially cued escape response in a water maze task (reviewed by McNamara and Skelton 1993). Similarly, administration of these compounds also impairs search behavior guided by spatial memory on appetitively motivated tasks such as the radial arm maze. The effects of these treatments seem largely attributable to the blockade of NMDA receptors in the hippocampus, as local administration of these compounds also impairs spatial learning. However, the administration of NMDA receptor antagonists after training have a substantially blunted effect, suggesting that hippocampal NMDA receptors are required for the acquisition and perhaps the initial ► consolidation of hippocampus-dependent memory, but not for its maintenance. These effects do not appear attributable to disruptions in motor or motivational processes because they do not interfere with the ability of animals to learn the approach at a single proximal cue, when, for example, rats must swim to a visible platform in a water maze. In contrast to the above mentioned findings, blockade of non-NMDA (e.g., ► AMPA) receptors impairs both the acquisition and retrieval of spatial information. In this regard, drugs that potentiate currents mediated by AMPA type ► glutamate receptors (ampakines) have shown efficacy in improving spatial and other forms of learning in animal models (Arai and Kessler 2007). The effects of drugs acting on ► metabotropic glutamate receptors have received less attention, although antagonists at mGlur1 and five sites have been reported to impair the acquisition of a water maze task.

The ability of NMDA antagonists to impair spatial learning has been proposed to be related to disruptions in certain forms of ► synaptic plasticity in the hippocampus, given that compounds that impair spatial learning also impede the induction of ► long-term potentiation (LTP) in this region. Notably, blockade of NMDA receptors does not affect maintenance of LTP. Similarly, systemic blockade of these receptors with competitive antagonists induces a selective disruption of the formation of ► place cell activity in the hippocampus. Place fields that formed *de novo* in the presence of NMDA antagonists are unstable, but these treatments do not affect the maintenance of previously established place fields, although they do disrupt the expansion of place fields that occurs with repeated exposure to an environment. These findings are in keeping with the dissociable effects of NMDA antagonism on learning versus ► retrieval of ► spatial memories (Nakazawa et al. 2004).

Acetylcholine

The hippocampus receives dense cholinergic enervation from the septum that mediates theta frequency oscillatory activity, thought to be important for the exploration of novel environments. The blockade of ► muscarinic cholinergic receptors with nonselective antagonists such as ► scopolamine or atropine severely disrupts both spatial learning and memory in a manner independent of the effects of these compounds on sensorimotor and procedural learning (McNamara and Skelton 1993). The use of these compounds in combination with spatial learning tasks has become a popular preclinical animal model for cognitive dysfunction for which to test the effects of potential ► cognitive enhancers. Perturbations in spatial learning induced by these drugs appear to be due to the blockade of postsynaptic M_1 receptors, as similar effects have been observed following peripheral or central administration of M_1 antagonists such as pirenzepine. Conversely, in some instances, enhancing cholinergic transmission can induce a beneficial effect on spatial learning. For example, blockade of M_2 autoreceptors with drugs such as methoctramine or AFDX 116 increases ► acetylcholine release and improves learning on tests of spatial abilities using different maze paradigms. Likewise, ► cholinesterase inhibitors (► physostigmine, ► tacrine) also can improve spatial learning, particularly in aged animals. Drugs of this nature have been used to offset aging-related cognitive decline occurring in human patients. ► Nicotinic cholinergic receptors have also been implicated in spatial learning. ► Nicotine or receptor subtype selective agonists improve spatial abilities in preclinical animal models. Current drug discovery research aimed at developing novel pro-cognitive compounds has focused on the alpha-7 subunit of the nicotinic receptor as a potential target. ► Genetically modified mice lacking this subunit display impairments in spatial and other forms of learning, whereas compounds, which stimulate receptors that include this

subunit, can enhance spatial learning and memory. The development of these compounds may prove beneficial for treating cognitive deficits observed in a number of disorders, including ► Alzheimer's and ► schizophrenia.

Although it is well established that the blockade of cholinergic transmission can impair spatial learning, it remains unclear where these compounds may be exerting their effects. The local administration of muscarinic antagonists into the hippocampus interferes with place cell firing. However, the deafferentation of cholinergic inputs to the hippocampus via 192 IgG-saporin lesions of the septum do not reliably impair spatial learning using water or radial maze tasks (Baxter 2001). This would suggest that impairments in spatial learning induced by the systemic administration of cholinergic antagonists occur via the blockade of extra-hippocampal cholinergic receptors, possibly in different regions of the cerebral cortex. Notably, cholinergic transmission has been heavily implicated in attentional processing. It has been proposed that acetylcholine serves to enhance the influence of feed-forward afferent input to the cortex while decreasing background activity by suppressing excitatory feedback connections within cortical circuits. By enhancing the response to sensory input, high levels of acetylcholine enhance attention to sensory stimuli in the environment and enhance the encoding of memory for specific stimuli (Hasselmo 2006). Thus, even though manipulations of cholinergic transmissions can influence acquisition and performance of tasks requiring the use of spatial cues to guide behavior, the effects of these compounds may not be due to a specific affect on the encoding or retrieval of spatial memories *per se*.

Monoamines

The systemic administration of dopamine antagonists acting at D_1 (SCH 23390) or D_2 (► haloperidol, ► sulpiride) receptors have been reported to impair spatial learning assessed with water maze tasks. In some instances, these effects were accompanied by motoric deficits as well, whereas other reports have shown that lower doses of these drugs that do not induce motor impairments are effective at impairing spatial learning. The hippocampus receives dopaminergic innervation, and studies combining behavioral and electrophysiological methodologies point to a role for D1 receptors in facilitating hippocampal synaptic plasticity, which may enhance the formation of novel spatial memories. Dopamine has been shown to modulate acetylcholine release, which may contribute to some of the effects of pharmacological manipulation of dopamine transmission on spatial learning and memory. Furthermore, dopamine receptor activity in forebrain regions (ventral striatum, ► prefrontal cortex) also appear to be required for some forms of spatial learning and memory, as the local infusion of dopamine antagonists into these regions can also impede acquisition and recall.

Noradrenergic inputs to the hippocampus stem exclusively from the locus coeruleus, the majority of which terminates in the dentate gyrus. Pharmacological manipulations of noradrenergic receptors, particularly the beta subtype with agonists such as isoproterenol can modulate the formation of long-term potentiation in the hippocampus. Furthermore, increases or decreases in noradrenergic tone via blockade (atipamezole) or stimulation (dexmedetomidine) of alpha-2 adrenergic autoreceptors leads to instability of place fields in the hippocampus. Interestingly, however, the depletion of central ► noradrenaline with selective ► neurotoxins does not impair the learning of spatial tasks. Nevertheless, drugs that enhance central noradrenergic activity can improve performance on spatial memory tasks. Much of this research has focused on the contribution of noradrenergic transmission in the memory modulating effects of stress (Roozendaal et al. 2006). For example, the ability of glucocorticoid stress hormones to disrupt spatial and other forms of memory are blocked by the coadministration of beta-1 receptor adrenergic antagonists such as atenolol either systemically or directly into the hippocampus. Conversely, the post-training activation of adrenergic receptors with adrenaline improves subsequent performance of spatial memory tasks, and these effects are blocked by the coadministration of beta-receptor antagonists. These findings suggest that under some conditions, acute increases of noradrenergic activity facilitate the consolidation of new spatial memories. A particularly interesting aspect of these findings is that post-training infusions of these compounds into the basolateral ► amygdala (a region that normally does not contribute to spatial learning) also enhances the consolidation of spatial memories (as well as other forms of learning; Ferry et al. 1999). Enhancements in learning induced by the activation of amygdala adrenoreceptors are thought to be part of a neural mechanism through which stressful or emotionally charged events augment the encoding of new memories.

The hippocampus receives considerable serotonergic innervation and contains a high density of 5-HT receptors, yet, global depletions of brain ► serotonin typically do not impair spatial learning. Nevertheless, the pharmacological manipulation of different 5-HT receptors has been shown to affect spatial learning processes. In general, the blockade of different 5-HT receptors tends to improve

spatial learning, whereas the administration of relatively selective 5-HT agonists induce detrimental effects. For example, systemic or intra-hippocampal administration agonists active at either 5-HT_{1A} (8-OH-DPAT) or 1B (anpirtoline) receptors generally leads to impairments in spatial learning in the water maze (Ogren et al. 2008). Furthermore, the administration of the 5-HT_{1A} antagonist WAY 100635 ameliorates impairments in spatial memory induced by muscarinic antagonism with scopolamine, indicated that 5-HT1A receptor agents may modify spatial memory through interactions with the cholinergic system. Similar improvements in spatial learning have been observed following intra-hippocampal blockade of $5HT_{2A/2C}$ antagonist with ritanserin, or systemic blockade of 5-HT_6 receptors (SB-271046). Thus, it appears that the blockade of multiple 5-HT receptors may actually exert a beneficial effect on spatial learning. Accordingly, identifying novel 5-HT antagonists may prove to be a fruitful strategy in the development of cognitive enhancing drugs.

Spatial memory is often used to describe spatial navigation and encompasses egocentric and allocentric memories

Definition

Spatial memory describes information storage and retrieval required for identification and navigation of proximal or distal space. This is distinct from spatial working memory which refers to active representations stored and manipulated over seconds. Two main frames of reference have been described: egocentric, which is related directly to the observer, and allocentric, which is dependent on the relational position of objects in space. Routes depend more on egocentric frames of reference, whereas maps are more flexible to landmark changes and thus depend more on allocentric frames of reference. Although often discussed separately, an emerging view is that both egocentric and allocentric spatial memories are coded but these may interact and depend on interacting brain regions. Spatial memories can be representations of salient cues for navigation or be more detailed representations, including topography, allowing reexperiencing of the environment (Moscovitch et al. 2005). A useful analogy has been proposed such that schematic representations of topography correspond to ▶ semantic memory and detailed representations correspond to ▶ episodic, autobiographical memory. Classic tasks of spatial memory in experimental animals include the ▶ Morris water maze, Olton maze, and ▶ radial arm maze (although these latter tasks can incorporate a large ▶ working memory component). In humans, both static (route reporting

and drawing) as well as real-world tasks can be used and while being informative, they are severely limited in interpretability and control of motivation and strategy. Emerging use of virtual reality provides a mechanism to integrate realistic representations of space and environment with controlled laboratory assessments, including functional brain imaging, which requires the participant to remain still during the course of an experiment.

Functional Neuroanatomy

The human visual system comprises two processing streams, a dorsal "where" system important for spatial navigation and a ventral "what" system for object recognition. Goodale and Milner (1992) emphasized the transformations that may be required for information in each stream, relabeling the dorsal stream as a "how" system. This system was proposed to be involved in action preparation via transformation of visual information using an egocentric frame of reference, whereas the ventral system processed transformation for long-lasting representations using multiple frames of reference. Functional brain imaging, including studies using virtual reality, largely supports this general distinction. For example, Aguirre and D'Esposito (1997) initially trained subjects on learning the location of 16 objects in a virtual town. ► Functional MRI (fMRI) scanning was performed during two conditions in which they judged (1) if the appearance of a location within the town matched the name of a location – the appearance condition; or (2) the direction of travel from a displayed location in the town to a given new location – the position condition. When contrasted against each other, the appearance condition showed greater activation in the fusiform and parahippocampal gyrus as well as occipital regions, whereas the position condition showed greater activation in more dorsal areas (i.e., superior and inferior parietal lobes). This study was performed in only four volunteers, but in general there is an agreement that the ► hippocampus and medial temporal lobe structures are required for the acquisition of spatial memories in humans (Parslow et al. 2005) and while fewer studies have examined retention and retrieval of spatial memories, the results of the ► fMRI study fit with studies showing that detailed episodic spatial memories cannot survive damage to the hippocampus/medial temporal lobe (Moscovitch et al. 2005) and retrieval of spatial memories of taxi drivers in London activates hippocampus/parahippocampal gyrus (Maguire et al. 1997). An alternate view is that the hippocampus may not have a selective role in allocentric spatial memory. For example, in a group of six patients with hippocampal damage performing an image-location memory task, impairments were dependent on the number of items rather than the degree of rotation between study and test phases (Shrager et al. 2007), although the use of smooth rotation might have favored egocentric mental rotation strategies (Burgess 2008).

Overall, these studies align with the presence of hippocampus ► place cells in the rodent, monkey, and human brain. In humans, these cells were first described in seven patients with intractable epilepsy undergoing presurgical invasive monitoring, who played the role of a taxi driver in a spatial navigation game (Ekstrom et al. 2003). Cells that responded to specific locations were primarily located in the hippocampus, whereas cells that responded to views of landmarks were primarily located in the parahippocampal region. Indeed, forming memories of places, or landmarks or associating objects with particular locations, appears to require the parahippocampal cortex. Other extrahippocampal regions also important for spatial memory task performance include the posterior parietal cortex and striatum. The former is necessary in the representation of spatial information in terms of egocentric coordinates, allowing reaching and movement plans to be formulated as well as egocentric imagery. The striatum is generally thought to have a role in the learning of the procedural aspects of tasks, and may have dissociable roles in egocentric and allocentric spatial memory consolidation (De Leonibus et al. 2005). Using a task of object exploration with animals entering the same location (egocentric reference frame) or different locations (allocentric reference frame), focal injection of an NMDA receptor antagonist into the dorsal striatum impaired consolidation of the egocentric procedure, whereas intra-accumbens administration impaired both procedures.

Impact of Psychoactive Drugs

In experimental animals, the neurobiology and psychopharmacology of spatial memory have been extensively studied, dominated by the use of the Morris water maze (McNamara and Skelton 1993). The neurotransmitter and molecular mechanisms of medial temporal lobe and cortical structures involved in spatial memory implicate specific drug systems in the accurate acquisition and expression of these memories. Focusing on the hippocampus as the most studied of these regions implicates glutamergic neurotransmittion through ► AMPA and ► NMDA receptors, as well as modulatory influences of the cholinergic and serotonergic inputs. Muscarinic and nicotinic cholinergic receptor blockade as well as serotonin receptor antagonism can all modulate hippocampal glutamatergic and ► GABAergic neurotransmission as well

as the theta rhythm, which is hypothesized to allow rapid transitions between encoding and retrieval.

Glutamate Receptors

The ► NMDA receptor is a major target for glutamate in the brain and its role in ► long-term potentiation is thought to be related to mnemonic encoding. It is no surprise that NMDA blockade using compounds such as AP5, ► ketamine, or MK-801, either intrahippocampal or intracerebral in rats impairs spatial learning using the Morris water maze, without affecting perceptual or motivational processes. For example, a degree of selectivity is suggested by the lack of impairment on a nonspatial discrimination task following AP5 infusion (McNamara and Skelton 1993). ► Metabotropic glutamate receptor agents can also modulate spatial learning. For examples, an mGluR5 allosteric modulator enhances spatial learning in the rat, probably by enhancing LTP and LTD, and an mGluR2 receptor antagonist can impair spatial learning when infused into the nucleus accumbens. Although they are likely to play a role, the function of AMPA and kainate receptors in specific modulation of glutamatergic activity during spatial memory tasks is not well understood; similarly for the influence of NMDA receptor subunits. Aging, at least in mice, is known to be associated with changes in NMDA subunit expression which may contribute to memory decline with aging (Zhao et al. 2009).

Cholinergic Receptors

Studies employing lesions of the cholinergic cell groups in the basal forebrain nucleus basalis magnocellularis or medial septum, pharmacological blockade of acetylcholine receptors, age-related decreases in ► acetylcholine activity, and ► microdialysis to index acetylcholine release provide compelling converging evidence for the important role of the acetylcholine system in spatial memory. However, it is now generally accepted that cholinergic modulation can also influence visual attention, altering cue processing (e.g., Muir et al. 1993), and thus it is important that these additional effects are taken into account. In humans, fMRI and positron emission tomography (► PET) have confirmed the effects of cholinergic enhancement with ► physostigmine on stimulus-driven shifts in ► attention, which can reduce demands on working memory processes in the ► prefrontal cortex.

Within the hippocampus, microdialysis in the rat clearly shows a positive relationship between acetylcholine and spatial learning and memory performance, and in humans it is predicted that patients with cholinergic dysfunction (e.g., ► Alzheimer's disease) or volunteers administered scopolamine will be impaired on tasks of spatial memory via alteration of hippocampal activity based on the proposal that acetylcholine activity dynamics modulates hippocampal-based encoding of new information (Hasselmo 2006). Using a virtual reality-based spatial memory task based on the Morris water maze, deficits in hippocampal activation following scopolamine (0.4 mg s.c.) have been demonstrated in healthy volunteers (Antonova et al. 2009). The task requires the movement (using a trackball) to a platform in a virtual reality arena surrounded by abstract images (see Fig. 1). The memory for place is assessed by removing the platform and asking the volunteer to move to the platform location from the same starting point with different environmental cues (viewpoint-dependent or egocentric condition), or from different starting points with the same environment cues (viewpoint-independent or allocentric condition). Using a different task of spatial navigation (Gron et al. 2006), the ► acetylcholinesterase inhibitor and nicotinic cholinergic receptor agonist, ► galantamine (4 mg b.i.d. for 7 days), has been shown to modulate neural activity in a group of ten patients with ► mild cognitive impairment (these patients have an increased risk for developing clinically defined Alzheimer's disease). Using one-sample *t*-tests galantamine was shown to decrease activity in the supplementary motor area and increase activity in a network of regions known to be associated with this task in young healthy volunteers: occiptotemporal junction, fusiform gyrus, posterior cingulate, parahippocampal gyrus, and hippocampus. While the task depended in part on spatial memory, the use of egocentric or allocentric frames of

The goal of the task is to move toward the pole, at first with the pole visible and subsequently after removal of the pole. Changes in the starting position and background environment allow the control of the frames of reference likely to be used in spatial memory recall.

reference was not controlled and the role of motivational and decision-making processes in the completion of such tasks is poorly understood.

Other Neurotransmitters

γ-Aminobutyric acid ► (GABA) receptors control the flow of excitation through the brain. Within the hippocampus, GABA receptors are categorized as ► $GABA_A$ and $GABA_B$, which have differential distribution and control of neuronal activity. Expression of the α_5 subunit of the $GABA_A$ receptor is enriched in pyramidal cells of the hippocampus, thus the knockout mouse can be considered a model of hippocampal $GABA_A$ functionality. Performance is improved in the α_5 subunit knockout mouse after administration of a full ► inverse agonist of the α_5 subunit on the delayed match-to-place Morris water maze task, in which the platform is moved between trials. Dopamine systems have previously been associated with the learning aspects of spatial memory tasks, with degeneration of the nigrostriatal dopamine system associated with learning deficits in the Morris water maze. Long-term effects on the consolidation of aspects of spatial memory, including object displacement tasks impaired after intra-accumbens injection of dopamine D1 and D2 antagonists, as well as improvements with ► levodopa, highlight a role for the striatal dopamine system. However, in terms of normal aging, analysis of impaired performance on the Morris water maze with age, in relation to hippocampal receptor density, showed no associations with dopamine D1 receptors. $Serotonin_{1A}$ receptor binding sites were, however, increased in poor performers in keeping with the proposed role of $5\text{-}HT_{1A}$ receptors in encoding and consolidation of spatial memory rather than retrieval. Interestingly, $5\text{-}HT_{1B}$ knockout mice appear protected against age-related hippocampal memory decline. However, a selective role in spatial memory has been questioned by 5-HT release being associated more closely with motor behavior and feeding behavior during spatial memory tasks rather than task performance. To date, there are no studies in humans that test other agents against spatial memory tasks.

Conclusions

Spatial memory describes a collection of functions associated with spatial information processing including navigation and localizing of objects. Egocentric and allocentric frames of reference have been proposed for spatial processing, but are likely to interact in many situations. Nonetheless, separable functional neuroanatomy appears plausible for egocentric (parietal lobes) and allocentric (hippocampal region/striatum) memory tasks, with the latter emerging recently in functional imaging investigations using virtual reality. In keeping with the research in experimental animals, the hippocampal and proximal medial temporal lobe structures have a central role in spatial memory processing in humans. Predictions from hippocampal neuropharmacology of important neurotransmitters in spatial memory processing imply a degree of opportunity for enhancement in human populations although this remains largely unexplored. A positive association between cholinergic activity and spatial memory in healthy volunteers (using scopolamine) and patients with mild cognitive impairment (using galantamine) is a strong indicator for the scope of behavioral modulation possible with the correct target compounds. Further work with GABAergic agents, particularly α_5 inverse agonists, dopaminergic, and serotonergic compounds is required to validate predictions from experimental animals.

Definition

SPECT is a nuclear imaging method that uses a radioactive tracer (radiopharmaceutical) to measure blood flow or to label brain molecules of interest. The radioactive tracers used in SPECT produce a single photon that is detected by a camera sensitive to photon emissions (gamma camera). SPECT can be used in animal and human research and in human clinical diagnosis to non-invasively assay cerebral blood flow (as an indirect marker of neuronal activity) and cell molecular components of interest (targets) such as neurotransmitter receptors, neurotransmitter reuptake transporters, and other proteins of interest. SPECT methods and uses overlap considerably with those of positron emission tomography (► PET), another nuclear imaging method widely used in psychopharmacology.

Principles and Role in Psychopharmacology

Basic Method

The fundamental principle of SPECT imaging consists of detecting, localizing, and quantifying gamma ray emissions from radiolabeled compounds. Gamma ray emissions are produced when an unstable isotope decays, emitting a photon. The radiolabeled compound is injected intravenously into an animal or human where it circulates throughout the body and to the brain. The photons emitted by the radiolabled compound are then detected with the ► Gamma Camara System. Figure 1 shows a schematic of a SPECT imaging method, and Fig. 2 is an example of a human SPECT imaging system with two gamma cameras that can be positioned to image an area of interest.

SPECT tracers in psychopharmacology are primarily of two types: (1) those that cross the ► blood-brain barrier and distribute nonspecifically in the brain (perfusion radiopharmaceuticals), and (2) those that cross the blood-brain barrier and distribute according to specific molecular targets (target molecule-binding radiopharmaceuticals).

SPECT perfusion ► radiopharmaceuticals (used to measure blood flow) are compounds that cross the blood-brain barrier and then distribute into the extracellular space in proportion to the blood flow to a region (Masdeu and Arbizu 2008). A successful SPECT perfusion tracer must have the correct lipophilicity properties so that it crosses the blood-brain barrier easily, but it must also have no specific binding to brain components. Once

the photon counts are detected by the gamma camera system, the relative cerebral blood flow to an area can be determined. Since local neuronal activity is strongly coupled to cerebral blood flow, SPECT tracers can therefore be used as indirect indicators of changes in local neuronal activity.

Unlike SPECT perfusion radiopharmaceuticals, target molecule-binding radiopharmaceuticals must have high ► affinity and specificity for the target molecule. Usually, the affinity for the specific target molecule is at least tenfold greater than the concentration of the target molecule to be imaged. This requires that target molecule-binding radiopharmaceuticals have affinities for their target molecules in the low nanomolar to picomolar range. In addition, these radiotracers must have sufficient lipophilicity to allow penetrance of the blood-brain barrier, but not so high a lipophilicity as to produce high nonspecific binding.

Radiopharmaceutical Synthesis

SPECT radiopharmaceutical synthesis begins with a ► Radionuclide. The two most widely used radionuclides in SPECT imaging are technetium (Tc) as [^{99m}Tc] and iodine (I) as [^{123}I]. SPECT radionuclides are made primarily by irradiating atoms with charged particles (Leslie and Greenberg 2003; Mettler and Guiberteau 2006). A pharmacological molecule of interest, for example a neurotransmitter receptor or reuptake transporter binding ligand, is then chemically attached to the radionuclide to create the ► Radiopharmaceutical. Because ^{123}I, ^{99m}Tc, and other single photon emitting radionuclides are relatively heavy atoms, it is difficult to attach them to small biologically active molecules such as glucose and have such small molecules retain their biological activity. As a result, SPECT radiopharmaceuticals for brain imaging are restricted to molecules with molecular weights of a few hundred, but cannot be too large as they will not pass the blood-brain barrier.

Image Construction

Image construction for SPECT requires the use of a specialized detection system called a gamma camera that uses hardware and software approaches to generate an image that shows the location and intensity of the tracer (Accorsi 2008).

In both SPECT perfusion imaging and SPECT target molecule imaging, mathematical models are used to interpret the results. These models account for the intrinsic properties of the tracer, such as the rate at which the tracer reaches equilibrium in the brain and nonspecific binding of the tracer.

Brain SPECT imaging is often combined with computed ► Tomography (CT) to provide a detailed structural brain image for overlaying SPECT data.

Resolution

The resolution of SPECT imaging is determined largely by the design of the hardware and software for the gamma camera system. Modern SPECT scanners in general clinical use have resolutions of around 1 cm but special small-animal research SPECT scans, using modified hardware and software for image construction, can achieve resolutions of less than 1 mm (Masdeau and Arbizu 2008; Spanoudaki and Ziegler 2008).

Time Course and Availability

SPECT radionuclides have relatively long ► half-lives, for example the half-life for two widely used radionuclides is about 13 h for ^{123}I compounds and about 6 h for ^{99m}Tc compounds. Because of this stability, SPECT ligands can be injected up to several hours before the actual scanning procedure. Some commonly used SPECT radiopharmaceuticals and their indications are shown in Table 1. It is important to note that the availability of these ligands for human research or clinical applications is determined by the rules of each country, so that not all ligands are available in all regions.

Uses

SPECT therefore has broad applicability in basic research and clinical research, diagnosis, and treatment. Based on the principle that increased regional cerebral neuronal activity is associated with increased blood flow, SPECT perfusion studies can provide indirect information related to local neuronal activity and metabolism. SPECT perfusion studies are used to measure baseline blood flow, blood flow changes associated with task-related activity, or blood flow changes associated with drug effects (Malizia 2006).

SPECT imaging with target molecule-binding radiopharmaceuticals can be used to measure the baseline levels of target molecules and can measure the influence of experimental manipulations, genetics, and disease states on target molecules. Two useful examples of SPECT methods as applied to human clinical and research conditions include the study of Parkinson's disease and substance abuse disorders.

demonstrate reductions in the levels of the presynaptic ► dopamine transporter (DAT) and increased levels of postsynaptic dopamine receptors (D2 subtype). SPECT may also have utility in monitoring Parkinson's disease progression and assessing the success of treatment interventions. In clinical conditions suggestive of early Parkinson's disease, SPECT assays of dopamine status may aid in diagnosis by determining whether early alterations in the DAT or D2 receptors are consistent with this illness (Booij and Knol 2007). Figure 3 illustrates the difference between a healthy control subject and patient's with Parkinson's disease at different levels of severity. As disease severity worsens, there is near complete absence of detectable DAT binding as measured using the DAT ligand [^{99m}Tc] TRODAT-1 (Huang et al. 2004).

As reviewed by Volkow and others (Volkow et al. 2003; Felicio et al. 2009), SPECT (and PET) methods are used widely to study the effects of substance abuse and dependence and have contributed greatly to our understanding of drug effects in humans. For example, SPECT has been used to detect drug-induced changes in the ► serotonin transporter, serotonin receptors, and cerebral blood flow following recreational exposure to 3,4-methylenedioxymethamphetamine (► MDMA; Ecstasy). For multiple drugs of abuse, SPECT imaging has been successful in documenting the effects of drug exposure on receptor and transporter systems (for multiple neurotransmitters, but especially the dopamine system) and on cerebral blood flow. SPECT imaging has also proven critical in documenting the time course of neurotransmitter and blood flow changes associated with acute and chronic drug exposure and following drug withdrawal.

Strengths and Limitations

Strengths of SPECT are considerable. Some SPECT radiopharmaceuticals are less costly, more easily synthesized, and provide a lower radiation dosage than some PET tracers. This enhances the ease of use and acceptability of SPECT for human psychopharmacological research. Limitations of SPECT include the relatively small number

of available radiopharmaceuticals and the resolution of this technique as commonly available for basic and clinical research. Unlike PET, where 18-fluorine-flouro-deoxy-glucose [18FDG] is commonly used to examine cerebral glucose metabolism, there is no comparable SPECT tracer for measuring cerebral glucose metabolism.

Emerging Technology

Emerging technologies include the use of modified gamma camera systems to provide very high spatial resolutions (in the submillimeter range) in animal nuclear imaging research studies. Dual tracer or multi-isotope imaging, in which different tracers are used to image two components simultaneously (e.g., perfusion and receptor binding) hold promise (Accorsi 2008).

Future Directions

With the development of high-resolution gamma cameras and additional radiopharmaceuticals, SPECT imaging can be expected to play an increasingly significant role in psychopharmacological research. In addition to the potential for high resolution pharmacological mapping of neurotransmitter systems in animal models, human applications may increasingly expand to include clinical diagnostic applications such as those detecting early types of degenerative illnesses (such as Alzheimer's Disease or Parkinson's Disease) or neurodevelopmental illnesses (such as ► Autism or ► Schizophrenia).

Spinal Cord Primary Sensory Neurons

Definition

These are neurons with cell bodies located in sensory ganglia with processes terminating in the periphery (skin, viscera, other) and in the spinal cord in the CNS. They convey the first (primary) sensory information to the spinal cord. They vary in cell body size, axon diameter, conduction velocity, and their content of neurotransmitters and neuroactive peptides. These differences and the distribution of central and peripheral ends account for sensory modality content. Small-diameter primary sensory neurons might, in addition, liberate neuropeptides antidromically with pro-inflammatory consequences.

Serotonin antidepressants

Definition

Selective serotonin reuptake inhibitors (SSRIs) are a class of drugs primarily developed for the treatment of major depressive disorder (MDD), although most agents now have additional indications, particularly for the treatment of various anxiety disorders. These drugs share a common mechanism of action in that they inhibit the ► serotonin transporter in its reuptake of synaptic serotonin.

Pharmacological Properties

History

First generation ▶ tricyclic antidepressants (▶ TCAs), particularly ▶ clomipramine, are potent inhibitors of the serotonin transporter, but these agents have a wide range of effects on various neurotransmitter receptors, resulting in a substantial side effect burden. Although zimelidine was the first SSRI to receive approval as an antidepressant in Europe, plans to launch it in the United States were abandoned when several cases of Guillain-Barre syndrome were reported. ▶ Fluoxetine became the first SSRI to be licensed in the United States in 1987, and paved the way for an attack on stigma and under-detection of ▶ depression, with an expectation that greater safety and tolerability would be associated with superior treatment outcomes (Kramer 1999). Although this proved not to be the case, it heralded the beginning of a new era in drug development for the treatment of MDD. Over the next decade a whole class of SSRI antidepressants emerged as first line agents for the treatment of MDD, accounting for 60% of prescribed antidepressants in the U.S. Medicaid program (Chen et al. 2008; Healy 1999).

Mechanism of Action

As their name implies, the SSRIs selectively block ▶ serotonin (5HT) reuptake. This occurs through inhibitory actions on the Na^+/K^+ adenosine triphosphatase-dependent carrier on presynaptic neurons. Among the six available SSRIs, ▶ citalopram, ▶ escitalopram and ▶ paroxetine are the most potent blockers of 5HT reuptake. Some SSRIs have additional ▶ antagonist effects on neurotransmitter receptors (Table 1). For example, paroxetine and citalopram have moderate anticholinergic effects and sertraline blocks presynaptic dopamine receptors. Escitalopram is a stereoisomer of citalopram and has been shown to exert actions at both the primary binding sites for the serotonin transporter, and also on secondary ▶ allosteric binding sites, a property not shared by other SSRIs (Sanchez 2006).

There is also evidence from position emission tomography (▶ PET) using a ligand for the serotonin transporter, that 80% or greater occupancy of the transporter occurs with citalopram, paroxetine, and sertraline at standard doses, and no additional binding occurs at higher doses (Meyer 2007). These findings are based on only a small sample of depressed patients, and the SSRIs were not examined across a wide range of doses.

The SSRIs, like their predecessors the TCAs, inhibit neurotransmitter reuptake almost immediately, but often take 2–3 weeks to exert clinically meaningful benefit.

NE = norepinephrine; ACH = acetylcholine; H1 = histamine 1; DA = dopamine; MDD = major depressive disorder; GAD = generalized anxiety disorder, OCD = obsessive compulsive disorder; PTSD = post-traumatic stress disorder; SAD = social anxiety disorder

This has been linked to down regulation of the $5HT_{1A}$ terminal autoreceptors. In addition, SSRIs, like other antidepressants, stimulate ▶ neurogenesis, particularly in the CA_3 layer of the ▶ hippocampus after 2–3 weeks of exposure. Animal models of depression using stress paradigms show suppression of neurogenesis which is reversed by antidepressants (Schmidt and Duman 2007).

▶ Pharmacokinetics

The SSRIs are generally well absorbed and not affected by food administration, with the exception of sertraline, where food can increase levels of the drug in plasma. They are metabolized by hepatic microsomal enzymes that are part of the ▶ cytochrome P_{450} system, particularly the CYP_{2D6} isoenzyme, although the $2C_9$, $2C_{19}$ and $3A_4$ isoenzymes are also substrates for several SSRIs (Table 2) (Kennedy et al. 2007).

SSRIs and Related Compounds. Table 2. Pharmacokinetic profile of SSRIs.

Drug	% Bioavailability	Metabolism	Active metabolites	Half life (hours)
Citalopram	80	CYP3A4 CYP219 CYP2D6 Weakly inhibits: CYP2D6	Demethylcitalopram Didmethylcitalopram	35
Escitalopram	80	CYP3A4 CYP219 CYP2D6 Weakly inhibits: CYP2D6	Demethylescitalopram	27–32
Fluoxetine	72	CYP2D6 CYP2C19 Inhibits: CYP2D6, 2C9, 2C19	Norfluoxetine	24–72
Fluvoxamine	53	CYP2D6 CYP2C9 Inhibits: CYP2C19, 2D6, 1A2, 3A4	None	15.6
Paroxetine	50	CYP2D6 Inhibits: CYP2D6	None	21–24
Sertraline	44	CYP3A4 Weakly inhibits: CYP2D6,2C9	Norsertraline	26

It is important to note that certain SSRIs inhibit their own clearance through the inhibition of their metabolizing enzyme, resulting in elevated plasma levels and increased side effects. Both fluoxetine and paroxetine are strong inhibitors of the CYP_{2D6} enzyme, and fluvoxamine is a potent inhibitor of CYP_{1A2}, CYP_{3A4}, and CYP_{2C19}. Therefore, caution should be exercised when combining these drugs with other medications that are metabolized through any of these enzymes, as in the following two examples. ► Codeine requires CYP_{2D6} for its conversion to ► morphine and analgesic effects, and inhibiting this pathway prevents the analgesic effects. In the case of desipramine, a secondary tricyclic antidepressant, combining it with fluoxetine will result in increased plasma levels due to the inhibition of CYP_{2D6}. This can cause cardiotoxicity and, in rare instances, death.

The ► half-life of SSRIs ranges from about 15 h (► fluvoxamine) to over 60 h (fluoxetine), with other agents in the 30 ± 6 h range. This means that in all cases, SSRIs can be prescribed at least once daily and in the case of fluoxetine, the drug remains capable of causing drug-drug interactions 2–3 weeks after the last dose.

Genetic Polymorphisms

There is emerging evidence to support a relationship between ► genetic polymorphisms of the serotonin transporter (5HTT) and response to SSRIs. The 5HTT gene-linked polymorphic region (5HTT-LPR) significantly influences transcription of 5HTT, resulting in differential expression of the serotonin transporter. To date, several reports have linked the 5HTT-LPR "l" allele to superior or faster response to SSRI therapy and the 5HTTLPR "s" allele to greater SSRI-related side effects. However, these findings were not substantiated in a report from the "Sequenced Treatment Alternatives to Relieve Depression" (STAR*D) study, where a search for genetic predictors of treatment outcome with citalopram yielded an association between treatment outcome and a gene that encodes the $5HT_{2A}$ receptor (McMahon et al. 2006).

Efficacy and Effectiveness

The SSRIs have primarily been used to treat patients with MDD, but in nearly all cases, there are additional indications for the treatment of anxiety disorders (Table 1) (Kennedy et al. 2007). While it was initially believed that SSRIs manifested little, if any, variation in ► efficacy for MDD across the class of agents, subsequent meta-analyses have suggested that they do not perform equally. Since most trials were designed with sufficient sample sizes (power) only to detect differences between the novel agent and ► placebo, the inclusion of an active comparator agent to ensure assay sensitivity did not provide sufficient power to compare efficacy between the two active drugs. However, when similar trial design and outcome measures are applied across a series of trials, it is justifiable to pool the data from all subjects and conduct

a ▶ meta-analysis. This methodology provides a large enough sample to detect differences between active agents.

Escitalopram has demonstrated modest but consistent advantages over other SSRIs, but these differences were most significant in the comparisons with citalopram. Using a "multiple-treatments meta-analysis" method, which includes both direct and indirect comparisons of drugs, the efficacy and acceptability of 12 new-generation antidepressants (including the 6 SSRIs) were compared across 117 randomized control trials (Cipriani et al. 2009). Two SSRIs, escitalopram and sertraline, were among the four drugs with significant advantages over the other antidepressants in terms of efficacy. These two agents also had the best tolerability profiles, making them the most favorably ranked overall.

Tolerability

Even though the tolerability and safety profile of SSRIs is superior to the previous generation of TCAs, lack of compliance due to treatment-emergent side-effects remains a significant issue. There are both early transient adverse effects and persistent effects, which frequently result in drug discontinuation. Acute effects most often involve the central nervous system (CNS) and the gastrointestinal (GI) system, while later sustained effects are more likely to influence metabolism and sexual dysfunction (Table 3) (Kennedy et al. 2007).

Sertraline	50–200mg	CNS over arousal, dizziness, sexual dysfunction	Headaches and nausea

[1]Drug-placebo differences modified from product monographs
CNS = central nervous system

Central Nervous System

Headache, sleep disturbance, sedation, and paraesethesia are commonly reported in the acute phase of treatment with any SSRI. Although some aspects of sleep are improved with SSRIs, there are reports that SSRIs disrupt sleep continuity and may exacerbate ▶ bruxism and restless leg syndrome. Additionally, while SSRIs generally improve cognitive dysfunction associated with depression, there is evidence, specifically with paroxetine, of drug-related cognitive side effects, likely due to its additional anticholinergic effects.

Gastrointestinal and Metabolic Effects

Nausea is a common gastrointestinal side-effect during the first 2 weeks of treatment with an SSRI, and is most pronounced for fluvoxamine and sertraline. This is generally a transient effect.

Weight gain is a factor that can severely decrease drug compliance. Although initial treatment with SSRIs can result in weight loss, mainly due to nausea and an enhanced feeling of early ▶ satiety, long-term use of SSRIs has been associated with weight gain, particularly with paroxetine (Fava et al. 2000; Kennedy et al. 2007).

Recent studies have suggested that SSRIs may result in the loss of bone mineral density during long-term use. This appears to reflect inhibitory actions of serotonin on osteogenesis. Whether this might contribute to the development of clinical osteopenia or osteoporosis is still unclear.

Sexual Dysfunction

The consensus from a series of well designed comparative studies is that up to 60% of patients receiving SSRIs report some form of treatment emergent sexual dysfunction, with paroxetine and sertraline exerting the greatest burden of sexual side effects (Kennedy and Rizvi 2009). All of the SSRIs have been associated with delayed or absent orgasm/ejaculation and, in some instances, a reduction in libido and arousal. These effects appear to be related to the stimulation of serotonin, particularly its ▶ agonist effects on $5HT_2$ receptors. However, other mechanisms that block cholinergic receptors and inhibit nitric oxide synthase are also likely to be involved as well. This may explain why patients receiving paroxetine compared with

other SSRIs had a significantly greater incidence of erectile dysfunction or reduced vaginal lubrication.

Safety

Suicidality

Depressed patients are at greatest risk for ►suicide attempts during the month before and the first month after starting medication, and the risk progressively declines with treatment. Although most population studies have shown a reduction in rates of completed suicide associated with increased use of modern antidepressants, the issue of suicidality with SSRIs has attracted considerable media attention and appears to be most pronounced in adolescents. The "►black-box" warning for SSRIs in the U.S., Canada and elsewhere, due to findings of increased suicidal ideation, has likely contributed to a decrease in antidepressant prescriptions for children and adolescents. Since the 2003–2004 warning, studies indicate that U.S. and Canadian rates of completed suicide hasve increased for the first time in a decade for adolescents. In adults, meta-analyses of ►randomized controlled trials (RCTs), or analyses of research databases, have found no support for increased suicides with antidepressant use (Möller 2006).

Serotonin syndrome

Excessive serotonin release may result in a clinically significant "►serotonin syndrome", characterized by diarrhea, delirium, tremor, muscle rigidity and hypothermia. This may occur when patients are taking two SSRIs or taking an SSRI with another serotonin-enhancing agent. Therefore, caution must be applied when combining treatments and during dose increases.

Conclusions

Since the launch of fluoxetine, SSRI use has increased to the extent that this is now the most widely prescribed antidepressant class, reflecting a favorable balance between efficacy and tolerability. The ►pharmacokinetic profile of SSRIs allows for easy dosing and long-term use. Future research should be directed to increasing the specificity of agents at the serotonin receptor and transporter sites.

State Dependence of Memory

Francis C. Colpaert
SCEA-CBC, Puylaurens, France

Synonyms

Dissociated learning; State-dependent learning

Definition

Traditionally, state dependence is said to occur when an organism remembers better when it is in a state similar to the one in which it learned what is to be remembered than when it is in a different state. While this observation remains essential, progress indicates that the phenomenon of state dependence is not necessarily related or limited to the ability to learn per se in a particular state. Dependence on state occurs with memory processes other than learning as the latter is conventionally understood and may determine what is remembered and when; beyond conscious cognition, it also concerns such functions as emotion, mood, and motor behavior. Thus, the term "state dependence of memory," refers to an attribute of the ability to remember and act upon past experience, which is broader than that implied by "state-dependent learning."

Impact of Psychoactive Drugs

A Word of History

Awareness of state dependence arose in seventeenth century popular and medical culture and concerned states of the internal, physiological, and mental milieu (Siegel 1985). Both that century's most acknowledged accounts and the first experimental investigation of state dependence (Girden and Culler 1937) involved states induced by drugs. Influentially capturing the perception of state dependence at that time, (Overton 1983) attributed state dependence to high, "toxic" doses of drugs; considered state dependence to be genuine only if bidirectional (i.e., if occurring upon both drug-to-placebo and placebo-to-drug changes of state); struggled with the issue as to whether state dependence requires that drug-to-placebo and placebo-to-drug state changes should produce symmetrical failures to remember; and argued on theoretical grounds that state

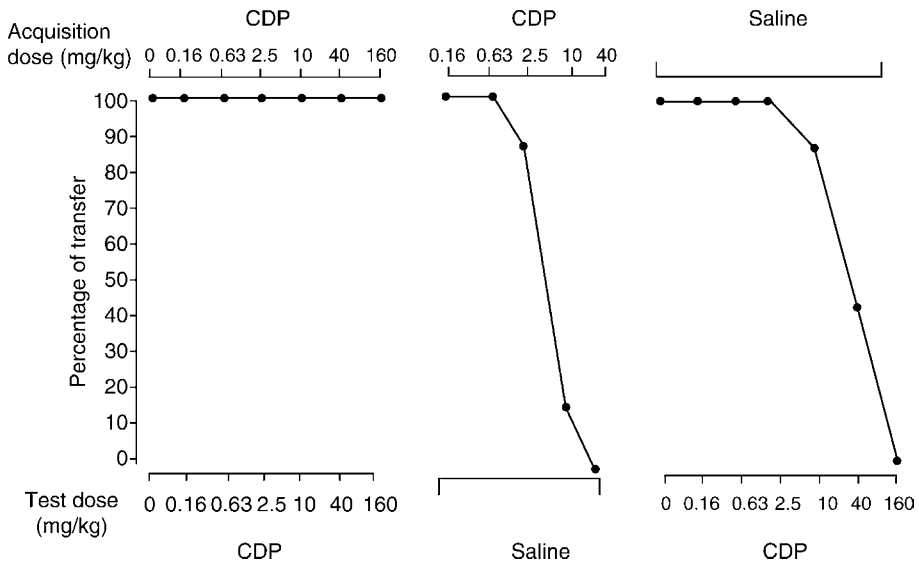
dependence and ► drug discrimination are fundamentally similar. As will be apparent in the following lines, the state dependence concept has much evolved; how and when state dependence occurs has since been studied extensively in humans and animals in well-controlled experimental investigations in laboratory settings.

A Case of State Dependence

Studies of state dependence involve ► learning. The learning assays used may include single trials or multiple-trial learning opportunities, single or multiple-session classical conditioning, or acquisition of an appetitively or aversively motivated instrumental response. As in many ► memory researches, the key dependent variables assess the ability to remember, and recall is often measured operationally by the latency with which a remembered response occurs. The special issue of interest here about the functioning of memory is how memory may vary depending on the similarity or dissimilarity between the state that prevailed at the time of learning and the state that prevails at the time of recall. States thus constitute the independent variable. Failures of "transfer" of the ► engram, or memory trace, are said to occur when recall is hampered by a change of state.

Figure 1 offers an example of state dependence; here, rats are trained in 15 min sessions everyday to press a lever for food reward; every tenth lever press yields access to food (► fixed-ratio: 10, or FR10 schedule). The rat reaches the acquisition criterion when, on a given training session, it completes 10 lever presses within 120 s after the session begins. Two days later, in a test session, recall is measured by determining whether the animal again completes the first FR10 schedule within 120 s. Different groups of rats are trained with (i.e., before the training sessions receive an injection and thus are "under the influence of") either saline or one of different "training" doses of the benzodiazepine, ► chlordiazepoxide (CDP). Later, the rats are tested with (i.e., "under the influence of") either saline or one of different CDP "test" doses.

As shown in the left panel of Fig. 1, recall was perfect by rats that were both trained and tested with saline (points at "0") and by rats that acquired the response while treated with one CDP dose (0.16–40 mg/kg for different rats) and then tested with the same dose. However, as shown in the middle panel, rats trained with 0.16–40 mg/kg doses of CDP and then tested with saline failed to recall in a manner that depended on the training dose, complete failure occurring with 40 mg/kg. Conversely (right panel), rats trained with saline and then tested with 0.16–160 mg/kg doses also failed to recall, now in a manner that varied with the CDP test dose. Thus, state dependence can occur with both drug-to-saline and



State Dependence of Memory. Fig. 1. Results of transfer tests in groups of rats that acquired an operant response in one pharmacological condition (i.e., saline or one of several doses of chlordiazepoxide(CDP) and were tested in either the same or another condition. Upper and lower abscissa: CDP dose at which the animals were trained and tested, respectively; 0 refers to saline. Ordinate: percentage of rats (n=7/group) that in test sessions completed the first FR10 schedule within 120 s. (Redrawn from Colpaert 1990.)

saline-to-drug changes of state, albeit not necessarily at the same dose; here, drug-to-saline transfer failure occurred at doses that were about three-fold lower than those at which saline-to-drug state changes caused transfer to fail (► ED_{50}: 9.8 and 29 mg/kg, respectively).

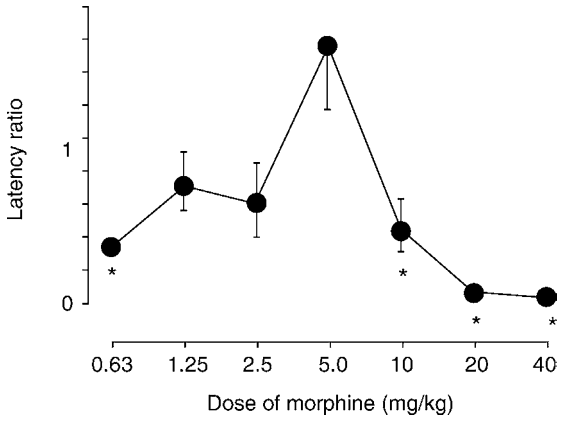
State changes can produce powerful memory failure; under the conditions described above, extreme food deprivation to the point of starvation fails to overcome the inability to remember. Remarkably, studies involving agents such as ► benzodiazepines and ► opiates, to which ► tolerance is considered to readily develop, have so far failed to reveal any evidence that tolerance develops to those agents' ability to induce state dependence; training with drug followed by numerous further drug ("over-") training sessions does not prevent failures of recall when the subjects are later tested with saline.

The state-dependent memory failure is, however, surmountable. Rats trained with saline or CDP 40 mg/kg fail to remember when tested for the first time with CDP 40 mg/kg or saline, respectively; but if later provided the opportunity to learn the same response in the alternative state (i.e., after administration of saline or CDP 40 mg/kg, respectively) rats will eventually learn to recall the response in either state. It is uncertain, though, whether such recall in either state implements only one as opposed to one of two separate ► engrams (Colpaert 1990).

State Specificity

When a response is acquired with saline or with any given agent, the extent to which transfer occurs to other agents may vary widely but it can also be the case that transfer is confined to a narrow class of pharmacologically similar agents. For example, rats trained with ► morphine demonstrate transfer when tested with another μ-opiate receptor agonist, but not with lower-efficacy opiates or any other drug. Recall may be further limited to a particular dose; rats trained with 5 mg/kg morphine remember well when tested with 5 mg/kg, but not with lower or higher doses of morphine (Fig. 2). Thus, ► retrieval can be confined to an exquisitely exclusive, molecularly defined magnitude of activation of a single, particular neurotransmitter receptor (sub)type; these findings highlight memory's state specificity in addition to its state dependence (Bruins Slot and Colpaert 1999).

Specificity can also extend to conditions other than the drug state. For example, a given agent may render state dependent a response that is acquired in a particular set of conditions of arousal and drive for instance, but not the same response in another set of conditions. Equally, with a given agent, a normal-to-drug change of state may impair



State Dependence of Memory. Fig. 2. Results of transfer tests in groups of rats (n=7/group) that acquired an operant response after 5 mg/kg morphine injections and were tested for retrieval with either the same or a lower or higher morphine dose. Retrieval here is measured by the (log-transformed) ratio of the response latency in the last training session to that in the test session (ordinate); data are mean + SEM. (Redrawn from Bruins Slot and Colpaert 1999.)

the retrieval of some but not all items of memory that were acquired in one or another normal set of conditions.

Both these two instances of specificity underlie the ability of states to operate in an often incisive, discrete manner. Partly because of this, state dependence is in many instances overlooked in accounts of CNS function and of CNS drug actions.

State Change: A Mechanism

States and state changes regulate, shape, and direct memory throughout ontogeny; they govern mnemonic normalcy as well as psychiatric and neurological pathogenesis and may constitute the essential neurobiological, or "system," mechanism of different CNS agents.

State Changes in Cognition

Compounds such as ► ketamine and – most prominently – the muscarinic acetylcholine receptor antagonist, ► scopolamine offer drug models of memory disorders, mimicking in unaffected humans the deficiencies that are found in ► Alzheimer's disease. Surprisingly, scopolamine actually may allow fully adequate learning, retrieval ► encoding, ► re-encoding, and ► retention of complex tasks provided that all these memory processes take place in the scopolamine state. However, each of these processes is profoundly impaired when subjects switch from the normal to the drug state (or from the drug to the normal state) as they move from one to the other process. As a

result, the state change that acute scopolamine administration produces in subjects having learned the task in the normal state simulates the regressive, temporally graded retrograde amnesia that is characteristic of Alzheimer's disease. That is, as a function of the scopolamine dose, what can be remembered is limited to what was learned at an increasingly remote point of time in the past while what was learned more recently has become inaccessible (Figs. 3 and 4). Importantly, the state dependence analysis emphasizes the role of state instability, in addition to but more so than that of putative cholinergic hypo-function, in the pathophysiology of such disorders (Colpaert et al. 2001).

Some drug states that are induced after learning or retrieval that occurred in the normal state (i.e., at the time of encoding or re-encoding, respectively) impair subsequent retrieval in the normal state. Drugs may thus pre-empt or erase the normal-state memory of traumatic, pathogenic life events.

State Changes in Anxiety

► Anxiety has long been considered as an acquired drive; i.e., a motivation that is learned in the course of ontogeny. Benzodiazepines exert anxiolytic effects only in as much as they also impair the retrieval of, for example, a food-reinforced ► operant response. In each situation, the benzodiazepines institute a state of memory in which material previously acquired in the normal state cannot be retrieved. Thus, it has been proposed that benzodiazepines impair the retrieval of what in a normal state has previously been acquired what is referred to as anxiety, rather than selectively reducing, or "lysing," anxiety (Colpaert 1990).

State Changes in Pain and Opiate Actions

Pain can be of either physiological (e.g., nociceptive) or pathological (e.g., neuropathic) origin and relates to both its somatosensory and affective/motivational dimensions; the affective/motivational dimension of pathological pain is particularly susceptible to state dependence.

Mammalian newborns learn to synchronize their breathing, which at the prenatal stage is erratic, chaotic, and utterly ineffectual, with the acidity (pH) of arterial blood. This synchrony governs mature breathing, and it has been suggested that rather than merely depress respiration, opiates induce a state in which this learned synchronization cannot be retrieved (Bruins Slot and Colpaert 1999).

State Changes in Affective Disorders

Mood states fluctuate and the memory that prevails at any time is governed by mood congruency, or sameness of mood state. Depressed subjects better memorize new negative-affect than new positive-affect items and remember negative-affect items more effectively in a subsequent depressed episode than in a more elated mood (Blaney 1986; Bower 1981; Colpaert et al. 2000; Eich 2007). While allowing for possible predisposing biological variables, the state dependence of memory uncovers a remarkable pathophysiological mechanism of mood disorders as well as an equally remarkable neurobiological mechanism of antidepressant drug action both of which emphasize the ability to acquire and remember, and disremember, mood.

State Changes in Neurological Disorders

Importantly, states and state changes not only govern cognition, but also pervade and affect motor behavior while spanning large swaths of ontogeny. The peculiar features of horizontal locomotion in Parkinson's disease (difficulty with both initiating and arresting locomotion, continuous postural disequilibrium during movement) closely resemble those of 10-month old infants who learn to walk. Under l-DOPA treatment and fluctuating between ON and OFF states, the parkinsonian patient when in an ON state may walk adequately while not remembering what precisely the difficulty it is that he or she has in the OFF state; when in OFF, the patient fails to remember just how he or she succeeds to walk when in ON. Gilles de la Tourette patients similarly alternate episodes of "remembering" with those of "forgetting" their condition, making no distinction between the memory, the knowledge, the impulse, and the act. The patient may or may not be aware of his current state, but any awareness fails to affect the state's implications.

Dependence

Whether occurring in a normal or pathogenic manner in the course of ontogeny, or drug-induced, states create a dependence: one of memory and of the capabilities that it enables to the very point of survival. As such, state dependence is akin to drug dependence in as much the state is required to maintain the homeostasis of memory. When induced by a drug, state dependence constitutes an instance and learned form of drug dependence.

State-dependent memory may or may not encompass the subject's seeking to modify that state; such action appears to depend on the state's perceived affective valence and on the opportunities that are available to acquire behaviors that are instrumental in overcoming or modifying those consequences. Alzheimer patients may be little able to gauge their cognitive deficit and, available treatments being only marginally effective, to learn how to instrumentally overcome the deficit. But, state dependent, compulsive seeking to restore the

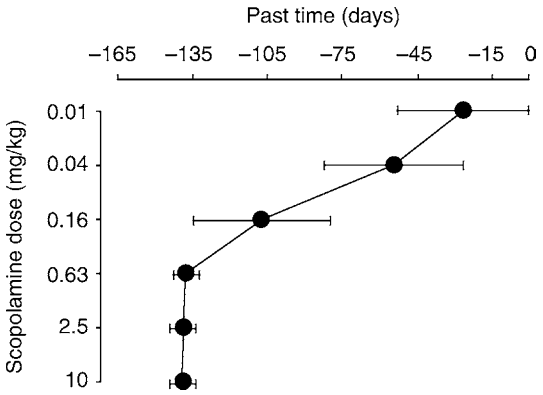
original state does appear to underlie opiate addiction, in effect constituting its very "system" mechanism. This implies that the signal transductions that are involved in pain processing and opiate actions thereon are currently thought to proceed in a bidirectional manner; any input to such systems induces not a single but two dual effects that are opposite in sign. Thus, morphine causes not only analgesia as a "first-order" effect, but also a "second-order" hyperalgesia or frank pain that outlasts the analgesia for some time. With chronic opiate exposure, the second-order pain grows and masks the first-order analgesia, resulting in analgesic tolerance. In a parallel manner, opiates also induce two distinct memory states that coincide temporally with their first and second-order effects on pain processing. The first-order opiate memory state is one in which analgesia is encoded, but the second-order state is one in which the individual experiences a possibly excruciating, opiate-induced pain and is enabled to learn and remember that the next opiate administration powerfully relieves that pain, however temporarily. Thus emerges the view that opiate addiction represents the self-medication of compelling opiate pain, with both that pain and the pain-relieving instrumental behavior being encoded in the second-order (withdrawal) state of memory (Colpaert et al. 2006).



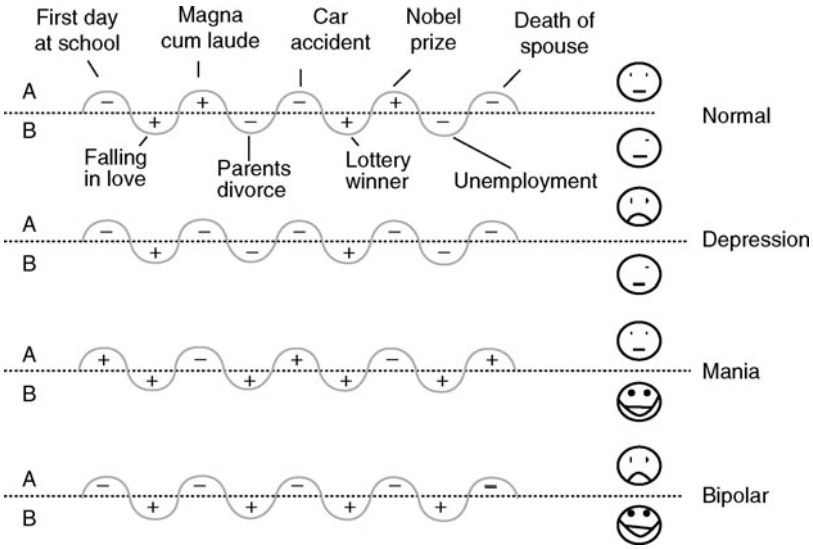
State Dependence of Memory. Fig. 4. Regressive, temporally graded retrograde amnesia induced by a normal-to-scopolamine state changes. Rats were in the normal state trained in a complex task in which learning was assessed from five parameters that characterize the newly acquired behavior (Fig. 3). The acute injection of different doses (ordinate) of scopolamine caused the parameters to assume values that resembled those observed at one or another point in the course of training. The abscissa indicates the remoteness in time (relative to day 0, the last day of training) of such corresponding points (mean ± SEM of the five parameters; day – 165 corresponds to the beginning of training). Increasing doses resulted in a behavior similar to that observed at increasingly remote stages of the acquisition that preceded the drug test. (Redrawn from Colpaert et al. 2001.)

States

Clearly, an organism's memory can operate in any one of a decidedly large number of different states in which engrams can be specifically stored. Such state dependence of memory challenges the common view that an individual possesses a single, unified memory that integrates all past experience and can be acted upon at any time. Rather, at any point of time, memory appears to be locked into, limited to, but also enabled with the unique capabilities of one particular state. As time moves from one to another point, so memory comprises another, equally unique set of retrievable capabilities based on current state.

The state dependence of memory invites the question as to whether ► forgetting occurs at all; it is unclear

State Dependence of Memory. Fig. 3. Studies examining the effects of saline-to-scopolamine changes of mnemonic state on the recall of five aspects of learned behavior. (**a**) Rats were trained for in all 165 days in a complex task in which the different independent measures (e.g., total responding) reflect different aspects (e.g., performance) of what was learned. (**b**) The acquisition data in panel A are here plotted as the % of animals satisfying the learning criterion that was applied to each of the five measures. These % data were fit by best-fitting functions to generate the five learning curves shown in panel B. (**c**) Over the 8-month period that followed training, rats were tested for retrieval after injection of different doses of scopolamine; data from these tests are shown here and expressed as in panel A. (**d**) The scopolamine test data in panel C are here plotted as the % of animals satisfying the criteria used to generate panel B and expressed as in the same manner. These % data were fit with the dose–response functions shown. At 0.01 mg/kg scopolamine, the outcome for each of the parameters was similar (i.e., about 100%) to that at the end of acquisition. Higher doses decreased each parameter value, such that the outcomes resembled those observed earlier in training. Projections are plotted (dashed lines) to identify the point in time-since-the-end-of-acquisition ("past time") with which the test data corresponded. These retrograde projections yielded outcomes that differed among the five parameters, the mean (M along past time) being – 136 days for the 0.16 mg/kg dose. In this manner, the mean was found for all doses, generating the function relating scopolamine dose to past time shown in Fig. 4. (Redrawn from Colpaert et al. 2001.)



State Dependence of Memory. Fig. 5. The shaping of mood states in ontogenesis. Though multiple states can exist, it is sufficient to assume here that memory operates in one of just two cyclically recurrent states (A or B) that are induced by some biological rhythm and are mutually exclusive. Throughout ontogeny (horizontal dotted line), the individual experiences and memorizes life events that have an affective valence that is positive (+) or negative (−). There is no a priori relationship between a state on the one hand and the (valence of) the events that are encountered in a state on the other. In this manner is most likely established in both states A and B, a cumulative memory that retains both positive and negative items (panel I); the overall affective valence of memory is rather neutral in either state and does not greatly differ, or swing, between A and B. This outcome being most probable, panel I represents what because of this greatest likelihood is perceived as a normal individual. However, chance may have it that the events experienced in A or B happen to predominantly be negative or positive (panels II and III, respectively); thus is established in one state a memory that retains items of polarized valence and that differs from the alternative, normal-affect state. These outcomes are less likely and result in recurring episodes of monopolar, depressed or manic, mood. An even smaller chance may result in large-amplitude bipolar mood swings (panel IV) (Colpaert et al. 2000).

whether such failure to remember results from a time-dependent dissipation of the engram or from the non-restoration of the state that prevailed in ontogeny at the time that the memory was established. State dependence definitely does not require forgetting to account for profound retrieval deficits, and state changes constitute a mechanism whereby an engram can be erased; when in an initial state the subject has learned and remembers and when then an alternative state is instituted shortly after retrieval (i.e., at the time of re-encoding), it may be the case that the engram in question is no longer available in the initial state. Further, such a state change may establish, in the alternative state, a memory that is then false (► false memory).

A weakness of state-dependence research resides with a certain vagueness as to what defines a state. Awareness of state dependence historically arose from observations of humans who were "under the influence" of exogenous agents, and the use of drugs in studying state dependence has allowed that in this case states can at least operationally be defined in a highly precise, accurate, and reproducible manner. However, states also arise endogenously and current neurobiology and medicine invoke the existence of a varied array of states that operate at levels of integration ranging from the whole organism to cell assemblies, single cells, or molecular signal transduction (Lydic and Baghdoyan 1999). Fascinating examples include hormone-controlled phases, pacemaker assemblies and circadian and seasonal rhythms, as well as the rise and fall of entire neurotransmitter and other signaling systems in the course of ontogeny. Such states are usually investigated with regard to the particular stimulus–response relationships that they demonstrate, but a wide realm of knowledge remains to be gained in terms of whether and how those states regulate memory.

Learning and memory are also investigated from such perspectives as context-dependence and coincidence detection; how these perspectives shed light on and interlock with state dependence remains to be explored.

State-Dependent Retrieval

Definition
The notion that information studied in one state is better remembered when retrieved in the same rather than a different state.

Stationary Phase

Definition
The packing material in a column. In RP-HPLC, the most common stationary phases comprise beads of silica (glass-like material), covered by a layer of organic molecules (the bonded phase), comprising alkyl chains, chemically bonded to the silica. These are normally of eight (C8: octylsilane) or eighteen (C18: octadecylsilane: ODS) carbon molecules, tightly packed into the pores in the silica bead. The silica beads are normally 5 or 3μm diameter.

Stereoisomers

Enantiomers; Enantiomorphs; Optical isomers

Definition
These usually refer to pairs of drugs, which have identical physiochemical properties but rotate polarized light in different directions (left or right, designated as levo or dextro, "l-" or "d-" and "−" or "+," respectively). They are important as they often have different biological

activities. Thus, an atom found on the drug molecule has bonds that do not permit the attached functional groups to assume different positions relative to one another. For example, ► morphine derived from opium has one important carbon atom with functional groups in positions that rotate polarized light to the left (termed levorotatory). The configuration of this carbon atom also allows the morphine molecule to fit precisely into the pockets and contours of the opioid receptor and to activate it. In other words, the receptor has a structure that matches the levorotatory form. One can also construct morphine synthetically with the functional groups on the same carbon atom in different relative positions. The arrangement of the bonds is such that they precisely mirror those in the levorotatory form and the molecules of this morphine rotate polarized light to the right (show dextrorotatory activity). This synthesized substance is also morphine in a chemical sense, because it has all of the physicochemical properties of morphine made from opium. However, the dextrorotatory form of morphine evokes only the effects of normal morphine that have low chemical structure requirements (e.g., membrane stabilization, convulsions, taste aversion produced by systemic application of opioid); it does not activate the typical pharmacological effects attributed to activity on the opioid receptor. The use of opioid stereoisomers has been recommended in order to exclude so-called "nonspecific" pharmacological effects that are not due to interaction with the opioid receptor.

Stereotypical and Repetitive Behavior

Definition

Stereotypical and repetitive behavior is commonly seen in individuals with autism spectrum disorders (ASDs) and mental retardation (MR). In lower functioning individuals with ASDs or MR, this usually consists of self-stimulatory, nonfunctional, motor behaviors. However, in mild MR or higher functioning individuals with ASDs, this can consist of verbal and motor rituals, obsessive questioning, rigidly held routines, preoccupation with details, and desire for sameness and completeness.

In fMRI experiments, stimulation paradigms are applied to evoke brain activity and accordingly, increased or decreased cerebral perfusion. The variety of stimulation paradigms ranges from no stimulation (resting-state fMRI) over sensory (thermal, visual, or auditory), motor, language, or memory task to pharmacological stimuli. Aside from resting-state fMRI performed while no stimulation is applied, fMRI images are recorded during two states, a resting state (no stimulation) and the activated state during which the specific stimulation is applied. The applied stimulation paradigm is often incorporated as prior knowledge in the subsequent MR image analysis.

Stimulus Generalization

Synonyms
Cue (in psychology); Discriminative cue

Definition
Stimulus generalization occurs when a behavioral response conditioned to one stimulus is elicited by other novel stimuli that were not used during conditioning. For example, animals are conditioned to use a particular stimulus as a discriminative cue and are then tested with a novel stimulus that may resemble the training stimulus in one or more respects. If the animal responds to a test stimulus to the same extent that it does to the training stimulus, then stimulus generalization is said to have occurred. Generalization may be either complete or partial and can reflect both qualitative and quantitative differences between stimuli (e.g., color and brightness of visual stimuli).

Stop-Signal Task

Synonyms
Response inhibition task; SSRT

Definition
A neurocognitive task designed to provide a sensitive measure of the time taken by the brain to inhibit or suppress inappropriate motor responses. The stop-signal paradigm was originally developed by Gordon Logan in the 1980s, based on a cognitive task first used by Lappin and Erikson in 1966. Versions of the task have been developed both for humans and rats. The stop-signal reaction time (SSRT) task not only provides measures of reaction times and accuracy, but importantly also the latency to inhibit a prepotent response (SSRT). The stopping process is not directly observable and has to be estimated from a stochastic model, the so-called "race model." The model derives the SSRT from the distribution of "go" reaction times and the observed probability of responding on "stop" trials for a given stop-signal delay. The estimated SSRT gives a measure of the duration of the inhibitory process, which starts from the presentation of stop signal. In the version of the task for humans, participants are instructed to respond as fast as possible to a simple stimulus on a computer screen. On some trials, a stop signal is presented after the stimulus but before the response, and participants are instructed to try and stop or inhibit their response. Using this task, impairments in response inhibition have consistently been observed in neuropsychiatric disorders such as attention deficit hyperactivity disorder. In the version of the task for animals, differential presentations of reinforcers are used to train appropriate responding to "go" and "stop" signals. A network in the brain mediating the suppression of a motor response has been detected, involving numerous cortical and subcortical areas including the ► prefrontal cortex and subthalamic nucleus.

Stress

Definition

Stress is a complex psychological construct, which despite many years of research, has yet to be defined operationally in a satisfactory way. In the context of animal models of psychiatric disorders, stress can be defined broadly as forced exposure to events or conditions that are normally avoided. In humans, the definition is extended to incorporate cognitive and emotional responses – for example, "stress is a condition in which the environmental demands exceed the coping abilities of the individual." In laboratory animals, the precipitating events or conditions can be divided into two categories. The first category includes environmental events such as restraint, footshock, tail pinch, and defeat, as well as pharmacological events such as administration of a normally avoided drug (e.g., ► yohimbine). The second category includes food deprivation, social isolation, and ► maternal deprivation; each of these entails the removal of an environmental condition that is important for maintaining the animal's normal physiological and psychological steady-state conditions, a state that the subject will attempt to ameliorate by seeking food, conspecific partners, or the dam.

Definition

In humans, stress often refers to a condition in which environmental demands exceed an individual's coping abilities. In animal models of psychiatric disorders, stress can be defined broadly as a forced exposure to aversive events or conditions that are normally avoided. The term stress includes three related elements: stressors, stress responses, and genetic and environmental factors that modulate the effect of stressors on the organism. Stressors are events, physical or psychological, that profoundly interfere with the organism's normal steady state. These disruptions generate a stress response manifested at the physiological (e.g., activation of the sympathetic nervous system), psychological (e.g., ► anxiety, ► depression), and behavioral (e.g., performance deficits) levels. Factors that modulate the stress response include, among others, genetic predisposition to stress reactivity, and predictability and controllability of the stressors. These factors influence the relationship between the stressors and the stress response, leading to large individual differences in response to a given stressor.

Current Concepts and State of Knowledge

Background

Anecdotal reports that drug use is more likely to occur in individuals exposed to environmental stressors are supported by results from epidemiological studies indicating a high rate of ► comorbidity between stress-related psychiatric disorders such as ► post-traumatic stress disorder (PTSD), anxiety, and depression, and drug addiction. There is also evidence from laboratory studies in humans that exposure to stressors increases cigarette smoking and subjective measures of cocaine, opiate, and alcohol ► craving. The influence of stress on abused drugs appears to occur through all phases of the addiction process: stress facilitates the initiation of illicit drug use,

increases the frequency and amount of ongoing drug use, and precipitates relapse to drug use during periods of abstinence. Stress can also emerge as a consequence of drug addiction, because illicit drug use is associated with problems with the law, the workplace, and the family. The stress caused by the lifestyle of illicit drug users in turn promotes more severe forms of drug addiction. Finally, chronic use of addictive drugs can sensitize physiological and psychological responses to stress.

However, methodological and ethical considerations limit the scope of research that can be conducted in humans addicted to ► drugs of abuse. Consequently, it has been difficult to demonstrate a cause–effect relationship between stress and drug addiction in humans. Cause–effect relationships between stress and drug-taking behavior can be established in laboratory models of drug addiction. These models can be used to identify behavioral and neuronal mechanisms that mediate the effect of stress on drug-taking behavior. Below, we summarize results obtained from preclinical studies in laboratory rats on the mechanisms underlying the effect of environmental stressors on drug-taking behavior, as assessed using the intravenous ► drug self-administration procedure and the ► reinstatement procedure. The drug self-administration procedure is the gold-standard animal model used to assess the rewarding effects of drugs and their abuse liability. The reinstatement procedure is a widely used animal model of relapse to drug-taking behavior during periods of abstinence.

Before reviewing the empirical data on biological mechanisms of the effects of stress on drug-taking behavior, we would like to point out that we will not cover in this short chapter several research topics that are relevant to the relationship between stress and drug addiction. These include (1) the extant and conflicting literature on the effects of stress on oral opiate and ► alcohol self-administration; (2) the conflicting literature on the effects of adverse early life experience (maternal deprivation, social isolation) on drug self-administration in adulthood; (3) the literature on the role of stress systems in the mediation of physiological and psychological withdrawal symptoms of abused drugs; and (4) the literature on the role of the stress hormone corticosterone in the mediation of psychostimulant self-administration in the absence of stress.

Mechanisms of Stress Effects on Drug Self-administration

Investigators have used the drug self-administration procedure to assess the effects of stressors on the acquisition and maintenance of intravenous drug self-administration. When evaluating the findings on the effects of stressors on drug self-administration, it is important to remember that these effects are highly dependent on several variables, including stressor controllability, duration of stress exposure, the time interval between stress exposure and drug availability, the reinforcement schedule, and the dose of the self-administered drug. Additionally, there are large individual variations in the effects of stressors on drug self-administration. In studies on the mechanisms of stressor-induced increases in drug self-administration in rats, investigators have used several stressors including intermittent unpredictable footshock, food deprivation, and ► social defeat.

The stress hormone corticosterone (or cortisol in humans) is released from the adrenals when stressors activate the ► hypothalamic–pituitary–adrenal (HPA) axis. There is evidence that stressor-induced corticosterone secretion is required for the ability of intermittent footshock and food deprivation stressors to facilitate the initiation of ► cocaine self-administration. Additionally, corticosterone may contribute to footshock stress-induced escalation of cocaine self-administration once the self-administration behavior has been established. The mechanisms through which corticosterone promotes the self-administration of ► psychostimulant drugs may involve modulation of dopaminergic neurotransmission in both the ► ventral tegmental area (VTA), the cell body region of the ► mesolimbic dopamine system, and one of its projection areas, the ► nucleus accumbens. The mesolimbic dopamine system is known to mediate the rewarding effects of psychostimulant drugs.

In most previous studies on the effects of stress on intravenous self-administration of psychostimulant drugs, investigators limited access to the drugs for a few hours per day; under these conditions, rats typically maintain stable drug intake over time. Human addicts, however, self-administer psychostimulant drugs such as cocaine in a binge-like pattern that is characterized by extended periods of intense and escalated drug intake over many hours and even days. This binge-like pattern of drug self-administration is also observed in rats that are given unlimited access to cocaine. Thus, after about 20–24 h of continuous cocaine self-administration, rats shift from regulated drug intake, characterized by stable inter-infusion intervals, to dysregulated "out-of-control" drug intake, characterized by unstable inter-infusion intervals and higher hourly drug intake. The emergence of this binge-like pattern of cocaine intake is facilitated by prior exposure to social defeat stress. There is evidence that this

effect of social defeat stress on binge-like cocaine self-administration is due to sensitization of dopamine neurons in the VTA. This sensitization is likely mediated by stressor-induced activation of glutamatergic projections to the VTA. As the neuronal and hormonal responses to stressors are typically stressor-specific, a question for future research is whether the neurobiological mechanism identified for the effect of social defeat stress on binge-like cocaine self-administration generalizes to other stressors.

Stress and Reinstatement of Drug Seeking

The phenomenon of stress-induced ► reinstatement of drug seeking has been demonstrated using several stressors, including intermittent footshock and acute food deprivation. Stress-induced reinstatement is critically dependent on the stress neuropeptide corticotrophin-releasing factor (CRF). This neuropeptide acts in the paraventricular nucleus of the ► hypothalamus to activate the HPA–endocrine stress axis. Additionally, many physiological and behavioral responses to stress are mediated by CRF's effects on extrahypothalamic sites within the central nervous system (CNS).

CRF receptor antagonists decrease both footshock- and food-deprivation-induced reinstatement of drug seeking, while ventricular injections of CRF reinstate drug seeking. Results from studies using pharmacological and endocrine methods indicate that the reinstating effects of stressors are independent of their ability to activate the HPA axis. The critical extrahypothalamic brain sites and projections for CRF's role in footshock-induced reinstatement include the bed nucleus of the stria terminalis (BNST), VTA, and a projection from the central amygdala to the BNST. Within the VTA, footshock causes local CRF release, which leads to increased ► glutamate transmission. This enhanced glutamatergic neurotransmission is critical for stressor-induced reinstatement, presumably due to activation of the mesocorticolimbic dopamine system. This possibility is supported by the findings that injections of D1-family dopamine receptor antagonists into the dorsal, medial ► prefrontal cortex (mPFC) or the orbitofrontal cortex, or of a preferential D3 dopamine receptor antagonist into the nucleus accumbens, decrease stressor-induced reinstatement.

Footshock stress-induced reinstatement is also dependent on noradrenaline transmission: systemic injections of alpha-2 adrenoceptor agonists (which decrease central noradrenaline release) decrease footshock-induced reinstatement, while systemic injections of the alpha-2 adrenoceptor antagonist ► yohimbine (which increases central ► noradrenaline release) cause reinstatement of drug seeking. The critical brain sites and projections for noradrenaline's role in footshock-induced reinstatement include the central amygdala and BNST, and the noradrenergic projection from the lateral tegmental nuclei to these brain sites.

Results from studies in which discrete brain areas were reversibly inactivated confirm the previous findings discussed above on the role of the dorsal mPFC, BNST, central amygdala, accumbens, and VTA in stress-induced reinstatement, and further suggest that the ventral pallidum plays a role in this reinstatement. Results from these studies also indicate that the glutamatergic projection from the mPFC to the accumbens plays an important role in stress-induced reinstatement. This glutamatergic projection is also involved in reinstatement of drug seeking induced by acute reexposure to the self-administered drug.

Recent evidence suggests that the magnitude of footshock- and CRF-induced reinstatement of cocaine seeking depends on the history of prior drug exposure: these effects were significantly stronger in rats that were previously given extended access to cocaine for 6 h/day during training than in rats given drug access for 2 h/day. These and related findings indicate that prior exposure to high doses of cocaine over many days sensitizes brain CRF stress systems, leading to increased vulnerability to stress-induced reinstatement of cocaine seeking. These findings parallel results from human studies demonstrating more pronounced stress-induced craving, anxiety, and physiological responses in abstinent, previously high-frequency drug users than in individuals with a history of less frequent drug use.

Finally, there is evidence from studies in which pharmacological agents were used for a role for several other neurotransmitter systems in stress-induced reinstatement. These include the neurotransmitter ► serotonin, and the neuropeptides ► dynorphin, ► hypocretin (orexin), and nociceptin/orphanin FQ.

Implications for Treatment

The recognition that stress is a key contributor to drug-taking behavior highlights the need for the development and implementation of therapeutic strategies aimed at minimizing the contribution of stress to drug addiction. This is especially important in subpopulations of addicts whose drug use is stress-driven. Identifying which addicts will benefit most from such approaches poses a challenge to drug-addiction treatment providers and will likely require the establishment of new assessment tools for identifying the role of stress in an individual's drug use. The development and approval of new drugs that block CRF receptors and other receptors implicated in stress-induced

drug seeking will hopefully provide important tools for the management of drug addiction.

Neostriatum

Definition
The striatum is a subcortical brain structure. The *corpus striatum*, which includes the putamen rostrally and the caudate nucleus caudally, is a component of the ventral cerebral hemisphere, receiving strong projections from the cerebral cortex and projecting back to it via the thalamus. In addition, the striatum receives a robust dopaminergic innervation from the *substantia nigra* and the ventral tegmental area. It is fundamental for the selection of motor programs in response to external signals, which is triggered by dopaminergic signaling. Its ventral component, the ventral striatum or nucleus accumbens, is a key element in the response to salient stimuli predicting reward, hence inducing intensely motivated states.

Suicide

Definition

Suicide is an act of taking one's own life voluntarily, usually intentionally. Suicidal behavior is a general term used to refer to suicide and suicide attempts. Under the latter, we refer to the actions taken to end one's life, irrespective of the degree of intentionality, which does not result in death. While suicidal ideation is not a behavior, it is often considered under the category of suicidal behaviors. It refers to the wish to die, including thoughts of actively ending one's life.

Current Concepts and State of Knowledge

Suicide is one of the leading causes of death worldwide, among the top ten causes of death in most of the world and one of the three leading causes of death for people between the ages of 15–34 (WHO 2000). As such, it has been referred to as the 'leading cause of unnecessary and premature death.' Over the last 45 years, suicide rates have been increasing dramatically, by as much as 60% in some countries. In the USA, this rate is approximately 11 per 100,000, while much of Asia sees a rate exceeding 13 per 100,000. With the notable exception of rural China, suicide is significantly more common among males than females. Western countries, and particularly those from Northern Europe and the ex-Soviet Union, present larger gender effects on suicide rates, while Asian countries tend to have sex ratios closer to one. Age is another important demographic factor that seems to have a large impact on suicide risk. Accordingly, the distribution of suicide risk through the lifespan displays marked age effects, with peaks among youth and elderly age groups.

Suicide methods vary considerably among different countries and world regions and relate to the availability of means to suicide, as well as popular concepts and imagery associated with suicide. As such, in North America, suicide by firearms and hanging are the most common methods, whereas in Asia, suicide by pesticides is the most prevalent. Suicidal behavior has been classified as violent and nonviolent, depending exclusively on the method used. In general, the term nonviolent refers to suicidal behavior by substance intoxication (typically medication overdose) or superficial cuts, which are generally associated with low suicide intent and are frequently of low lethality. All other methods are considered violent.

Suicide is strongly associated with psychopathology (Arsenault-Lapierre et al. 2004). While there is significant regional variability in the percentages found, all studies have consistently shown that most individuals who have died by suicide were affected by mental disorders in the last months of their life. Meta-analyses of studies investigating rates of mental disorders among individuals who died by suicide suggest that up to 90% of suicides had a history of mental illness. Table 1 lists the most common mental disorders found among suicide completers, according to different world regions. Mood disorders, and ► major depressive disorder, in particular, are the most common diagnoses among individuals who died by suicide.

Predictors of Suicide

Suicide is a complex behavior, likely the result of several interacting factors. Figure 1 conceptualizes the relationships among key factors believed to play an important role in suicide. While, as mentioned earlier, psychopathology is strongly associated with suicide risk, it is neither sufficient nor specific, as only a fraction of people affected by mental illness will die by suicide.

Suicide. Fig. 1.

A positive history of suicide attempts, a history of childhood adversity, certain demographic variables, and issues related to social and medical support have been found to be stronger predictors of suicidal behaviors among psychiatric patients. The risk of suicide completion among clinical populations varies as a function of diagnosis and clinical features. For instance, among patients with major depressive disorder, the risk is conditional on the population of depressed patients, i.e., suicide risk is higher among depressed inpatients, lower among depressed patients from the general population and somewhere in between for depressed outpatients. For the latter group, the percentage of individuals who die by suicide is estimated to be between 2% and 5%. Clinical predictors of suicide among patients with major depression include symptom severity (as measured by a requirement of hospitalization), comorbidity with substance-related disorders, high levels of hopelessness, and a history of a past suicide attempt.

Over the last decades, it has become increasingly clear that individuals who die by suicide also have constitutional risk factors. However, the relationship

between these predisposing factors, which to a certain extent are conferred by the individual's biological make-up, and suicide is not direct, but seems to be mediated and moderated by a number of different factors. Among these factors are clinical and demographic risk factors, such as those listed earlier, history of early life sexual and physical abuse, personality variants such as behavioral traits, and triggering factors such as recent life events and interpersonal stressors.

Epidemiological and clinical studies have consistently suggested that a positive family history of suicide acts as an important risk factor for suicide. As psychopathology also runs in families, a major question has been to what extent suicide aggregates in families independently of psychopathology. Studies have suggested that first-degree relatives of suicide probands have a 4–10 times higher risk of suicidal behavior than relatives of psychiatrically normal controls, and this is once other risk factors and psychopathology are accounted for. Genetic-epidemiological studies suggest that at least part of this familial aggregation is attributable to genetic effects (Turecki 2001).

Several lines of evidence point to the fact that familial transmission of suicidal behavior may be mediated through the transmission of personality traits such as impulsive–aggressive behaviors. Personality traits represent emotional, behavioral, motivational, interpersonal, experiential, and cognitive styles that help us relate to and cope with the world. Clinical and community research suggest links between suicidality and extreme personality profiles. For instance, children who score high on a measure of disruptive behavior, a composite of aggressive, impulsive, and hyperactive behaviors, were found to be more likely to attempt suicide as young adults (Brezo et al. 2008). In general, most clinical and psychological autopsy studies (which use proxy-based interviews to investigate individuals who died by suicide) report elevated measures of ▶ impulsivity and ▶ aggressive behaviors among suicide attempters and completers as compared to controls, particularly among younger individuals. There is also direct and indirect evidence suggesting that relatives of suicide completers and suicide attempters have higher scores on these personality traits than controls.

Impulsivity may be conceptualized as the inability to resist impulses, which, from the strict phenomenological point of view, refer to explosive and instantaneous, automatic or semiautomatic psychomotor actions that are characterized by their sudden and incoercible nature. A more behavioral definition considers impulsivity as a drive, stimulus, or behavior that occurs without reflection or consideration for the consequences of such behavior. However, studies suggest that it is not the exclusive presence of impulsivity that appears to account for its observed association with suicide. Rather, impulsivity is frequently comorbid with other personality traits, particularly aggressive behaviors. As such, suicides tend to have high levels of aggressive–destructive impulsive traits, generally referred to as impulsive–aggressive behaviors. These have been operationally defined in suicide studies as a tendency to react with animosity or overt hostility, without consideration of possible consequences, when piqued or under stress.

Neurobiology of Suicide

The last decades have seen a growing interest in the understanding of the biological processes underlying suicide. Suicidal behavior has been associated with several neurobiological alterations, particularly in neurotransmission. For close to four decades, molecular studies have considered ▶ monoamines as prime suspects in suicidal behavior. ▶ Serotonin, in particular, has been the most investigated monoaminergic neurotransmitter system, and several lines of evidence suggest its involvement in the vulnerability to, and process of, suicide (Turecki and Lalovic 2005). Overall, while not always consistent, studies suggest that suicidal behavior is associated with reduced serotonergic neurotransmission. The evidence supporting serotonergic changes associated with suicide comes from studies using different and complementary approaches, including, but not limited to, investigations of cerebrospinal fluid levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA), neuroendocrine challenges, postmortem receptor binding and imaging studies with receptor ligands. The serotonergic alterations seem to be more pronounced in the prefrontal cortex, where there is evidence of a decrease in presynaptic ▶ serotonin transporter binding and an upregulation of postsynaptic serotonin receptors. Together, these results imply reduced serotonergic input to this brain region. Among other functions, the ▶ prefrontal cortex is involved in the ▶ behavioral inhibition and expression of emotions. Reduced serotonergic input to this brain region could result in the impaired inhibition of behaviors such as impulsive aggression, which in turn could increase suicide risk.

Although the most extensively investigated neurotransmitter alterations associated with suicide have been those related to serotonergic changes, other neurotransmitters have also been investigated. Among these neurotransmitters are the noradrenergic, dopaminergic, opioid, glutamatergic, and GABAergic neurotransmitter systems. More recently, promising and consistent results have pointed to the implication of the polyamine system, which is involved in the stress response, depression, and suicide.

Alterations have also been reported in several components of different signal transduction systems, as well as in neurotrophic factors, particularly ► brain-derived neurotrophic factor (BDNF) and ► TrkB. These studies suggest that the suicide process may be associated with an altered neuroplastic capacity.

Another interesting avenue investigated in suicide is a possible relationship with lipid metabolism, and more specifically with low cholesterol levels. This intriguing association is supported by evidence from studies that have used different designs, including large cohort studies, observational studies in suicidal, impulsive or violent populations, and experimental studies in animals, as well as postmortem brain studies (Golomb 1998). The use of different study designs and the replication of the findings across different populations have added validity to this still polemical association. A number of hypotheses have been advanced in an attempt to understand the possible relationship between cholesterol and suicide, but only a few of these hypotheses have been the subject of experimental testing. Whether this association proves to be true or not, one possible way to understand it is through an evolutionary point of view. It is not unreasonable to think that dietary needs, hence cholesterol levels, should be associated with certain behaviors, such as ► aggression. Aggressive behaviors may have conferred advantages on early humans who were hunting for food. Such an evolutionary link between cholesterol and aggression, preserved in the link between impulsive aggression and suicide, could underlie the observed relationship between cholesterol and suicide risk. If this is the case, there should also be molecular mechanisms connecting cholesterol levels to molecular correlates of aggression/suicide.

Treatment

There is no specific pharmacological treatment for suicidal behavior. There is evidence, however, that certain pharmacological interventions used for the treatment of the underlying mental disorder are more effective than other ones in reducing suicidal behavior in these patients. Two examples of such treatments are lithium and clozapine. ► Lithium is a salt used primarily in the maintenance treatment of ► bipolar disorder. There is substantial evidence indicating that lithium is effective in reducing the risk of suicidal behavior among bipolar patients (Baldessarini et al. 2006). While some preliminary evidence suggests that the antisuicidal effect of lithium may be independent of its mood-stabilizing properties, this issue requires further investigation. Similarly, ► clozapine, an atypical ► antipsychotic drug, is believed to have antisuicidal properties (Meltzer 2005). As for lithium, it is unclear if the antisuicidal properties are independent of its neuroleptic effects.

Two psychotherapeutic interventions have provided evidence of efficacy in reducing suicidal behavior. Cognitive-behavioral therapy applied in 10 sessions designed specifically to prevent suicide attempts has been shown to be effective in primarily depressed adults with recent histories of suicide attempts (Brown et al. 2005). Dialectic behavioral therapy, which is a variant of cognitive behavioral therapy developed specifically to treat patients with borderline personality disorder, has also shown evidence that it reduces suicidal behavior in this population (Linehan et al. 1991).

Sulpiride

Definition

Sulpiride is a ► typical antipsychotic based on antagonism of postsynaptic D_2 dopamine receptors. Agonism at the gamma-hydroxybutyrate receptor may contribute to its antipsychotic properties. Sulpiride has fewer ► extrapyramidal side effects, but also reduced antipsychotic potency, as compared with many other typical antipsychotics. At lower doses than used for antipsychotic treatment, its prominent action is presynaptic dopamine autoreceptor antagonism, giving rise to antidepressant and stimulating effects. Secondary clinical uses are thus treatment of depression and vertigo. Sulpiride is currently not approved in the USA and Canada. Together with the atypical antipsychotic ► sultopride, sulpiride falls under the chemical class of benzamides.

Sultopride

Definition

Sultopride is an ► atypical antipsychotic of the same chemical class as sulpiride (benzamides). Sultopride's action at antipsychotic doses exceeds D_2 dopamine receptor blockade to include antagonism of D_3 and 5-HT_7 receptors. Agonism of the GHB receptor may contribute to its properties. Like sulpiride, low doses of sultopride predominantly block dopaminergic autoreceptors, facilitating dopamine release. This action, as well as its 5-HT_7 receptor antagonism, likely explains it efficacy at low doses for treating depression. Sultopride is not currently approved in the USA.

Product information; SPC

Definition

The SPC is the basis of information for healthcare professionals on how to use a medicinal product safely and effectively. The package leaflet (PL) is drawn up in accordance with the SPC. The SPC sets out the agreed position of the medicinal product as distilled during the course of the assessment process. The content cannot be changed except with the approval of the originating competent authority.

Summation Test

Definition

The summation test is one of two widely accepted tests for whether a stimulus functions as a ► conditioned inhibitor (► retardation of acquisition test is the other). In the summation test, a putative conditioned inhibitor is presented in compound with a separately trained excitatory conditioned stimulus (CS) – that is, one that evokes a conditioned response. If the stimulus functions as a conditioned inhibitor, it should decrease conditioned responding evoked by the separately trained excitor relative to controls that receive the excitatory CS alone, and the excitor in compound with an alternative stimulus that was not a signal for non-reinforcement. Because alternative accounts for response inhibition remain with just the summation test, the strongest case for a stimulus functioning as a conditioned inhibitor also requires the use of the retardation test.

Vigilance

Definition

Sustained attention is the capacity to maintain attention over time on repetitive tasks. It is the need for continuous allocation of processing resources that distinguishes vigilance from other forms of attention, such as divided or selective attention. In humans and other animals, under normal conditions, deficits in sustained attention emerge during "boring" and/or routine activities, especially in situations of low event rate.

Sympathectomy

Definition

Lesion of the sympathetic (noradrenergic) branch of the peripheral autonomic nervous system. Experimental sympathectomy is achieved by administration of a systemic toxin, affecting all branches of the system or by extirpation of individual spinal or cervical ganglia to deafferent specific branches.

Sympathetic Neurons

Definition

These are neurons located in prevertebral and paravertebral ganglia. They are a main component of the so-called autonomic nervous system. These neurons are controlled by preganglionar terminations originating in the spinal cord and their axons are distributed throughout the skin, blood vessels, glands, the heart, and viscera. Upon stimulation, they release the neurotransmitter ► noradrenaline (norepinephrine) with the exception of some neurons innervating the sweat glands that release ► acetylcholine. The main functions are maintaining the peripheral vascular tone, accelerating the heart frequency, and inhibiting gastrointestinal motility.

Neuronal plasticity; Short-term plasticity

Definition

In general terms, synaptic plasticity describes a change, persistent or transient, of morphology, composition, or signal transduction efficiency at a neuronal synapse in response to intrinsic or extrinsic signals. ► Long-term potentiation (LTP) and ► long-term depression (LTD) likely represent the most extensively studied forms of synaptic

plasticity, which itself is the best characterized form of neuronal plasticity, the cellular substrate for learning and memory.

Physiology and psychopharmacological modulation of LTP and LTD are described in detail elsewhere (see Cross-References). Like these special cases, most other forms of synaptic plasticity are induced by an associative coincidence of signals in space and time, in line with the theory of the so-called "Hebbian plasticity": A convergence of different second messenger pathways or pre- and postsynaptic activity at the synapse itself. Of note, the term "synaptic" could either point to the origin or the affected target of such signals. However, for many phenomena related to drug effects, this distinction cannot be conclusively drawn because a differentiation of cause and effect in neuronal networks is inherently difficult for drugs acting at multiple sites and over a relatively long period of time.

Forms of synaptic plasticity beyond LTP and LTD comprise short-term plasticity (STP) based on presynaptic transmitter release probability, postsynaptic spine motility, translocation of proteins between extrasynapticand synaptic sites, epigenetic, post-transcriptional or post-translational modifications of synaptic proteins, and changes of intra- and extracellular ion concentrations. Some of those changes are described as "► meta-plasticity" because they have been shown to change the ability of synapses to undergo classical forms of plasticity like LTP or LTD (Abraham 2008). Common to all those changes is their link to an altered function of synaptic transmission. This could be experimentally shown for some but not all of the above-mentioned examples, and there are certainly more mechanisms to be uncovered by improved and refined approaches and technologies.

The concept of synaptic plasticity was already introduced more than 100 years ago, with W. James, E. Tanzi, E. Lugaro, and D.O. Hebb making milestone contributions in the development of this principle, long before T. Lomo and T.V. Bliss in P. Andersens laboratory could experimentally show in 1973 that specific electric stimuli induce persistent changes in synaptic transmission efficiency, both in vitro and in vivo (see Berlucchi and Buchtel 2009 for a recent review of historical aspects of synaptic plasticity).

For a long time, electrophysiological techniques like extra- or intracellular recordings remained the gold standard to observe synaptic physiology. It is only recently, that optical imaging complemented the functional information with structural data at the level of single synapses in living tissue.

Models of synapses usually show synaptic signal transmission between neurons as a "static element" that can be described by a fixed input–output relation: for a single event of chemical signal transmission between neurons, a presynaptic stimulus leads to a defined postsynaptic response. In the most classical case of synaptic transmission, a presynaptic action potential depolarizes the ► presynaptic bouton, which contains the machinery for vesicular release. A rise of intracellular calcium ($[Ca^{2+}]_{int}$) induces the release of vesicle-stored neurotransmitters into the synaptic cleft. The transmitter activates postsynaptic receptors that trigger electric or second messenger signals in the postsynaptic cell. When one or several of the contributing synaptic components change their function, the synapse undergoes plastic changes that can last from milliseconds to days or years. More special cases of synaptic signal transmission, like electrical synapses formed by gap junctions, are not described further, as there are to date still very few studies on their structural or functional plasticity. Figure 1

shows some examples of synaptic plasticity across a large temporal spectrum. In vivo optical imaging of postsynaptic compartments in glutamatergic neurons, so-called ▶ dendritic spines, suggests that synaptic plasticity is the rule rather than the exception in the lifetime of a synapse.

Impact of Psychoactive Drugs

The diversity of synaptic plasticity implicates that there are numerous potential pharmacological mechanisms that affect synapses and their function. The below-given examples only reflect a selection of the better studied links between psychopharmaceuticals and synaptic plasticity. As for many other aspects of psychoactive drugs, we have to acknowledge that there are still many gaps in our understanding of their molecular mechanism of action and link to synaptic function. As a general rule – taking into consideration the prerequisite for ▶ spatio-temporal coincidence – it is helpful for deciphering such links to focus on ▶ second messenger systems triggered by targets of psychopharmacological drugs and study their effect on synaptic proteins that are involved in the above-described plasticity process.

Linking Dopamine Receptors with NMDA Receptors via DARPP-32

A prominent example of this approach is the link between ▶ dopamine and *N*-methyl-D-aspartate ▶ (NMDA) receptors that are key mediators of many forms of LTP. This connection may even provide a molecular basis for the clinical manifestation of both positive and negative symptoms in schizophrenia via the mutual interaction between dopaminergic and glutamatergic signaling networks (Stone et al. 2007). Phosphorylation of the dopamine and cAMP-regulated phosphoprotein (▶ DARPP-32) by either dopamine receptor-induced protein kinase A (PKA) or by NMDA receptor-triggered calcineurin reciprocally affects either receptor system via protein phosphatase 1 (PP1), and modulates the late phase of LTP by influencing the extracellular signal-regulated kinase (ERK) pathway. With its multiple phosphorylation sites, DARPP-32 is an excellent coincidence detector and signal integrator, as many more protein kinases and phosphatases regulate the signaling properties of DARPP-32. Stimulants like ▶ amphetamines, ▶ nicotine, and ▶ caffeine all show impaired efficacy in transgenic mice with ablation or genetically diminished phosphorylation capacity of DARPP-32. Antipsychotics like ▶ haloperidol that block dopamine receptors were also shown to affect DARPP-32 phosphorylation in the same direction as the above-described stimulants. The differential behavioral consequences induced by both classes of drugs may arise from cell-specificity in DARPP-32 phosphorylation as found in striatonigral versus striatopallidal neurons (Bateup et al. 2008). Several alternative explanations exist. The activation of the immediate early gene necessary for LTP maintenance, Arc/Arg3.1, for example, needs simultaneous signaling of Gαs-coupled receptors like dopamine D_1 receptors, and calcium influx through NMDA receptors. It will need further studies to fully understand the interaction between dopaminergic and glutamatergic systems at the synaptic level.

Proteins involved in DARPP-32 signaling, especially PP1 and calcineurin, provide an interesting additional link between receptor function and synaptic plasticity via their modulation of the actin cytoskeleton in postsynaptic compartments.

Antidepressants, Mood Stabilizers, and Antidementia Drugs Modulate the Number of Dendritic Spines in the Hippocampus

The plasticity of synaptic morphology received much attention in recent years because of the technological revolution in genetic labeling and optical imaging. With two-photon, confocal, or evanescent wave imaging, it became possible to investigate single synapses at submicron resolution in unstained tissue. This development significantly accelerated studies on synaptic morphology that formerly required fixation and often electron microscopy. It was also the basis to identify a new downstream effector system of ▶ antidepressant drugs and the mood-stabilizer ▶ lithium in relation to synaptic plasticity: dendritic and postsynaptic morphology. This was first shown in a rodent model for depression, the bulbectomized rat. One of the anatomical consequences of bulbectomy is a decreased hippocampal volume. It could be shown that the ablation of the olfactory bulb, over a period of several weeks, induced a significant reduction in dendritic spines at glutamatergic neurons in the hippocampus. Loss of dendritic spines is thought to be equivalent to a loss of synaptic function. The antidepressant tianeptin was effectively protecting against spine loss in this animal model. Corroborating this finding, electron microscopy studies in ovariectomized rats found a similar increase in synapse number after short-term ▶ fluoxetine treatment, and subchronic treatment of ▶ imipramine was found to significantly modify synaptic morphology and increase dendritic spine density in hippocampal subregions of healthy adult rats. Increased expression of neurotrophic factors like BDNF may provide a mechanistic link between the monoaminergic system modulated by antidepressants

and synaptic morphogens like filamentous actin. Tyrosine phosphorylation of β-catenin by BDNF is known to promote dissociation from cadherin, a major structural component of many synapses. Notably, β-catenin is also downstream of glycogen synthase kinase GSK-3β, the molecular target of mood stabilizers like lithium. Lithium treatment of stressed rats increased dendritic arborization of hippocampal pyramidal cells, also affecting the number of dendritic spines in this brain region (see also Pittenger and Duman 2008).

Dendritic spines can grow and collapse within minutes, and the NMDA receptor was shown to be a necessary trigger for such major though reversible changes in synaptic morphology. ► Memantine, one of the few available drugs for the treatment of ► Alzheimer's Disease (AD), acts as a partial NMDA receptor antagonist. In primary hippocampal cultures, memantine was shown to prevent dendritic spine loss and shape changes induced by oligomers of amyloid β (Calabrese et al. 2007), providing a potential mechanism for its therapeutic efficacy in AD patients. Beyond AD, the ► Fragile X Syndrome, the most common inherited cause of mental impairment and the most common known cause of autism, was linked to defects in synaptic plasticity. Lack of the Fragile X Mental Retardation Protein (FMRP) induces dysregulation of spine morphogenesis and exaggerated metabotropic glutamate receptor-dependent LTD. FMRP is a synaptic protein regulating dendritic RNA delivery and translational repression. Based on pharmacological and genetic experiments, current theories see FMRP and the metabotropic glutamate receptor 5 (mGluR5) as counterparts in dendritic protein synthesis. There is pre-clinical evidence that genetic suppression of mGluR5 or the mGluR5 antagonists MPEP and fenobam can re-balance the system at the physiological level and improve cognitive performance of mice lacking FMRP. This was corroborated by a pilot clinical trial with the mGluR5 antagonist fenobam (Berry-Kravis et al. 2009) and will followed up by further clinical studies using improved drugs from this new evolving class of psychoactive drugs.

Synaptic plasticity is not a phenomenon restricted to the postsynaptic part of neuronal synapses. In the example of amyloid β-induced spine collapse, presynaptic boutons have been also affected and spontaneous synaptic transmission impaired. Morphological changes of presynaptic structures currently are targets of numerous studies. Functional plasticity of presynaptic proteins is particularly important for LTP at GABAergic synapses and most forms of STP. This short-lasting form of plasticity is dependent on the vesicular release machinery and modulated by a number of mechanisms regulating presynaptic calcium (Zucker and Regehr 2002).

Nicotine Receptors Affect Short-term Plasticity by Regulation of Vesicular Transmitter release

Presynaptic nicotinic acetylcholine receptors (nAChR) are an important trigger for increased presynaptic calcium and have been shown to regulate STP in a number of brain areas. Particularly, the α7 nAChR channel is a target for a number of drug candidates currently in clinical development for the treatment of negative symptoms in ► schizophrenia or ► mild cognitive impairment. Those receptors are expressed in many neurons at presynaptic sites while they control as postsynaptic receptors on GABAergic neurons the inhibitory tone in the hippocampus. Presynaptically, there is strong evidence that nAChR control release probability of several neurotransmitters, notably also of ► dopamine. Earlier studies using tonic application of subtype selective nAChR agonists showed a role for non-α7 AChRs in the regulation of dopamine release. More recently, phasic and short-term activation pattern of synaptosomes revealed a significant role of α7 receptors in the control of the readily releasable pool of dopamine (Turner 2004). The increase in dopamine release upon phasic AChR stimulation was dependent on the calcium-binding protein calmodulin but not on presynaptic high-voltage-activated calcium channels, as was the case for the non-α7 receptor mediated dopamine release. An increase in the number of vesicles ready to release their neurotransmitter upon stimulation facilitates neurotransmission for the next few synaptic events, and thus represents a form of STP. Nicotinic α7 receptors show an agonist-dependent rapid and strong desensitization after activation, and this desensitization likely turns strongly desensitizing agonists such as nicotine into functional antagonists when they are constantly present. Partial α7 receptor agonists like MEM3454 from Memory Pharmaceuticals may well have a different effect due to their increased activation of α7 receptor mediated steady-state current. Still, a continuous presence of the drug may impair phasic cholinergic signaling via those receptors. In this respect, allosteric positive α7 receptor modulators are likely to keep ► phasic signal transmission intact and thus may show a stronger impact on synaptic facilitation at dopaminergic synapses and therapeutic efficacy.

In summary, there is good evidence that psychotherapeutics influence forms of synaptic plasticity beyond LTP and LTD. Whether changes of synaptic structure or function upon treatment with psychoactive drugs are purely coincidental or causally correlated with their therapeutic

effect remains to be determined for most cases. Given the relevance of synaptic plasticity for cognitive and emotional processes, this form of neuronal plasticity is no doubt a major contributor to the behavioral effects induced by psychopharmacological drugs.

Synaptic Pruning

Definition

A process by which synaptic contacts between neurons, across which neurotransmitters and other chemical messengers are released in support of information processing, are normally reduced or eliminated in postnatal development. The overabundance of metabolically expensive synaptic contacts present in many brain regions in early life is thought to set the stage for processes of competitive elimination, in which those neural connections that carry the most functionally relevant forms of information survive and grow, while those carrying the least are removed. In many brain regions, this process may be particularly robust or entering its finishing stages during adolescent neurodevelopment.

Tachykinins

Marc Turiault, Caroline Cohen, Guy Griebel
CNS Research Department, Sanofi-Aventis, Bagneux, France

Definition

Tachykinins are short-chain amino acid neuromodulators found from invertebrates to mammals sharing the common C-terminal amino-acid sequence: Gly-Leu-Met-NH2. The name Tachykinin suggests the ability of these molecules to induce rapidly (tachys, swift) a contraction of smooth muscles (kineo, to move).

Pharmacological Properties

History

In 1931, Euler and Gaddum characterized an unidentified substance able to induce rapidly contraction of intestinal tissue. They named it ► substance P (SP) because it was stable in a dry powder form. Substance P remained the unique mammalian member of the tachykinin family until identification of ► neurokinin A (NKA) in 1983. Other mammalian tachykinins have been isolated since: neuropeptide K (NPK), neuropeptide γ (NP γ), ► neurokinin B (NKB), endokinins, and hemokinins. Studies of the distribution pattern of tachykinins showed a widespread expression in peripheral tissues where they have various effects such as inducing vasodilatation, hypotension, or contraction of smooth muscle. In the central nervous system, the three prominent mammalian tachykinins SP, NKA, and NKB are widely distributed with different distribution patterns. Maximal NKB concentrations are found in the cortex, whereas SP and NKA share a more similar distribution with a strong expression in the spinal cord and in the nuclei implicated in emotional process (e.g., nucleus accumbens, septum, amygdala). At a cellular level, SP and NKA are mostly co-localized in neurons and interneurons with glutamate, GABA, monoamines or acetylcholine. One or several tachykinins can be expressed within the same neurons and be co-released with classical neurotransmitters or neuromodulators (Beaujouan et al. 2004). The co-expression of SP and NKA is not surprising since there are three genes that encode for all known mammalian tachykinins. SP, NKA, NPK and NP γ mRNA are generated by alternative splicing of a unique preprotachykinin-A (PPT-A) gene. NKB is derived from a second gene, the preprotachykinin-B (PPT-B) gene. A third gene, the more recently cloned preprotachykinin-C, is coding for hemokinins and endokinins that are primarily expressed in non-neuronal cells.

In parallel with the discovery of new peptides from the mammalian tachykinin family, three types of receptors have been identified. They belong to the ► G-protein coupled receptors (GPCR) superfamily containing seven transmembrane domains. The activation of tachykinin receptors leads to a transduction cascade, which in turn activates, among others, phospholipase C, the release of intracellular Ca^{2+} and the stimulation of neurotransmitter release (Chahl 2006). However, tachykinins are neuromodulators, preferentially released when neurons are strongly activated (or under pathological conditions). Consequently, blockade of their receptors by ► antagonists may result in effects only when the system is stimulated (Hökfelt et al. 2000). This is of great relevance as it may provide pharmacological targets for therapeutic applications with potentially less pronounced side effects than drugs acting on tonically active modulators such as ► monoamines. Tachykinin receptors termed NK1, NK2 and NK3 bind with a high affinity respectively, SP, NKA, and NKB. Antagonists for these receptors have been suggested to have therapeutic value in a variety of areas, including inflammation, emesis, ► anxiety and ► depression However, the development of highly selective antagonists was hampered by findings from pharmacological and molecular studies that showed the existence of NK1 receptor isoforms with different affinities for tachykinins and a tissue specific expression. Furthermore, it was observed that several NK1 receptor antagonists have a greater affinity for the guinea-pig and human receptor than for the rat and mouse receptor (Beaujouan et al. 2004). This species heterogeneity, evidenced for NK1 and NK3, but not for NK2 receptors, had a major impact in the development of specific antagonists for these receptors as it

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

required the development of suitable behavioral models in atypical species such as guinea pigs and gerbils to characterize their psychopharmacological properties.

NK1 Receptor Antagonists

The development of highly selective NK1 receptor antagonists was initiated after the discovery of the role of substance P as a key mediator of pain processes. NK1 antagonists were used as tools to specify the topological and functional features of NK1 receptors leading to the idea that SP could be used for the treatment of other pathologies such as emesis, ► Parkinson's disease, anxiety or depression. Thus, the use of these antagonists in experimental research on depression and anxiety was based, for instance, on findings showing (1) an expression of SP and NK1 receptor in fear and depression-associated pathways; (2) fear-related behaviors after intracerebroventricular injection of SP and reduced fear following the peripheral administration of NK1 receptor antagonists; (3) that binding sites for SP are co-localized with those of monoamine transmitters in the human brain.

The antidepressant- and anxiolytic-like effects of MK-0869 (aprepitant), the first NK1 receptor antagonist tested in human, were initially demonstrated in a range of animal models. The further development of NK1 and SP receptor knock-out mice confirmed these results as mutant animals displayed an anxiolytic- and antidepressant-like phenotype.

Several randomized, ► placebo-controlled, ► double-blind, clinical studies were carried out to measure the safety and efficacy of aprepitant. In an initial clinical phase II trial, aprepitant was shown to display significant antidepressant activity. It was well tolerated, and had fewer side effects than the selective serotonin reuptake inhibitor, ► paroxetine, which was used as a positive control in this study. Unfortunately, this result was never replicated in phase III clinical trials, thereby questioning the idea that NK1 receptor antagonists may be effective antidepressants (Rost et al. 2006).

NK2 Receptor Antagonists

The identification of NK2 receptors in a number of peripheral tissues such as the smooth muscles of the gastrointestinal tract, the respiratory and the urinary tracts, along with studies using selective NK2 receptor antagonists has led to the idea that this receptor may represent a potential therapeutic target for a wide-range of disorders, including irritable bowel syndrome, pulmonary and urinary tract disorders. The demonstration of the existence of NK2 receptors in the brain has been made much later. Data obtained from adult brain were not convincing due to non-specific binding and poor selectivity of ligands, and weak expression of the NK2 receptor. In 2001, the demonstration of the existence of central NK2 receptors was made using radiolabelled endogenous NKA in the presence of NK1 and NK3 receptor antagonists to avoid labeling of other tachykinin binding sites. These results were strengthened by detection of NK2 receptor mRNA in human and rat in brain structures affected in mood disorders, such as the ► prefrontal cortex and the ► hippocampus. Moreover neurochemical studies have identified a central regulatory role of NK2 receptors on monoaminergic and cholinergic neurotransmission. For instance, in anesthetized rats, the peripheral administration of the NK2 receptor antagonist, saredutant, has no effects on basal ► norepinephrine levels in the prefrontal cortex but reduces its release elicited by tail pinch. In addition, in non-anesthetized rats, local infusion of saredutant in the septum blocks stress-induced increase of hippocampal acetylcholine release but has no effect on basal conditions (Desvignes et al. 2003). These results underline the ability of NK2 receptor antagonists to regulate neurotransmission only when systems are activated (Steinberg et al. 2001).

Furthermore, recent data suggest an interaction between the tachykinin system and ► corticotropin-releasing factor (CRF). CRF is a neurohormone known to be involved in the regulation of the stress axis and in the etiology of mood disorders. The injection of saredutant was found to block CRF-induced increase in acetylcholine and norepinephrine release, suggesting that NK2 receptor antagonists counteract, at least in part, the effects of stress on neurotransmission.

At a behavioral level, the activation of central NK2 receptors by intracerebroventricular administration of NKA produces ► anxiogenic-like effects. Moreover several NK2 receptor antagonists have been shown to produce ► anxiolytic-like activity in animal studies. For example, GR159897 and saredutant exhibited anxiolytic-like effects in exploration-based procedures such as the light/dark and the ► elevated plus-maze tests. It is noteworthy that the anxiolytic-like properties of saredutant were observed across species as evidenced in the mouse defense test battery, the marmoset human intruder test and the social interaction test in gerbils and rats. In addition, saredutant also exhibited antidepressant-like properties in the rat forced swim test. Moreover, the drug attenuated physical degradation in the mouse ► chronic mild stress test (Griebel et al. 2001; Louis et al. 2008). In addition to the neurochemical and behavioral effects of NK2 receptor antagonists, molecular and cellular studies showed that

chronic treatment with saredutant upregulates cAMP response element binding protein (CREB) and promotes ► neurogenesis in ► hippocampus after chronic stress exposure in mice. Similar effects are observed with classical antidepressant treatment such as ► fluoxetine. Together, these results suggested that selective NK2 receptor antagonists could have therapeutic utility for the pharmacological treatment of ► mood disorders and anxiety. Unfortunately, the low efficacy and poor brain penetration of the NK2 receptor antagonist tested in recent clinical trials did not allow a definitive conclusion on the pertinence of the target.

NK3 Receptor Antagonists

The NK3 receptor has been the least studied of the NK receptor family. The first paper on a selective NK3 receptor antagonist, published in 1995, was the starting point of numerous studies which explored the pharmacology of the NK3 receptor (Edmond-Alt et al. 1995).

In peripheral tissues, similar to other tachykinin receptors, it was found that the NK3 receptor plays a role in smooth muscle contraction. However, NK3 receptors are mostly expressed in the central nervous system with a wide distribution throughout the spinal cord and brain, in particular in limbic areas, well known to play a crucial role in psychiatric disorders. Importantly, the activation of NK3 receptors expressed on dopaminergic neurons by the highly selective agonist senktide leads to an increased dopamine release in the striatum and the prefrontal cortex. This excitatory activity, as well as the stimulation of serotoninergic and noradrenergic systems, is blocked by the selective NK3 receptor antagonist osanetant, but not by NK1 or NK2 antagonists (Spooren et al. 2005). Decreasing the dopaminergic activity may be of interest for the treatment of the positive symptoms of ► schizophrenia since all currently approved antipsychotics share this feature.

Tachyphylaxis

Definition

Tacyphylaxis is the rapid development of tolerance to the effect of a drug. That is, the response to a drug rapidly decreases after a few initial doses. In the case of hallucinogens, the process is thought to be a result of rapid desensitization and internalization of serotonin 5-HT_{2A} receptor.

Tandospirone

Definition

Tandospirone displays anxiolytic and antidepressant properties with a short ► half-life. Its main pharmacological mode of action is as a potent 5-HT_{1A} receptor ► partial agonist. Its active metabolite displays antagonistic action at α_2-adrenergic receptors. Tandospirone is a member of the piperazine and azapirone chemical classes. It is prescribed mainly in Japan and China. A Western equivalent of the same pharmacological class is buspirone, which is prescribed for ► generalized anxiety disorder, ► panic attacks, and as augmentation of treatment with serotonin reuptake inhibitors.

Tardive Dyskinesia

Definition

Tardive dyskinesia (TD) is a chronic neuromotor side effect of dopamine-blocking medications, characterized by abnormal involuntary movements of voluntary musculature that are generally slow and that can be irreversible. It can include abnormal rotatory or sinuous movements of the mouth, lips, neck, trunk, hands, arms, and legs. It is identified as a side effect of long-term antipsychotic use; risk factors have been identified (e.g., age, duration of exposure), but there is no specific means of precisely predicting who will develop TD. With the ► first-generation antipsychotics, prevalence rates in chronically treated patients approximated to 25%. Evidence for the newer, ► "atypical" antipsychotics indicates that none of these agents are without risk of TD, although prevalence rates appear notably lower. The precise pathophysiologic mechanisms underlying TD have not been elucidated, although high and sustained levels of dopamine D_2 occupancy have been implicated. Many putative pharmacologic treatments have been investigated, although only a few (e.g., ► tetrabenazine in Canada) have gained an indication for treatment of TD. TD has proven inconsistent in its response to all treatments, variable over the course of the illness, and is frequently irreversible. Other tardive movements (e.g., tardive dystonia) are also linked to chronic antipsychotic exposure.

Taste Reactivity Test

Definition

This is a method that can be used to determine in the rat the motivational valence of a taste without having the test subject actually ingest the fluid. Ralph Norgren and Harvey Grill discovered that rats show distinct orofacial (movement of the mouth and tongue and opening of the mouth, gaping and face washing and wiping) reactions to the intraoral application of sapid solutions. The reactions observed can be characterized as appetitive or aversive, depending on whether the fluid evokes an ingestive or rejective reaction. This test can be used as a method to assess tastes paired with drugs that produce conditioned taste preferences or taste aversions.

Temazepam

Definition

Temazepam is an intermediate-acting (half-life 8–20 h) benzodiazepine used to treat insomnia. Side effects include a hangover effect (residual drowsiness) the next morning, dizziness, nausea, and vomiting. Prolonged use of this drug is not recommended because of risks for dependence. Temazepam is also used recreationally usually to dampen the effects of withdrawal associated with other drugs, for example, cocaine and MDMA. The gel capsule form of temazepam (called "jellys") was withdrawn after being associated with intra-arterial injection for the purposes of getting high, which caused severe vascular injury and limb ischemia leading to amputations.

Tetrabenazine

Definition

Tetrabenazine is a reversible inhibitor of vesicular monoamine transporters. It reduces uptake of monoamines such as dopamine into synaptic vesicles causing depletion of monoamine stores. It is approved for the treatment of chorea (abnormal involuntary movements) associated with ► Huntington's disease. ► Extrapyramidal side effects are much less common with tetrabenazine than with typical ► neuroleptics. However, it can amplify the risk of depression, and suicidal thoughts and behavior already seen in Huntington's disease patients. Other common side effects of tetrabenazine include drowsiness, insomnia, and ► akathisia. Tetrabenazine has also been clinically evaluated in the treatment of other hyperkinetic disorders including Gilles de la Tourette's syndrome (Tourette's syndrome). It was also used in experimental psychopharmacology as an amine depletor, enabling the role of endogenous amines in responses to other drugs to be investigated. In this application, it has fallen out of use due to the nonspecific nature of the depletions that it produces.

Therapeutic Drug Monitoring

Pierre Baumann
Département de psychiatrie, CHUV (DP-CHUV), Prilly-Lausanne, Switzerland

Synonyms

Drug plasma level determination for therapy optimization; TDM; Therapeutic drug plasma level monitoring

Definition

The rationale of therapeutic drug monitoring is based on the hypothesis that drug plasma concentrations in the patient reflect better than drug dose the brain concentrations of the active components. For specific drugs, a «therapeutic window» (therapeutic range) can be defined: it represents a drug plasma concentration range defined by a lower threshold below which there is a high probability for an insufficient clinical response. In contrast, drug plasma concentrations higher than the upper threshold result in an increased risk for adverse effects. Drug plasma concentrations within the "therapeutic window" should therefore be synonymous with optimal clinical response. Hence, TDM is the measurement of drug concentrations in the blood of patients in order to facilitate dose adaptation for optimizing treatment. Recently, a consensus guideline was published by a group of experts (AGNP-TDM group (Arbeitsgemeinschaft für Neuropsychopharmacologie und Pharmacopsychiatrie), which should help the clinician to take optimal clinical benefit of TDM in psychiatry (Baumann et al. 2004).

Current Concepts and State of Knowledge

► Pharmacokinetics and Metabolism

The majority of psychiatric patients are treated with psychotropic drugs including antidepressants, mood stabilizers, antipsychotic or anxiolytic/hypnotic drugs, but complications such as non-response, poor tolerance, non-compliance or drug interactions are frequent. Besides pharmacodynamic, pharmacokinetic factors may also be responsible for unsuccessful treatments, in that, in the body and particularly in the brain, inadequate drug concentrations are reached for different reasons, as both environmental and genetic factors control the fate of the drug in the organism.

In order to reach the target organ, the brain, psychotropic drugs are submitted to several steps: ► absorption, ► distribution, ► metabolism, and elimination (ADME). The ► bioavailability of these drugs is 100% when intravenously administered. However, after oral administration it generally varies between 20% and 80%, depending on the drug but also on environmental and genetic factors, due to a limited absorption from the intestine and to metabolism in the liver ("first pass-effect").

Most psychotropic drugs are submitted to metabolism in the liver, in the intestine and in other organs, by phase I (e.g., ► cytochrome P-450) and phase II (e.g., UTP-glucuronyltransferase) reactions. An important consequence is the possible formation of active metabolites, mainly after formation by phase I and rarely by phase II enzymes. These products may differ in their pharmacological and pharmacokinetic properties from their parent compound, but they contribute to the overall clinical profile of the drug.

► Pharmacogenetics

Cytochrome P-450 is the most important enzymatic system implicated in the biotransformation of psychotropic compounds, which are metabolized by one or several isozymes, mainly CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, and/or CYP3A/5/7. Some of them are inducible (CYP1A2, CYP2C9, CYP2C19, and CYP3A) and most of them display a ► genetic polymorphism. This can be defined as the presence of at least two genetically determined variants (e.g., alleles) in a population, and such a variant allele has to occur in at least 1% of the population. As a consequence, a high, genetically determined variability may exist in the expression of an active enzyme protein, and patients can be categorized according to

their phenotype: poor (PM), intermediate (IM), extensive (EM), and ultrarapid (UM) metabolizers can be observed. In some UM, gene multiplication is observed, and therefore, the presence of at least three active alleles. These patients are at risk for poor clinical response, as drug levels may never reach concentrations needed for clinical efficacy. In contrast, due to the absence of active alleles, drug plasma concentrations in PM may be within a range leading to adverse effects, already at usual drug doses. IM and EM are characterized by the presence of one or two "normally" active alleles, respectively, but the distinction between these groups is sometimes difficult (Ingelman-Sundberg 2004; Kirchheiner et al. 2004). This has to be considered as a somewhat simplified presentation of the relationship between the genotype and phenotype. Patients may be genotyped, or phenotyped using probes which are specific substrates of the isozyme to be examined (Fuhr et al. 2007). Generally, a single dose of these probes is administered to the patients, and urine or blood is then collected during or after a well-defined period of time for the analysis of the parent compound and its metabolite formed by the enzyme. The metabolic ratio (metabolite/parent compound) informs on the metabolic status, i.e., phenotype, of the patient. Typically, debrisoquin or dextromethorphan are used as probes for phenotyping patients with regard to CYP2D6 activity.

Numerous psychotropic drugs are substrates, inhibitors, and/or inducers of the transporter molecule P-glycoprotein, which extrudes drugs and other xenobiotics from the intracellular to the extracellular space (Thuerauf and Fromm 2006). This transmembrane efflux transporter is expressed in many tissues such as the intestine, liver, and at the ►blood brain barrier and it is encoded by the multidrug resistance 1 gene (*ABCB1*) and belongs to the adenosine triphosphate-binding cassette (ABC) family. It presents a genetic polymorphism and depending on the genotype of the patients, this may have consequences on the transport of drugs in the organism. Therefore, the contribution of this transporter molecule in the regulation of drug distribution in the organism is increasingly recognized; however, the clinical relevance of genotyping patients for P-glycoprotein needs to be further investigated.

On the pharmacodynamic level, most receptor and transporter molecules which are binding neurotransmitters such as norepinephrine and serotonin also present genetic polymorphisms. Numerous studies suggest that there may be a relationship between the pharmacogenetic-pharmacodynamic status of the patients and their response to psychotropic drugs, but these tests are not yet sufficiently validated for their routine use in clinical practice (Arranz and de Leon 2007).

In conclusion, TDM may be advantageously combined with pharmacogenetic tests especially regarding cytochrome P-450, as these tests may provide a useful help for diagnosing pharmacokinetic particularities (Gardiner and Begg 2006).

Indications for TDM

This presentation of the consequences of a pharmacogenetic variability in drug metabolism already demonstrates an indication for TDM. Table 1 summarizes important indications for TDM, which is however absolutely mandatory only for a few psychotropic drugs such as ►lithium, but the clinical usefulness of TDM of antidepressants (Wille et al. 2008) and antipsychotics (Mauri et al. 2007) is widely recognized (Baumann et al. 2004). Indeed, drugs such as lithium, ►tricyclic antidepressants, and the antipsychotic drug ►clozapine display a relatively narrow therapeutic range, while it is wide for some ►antidepressants including SSRI (Fig. 1). One of the main problems in pharmacotherapy is the lack of compliance in patients, as it leads to nonresponse and enhances the risk for hospitalization and rehospitalization. However, there may also be other reasons for insufficient response or adverse effects which lead to interruption of the treatment despite the prescription of doses considered as adequate. This may be a consequence of pharmacokinetic interactions leading to an inhibition or induction of the metabolism of the administered drug. Combination treatments are frequent, as many patients suffering from comorbidities need comedications, or in situations of poor response, they are comedicated with augmenting but pharmacokinetically interacting agents. TDM is also recommended in pharmacovigilance programs as it represents an interesting diagnostic tool. Increasingly, the need for long-term treatments is recognized in order to prevent relapse, but despite apparently good compliance, recurrence of the illness may occur. The pharmacokinetics of psychotropic drugs may be particular in many subjects belonging to the category of "special populations," such as children and adolescents, elderly patients, patients suffering from comorbidities which may result in an impaired absorption, distribution, metabolism, or elimination of the drug. Similarly, problems may occur at the level absorption when galenic forms of drugs are changed, e.g., switching from an original preparation to a generic brand, and vice versa. Depending on the indication, either the availability of "therapeutic ranges" or the knowledge of plasma drug concentrations at defined doses may primarily be helpful for the clinician (Table 1). Table 2 presents a list of recommended plasma concentrations of antidepressants and antipsychotics as defined by the already mentioned group of experts (Baumann et al. 2004).

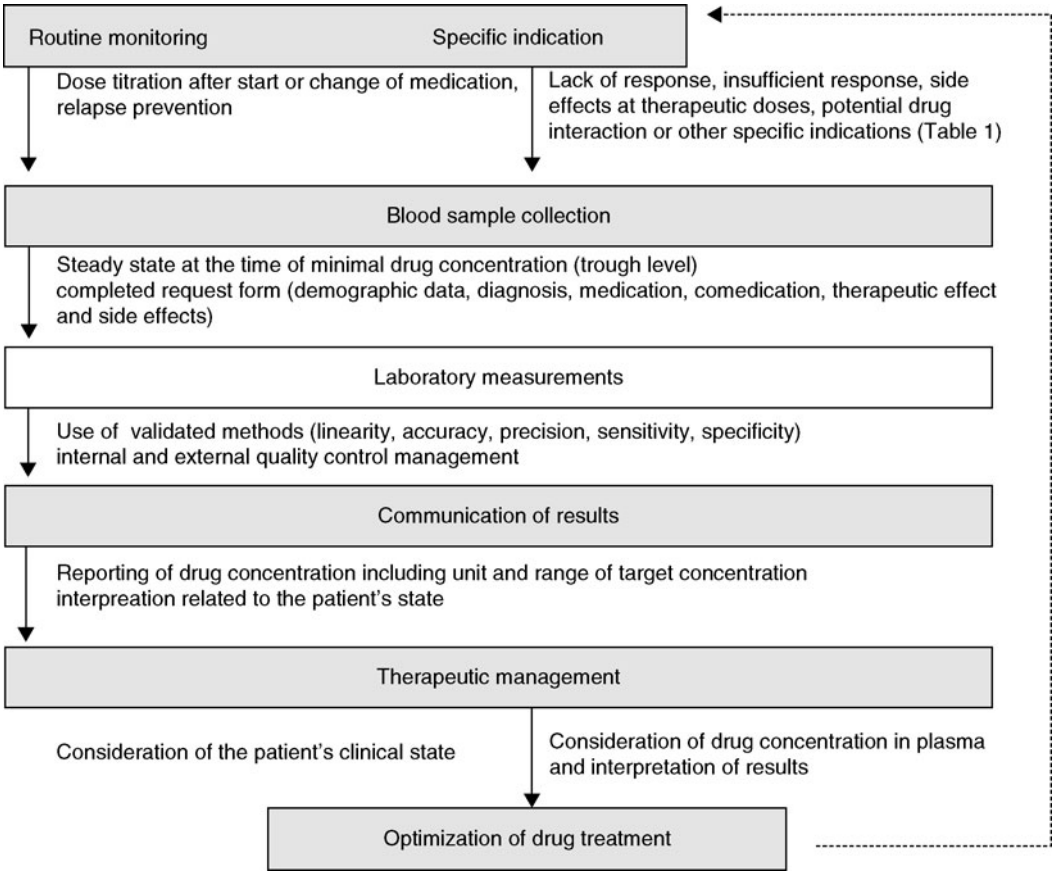
[b]*Level of recommendation*

In addition, the levels of recommendation are indicated for each drug, as defined according to the present evidence from studies reported in the literature and to the conclusion from the expert group.

1. *Strongly recommended (for lithium TDM should be a standard of care)*: Established therapeutic range
2. *Recommended*: Suggested therapeutic ranges obtained from plasma concentrations at therapeutically effective doses (fixed dose studies)
3. *Useful*: Suggested therapeutic ranges are plasma concentrations at therapeutically effective doses obtained from steady-state pharmacokinetic studies
4. *Probably useful*: Suggested therapeutic ranges from steady-state pharmacokinetic studies at therapeutically effective doses
5. Not recommended

Practical issues

Figure 2 summarizes the steps which should be considered when TDM is envisaged in a patient. Successful TDM is the result of a fruitful collaboration between the treating physician, laboratory specialists, and, in special circumstances, the clinical pharmacologist. From a pharmacokinetic point of view, TDM should be carried out in



Therapeutic Drug Monitoring. Fig. 2. Schematic presentation of the TDM process for optimization of psychopharmacotherapy (Baumann et al. 2004).

steady-state conditions of both the parent compound and its active metabolite to be co-monitored (Fig. 1). This situation is generally reached within a time period of 4–5 half-lives of the active constituents after treatment is initiated or after adaptation of the dose. Moreover, trough levels (Fig. 1) should be measured, i.e., generally 12–16 h after the last intake of the drug, or in the morning before the first dose of the day is administered. In situations of pharmacokinetic interactions, two situations have to be considered separately. In the case an inhibitor of the metabolism of the drug to be monitored is administered, its new steady-state concentrations are only reached after the inhibitor has reached steady-state conditions, when it exerts a maximal inhibiting effect. After comedication with a metabolism inducing drug, maximal induction is only reached after the inhibitor itself reached steady state and after maximal inducing effect, i.e., stimulation of protein synthesis, is obtained (Fig. 1). This takes generally 1–2 weeks. Practically, it is difficult to be compliant with all these recommendations, as many drugs are administered several times per day, and others display very short (e.g., quetiapine: 2–4 h) or very long elimination half-lives, respectively (e.g., fluoxetine (and its active metabolite norfluoxetine): 3–4 days).

Finally, an example of a frequent but complicated situation is presented in Fig. 3, when adverse effects are observed in a patient during a drug treatment. It presents a decision tree about the optimal combination of TDM with pharmacogenetic tests, as useful tools for the diagnosis of the cause of an unexpected pharmacokinetic behavior of the drug leading to a pharmacovigilance problem (Jaquenoud Sirot et al. 2006).

Thioridazine

Definition

Thioridazine, like other compounds of its chemical class (► phenothiazines), is classified as a typical antipsychotic, although its pharmacological profile exceeds dopamine D_2 receptor blockade to include antagonism at dopamine D1, alpha-1 adrenergic, and muscarinic cholinergic receptors, and it produces a relatively low incidence of ► extrapyramidal side effects. Cardiotoxicity, retinopathy, and other serious side effects have reduced its use to patients who do not respond to other commonly used antipsychotic compounds.

Tiagabine

Definition

Tiagabine is an anticonvulsant drug that is used as a third-line adjunct medication for the treatment of partial seizures in adults and children. It acts by selectively inhibiting the GABA transporter 1 reuptake inhibitor. Thus, it enhances inhibitory ► GABAergic neurotransmission and prevents propagation of neuronal impulses and seizures. Tiagabine reduces seizure frequency but does not produce freedom from seizures and has a low tolerability, for example, low anticonvulsant efficacy compared to other third-line antiepileptic drugs. It also has a high rate of side effects including dizziness, lack of energy, nausea, and nonconvulsive status epilepticus. Open-label investigations have suggested that tiagabine may be used as an add-on medication in anxiety disorders, for example, ► generalized anxiety disorder, and for the treatment of alcohol dependence. It is thought that tiagabine may reduce both ► anxiety and alcohol ► craving in withdrawal, possibly via indirect GABA inhibition of the ► mesolimbic dopamine system. However, its efficacy for these indications has not yet been confirmed in double-blind placebo-controlled studies.

Definition

Tic disorders of childhood are a group of probably related conditions characterized by the presence of motor tics and/or vocalizations. Motor ► tics tend to be rapid, jerky movements of the head and neck regions, though other muscle groups may also be involved. Common vocal tics include repetitive throatclearing, grunting, snorting, or shouts. Tic disorders are described as transient or chronic according to the duration. The differential diagnosis is also based on whether both motor and vocal tics are present. The diagnosis of a tic disorder also requires that the tics are not due to the effects of a substance (e.g., stimulants) or another medical condition (e.g., Huntington's chorea).

Role of Pharmacotherapy

Tics are common in children, affecting as many as 20% of the school-age population. In most of these children, the tics are transient and require no intervention. An estimated 1% of children show a pattern of chronic tics that endure over time. Tourette syndrome, defined by the presence of both motor and vocal tics persisting for at least a year, affects 3–8/1,000 children (Scahill et al. 2005). Even among children with chronic tics, many cases are mild, and medication is not warranted. Children with tic disorders appear to be at higher risk for co-occurring conditions such as ► attention deficit hyperactivity disorder (ADHD) and ► obsessive–compulsive disorder (OCD). Thus, the first step in selecting medication for the treatment of children with tic disorders is to identify the most important source of impairment: tics, ADHD, or OCD. The use of pharmacotherapy in children with tic disorders should always be combined with education for the child and the family about the medication, as well as the natural history of tic disorders.

Diagnostic Categories

The following are the three main diagnostic categories of childhood onset of tic disorders:

1. Transient tic disorder (motor and/or vocal tics lasting for at least two weeks but less than 1 year)
2. Chronic tic disorder (motor or vocal tics lasting for more than a year)
3. Tourette syndrome (multiple motor tics and at least one vocal tic lasting for more than a year) (American Psychiatric Association 2000)

All three tic disorders require the onset of tics before the age of 18 years. In addition to the duration criterion, the diagnosis of a chronic tic disorder also requires that there should not have been any significant tic-free period following the onset of tics. Although not specified for the diagnosis, parents often report a fluctuating course for the tics (tendency to rise and fall in frequency and intensity over time). By age 10 years, most patients will report a capacity to suppress tics at least for brief periods and the presence of a warning or ► premonitory urge before the occurrence of some or all of their tics.

There are no diagnostic tests for tic disorders. Except for the tics, the physical and neurologic examinations are usually normal. Neuroimaging procedures (e.g., magnetic resonance imaging) or electroencephalography is rarely indicated. Thus, the assessment of a child referred for a tic disorder includes tracing the onset and course of symptoms, documenting the current severity of motor and phonic tics, inquiring about the presence of premonitory sensations and capacity for tic suppression, establishing the overall impairment caused by the tics, and surveying the treatment approaches implemented to date. Due to their common co-occurrence, ADHD and OCD warrant particular attention in the assessment. The presence of other psychiatric disorders, such as anxiety and depression, also deserves consideration. Because stereotypic movements in children with ► pervasive developmental disorders can resemble tics, overall development as well as social and language competence should also be part of the assessment (Scahill et al. 2006).

Medications Used in the Treatment of Children with Tic Disorders

Drugs Used to Treat Tics. The most widely prescribed drugs for the treatment of tics include ► antipsychotic medications and the alpha 2-adrenergic agonists (see Table 1). Other medications such as tiapride (available in Europe), ► pergolide, botulinum toxin injections, ► topiramate, and ► tetrabenazine have also been used for the treatment of tics. Empirical support for these medications varies. For example, botulinum toxin, topiramate and tiapride have each been shown superior to placebo, tetrabenazine has not. Pergolide, which is a dopamine ► partial agonist, appears to be effective in reducing tics, but has fallen out of use due to concern about adverse effects. The other dopamine partial agonists have not been rigorously evaluated.

Efficacy. To date, most pharmacological trials for the treatment of tics have been relatively small (ranging from 30 to 60 subjects). The magnitude of effect ranges from 30–50% reduction in tics, suggesting that even effective medications are not associated with a large reduction in tics.

Tolerability. The antipsychotics are predictably the most effective medications, but are also associated with a large range of ► adverse effects. The newer ► atypical antipsychotics offered the promise of decreased risk of motor adverse effects. However, the issue of weight gain and the liabilities associated with obesity have emerged as important concerns.

Clinical Use. Given the fluctuating course of tics, medication for tics should be considered only when there clear evidence that the tics are causing persistent interference in everyday life. Frequent and forceful tics may cause direct interference with motor activities or speech. In other cases, the child may be distracted by the bombardment of premonitory sensations and efforts to suppress tics. Still other children may suffer social consequences from noticeable tics. Families need education about the fluctuating course of tics. For example, even

after achieving satisfactory results with a tic-suppressing medication, tic exacerbations will occur. The impulse to increase the medication dose with the inevitable exacerbations of tics should be tempered by the increased risk of adverse effects. Finally, there is the matter of how long to maintain children on a tic-suppressing medication. To date, no clinical trials that have adequately addressed this important clinical question. Follow-up studies have shown that many children will have fewer tics at age 18 years compared to 12 years of age. This replicated finding suggests that it is reasonable to consider a decrease or even discontinuation of a tic-suppressing medication in the mid to late teenage years. Understandably, adolescents and their parents may be reluctant to undertake such a course of action. Based primarily on clinical consensus, medication withdrawal should be done gradually. In the case of the antipsychotics (even atypicals), abrupt cessation may result in withdrawal ► dyskinesias and rebound increase in tics. Gradual withdrawal spread over months may also be more acceptable to adolescents and parents.

Drugs used to treat ADHD in Children with Tic Disorders. Based on several case reports of tic worsening upon exposure to stimulant medication, the stimulants have been contraindicated for children with ADHD and a tic disorder. However, accumulated evidence over the past 15 years disputes this as an ironclad contraindication. As in children with ADHD, who do not have tics, the stimulants may fail. Thus, if stimulant medication is not successful either due to tic worsening, other adverse effects, or lack of efficacy, non-stimulant alternatives warrant consideration. Table 2 presents a summary of information on medications that are commonly used and have been studied in children with a tic disorder and ADHD.

Drugs used to treat OCD in Children with Tic Disorders. Children with tic disorders ascertained from clinical settings also have an increased likelihood of OCD compared to general population samples. It has been noted that the obsessive–compulsive symptoms in children with tic disorders differ from those with OCD in the absence of tics. Indeed, a recurring challenge in the assessment of children with tic disorders can be differentiating between tics and compulsive behaviors. For example, some children with OCD express the anxious worry (obsession) that "something bad will happen" if a specific ritual (compulsion) to prevent harm is not completed. By contrast, children with the tic-related form of OCD are more likely to report a feeling or urge to carry out the repetitive behavior and a need to achieve a sense of completion rather than a need to prevent harm. The repetitive behavior in children with Tourette syndrome may be stereotypic in form, such as arranging objects to achieve symmetry or repeatedly picking up and setting down an object on a table.

The first-line treatments for OCD in children are the ► serotonin reuptake inhibitors (SSRIs). Based on available evidence, there is no compelling evidence to support the selection of any one SSRI over another. Clomipramine, fluoxetine, sertraline, and fluvoxamine have demonstrated efficacy in children with OCD in placebo-controlled trials. Citalopram, escitalopram, and paroxetine are also used in clinical settings. In general, the approach to treating a child with a tic disorder and OCD is similar to treating children with OCD who do not have a tic disorder. However, several points warrant consideration when selecting a medication for the treatment of children with OCD. First, 30–40% of children with OCD who are treated with an anti-obsessional medication do not achieve a positive response. In addition, the magnitude of benefit is not large, even for those showing a positive response. Therefore, the benefits of an SRI should not be over stated to children and parents. Second, although compulsive behaviors are common in children with tic disorders, these behaviors may be mild and

medication may not be indicated. Third, and a closely related point, there is evidence in adults with OCD that subjects with co-occurring tics are less likely to show a positive response to monotherapy with an anti-obsessional medication. Fourth, although the magnitude of effect appears similar for clomipramine and the more selective SRIs, clomipramine requires periodic electrocardiograms and blood levels, and it is more vulnerable to drug–drug interactions. Thus, clomipramine is generally regarded as a second-line drug for OCD. Fifth, the combination of anti-obsessional medication plus exposure and response prevention therapy appears more effective than medication alone.

Conclusion

Tic disorders of childhood may be chronic, but they are not usually progressive. The severity of tics range from mild to severe and tics show a fluctuating course. A substantial percentage of children with tics will show a decline by the end of the second decade of life. In addition to tics, children with tic disorders are at higher risk for ADHD and OCD. The aim of assessment and treatment is to identify and remediate the most important source of impairment in order to promote the child's overall development. Pharmacotherapy has an important role to play in the management of children with tic disorders. In addition to medication, children and families are likely to need education about tics and related problems. Behavioral interventions may be used to augment medication or as an alternative to medication in some cases (Woods et al. 2007). Advocacy and education of school teachers and administrators is often critical in securing appropriate school placement and minimizing the social fallout due to tics.

Tics, Motor

Definition

These may be simple or complex. For example, simple tics may involve single or related muscle groups such as blinking, facial grimacing, or shrugging. Complex tics may include tics occurring in a sequence, such as an arm thrust with near simultaneous head-jerking, or movement such as bending or twirling.

Tics, Vocal

Definition

Vocal tics may be simple or complex. Simple vocal tics may include throat-clearing, grunting, coughing, or snorting. Complex vocal tics may include loud shrieks or blurting out words or parts of words. Verbal tics may involve cursing or other socially inappropriate references, but these tics are not common among patients with Tourette syndrome.

Definition
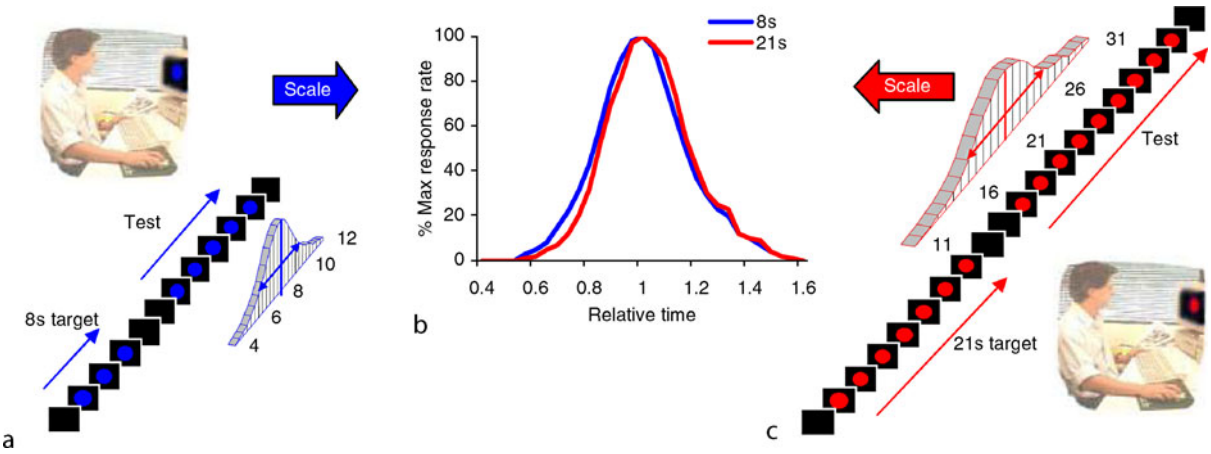
Timing behavior refers to the capacity of subjects to perceive, estimate, and discriminate time intervals (e.g., durations of and between events), to emit (or avoid emitting) behavioral responses at appropriate time intervals, and more generally, to modulate their behavior in time (Buhusi and Meck 2005; Gibbon et al. 1997). Timing behavior includes millisecond timing, ► interval timing, and circadian timing. Millisecond timing refers to the perception, estimation, and discrimination of durations in the subsecond range, crucial for motor control, speech generation and recognition, and music production and perception. Disorders of millisecond timing may result in disorders of motor control (see ► motor activity and stereotypy). Circadian timing (see ► circadian rhythms) refers to repetition of certain phenomena at about the same time each day as a function of the light/dark cycle. The most studied circadian rhythm is sleep, but other examples include body temperature, blood pressure, production of hormones, and digestive secretions. Here, we discuss the effect of psychoactive drugs on timing behavior in the seconds-to-minutes range (interval timing) which is considered crucial to learning and cognition (Gallistel and Gibbon 2000; Williamson et al. 2008).

Impact of Psychoactive Drugs

Protocols Used to Investigate the Neuropharmacology of Interval Timing
The most reliable approach to investigate the neuropharmacology of interval timing in humans and animals is to use a ► reproduction protocol, such as the ► peak-interval (PI) procedure (Matell et al. 2006) although a variety of different timing procedures can be used (see Paule et al. 1999). Idealized data from a PI procedure in two groups of subjects trained to time different durations are shown in Fig. 1. The subject's responses distribute normally around the criterion duration, and the width of this distribution is proportional to the criterion. The way in which the mean and standard deviation of the response distribution covary is typically referred to as the ► scalar property (Gibbon et al. 1997), a strong form of Weber's Law, which is obeyed by most sensory dimensions. The scalar property applies not only to behavioral responses, but also to neural activity as measured by electrophysiological recordings as well as the hemodynamic response



Timing Behavior. Fig. 1. The scalar property is a hallmark of interval timing at both the behavioral and neural levels. In a typical duration reproduction procedure called the PI procedure, subjects receive training trials, during which they are presented with target stimuli of specific durations (here, panel A: 8 s, panel C: 21 s), and test trials, in which the subjects are asked to reproduce the criterion duration. Typically, in peak trials the responses distribute normally around the criterion duration with a width that is proportional to the criterion. When the response distributions are scaled both in amplitude and duration they superimpose, thus demonstrating the scalar property at the behavioral level. (Redrawn from Buhusi and Meck 2005.)

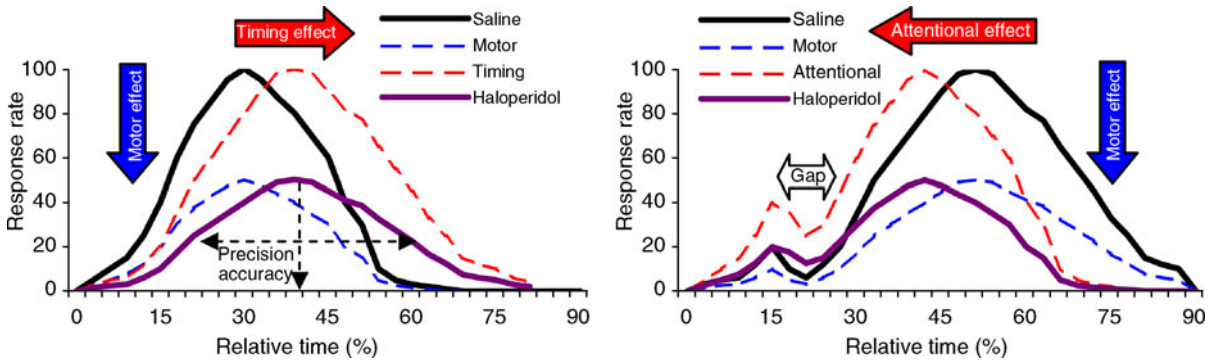
associated with a subject's active reproduction of a timed interval, but not for passive responses triggered at the untimed interval (Buhusi and Meck 2005).

Estimating the Effect of Psychoactive Drugs

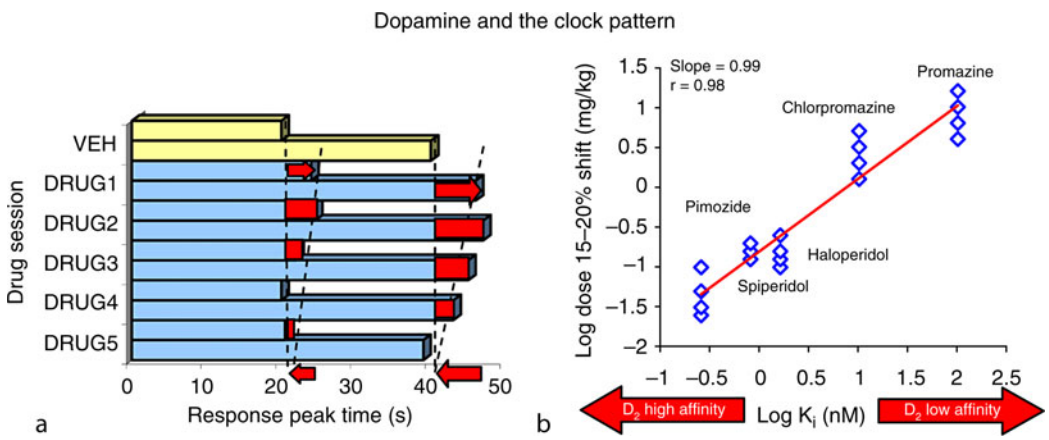
The PI procedure with gaps allows the independent assessment of the effect of psychoactive drugs on timing (► timing accuracy and ► timing precision), as well as their ► attentional effect, and allows the dissociation of these effects from motor/motivational effects as illustrated in Fig. 2. Generally speaking motor/motivational effects of drugs are observed as shifts in the amplitude of the response functions along the vertical axis, while effects on timing are observed as leftward or rightward shifts in the response function along the horizontal axis. Timing accuracy is estimated by the peak of the response function in ► peak trials (Fig. 2 – *left panel*). Timing precision is estimated by the width of the response function in peak trials (Fig. 2 – *left panel*). ► Attentional effects are estimated by inserting gaps (e.g., retention intervals) in a subset of peak trials (Fig. 2 – *right panel*). For illustrative purposes, Fig. 2 shows the effect of systemic administration of the dopamine D_2 antagonist ► haloperidol in the PI procedure with gaps. Haloperidol has both motor/motivational and timing effects: It not only reduces the amplitude of the response function (Fig. 2 – *left and right panels*), but also produces an immediate proportional rightward shift in the peak function (e.g., slows down the speed of the clock as shown in Fig. 2 – *left panel*). When retention intervals are inserted in the to-be-timed duration, haloperidol also increases the attention to time (attentional effect): It diminishes the resetting effect of the retention intervals as shown in Fig. 2 (*right panel*) (Buhusi 2003).

Dopaminergic Drugs: The Clock-Speed Effect

Dopaminergic drugs selectively affect the subjective speed of an internal clock in a variety of animals (Buhusi and Meck 2005; Meck 1996) (Fig. 3). More specifically, when timing is evaluated in the PI procedure, dopamine agonists produce an immediate leftward shift of response function in proportion to the to-be-timed criterion, indicative of an increase of the speed of an internal clock. In contrast, dopamine antagonists produce an immediate rightward shift of response function in proportion to the to-be-timed criterion, indicative of a decrease in the speed of an internal clock (Fig. 3a) (Meck 1996). Repeated administration of dopaminergic drugs is followed by a characteristic decrease in the effect of the drug (Fig. 3a), which is not interpreted as desensitization but rather as recalibration of the timer. The interruption of the drug regimen results in a rebound in the opposite direction (Meck 1996). Dopamine antagonists were shown to produce a deceleration of the subjective clock speed in proportion to their affinity to dopamine D_2 receptor (Fig. 3b) (Meck 1996). The effects of dopamine drugs on clock speed are diminished as a function of experience with the timing task (habit formation) prior to drug administration which



Timing Behavior. Fig. 2. The PI procedure with gaps allows the independent assessment of the effect of a drug on timing accuracy, timing precision, and attention to timing. Here are data from groups of subjects trained to time a 30-s PI procedure, tested under systemic administration of saline and the dopamine D_2 antagonist haloperidol (0.04–0.06 mg/kg i.p). Timing accuracy is estimated by the peak response rate, timing precision by the width of the response function, and attentional effect by the delay of the response function in trials with gaps (*right*) relative to trials without gaps (*left*). *Left panel (peak trials)*: Motor/motivational effects are observed as changes on the vertical axis, while timing effects are observed as proportional changes on the horizontal axis. Here, haloperidol has both motor/motivational effect as well as effect on timing: It slows down timing (rightward shift relative to saline control). *Right panel (gap trials)*: Attentional effects are evaluated by introducing a gap (retention interval) on a subset of peak trials, which delays the response function. Motor/motivational effects are observed as changes on the vertical axis, while attentional effects are observed as absolute changes on the horizontal axis. Here, haloperidol has both a motor/motivational effect and an attentional effect: It reduces the delay following a retention interval, suggesting that subjects are paying more attention to the task. (Adapted from Buhusi 2003.)



Timing Behavior. Fig. 3. The effects of the dopamine D_2 antagonist haloperidol on interval timing are consistent with the slowing down of time accumulation. *Panel A*: Two groups of subjects were trained to time two durations, using 20-s and 40-s PI procedures. Afterward, in test sessions, subjects received systemic administration of vehicle (VEH), then five consecutive sessions with systemic administration of haloperidol. Acute administration of haloperidol results in a sudden rightward shift that is proportional to the estimated durations, whereas its repeated administration results in a gradual return of the estimated time to the criterion duration. *Panel B*: The rightward shift of the estimated time is proportional to the affinity of the drug for the D_2 dopamine receptor. (Adapted from Buhusi and Meck 2005.)

may reflect a change in the balance between dopamine–glutamate interactions (Williamson et al. 2008).

Cholinergic Drugs: The Memory-Storage Effect

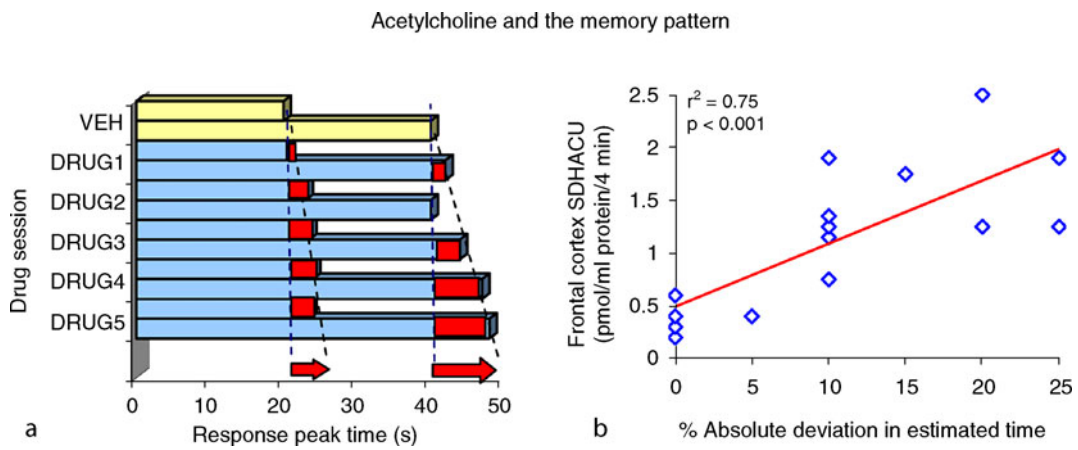
When initially administered, cholinergic drugs have no immediate effects on interval timing. However, repeated administration of cholinergic agonists results in a gradual decrease of the estimated duration, while cholinergic antagonists result in a gradual increase of the estimated duration (Fig. 4a). Discontinuing the drug administration results in a gradual return to the baseline. These results are interpreted as alteration of memory storage of duration. More specifically, reference memory error was found to vary in proportion to cholinergic activity in frontal cortex (Buhusi and Meck 2005; Meck 1996) (Fig. 4b).

Serotonergic Drugs: The Attentional Effect

Time accumulation and attention to the timing task can be dissociated pharmacologically, and they depend on the dopamine and serotonin systems in the cortex and ▶ striatum (Buhusi and Meck 2009; Ho et al. 2002). Administration of the indirect dopamine agonist ▶ methamphetamine shortens estimated durations, and decreases attention to timing (Buhusi 2003). In turn, the dopamine D_2 receptor blocker haloperidol lengthens estimated durations, but facilitates the maintenance in temporal information in working memory (Buhusi 2003). However, the effect of methamphetamine to shorten estimated durations is blocked by depletion of serotonin, suggesting that an intact serotonergic system is required for interval timing. Indeed, specific stimulation of either 5-HT_{1A} or 5-HT_{2A} receptors shortens estimated durations in qualitatively similar ways, an effect antagonized by specific blockade of these receptors. Interestingly, ▶ clozapine – a drug acting on both dopamine and serotonin systems – not only shortens the estimated durations but also facilitates the attention to time (attentional effect) during retention intervals (Buhusi and Meck 2009). Clozapine is reported to have differential effects on dopamine levels in the frontal cortex and striatum: It serves as a dopamine receptor antagonist in the mesolimbic dopaminergic system and as an indirect dopamine agonist in the frontal cortex by its activation of the serotonin 5-HT_{2A} receptors on dopamine neurons. This pattern of pharmacological results is consistent with the hypothesis that the effect of clozapine on time estimation is due to an increase in dopamine neurotransmission in frontal cortex, but not in the dorsal striatum. Together, these data suggest that drug effects on time accumulation and attention to time rely on the interaction between the dopaminergic and serotonergic activation in frontal cortex and striatum (Buhusi and Meck 2009; Ho et al. 2002).

Drugs of Addiction

Acute exposure to ▶ psychostimulants, e.g., ▶ cocaine, ▶ methamphetamine, ▶ nicotine, etc., produces results compatible with the speeding up of an internal clock (Matell et al. 2006; Meck 1996; Paule et al. 1999). These



Timing Behavior. Fig. 4. The effects of cholinergic drugs are consistent with effects on reference memory. *Panel A*: Two groups of subjects were trained to time two durations, using 20-s and 40-s PI procedures. Afterward, in test sessions, subjects received systemic administration of VEH, then five consecutive sessions with systemic administration of the muscarinic cholinergic receptor atropine. Acute administration of atropine results in a gradual scalar (proportional to the timed criterion) rightward shift of the estimated time. *Panel B*: The effect is correlated with the activity of cholinergic neurons in the frontal cortex as measured by sodium-dependent high-affinity choline uptake (SDHACU). (Redrawn from Buhusi and Meck 2005.)

effects are believed to be linked to the addictive and rewarding properties of psychostimulants (see ► self-administration of drugs, ► addictive disorder, animal model), and are susceptible to the effects of overtraining and habit formation. In addition, repetitive, high-dose exposure to psychostimulants such as methamphetamine produces deficits in time perception, possibly due to neurotoxic effects on the dopaminergic system. Of particular interest is the observation that stimulant-dependent individuals exhibit impaired timing and time perception. Taken together, these findings may help to explain why human subjects that abuse methamphetamine or cocaine show more ► impulsivity and less self-control in decision making due to greater discounting of delayed rewards (Williamson et al. 2008).

A Model of Drug Action on Interval Timing

The striatal beat frequency (SBF) model of interval timing ascribes a mechanism for detecting event durations to medium spiny neurons within the dorsal striatum (Buhusi and Meck 2005). These striatal neurons have a set of functional properties that place them in an ideal position to detect behaviorally relevant patterns of afferent cortical input. Briefly, the SBF model posits that medium spiny neurons in the dorsal striatum become entrained to fire in response to oscillating, coincident cortical inputs that become active at a previously trained event duration. In the context of this model, the clock effect of dopaminergic drugs is interpreted as reflecting tonic dopamine levels within the striatum, modulating the oscillatory frequency within the cortex through corticostriato-thalamo-cortical feedback mechanisms. Similarly, the memory effect of cholinergic drugs is interpreted as affecting the synaptic weights of striatal median spiny neurons and tonically active interneurons (Buhusi and Meck 2009; Matell et al. 2006; Williamson et al. 2008).

Definition

Timing precision refers to the trial-by-trial errors in the estimated duration. Timing precision is estimated by the width of the response distribution (see Gibbon et al., 1997).

Timiperone

Definition

Timiperone is a first-generation (typical) antipsychotic drug that belongs to the butyrophenone type approved in Japan for the treatment of schizophrenia. It has general properties similar to those of haloperidol, but it has higher affinity (as an antagonist) for D_2 and 5-HT_{2A} receptors. It also has modest binding affinity for sigma receptors. It can induce ► extrapyramidal motor side effects, drowsiness, and constipation, but it displays low toxicity.

Tolcapone is a reversible catechol-*O*-methyl-transferase (COMT) inhibitor. Used as an adjunct to l-DOPA or carbidopa therapy for patients with ► Parkinson's disease, tolcapone extends the ► half-life of l-DOPA by inhibiting its breakdown into 3-O-methyldopa and that of dopamine to 3-methoxytyramine. Tolcapone crosses the ► blood–brain barrier and is able to inhibit the breakdown of l-DOPA by COMT both peripherally and centrally. Clinically, it is often used in patients experiencing fluctuations in symptoms and "wearing-off" of l-DOPA effects. Serious adverse effects include liver toxicity with risk of acute fulminant hepatic failure.

Tolerance

Synonyms

Acquired tolerance; Resistance

Definition

Tolerance is the diminution of a drug effect after its repeated administration. Tolerance is often identified as a shift to the right in a function that describes the ability of a range of doses of a drug to produce a particular response (dose–response curve). Such tolerance is surmountable in the sense that the original drug effect can be restored increasing the dose at which the substance is administered. Insurmountable tolerance is characterized by a downward shift in the dose–response curve and it is not sensitive to dose adjustment.

Toluene

Synonyms

Methyl benzene, toluol

Definition

Toluene is a highly volatile liquid at room temperatures with a distinctive sweet odor. It is one of the most widely abused inhalants. Pure toluene is readily available as a household and industrial product, used primary as a paint thinner and remover. Toluene is also a constituent of many other products such as adhesives, inks, paints, sealants, and disinfectants. It is also a component of gasoline. Toluene is typically abused by sniffing directly from the container or by placing the liquid on a rag or paper bag and breathing the vapors. A particularly dangerous practice is placing a toluene-laden plastic bag over one's head. Overdose death from toluene exposure is possible when users become unconscious while still exposed to the vapor. Toluene metabolites such as hippuric acid can be detected in the blood of users; tests for this can be used to diagnose toluene abuse. Neurological problems are often seen in toluene abusers.

Toluene has been the most widely studied abused inhalant in animal and neuropharmacology studies. When given to animals, it produces abuse-related behavioral effects similar to those produced by ► alcohol and other depressant drugs. Toluene produces very specific cellular effects, primarily on ligand-gated ion channels.

Topiramate

Definition

Topiramate is an ► anticonvulsant drug that is used in the treatment of epilepsy in adults and children. Topiramate has several pharmacodynamic actions that contribute to its anticonvulsant properties including inhibitory effects upon voltage-gated NA^+ and Ca^{2+} channels, inhibitory effects at ► AMPA and kainate glutamate receptors, in particular the GluR5 ► glutamate receptor, and positive or negative modulatory actions at certain subtypes of ► $GABA_A$ receptor. Other actions of topiramate that may contribute to its anticonvulsant activity include positive modulation of some voltage-gated K^+ channels, inhibition of carbonic anhydrase, modulation of presynaptic neurotransmitter release, and effects upon intracellular concentrations of GABA in GABAergic neurons. Topiramate is also approved for the prophylaxis of migraine. Its efficacy as an anti-migraine medication is mainly due to inhibitory effects upon AMPA and kainate glutamate receptors and to a lesser extent, inhibitory effects upon voltage-gated Ca^{2+} channels. Topiramate has a wide therapeutic window, that is, the difference between the minimum effective anticonvulsant dose and that causing motor impairment; however, there are several recognized adverse effects of topiramate including paresthesia (unpleasant tingling in the limbs especially the fingers and toes), metabolic acidosis, kidney stones, and acute cognitive impairment. Like other anticonvulsant medications, topiramate has teratogenic effects and should not be administered during pregnancy. Other potential indications for topiramate include weight loss (involving complex pharmacodynamic actions at ► neuropeptide-Y, ► corticotrophin-releasing hormone, and ► glucocorticoid receptors), diabetes (topiramate promotes glucose transporter activation), and binge-eating, drug addiction, and anxiety-related disorders (most likely via effects at AMPA, kainate, and $GABA_A$ receptors).

Tourette's Syndrome

Definition

Tourette's syndrome is a neuropsychiatric syndrome that typically presents in young children and is characterized by both motor and vocal tics (abrupt, rapid, repetitive, nonrhythmic, stereotyped, temporally suppressible movement/vocalization). Premonitory urges accompany these tics that can range from simple movements/vocalizations, such as blinking, sniffling, or barking, to the more complex squatting, twirling, or coprolalia (obscene utterances). Tic severity and type fluctuate over time, usually becoming less severe or nonexistent into adulthood.

Trace Amines

Synonyms

Arylalkylamines; Microamines

Definition

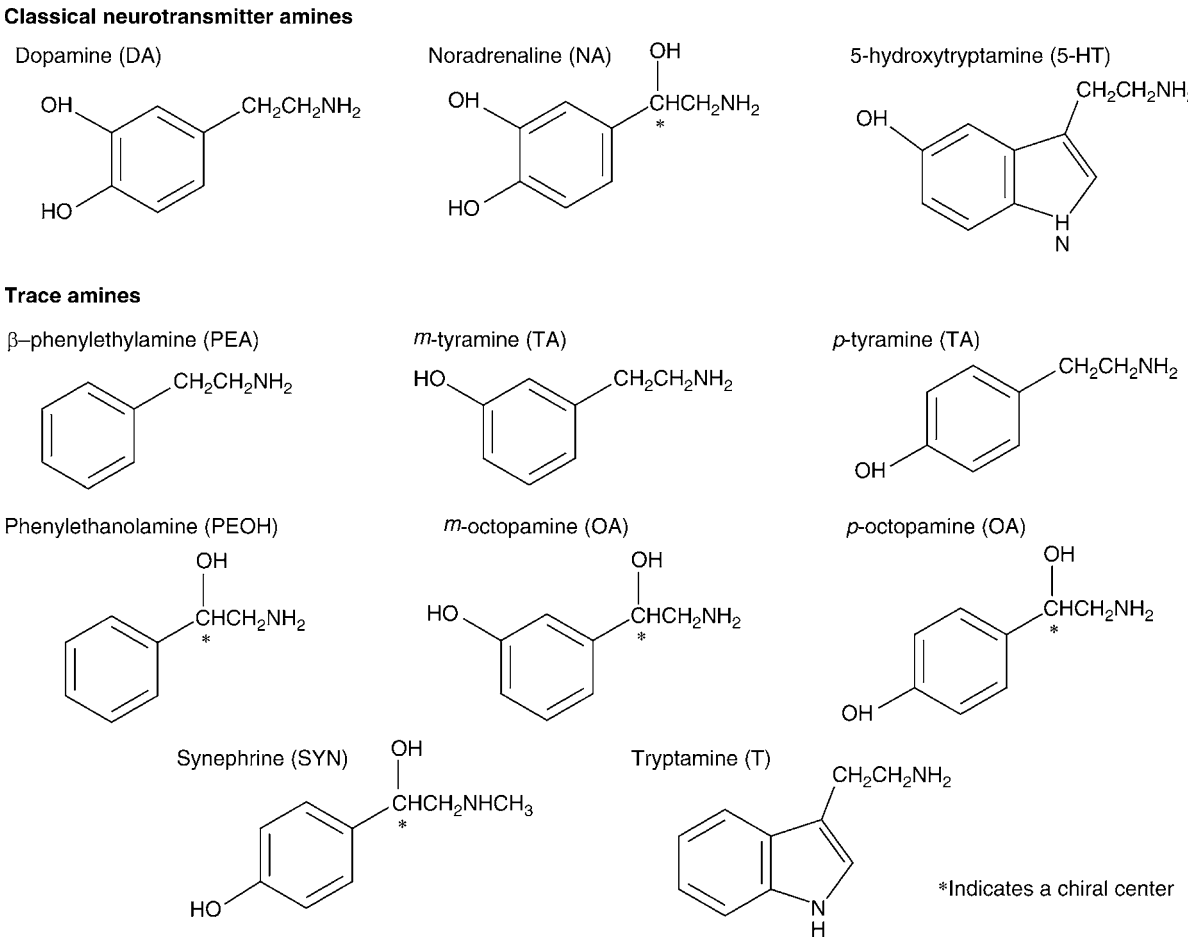
Trace amines, which include β-phenylethylamine (PEA), tryptamine (T), phenylethanolamine (PEOH), the tyramines (TAs), octopamines (OAs), and synephrine (SYN) [some authors include *N*,*N*-dimethyltryptamine (DMT) in this list], are amines related structurally to, but present in the brain at much lower concentrations than, the classical neurotransmitter amines – dopamine (DA), noradrenaline (NA), and 5-hydroxytryptamine (5-HT, serotonin).

Pharmacological Properties

History

The trace amines are so named because of their low absolute concentrations in the brain compared to the classical neurotransmitter amines DA, NA, and 5-HT; they are very similar structurally to these neurotransmitter amines (Fig. 1), but have much higher turnover rates, and PEA and T pass the ▶ blood–brain barrier readily.

In the 1960s through the 1990s, there was a great deal of interest in the trace amines in the central nervous system (CNS) as behavioral and pharmacological studies in animals and neurochemical measurements in body fluids from human subjects suggested their involvement in the etiology and pharmacotherapy of a number of psychiatric and neurological disorders, including depression, ▶ schizophrenia, ▶ phenylketonuria (PKU), ▶ Reye's syndrome, Parkinson's disease, ▶ attention deficit hyperactivity disorder (ADHD), ▶ Tourette's syndrome, epilepsy, and migraine headaches (Baker et al. 1993; Berry 2007). In the 1970s, there was a flurry of activity in trace amine research because of the development of a number of elegant, sensitive analytical techniques which facilitated their measurement in the brain. During the 1980s, there were binding studies done on possible receptors for the trace amines



Trace Amines. Fig. 1. Structures of some classical neurotransmitter amines and trace amines.

and there was also electrophysiological and behavioral research performed which suggested that these amines might act as neuromodulators for DA, NA, or 5-HT. There was a resurgence of interest in the trace amines in 2001, following reports of the discovery of a novel family of ► G protein-coupled receptors, some of which appear to be selectively activated by trace amines.

Synthesis, Catabolism, and Localization

The trace amines PEA, T, and TA are synthesized in neuron terminals by decarboxylation of precursor amino acids (phenylalanine, ► tryptophan, and tyrosine, respectively), catalyzed by the enzyme aromatic L-amino-acid decarboxylase (AADC), the same enzyme involved in the decarboxylation of L-DOPA and 5-hydroxytrytophan (5-HTP) in the synthesis of the ► catecholamines (DA, NA) and 5-HT, respectively. However, tyrosine hydroxylase and tryptophan hydroxylase are the rate-limiting enzymes in the synthesis of the catecholamines and 5-HT, while AADC is the major enzyme involved in the synthesis of PEA, T, and TA. Thus, alterations of AADC activity would be expected to have little effect on brain levels of DA, NA, and 5-HT while possibly markedly affecting the levels of trace amines (Berry 2007).

Tyramine is further metabolized to OA and PEA to PEOH by dopamine β-hydroxylase (DBH). Tyramine and OA have been proposed to function as neurotransmitters rather than neuromodulators in invertebrates. Octopamine can be further metabolized to synephrine by phenylethanolamine *N*-methyltransferase (PMNT) or related methyltransferases. The trace amines are all substrates for monoamine oxidase (MAO), with PEA being a preferred substrate for the MAO-B isoform. Abnormal levels of the resultant acid metabolites of the trace amines have also been reported in several psychiatric and neurological disorders by a number of researchers (Berry 2007; Boulton et al. 1984, 1985).

The trace amines are distributed heterogeneously throughout the brain, with the highest concentrations generally reported in the ► striatum or ► hypothalamus. Burchett and Hicks (2006) have provided a comprehensive review of their regional brain distribution and localization relative to catecholaminergic and serotoninergic neuronal systems in the brain. Although PEA, T, and TA have been shown to be present in synaptosomes, studies with ► reserpine and ► neurotoxins suggest that *m*- and *p*-TA may be stored in vesicles while PEA and T are not (see chapter by Juorio in Boulton et al. 1984). PEA and T appear to cross cell membranes passively, but there is some evidence for activity-dependent veratridine (a neurotoxin causing persistent activation of sodium ion channels) – induced release of *m*- and *p*-TA from striatal slices.

What Is the Function of the Trace Amines in the CNS?

It has long been known that trace amines such as PEA have amphetamine-like effects on the CNS when administered to rats or mice. However, given that the levels required to reach such effects were far beyond normal concentrations in brain, another role was believed to exist under physiological conditions. Researchers found mounting evidence that trace amines may play a neuromodulatory role in the CNS. The trace amines are known to inhibit reuptake of and stimulate release of NA, DA, and/or 5-HT; and in electrophysiological studies, several trace amines have been shown to potentiate the actions of the classical monoamine neurotransmitter amines DA, NA, and/or 5-HT by altering the receptor sensitivity to these neurotransmitter amines, suggesting that the trace amines serve to maintain the activity of the classical monoamine neurotransmitters within defined physiological limits (Berry 2007). PEA has also been reported to stimulate acetylcholine release by activating glutamatergic signaling pathways, and PEA and *p*-TA have been demonstrated to depress $GABA_B$ receptor-mediated responses in dopaminergic neurons. In the 1980s, specific and saturable binding sites for radiolabeled PEA, T and *p*-TA were reported, suggesting that these amines might have a role independent of the classical neurotransmitter amines. Burchett and Hicks (2006) have suggested four kinds of trace amine activity in the CNS: cotransmitters released with the catecholamines or 5-HT; transmitters with their own receptors; false transmitters at catecholamine receptors; and neuromodulators.

Receptors

There has been a resurgence of interest in trace amines in the past few years with the publication of papers in 2001 on the discovery and cloning of a unique family of G protein-coupled receptors, some of which are selectively activated by trace amines (Borowsky et al. 2001; Bunzow et al. 2001), although the mechanisms by which the trace amines activate these receptors are not yet fully defined (Lindemann and Hoener 2005). However, to date only two members of the family have been demonstrated to be responsive to trace amines, and endogenous ligands other than the trace amines which have been proposed include O-methyl metabolites of catecholamines, thyronamine metabolites of thyroid hormones, and imidazoline ligands including β-carbolines (Berry 2007; Bunzow et al. 2001; Grandy 2007).

The trace amine-associated receptor (TAAR) family consists of three subgroups (TAAR1-4, TAAR5, and

TAAR6-9) which are phylogenetically and functionally distinct from other G protein-coupled receptor families and from invertebrate OA and TA receptors (Lindemann and Hoener 2005). Genes for TAARs have been discovered in humans, chimpanzees, rats, and mice. There are marked interspecies differences in the distribution of the TAARs. For example, there are as many as 18 TAARs in the rodent genome and 9 in the human genome. This variability has led some researchers to suggest that these receptors are linked in an intricate way to species-specific functioning (Berry 2007). In humans, all TAAR genes are located in a narrow region in the locus 6q23.1, which has also been linked to schizophrenia and ▶ bipolar disorder. Recent studies on TAAR1 knockout mice suggest that the TAAR1 is a regulator of dopaminergic neurotransmission and that such mice may represent a useful model for development of drugs for treatment of some positive symptoms of schizophrenia. Studies by Sotnikova et al. (2008) in TAAR1-knockout (KO) mice, DA transporter (DAT)-KO/TAAR1-KO mice, and TAAR1-deficient/DA-deficient mice suggested that the TAAR1 is involved in tonic inhibitory actions on locomotor activity, and the authors proposed that blockade of the TAAR1 by antagonists may represent a novel way to enhance the antiparkinsonian effects of L-DOPA.

Several amphetamines [▶ amphetamine, ▶ MDMA (Ecstasy), DOI, 4-hydroxyamphetamine] are relatively potent agonists at the TAAR1 receptor, as are ergometrine, dihydroergotamine, LSD, and the anti-Parkinson agents ▶ bromocriptine and lisuride, and inhibitors of the DA transporter. Interestingly, the trace amine *p*-TA has been demonstrated to be necessary for ▶ sensitization to ▶ cocaine to occur in *Drosophila*. These findings are of interest because it is possible that the TAAR1 may be a mediator of at least some of the effects of drugs of abuse, providing a possible future target for treatment of drug abuse. It is also of interest that several biogenic amine antagonists, including phentolamine, tolazoline, cyproheptadine, dihydroergotamine, ▶ metergoline, and ▶ chlorpromazine, as well as ▶ nomifensine and MPTP, act as agonists at the TAAR1 (Grandy 2007).

Involvement in Psychiatric and Neurologic Disorders: Neurochemical Studies

Several studies looking at the levels of trace amines and/or their acid metabolites in body fluids of patients with psychiatric or neurological disorders found potential links to ▶ depression, ▶ bipolar disorder, ▶ schizophrenia, ▶ Reye's syndrome, ADHD, ▶ Tourette's syndrome, and ▶ phenylketonuria (Baker et al. 1993; Berry 2007; Boulton et al. 1984, 1985), although these studies are not without controversy. Increased PEA levels have been reported in mania while depressed states have been found to be associated with deficits in PEA and the acid metabolites of OA and TA. Links between paranoid schizophrenia and increased PEA excretion have been proposed as well. Decreased body fluid levels of PEA have been reported in Parkinson's disease. Tryptamine levels in urine have also been reported to be increased in schizophrenics and to correlate with disease severity, and plasma levels of the *p*-TA metabolite p-hydroxyphenylacetic acid have been reported to be decreased in schizophrenia. Increased brain levels of PEA have been reported in phenylketonuria. Evidence to date from several research groups suggest decreased urinary PEA in ADHD and Tourette's syndrome; there is also evidence for decreased PEA levels in brain and plasma in ADHD and for decreased urinary levels of *m*- and *p*-TA and indole-3-acetic acid (the major metabolite of T) in Tourette's syndrome. Animal studies and limited data in humans suggest that elevated PEA may be associated with elevated stress and anxiety. Elevations of TA and OA have been reported in hepatic encephalopathy and Reye's syndrome. High doses of PEA can induce seizures in mice, and this effect can be antagonized by, ▶ benzodiazepines, suggesting an interaction with the GABA system. Other studies have suggested that PEA modulates glutamatergic and GABAergic systems. It is of interest that the gene for AADC, the major enzyme involved in the synthesis of the trace amines, is located in the same region of chromosome 7p that has been suggested as a susceptibility locus for ADHD; 7p has also been linked to nicotine dependence.

The effects of drugs used to treat psychiatric illnesses provide further support for the importance of trace amines. It is known that ▶ monoamine oxidase inhibitor ▶ antidepressants such as ▶ phenelzine and ▶ tranylcypromine cause a much greater increase in brain levels of trace amines than classical neurotransmitters such as 5-HT and NA, and increases in the brain levels of PEA have been reported with ▶ tricyclic antidepressants and ECT. l-Deprenyl (▶ selegiline) and rasagiline are used in the treatment of ▶ Parkinson's disease, and because they are selective inhibitors of MAO-B, they cause a marked increase in the brain levels of PEA relative to other amines. The antipsychotics ▶ chlorpromazine, ▶ fluphenazine, and ▶ haloperidol have been shown in studies in rodents to decrease striatal *p*-TA levels acutely; similar studies with PEA have found that antipsychotics increase the rate of PEA accumulation in the striatum (see chapters in Boulton et al. 1984, 1985 for studies on these drug effects).

Summary

Behavioral, pharmacological, and neurochemical studies in animals as well as investigations in body fluids of humans have long suggested that trace amines such as PEA, T, TA, and OA may be involved in the etiology and/or pharmacotherapy of a number of psychiatric and neurologic disorders. There has always been debate about whether the trace amines have a neurotransmitter role. Although there is good evidence that OA may be a neurotransmitter in invertebrates, electrophysiological research has suggested that trace amines act as neuromodulators in the human brain, with their activity related intimately to the classical neurotransmitters amines DA, NA, and 5-HT.

There has been a marked resurgence of interest in the trace amines since reports in 2001 of a unique family of G protein-coupled receptors, some of which are selectively activated by trace amines. These receptors, now termed TAARs, are helping to explain the possible role of the trace amines in the CNS (including their interactions with classical neurotransmitters), the effects of other compounds which may be endogenous ligands at these receptors, and the actions of a number of drugs of abuse and may prove to be very useful in discovering more selective future drugs for the treatment of psychiatric and neurological disorders.

Tracer Dose

Definition

A very small concentration at which a radiotracer is administered, such that the presence of the radiotracer itself does not noticeably influence the pharmacology or pharmacokinetics of the process being imaged. For reversibly binding ligands, the usual convention is that the peak binding of the radioligand does not exceed 5% of the available receptor pool. Because the equilibrium bound to free ligand ratio is $B/F = B_{max}/(F + K_D)$ and the free ligand associated with 5% occupancy is approximately 5% of K_D, this restriction insures that binding potential will be measured accurately to within 5%. From the data-fitting perspective, the use of tracer dose also insures that the linearization of the mass action law applied in the compartment model is justified.

Tramadol

Definition

Tramadol is a centrally acting analgesic used to treat mild to moderately severe pain. It is an opiate agonist and analog of ► codeine. Notably, tramadol acts quite selectively at the μ-opioid receptor whereas most other opiate analgesics do not share this property. However, it also acts outside the opioid system, enhancing of ► serotonin and ► norepinephrine neurotransmission. ► Serotonin syndrome may occur in patients taking combinations of tramadol and other agents that increase serotonin activity. The relative degree of contribution of each mechanism toward pain control is not fully understood. It is possible that tramadol may have future uses in the treatment of depression, anxiety, and phobias. In contrast to typical opioids, tramadol may enhance immune function. Side effects may include nausea, vomiting, sweating, constipation, and seizure. Tramadol can lead to a physical dependence such that rapid cessation leads to a severe ► withdrawal syndrome that includes tremors, nervousness, insomnia, and flu-like symptoms.

Translational Neuroimaging

Definition

Translational neuroimaging refers to the ability to perform imaging methods developed for animals in human subjects. Accordingly, these methods need to fulfill certain criteria such as being noninvasive (MRI) or at least minimal invasive (nuclear imaging techniques) and providing similar readouts taking size, anatomical and functional differences into account. In general, structural and functional MRI are translatable due to their inherent noninvasiveness. Administration of exogenous contrast agents or pharmacological compounds (as performed in fMRI) limit the ability to translate MR methods developed in animals to human subjects. ► Pharmacokinetics, safety, and ethical approval for human applications need to be clarified before administration.

Definition

Translational research aims to bring basic preclinical knowledge (from the bench) to clinical practice (to the bedside) by characterizing fundamental mechanisms that play a role in the disease in the laboratory, finding ways to measure this in the human disease state, and developing beneficial healthcare outcomes. It is an iterative process: not only should preclinical findings result in clinical applications, but clinical insights will inform and direct preclinical research. For psychopharmacology, translational research wants to enhance the confidence in a central mechanism that could be of relevance for the treatment of psychiatric or neurological patients by enhancing the predictive value of disease-relevant, preclinical models for the clinic, by refining these models based upon clinical findings (back-translation), and by developing innovative human tests based on preclinical findings (translation). It wants to ensure that the rationale for the progression of a psychoactive compound to man (and proper dose selection) is based on a link between target engagement in the brain and pharmacodynamic (PD) response, by integrating preclinical

neuroscience, experimental medicine (in particular psychiatry and neurology), and pharmacokinetic/pharmacodynamic (PK/PD) modeling expertise. This should result in greater confidence in a molecular target and a compound.

Principles and Role in Psychopharmacology

Over recent years, it has become apparent that the traditional (or classical) approach to develop novel psychoactive drugs to treat patients has not performed well. Many compounds that were identified preclinically failed in the clinic, because they either lacked appropriate efficacy, had poor drug-like PK properties or were hampered by safety issues. This was because many drugs proceeded into the clinic with a leap of faith, because often preclinical data were poor predictors for clinical effects and clinical measures allowing an early and reliable indication of efficacy did not exist, leading to late attrition in large and expensive patient studies only. Translational research should bridge the gap between preclinical research and clinical research, allowing for an early and quantitative indication of pharmacological activity that predicts the efficacy of a therapeutic intervention in patients (McArthur and Borsini 2008; O'Connel and Roblin 2006). It systematically addresses the questions whether a compound shows target tissue exposure, activity on the molecular target, and modulation of the desired biochemical pathways by looking at PK/PD markers, and whether activity in a model system is predictive of clinical outcome, trying to identify suitable surrogate endpoint markers. Besides predicting efficacy, translational research also addresses mechanism-based toxicology to de-risk drug development (of note, idiosyncratic toxicology, unrelated to the mechanism of action of a compound, cannot readily be predicted).

Surrogate Endpoint Markers

A surrogate endpoint marker could be a trait marker, reflecting diagnostic accuracy, or a state marker, being predictive of clinical outcome. In psychopharmacology, surrogate endpoint markers could comprise, for example, genetic or genomic markers, neurochemical markers (e.g., ► cerebrospinal fluid (CSF) measures), neuroendocrine markers (e.g., reflecting activity of the ► hypothalamic-pituitary-adrenal (HPA) axis), electrophysiological markers (e.g., electroencephalographic (► EEG) measures), molecular imaging data (e.g., functional magnetic resonance imaging (► fMRI), measures of brain metabolic activity using ► deoxyglucose imaging or target occupancy positron emission tomography (► PET) imaging to show target engagement), autonomic markers (e.g., measures of heart rate, skin conductance, or body temperature), or types of behavior that can be measured across species. Ideally, analogous or even homologous measures should be used, with the inherent assumption being that they are mediated by the same neural substrates across species. However, a problem inherent to these markers is that often the relationship between changes in marker activity in patients and clinical outcome is not clear. ► Prepulse inhibition (PPI), for example, can be readily measured and seems to be mediated by the same neural systems across species. PPI deficits have been reported in a number of psychiatric disorders, including ► schizophrenia. Antipsychotics have been reported to alleviate PPI deficits in schizophrenic patients, but how exactly this translates into clinical improvements remains elusive. Consequently, these markers are currently not accepted as clinical endpoints by health authorities in clinical trials.

Translation and Back-Translation

A translational approach refers to the development of clinical tests based on learning from preclinical experimentation. Current clinical trial endpoints are largely based on patient assessment using rating scales, although notable exceptions do exist, for example, the urine testing for illicit substances in the area of drug dependency, breath CO measures in tobacco smoking studies, or the measurement of CSF amyloid levels in ► Alzheimer's patients. With the growing emphasis on translational research, ever-increasing efforts are being undertaken to explore alternative, dimensional measures to align clinical research with preclinical findings. A behavioral example in the field of anxiety is ► fear-potentiated startle, a paradigm that was well characterized in animals and has been translated for use in humans (healthy volunteers and patients) (Nordquist et al. 2008).

Conversely, we can learn from the clinic and aim to back-translate to the preclinical setup. Of note, there are only a few signs and symptoms that are specific for a particular psychiatric disorder, while many symptoms cut across diagnoses. Therefore, preclinical behavioral tests most likely will address a certain diagnostic dimension that may be an important feature of multiple psychiatric disorders (Markou et al. 2009).

The degree to which we can back-translate will depend on the species-specificity of the diagnostic dimension under investigation. For example, we can readily measure ► sensorimotor gating in animals (e.g., using PPI), which is impaired in psychiatric disorders such as schizophrenia, and can assess motivational types of behavior

that resemble anhedonic symptoms seen in schizophrenia and depression, but we cannot readily measure animal equivalents of some psychiatric symptoms such as hallucinations, delusions, or suicidal thoughts. Non-behavioral, electrophysiological (e.g., EEG), neurochemical, neuroendocrine, autonomic, or imaging measures also lend themselves well to a (back-)translational approach, for example, the measurement of CSF amyloid levels in animals. Yet, other types of human pathological behavior have not been sufficiently explored in animals to allow conclusions whether preclinical equivalents exist (Markou et al. 2009), especially when going beyond ► face validity, for example, for some of the cognitive symptoms seen in schizophrenia, indicating the emerging nature of this field of research.

PK/PD Markers

PK/PD markers assess the relationship between the desired or undesired effects of a drug and its effect at the molecular target (PKs: what the body does to the drug; PDs: what the drug does to the body). Possibly the most straightforward marker would be the measurement of the plasma concentration of a drug in relation to its efficacy, either in preclinical species or man. Alternatively, one can study the concentration of a drug or its metabolites in CSF. Preclinically, target occupancy can be measured ► ex vivo or ► in vivo in tissue homogenates, brain slices, or other imaging techniques such as ► μPET, which then can be related to occupancy in man, provided a suitable radioactive PET ligand exists, and the degree of occupancy can be related to the desired or undesired effects of the drug under investigation. In principle, surrogate endpoint markers as those mentioned earlier could also be used as PK/PD markers, provided one can link the PD measures to target occupancy/drug levels. Once this relationship is firmly established preclinically, this information can be used to predict the pharmacologically active dose in man (Nordquist et al. 2008). Of note, occupancy only shows target engagement and the occupancy of a target required to induce desired or undesired effects in preclinical species can only be used as a guide since different levels of occupancy may be required in patients for a drug to have clinical effects.

The Model System

While it is possible to measure many markers across species (although several exceptions exist – see above), it is equally important to use an appropriate manipulation of the model organism, be it an animal or a healthy volunteer, leading to a model with high ► construct validity. This seems particularly relevant for the measurement of surrogate endpoint markers.

Psychiatric disorders have traditionally been challenging to model in animals in a manner directly translatable to human research (Markou et al. 2009). First, we lack a good understanding of the pathophysiology of psychiatric disorders, which makes it difficult if not impossible to develop an animal model that incorporates the causative factors leading to disease, that is, our ability to build models based on strong construct validity is limited. This is further complicated by the fact that classification schemes for psychiatric disorders are primarily based on symptom clusters, thereby risking that diseases with different underlying etiologies but related symptoms are grouped within the same category. Consequently, different animal models may be needed to address different etiological factors of a disorder as defined by contemporary classification schemes. Alternatively, different manipulations have to be performed in the same animal to better model the disease. While it seems relatively straight forward to model some psychiatric disorders in animals, for example, ► drug abuse (Kreek et al. 2009), we do not really know what the ideal model for other psychiatric disorders, such as schizophrenia or depression, should be (Markou et al. 2009).

Complicating this approach is the fact that psychiatric classification schemes have changed over time, sometimes rendering models that were established according to the definition of an older classification scheme inappropriate to depict a disorder as defined in the newer classification. For example, many preclinical anxiety tests were developed before anxiety disorders were split into different categories by the third edition Diagnostics and Statistical Manual of Mental Disorders of the American Psychiatric Association (DSM III), published in 1980. Currently, we need models that adhere to the classification scheme of the next edition, ► DSM IV, published in 1994, and in the future DSM V it can be anticipated that classification schemes will change again (Steckler et al. 2008).

In healthy volunteers, challenges are for ethical reasons more limited than those that can be performed preclinically. Such challenges, which are also used in preclinical research, can be pharmacological (e.g., NMDA antagonists to model the glutamatergic hypofunction in schizophrenia) or non-pharmacological (e.g., psychological stress exposure to increase stress-related anxiety). However, it should also be noted that not all challenges that are used in man have been successfully back-translated to animals, often because of species-dependent behavioral differences, and

often questions about the robustness of the healthy volunteer models remain to be addressed.

Predictive Validity – Key Requirement for Translational Research

Often, it is this combination of a model system mimicking (some of) the pathophysiology of a psychiatric disorder and the use of a relevant test that holds potential for a translational model, although notable exceptions do exist (e.g., target engagement often can be measured in healthy animals and humans and is very informative for expected target engagement in patients). A stringent requirement for the translational approach is the ability to link the readout from the model system to clinical outcome. Key for that is the demonstration that efficacious treatments in the clinic, be it a drug or other approach, are active in the model (correct positives), while treatments that fail to therapeutically improve the disorder of interest should be inactive on corresponding preclinical measures (correct negatives), that is, it needs to be demonstrated that the model has a high ▶ predictive validity. In the absence of a clinically used treatment, one may revert to treatments that have shown efficacy in healthy volunteer models following appropriate challenges to gain more confidence in the ▶ predictive validity of an animal model, but this then leaves one with uncertainty about the translational value of the healthy volunteer model for the patient situation, also because the ability to relate such experimental healthy volunteer data to accepted clinical outcome measures is often lacking. Unfortunately, there is a shortage of suitable treatment approaches that can be used for the validation of translational models in psychiatry because suitable treatments for many psychiatric symptoms simply do not exist than can be used as correct positives (Markou et al. 2009).

Advantages and Limitations of the Translational Approach

The major advantages of translational research reside in a more stringent approach to psychopharmacological drug development, trying to bridge more closely between preclinical and clinical measures and using model systems of high construct and predictive validity. It is hoped that this should lead to faster and better informed go/no-go decisions, more efficacious drugs, and consequently reduced attrition rates during late drug development. It is also evident, however, that we still lack good surrogate endpoint markers for certain diagnostic dimensions and also lack clarity on what would constitute the best model systems for certain psychiatric disorders.

Thus, although the approach seems highly credible and promising (Sultana et al. 2007), only time will tell whether translational research will be really advantageous over more classical approaches in drug development to reduce attrition rates (Wehling 2006).

Transmembrane Helix

Definition

Part of an integral membrane protein that spans the entire cell membrane, with the transmembrane part of the protein coiled as an helix.

Transporter

Definition

A protein whose function is to terminate signaling by a neurotransmitter that has been released into the synaptic cleft. It does so by removing (transporting) the neurotransmitter away from the receptors, and back into the nerve terminal that released it. It can then either be destroyed or repackaged for future use.

Tranxene

► Chlorazepate

Tranylcypromine

Definition

Tranylcypromine is a nonselective, irreversible inhibitor of the enzyme monoamine oxidase. It is a cyclopropyl analogue of ► amphetamine although its effects and mechanism of action are quite different. It was one of the earliest ► antidepressants and was much used prior to the development of more effective and safer medications. Its use is largely limited to cases of depression that have failed to respond to other medications. It increases tissue concentrations of ► catecholamine and ► indoleamine neurotransmitters by slowing their metabolism; it also elevates the effects of biologically active dietary amines by increasing their absorption from the gastrointestinal tract and by impairing their breakdown. Dangerous interactions occur if foodstuffs high in monoamines or their precursors are consumed, a common example being the hypertensive crisis caused by the ingestion of tyramine from mature cheese and red wine. Tranylcypromine also potentiates the effects of later antidepressants such as the tricyclics and may produce toxic reactions if taken together.

Posttraumatic stress disorder

Definition

Introduction

Conservative figures estimate that between one- and two-thirds of the population in Western countries are exposed to a traumatic event of a magnitude that might eventually lead to posttraumatic stress disorder (PTSD). Of those exposed, 10–20% develop PTSD, which is a long-lasting debilitating illness with substantial impact on the individual's work, family, social relations, and quality of life (Yehuda et al. 2005; Zohar et al. 2008). The disorder is characterized by the presence of three distinct, but co-occurring, symptom groups. *Re-experiencing* symptoms are intrusions of the traumatic memory in the form of distressing images, ► flashbacks, nightmares, or dissociative experiences. *Avoidance* symptoms consist of attempts to actively avoid reminders of the traumatic event including persons, places, or things associated with the trauma and/or passive behaviors reflecting ► emotional numbing and constriction. *Hyperarousal* symptoms include insomnia, irritability, impaired concentration, hypervigilance, and increased ► startle responses. In order to fulfill the criteria for PTSD, these symptoms must impair social, occupational, or interpersonal function, and persist for at least a month following the trauma.

What is unique with regard to the pharmacological treatment after an exposure to trauma is that it is heavily influenced by the time elapsed since the trauma and not only by the severity and nature of the symptoms (which are also judged along a time line) (Nutt et al. 2000; Stein et al. 2006, 2009a,b). Six different conditions might surface following trauma exposure and each might require different treatment strategies. These include: acute stress reaction (ASR), acute stress disorder (ASD), acute PTSD

(1–3 months), chronic PTSD (over 3 months), other psychiatric disorders (such as depression, panic disorder, obsessive compulsive disorder (OCD), psychosis, etc), and specific problems including sleep disorders, sexual dysfunction, aggression-impulsivity problems, addiction, etc (Bandelow et al. 2008; Davidson et al. 2005).

Role of Pharmacotherapy

Acute Stress Reaction (ASR)

This initial reaction to trauma includes symptoms of disorientation, autonomic symptoms of panic and anxiety (elevated heart rate, sweating, etc.), and sometimes amnesia of the traumatic event, lasting for a few days only.

This is considered a normal reaction (up to 70% of those exposed to a traumatic event meet the criteria for ASR). There is no recommendation for pharmacological intervention for the vast majority of individuals experiencing ASR, as there is no treatment that has been scientifically supported at this stage. However, in specific cases of extreme agitation, medications may be used. The tradition of frequent use of ▶ benzodiazepines has recently been criticized, as it might interfere with the normal spontaneous remission (which takes place in 80–90% of the cases) (Zohar et al. 2008).

Individuals having experienced such a reaction should be advised of the need for monitoring if symptoms do not subside within a few weeks. However, those with past history of depression, anxiety, and substance abuse, and those with ▶ dissociative reaction, panic-like response, and severe agitation should be followed up more closely, as they are all considered risk factors for developing PTSD (Bandelow et al. 2008; Stein et al. 2006, 2009a; Zohar et al. 2008).

Acute Stress Disorder

ASD is the severe end of ASR, and is diagnosed (according to ▶ DSM IV) when the prescribed symptoms of PTSD occur, along with dissociative symptoms (detachment, depersonalization, dissociative amnesia, etc.), but within 4 weeks of the trauma, and lasting for a minimum of 2 days. The risk of developing PTSD for those individuals is substantially higher, and might be up to 50%. As is the case for ASR, the "non-pharmacologizing" rule is applicable; however, closer monitoring is recommended (Bandelow et al. 2008; Stein et al. 2006, 2009a; Zohar et al. 2008).

Acute PTSD (up to 3 months)

Although there are no controlled studies for the treatment of acute PTSD, the data derived from treatment of chronic PTSD might be applicable. ▶ Paroxetine, ▶ fluoxetine, and ▶ sertraline are all FDA-approved for the treatment of PTSD. The recommendation for treatment with these medications (which are all ▶ selective serotonin reuptake inhibitors – SSRIs) is to aim for full therapeutic dose (e.g., paroxetine 20–40 mg or sertraline 100–150 mg), gradually titrated. If there is no response within 12 weeks, the condition is considered as chronic PTSD with one failed medication trial.

If the response is an improvement to the extent of complete remission of symptoms, it is advisable to continue the treatment for 6–12 months from attaining remission, and to taper off the medication very gradually. There are currently no studies supporting the efficacy of treatment lasting more than a year, but as in other anxiety disorders, continuing treatment beyond that is recommended. A follow-up visit is recommended within 3 months of stopping pharmacological treatment.

In cases in which ▶ anxiety and unrest symptoms are prominent, adjunctive treatments, including pharmacotherapies, can be used. In any case, it is advisable to monitor progress a month after beginning the extra treatment and, if there is no response or numerous side effects, to stop it. These treatments include: benzodiazepines for treatment of anxiety and unrest that are not responding to SSRI, or until the SSRI takes effect. A short-term use is recommended (but not immediately after the trauma). When using benzodiazepines, a high-potency drug is preferable, with a short half-life, such as ▶ alprazolam of 0.5–1 mg or ▶ lorazepam of 1 mg. If a lengthier (yet still limited) treatment is required, a drug with a long half-life is preferable (▶ clonazepam 10–30 mg, ▶ diazepam 5–10 mg, or ▶ clorazepate 1–2 mg). However, as there is high co-morbidity of addiction in PTSD, it is very important that the treatment be limited in time, and if ▶ tolerance develops to the drug, it should be gradually be tapered down. In any case, before recommending benzodiazepines, past drug, alcohol, or benzodiazepine dependence must be ruled out.

Low doses of second-generation antipsychotics, such as ▶ olanzapine 2.5–7.5 mg, ▶ quetiapine 50–200 mg, ▶ risperidone 1–3 mg, and ▶ amisulpride 50–200 mg have been studied. The efficacy of these medications in treatment of PTSD is yet to be tested in larger, controlled studies (Bandelow et al. 2008; Davidson et al. 2005; Stein et al. 2006, 2009a).

Chronic PTSD (over 3 months)

The first-line treatment here is SSRI, titrated gradually to a full therapeutic dose. Even if remission is achieved, guidelines suggest continuation of treatment for 6–12 months from attaining remission, and then to taper off

the medication very gradually. Although currently there are no studies supporting the efficacy of treatment lasting more than a year, the consensus is to continue treatment beyond that, as in other anxiety disorders. Follow-up visits are recommended at 3, 6, 9, and 12 months after cessation of pharmacological treatment. In cases of partial response (i.e., around 30% improvement), a dose increase and continuation of the same medication for a further 12 weeks is recommended. In the instance of non-response to a treatment trial (less than 50% decrease in symptom severity) after at least 12 weeks, a treatment change is recommended as follows.

In case of no response to SSRIs, switching strategies have been proposed. These include switching to another SSRI, switching to an SNRI at a dose that would enable dual action (e.g., ▶ venlafaxine 225 mg and above), or augmentation with an antidepressant with a different mode of action (e.g., desipramine 150–200 mg, ▶ reboxetine 4–8 mg, ▶ mirtazapine 15–45 mg, ▶ mianserin 30–60 mg) as an add-on to SSRI. However, when administering these drug in conjunction with SSRIs (e.g., ▶ fluoxetine, ▶ fluvoxamine, and ▶ paroxetine), drug–drug interactions should be monitored. It should be noted that none of these methods are supported by controlled trials, and thus, there is no solid evidence to prefer one over another.

Second-line treatment alternatives (after at least two other attempts) include switching to tricyclic drugs (▶ imipramine 150–300 mg), or a ▶ monoamine oxidase inhibitor (MAOI) (e.g., ▶ phenelzine 30–75 mg). Accepted precautions for the use of MAOI should be taken (washout period of at least 2 weeks after previous medication and dietary limitations).

Non-response or "resistant PTSD" is usually defined as occurring after three full treatment attempts as described earlier. In resistant PTSD, treatment combinations such as augmentation with ▶ second-generation antipsychotics may be considered (there are reports regarding the use of risperidone 1–3 mg and olanzapine 2.5–10 mg) as mood stabilizers (e.g., ▶ lamotrigine and ▶ topiramate). However, as these recommendations are largely based on case series and not controlled studies, they should be taken with "a pinch of salt." In any case, multiple medications should be avoided wherever possible, with a rule of thumb aiming at no more than 2–3 concurrent medications (Bandelow et al. 2008; Davidson et al. 2005; Nutt et al. 2000; Stein et al. 2003, 2006, 2009a,b).

Other Psychiatric Conditions

Co-morbidity is very common in chronic PTSD patients. Co-morbid diagnoses should be made according to the accepted criteria in ▶ DSM/▶ ICD. ▶ Major depressive disorder (MDD), ▶ OCD, ▶ panic disorder, alcohol and substance (drug) abuse, ▶ psychosis, and ▶ bipolar disorder are some of the most frequent co-morbidities.

In each of these disorders, the therapeutic approach is to treat both the PTSD and the co-morbid disorder. Consequently, the therapeutic approach is the accepted practice for each specific disorder. Priority of treatment will depend on the severity of each disorder and the subjective suffering of the patient or his or her immediate environment (partner, children, relatives, etc.) (Nutt et al. 2000; Stein et al. 2009a).

Specific Problems

Sleep Disorders

Complaints of sleep disruption are very common in PTSD, although there is sometimes a large discrepancy between the complaints and sleep laboratory data.

Therapeutic options include low doses of ▶ prazosin (5–10 mg) – currently, the only drug to have been tested in a ▶ double-blind study and found effective, particularly in cases of nightmares. Other possibilities (which have not been tested specifically) include ▶ melatonin 5–10 mg, clothiapine 20–60 mg, or levopromazine 12.5–50 mg.

Other treatment options include the following:

Hypnotic drugs. Common ▶ hypnotics, such as ▶ zolpidem 10–20 mg and ▶ zopiclone 7.5–15 mg, have clear benefits, but also disadvantages (e.g., developing tolerance). Therefore, it is not recommended to use these medications for more than 2–3 weeks consecutively. The recommendation is to treat for a defined period wherever possible, and not indefinitely.

Medications that are not considered "sleeping pills" and are not associated with tolerance, are antidepressants that cause drowsiness, such as mirtazapine 14–45 mg, ▶ trazodone 50–200 mg, or ▶ amitriptyline 10–25 mg.

Maintenance treatment for sleep disorders might focus on avoiding tolerance during long-term treatment.

If the patient takes a hypnotic drug, treatment should be discontinued after 2–3 weeks. In patients who take the drug for longer duration, it is advisable to stop as soon as an improvement is observed. In both cases, cessation of treatment should be carried out carefully and gradually.

There are reports of an increased prevalence of ▶ sleep apnea in PTSD. Therefore, patients at increased risk of sleep apnea (middle-aged, overweight men with short necks, and whose bed-partners report snoring) should undergo an appropriate screening, and if needed, a specific treatment tailored for them. Great care should be taken with these patients when prescribing drugs with side

effects such as depression of respiration (such as benzodiazepines, non-benzodiazepine hypnotics, and opioids).

Sexual Dysfunction

It is important to differentiate between problems with libido, arousal, orgasm, or combinations of these. Libido and orgasm problems could be side effects of one of the drug treatments, and if required, an alternative treatment could be tried.

► Erectile dysfunction can also be related to side effects of drug treatment. First, an organic cause should be ruled out (diabetes, dyslipidemia, high blood pressure, hormonal problems, etc.). When treating erectile dysfunction, phosphodiesterase inhibitors (► sildenafil [*Viagra*], vardenafil [*Cialis*]) can be effective.

Aggression and Impulsivity Problems

Available treatments include ► mood stabilizers (including topiramate 50–150 mg, lithium 600–1,500 mg, or ► valproaic acid 60–2,000 mg) whilst monitoring blood levels, β-blockers (e.g., propanolol 20–80 mg, monitoring pulse and blood pressure), and antipsychotic medications. These approaches are yet to be examined in controlled studies.

Addiction

► Alcohol dependence or cannabinoid, heroin, and ► cocaine addictions are prevalent in PTSD. The co-occurrence of addictions and PTSD is associated with poorer prognosis and increased risk for somatic comorbidity, and should therefore be specifically screened for and treated adequately (Bandelow et al. 2008; Davidson et al. 2005; Stein et al. 2009b).

Summary

The pharmacological approach for PTSD (which is mainly related to SSRIs) is only one component in the complex puzzle comprising appropriate treatment for PTSD. Psychoeducation to the patients and their families, including encouragement to resume previous activities as well as refraining from focusing on compensation issues, along with specific psychological intervention (i.e., prolonged exposure) and social and emotional support, might be as important as the current pharmacological interventions.

Trazodone

Definition

Trazodone is a triazolopyridine that was developed in Italy as an antidepressant and was much used for that indication, although its use has declined. It was one of the early atypical antidepressants and was developed according to the mental pain hypothesis, which postulated that major depression is associated with a decreased pain threshold. It inhibits the reuptake of ► serotonin with lower affinity and selectivity than for typical SSRIs such as ► fluoxetine, and also acts as an antagonist 5-HT_{2A} and 5-HT_{2C} receptors and a histamine antagonist. Its efficacy is comparable to that of ► tricyclic antidepressants but it has a superior side-effect profile. It has also been prescribed for insomnia but evidence of efficacy is lacking

and it is uncertain whether it has a favorable risk–benefit ratio. Adverse reactions reported include drowsiness and priapism (painful and prolonged penile erection). It is metabolized by the liver enzyme CYP3A4. Inhibition of the enzyme by other substances may result in high blood concentrations of trazodone. Grapefruit juice has such an inhibitory property and its consumption is discouraged when trazodone is prescribed.

Treatment-Resistant Depression

Synonyms

TRD

Definition

Treatment-resistant depression (TRD) is defined as a major depression disorder in patients who fail to achieve remission with standard antidepressant therapies. TRD can be further distinguished from chronic severe depression as some patients with milder depressive symptoms are still treatment resistant. Present treatments for TRD include ECT, vagus nerve stimulation, and ► transcranial magnetic stimulation.

Treatment-Resistant Schizophrenia

Synonyms

Refractory schizophrenia

Definition

Schizophrenia is considered as a heterogeneous illness with various trajectories of response and treatment outcome. A minority of individuals demonstrate complete resolution of symptoms; at the other end of the spectrum, approximately 25–30% of individuals show minimal response to treatment, at least with ► first-generation antipsychotics. It is these individuals who are designated as refractory or treatment resistant and there are now established criteria to make this diagnosis, criteria that take into consideration previous treatments (including drug, dose, and duration) as well as outcome.

It is important to distinguish this subpopulation of individuals from "partial responders." This latter group also manifests a suboptimal response, but it is more substantial than what is observed in the treatment-resistant population.

The distinction of treatment resistant has important clinical implications, as ► clozapine appears superior to all antipsychotics, including other atypicals, in treating this population. It is estimated that a significant response will be seen in approximately 30–50% of clozapine-treated individuals.

Treatment-resistant schizophrenia can be seen from the earliest stages of schizophrenia, although it can also be observed in individuals who initially appeared responsive to treatment. There are no well-established criteria that can be used clinically to predict which individuals will be refractory or responsive to clozapine.

Treatment Response

Definition

The magnitude of clinical change can be expressed as the mean change in baseline Y-BOCS scores on active drug compared to placebo, or as treatment "responders" versus "nonresponders." Though no universally accepted definition of treatment response exists, a CGI-I rating of "improved" or "very much improved" and a decrease in Y-BOCS of 25 or 35% are widely used and may separate active from inactive treatments. Thus, an accepted definition of "responder" is an individual who exhibits a Y-BOCS reduction of 35% after treatment as compared to pretreatment scores. This conservative level of improvement contrasts with the standard 50% improvement expected for successful treatment for ► major depressive disorder.

TR-FRET

Definition

TR-FRET unites TRF (time-resolved fluorescence) and FRET (fluorescence resonance energy transfer).

FRET uses two fluorescent molecules, a donor and an acceptor. Excitation of the donor by an energy source (e.g., a flashlamp) triggers an energy transfer to the acceptor, if the donor and the acceptor are within a given proximity to each other. The acceptor, in turn, emits light at a given wavelength. Because of this energy transfer, molecular interactions between molecules (e.g., a ligand and a receptor) can be assessed by coupling each partner with a fluorescent label and detecting the energy transfer. TRF uses long-lived fluorescent labels combined with time-resolved detection; a delay between excitation and emission detection minimizes prompt fluorescent interferences.

However, a high rate of reports of adverse effects including memory loss, confusion, anxiety, bizarre behavior, and hallucinations, as well as several legal cases, led to the drug's license being suspended in several countries including the UK. It is currently approved in the USA for use in small doses for the treatment of insomnia.

Trichloroethane

Synonyms

Methyl chloroform; TCE; 1,1,1-trichloroethane

Definition

Trichloroethane (TCE) is a highly volatile liquid whose vapors are often subject to inhalant abuse. It is a widely used industrial solvent and is contained in many household products including adhesives, cleaning solutions, inks, paints, correction fluids, and shoe polish. TCE is a source of environmental chlorine and as such its use was restricted by the Montreal Protocol to protect the ozone layer. Thus, the availability of TCE in products is much diminished. Nonetheless, TCE is an important abused inhalant because many animal and neuropharmacological studies are done with it as a representative halogenated hydrocarbon-abused solvent. Evidence suggests that it produced effects similar to ► alcohol, other depressant drugs, and abused inhalants.

Trichotillomania

Michael H. Bloch
Yale Child Study Center,
New Haven, CT, USA

Synonyms

Chronic hairpulling

Definition

Trichotillomania is classified as an ► impulse-control disorder in ► DSM-IV. Trichotillomania is characterized by recurrent hairpulling that causes noticeable hair loss and significant distress or impairment. Additionally, according to DSM-IV, trichotillomania requires that an individual should sometimes experience urges prior to pulling, and a sense of pleasure, gratification, or relief after the act.

Role of Pharmacotherapy

Trichotillomania has an estimated lifetime prevalence of roughly 0.6%. However, the estimated lifetime prevalence increases to roughly 3% when preceding urges and pleasure/relief afterward are removed from the diagnostic criteria. Trichotillomania patients have a high rate of ► comorbid illnesses, with approximately 82% of adults presenting for treatment experiencing at least one other Axis I psychiatric disorder (Woods et al. 2006a). Common comorbidities include depression, anxiety disorders, obsessive–compulsive disorder, substance use disorders, posttraumatic stress disorder, and other body-focused impulse control disorders. Trichotillomania in adults has a strong female predominance and a chronic, waxing and waning course. Longitudinal studies of adults with trichotillomania have demonstrated little improvement in symptoms over time (Keuthen et al. 2001). Trichotillomania has an average onset age of around 13 years. It should be distinguished from chronic hairpulling in young children. Hairpulling in young children is considered a behavior consistent with developmentally appropriate environmental exploration and is usually self-limited.

A proper assessment in a patient with trichotillomania involves getting a detailed history of their hairpulling. When discussing hair-pulling behaviors it is important to address (1) antecedent cognitions, behaviors, and feelings prior to pulling, (2) the settings in which pulling occurs, (3) body locations from which pulling occurs, and (4) post-pulling behavior. Trichotillomania patients commonly experience emotions such as boredom, tension, and anxiety prior to hair-pulling episodes and/or a physical urge to pull. Commonly experienced cognitions prior to hairpulling include beliefs about the inappropriate appearance of certain hairs (gray, coarse, etc.), that hairlines or lengths of hair need to be symmetrical or that the patient is unattractive or unlovable because of his or her appearance. Common post-pulling behaviors involve biting, rubbing, or eating the hair. Also, discarding of the hairs in fairly stereotyped ways is the norm. In patients who ingest their own hair, trichobezoars (conglomerations of hair and food that form in the gastrointestinal tract) are of particular concern as they can lead to weight loss, iron deficiency anemia, malabsorption, and even gastrointestinal tract obstruction.

Trichotillomania patients also usually have specific places where they engage in the behavior, i.e., the bedroom or the bathroom. The most common sites of hairpulling are the scalp (73%), eyebrows (56%), eyelashes (53%), pubic region (46%), and legs (15%) (Woods et al. 2006a). A physical examination of areas of hairpulling can uncover areas of irritation, follicle damage, and atypical regrowth of hair, all of which are common in patients with trichotillomania. Rating scales, such as the self-report Massachusetts General Hospital Hair-pulling Scale and the clinician-rated National Institute of Mental Health Trichotillomania Severity Scale, are useful in measuring the severity of trichotillomania symptoms and tracking changes in symptom severity over time.

► Selective serotonin reuptake inhibitors (SSRIs) are the most commonly utilized pharmacological intervention to treat trichotillomania (Woods et al. 2006a) (► SSRIs and related compounds). Initial open-label trials showed improvement over time in trichotillomania patients taking SSRIs. However, in four randomized, blinded, ► placebo-controlled trials, SSRIs have failed to show benefit compared to placebo (Christenson et al. 1991; Dougherty et al. 2006; Streichenwein and Thornby 1995; van Minnen et al. 2003). A ► meta-analysis that combined the results of the four previously conducted trials similarly failed to show any evidence of an improvement compared to placebo treatment (Bloch et al. 2007). Although there is substantial evidence that pharmacological treatment with SSRI is no more effective than placebo in the treatment of primary hairpulling in trichotillomania patients, these medications may still be quite effective in treating comorbid illness in these patients. ► Depression, ► anxiety disorders, and ► post traumatic stress disorder are all common comorbidities in trichotillomania patients, and there is substantial evidence demonstrating improvements in these conditions with SSRI pharmacotherapy. When SSRI pharmacotherapy is initiated in a trichotillomania patient, the goal of therapy should be to specifically target comorbid illness that is impairing to the patient, as SSRI pharmacotherapy for primary trichotillomania has little evidence of efficacy.

Clomipramine is a ► tricyclic antidepressant (TCA) that has been extensively studied in the treatment of trichotillomania (► antidepressants). Initial results from a 10-week, randomized, double-blind, crossover study of 13 women that compared ► clomipramine, a serotonergically potent TCA, to desipramine, a noradrenergically potent TCA, demonstrated substantial improvement in

trichotillomania patients treated with clomipramine (Swedo et al. 1989). However, most of the patients in this trial experienced a relapse in their symptoms after longer-term treatment with clomipramine. Another small, 9-week, randomized, placebo-controlled parallel-group study showed some increased improvement of trichotillomania symptoms with clomipramine compared to ▶ placebo, but not to the level of statistical significance (Ninan et al. 2000). Clomipramine was very poorly tolerated in this study, with 40% of subjects dropping out early due to side effects. Common side effects associated with clomipramine include weight gain, anticholinergic symptoms, and sedation. The meta-analysis of randomized trials with clomipramine suggests modest short-term benefits when compared to control conditions. However, evidence suggests that benefits from clomipramine are short-lived.

A substantial number of case reports and uncontrolled trials have suggested the possible efficacy of both typical and atypical antipsychotics in trichotillomania (▶ antipsychotic drugs). Additionally, case reports suggest the possible efficacy of glutamate-modulating agents such as riluzole, ▶ *n*-acetylcysteine, and ▶ topiramate. ▶ Naltrexone, a opioid antagonist used to treat urge-related disorders such as alcoholism and ▶ pathological gambling, has shown some evidence of efficacy in uncontrolled trials. Skepticism is warranted when viewing the likely efficacy of any treatment of trichotillomania studied in an unblinded, uncontrolled fashion. Many patients with trichotillomania improve over the short-term regardless of treatment after presenting for initial treatment. Greater familiarity and psychoeducation about the disorder, meeting other individuals with the disorder, supportive clinicians, and engaging in any active intervention against the disorder are all powerful forces toward patient improvement. These aspects of treatment, along with the waxing and waning course of the disorder, make it difficult to assess efficacy in uncontrolled trials.

Role of Non-Pharmacological Therapies

▶ Habit reversal therapy (HRT) is a behavioral therapy designed for the treatment of trichotillomania and tics. HRT is a manualized, behavioral technique that is administered over a period of 2–3 months with a maintenance period for relapse prevention. HRT involves several different components – self-monitoring, awareness training, stimulus control, and competing response training. The self-monitoring component of HRT requires patients to keep records of their hairpulling. Awareness training works to increase patient awareness of hair-pulling behaviors and of high-risk situations that increase the risk of hairpulling. Stimulus control employs interventions designed to decrease the opportunities to pull and to intervene or prevent pulling behaviors. Competing response training involves teaching a patient to engage in a behavior that is physically incompatible with pulling for a set period of time when they feel the urge to pull. In HRT, patients are only permitted to pull after they have engaged in the competing response behaviors.

Circles represent the point estimate and lines the 95% confidence intervals for effect sizes for each intervention. (Adapted with permission from Bloch et al. 2007.)

In three randomized, parallel-group studies, HRT demonstrated superior efficacy compared to wait-list or placebo controls (Ninan et al. 2000; van Minnen et al. 2003; Woods et al. 2006b). HRT also demonstrated superiority to pharmacotherapy with fluoxetine and clomipramine in two of these randomized trials (Ninan et al. 2000; van Minnen et al. 2003). A recent meta-analysis demonstrated that, in randomized, controlled trials, HRT shows superior ► effect sizes compared to pharmacological agents for trichotillomania (Bloch et al. 2007). Figure 1 depicts the relative effect sizes of HRT compared to pharmacotherapies for the treatment of trichotillomania. Further trials are needed to demonstrate that HRT will maintain efficacy when compared to control conditions that account for the nonspecific aspects of therapy (i.e., emotional support and psychoeducation).

Support groups (e.g., the Trichotillomania Learning Center in Santa Cruz, California, www.trich.org) can also be very helpful in treating trichotillomania. Such groups can provide treatment referrals and support to individuals experiencing the condition. Often times, hearing other individuals' stories, coping mechanisms and strategies can help the individual develop more effective personal approaches for adjusting to and managing the disorder.

Conclusion

Trichotillomania can cause substantial impairment for individuals who suffer from it. Individuals may have significant dermatological and medical problems as a direct result of hairpulling. Substantial psychosocial impairment may occur due to the resulting hair loss. Effective behavioral treatments for trichotillomania, such as HRT, have been developed over recent years. Access to skilled therapists practicing HRT remains a major challenge for trichotillomania treatment. Currently, expert HRT treatment for trichotillomania is available at only a few academic centers. No pharmacological agents have convincingly demonstrated long-term efficacy in the treatment of trichotillomania. Novel pharmacological treatments are urgently needed given the problem of access to effective behavioral treatments for most patients and given the substantial proportion of patients for whom this behavioral technique is not tolerable or who still do not experience adequate symptom relief.

TSST

Definition

The *Trier Social Stress Test* (Kirschbaum et al. 1993) is a protocol for the induction of moderate to intense psychosocial stress under laboratory conditions. It comprises a 3 min anticipatory period, a 5 min public speaking task, and a 5 min mental arithmetic task in front of an evaluative panel of two adults. The TSST can be employed in adolescents and adults of all ages; a slightly modified version is used when studying children from the age of 7 years and older (TSST-C). Today, the *TSST* is the most widely used psychosocial stress protocol in laboratory studies of human subjects and patient populations.

Principles and Role in Psychopharmacology

Stress and Biological Responses to Threat

Psychosocial stress is a major burden for individual and societies alike. The direct and indirect costs of stress amount to billions of Euros and US dollars in many countries because of the fact that approximately 50% of all days of work absence can be attributed to consequences of stress exposure. While such financial effects burden economies significantly, the individual suffering in response to traumatic or chronic psychosocial stress threatens physical and psychological health. In 2001, the World Health Organization (WHO) therefore listed stress "one of the most significant health problems of the twenty-first century."

In search of mechanisms how stress affects well-being and which measures need to be taken in order to avoid adverse health outcomes, research protocols are required for a reliable induction of stress under laboratory conditions. In animals, different footshock or restraint stress paradigms are widely used. Only relatively few laboratories, however, employ more complex stress protocols that mimic stress exposures in modern human societies.

In human stress research, several paradigms and protocols exist for induction of moderate, acute stress responses. Most of these procedures, such as the *cold pressor test* or the *Stroop test,* evoke sympathetic nervous system responses of small or moderate magnitudes. The other most important bodily system, which conveys the brain´s response to threatening and detrimental stimulation to the organs, remains unaffected by such protocols. The ► hypothalamus-pituitary-adrenal (HPA) axis requires more intense stimulation and threat to the ego before a significant increase in ► corticotropin-releasing hormone (CRH), ► adrenocorticotropin hormone (ACTH), or cortisol occurs.

Deliberate stress activation of the human HPA axis has proven to be difficult under ethically acceptable laboratory conditions. Only variable and inconsistent cortisol responses had been obtained with computerized or several other interactive tasks. As revealed in a meta analysis of 208 laboratory stress studies (Dickerson and Kemeny 2004), a combination of social evaluative threat and uncontrollability is required for a reliable and strong ACTH and cortisol release. Social evaluative threat and uncontrollability are key components of the TSST.

The TSST Protocol

The standard TSST protocol requires at least two different rooms and a total of three lab members as a minimum. Upon arrival at the laboratory, subjects are guided to a standard office room for a first rest period of 30–60 min. Then, the experimenter takes them to a second room for the actual stress task. This room is sparsely equipped with two tables and three chairs, a video camera and a microphone. Behind the larger table, two members of an *evaluation panel* are seated, dressed in white lab coats. The test subject is asked to stand at the microphone facing the seated panel approximately 2 m away. The panel members do not speak at this point yet while the experimenter gives instructions for the TSST to the subject. He or she should imagine having applied for open position at a company or an institution. Out of many other applications, he or she was invited to present him or herself before an evaluation panel to convince them that he or she was the best candidate for the job based on his or her personal characteristics. The first of two tasks therefore is to give an oral presentation about his or her personal strengths and positive aspects. The subjects are told that a video will be recorded for later analysis of nonverbal signs of stress and a voice frequency analysis. Furthermore, the two panel members are described as trained in the detection of verbal

and nonverbal stress signals. In order to prepare this speech, the subjects are given 3 min of preparation time, which they spend sitting at the small desk in the same room. Paper and pencil are provided for sketching the talk; however, the notes cannot be used later in the oral presentation. The experimenter now leaves the subject alone with the two evaluation panel members in the room.

After 3 min, the experimenter asks the test subject to step up to the microphone and to begin with the free speech about him or herself in a clear, loud voice. Most test subjects finish their talk after about 2–3 min of speech time. Then one of the panel members asks them to continue their speech since there was still time left. When the subject halts a second time before the first 5 min are over, the two panel members look at the subject with a neutral facial expression and do not speak for 20 s. Thereafter, they begin to ask personal questions (e.g., "Do you have friends?"). After 5 min exactly, the panel member stop the speech and proceed with a second task. They ask the subjects to perform mental arithmetic, subtracting an odd number from a larger number. Depending on the age of the subject, the difficulty of the problem is adjusted (e.g., for healthy young adults, they have to serially subtract 13, starting at 2011). The subjects are told that upon each error, the panel member would ask them to start anew from the initial number. After 5 min of mental arithmetic, the experimenter enters the room again and takes the subject back to the first room where he or she rests for another 20–120 min depending on the psychological or biological measures taken.

As a mandatory part of every TSST (unless a study on habituation of stress responses is conducted), the subjects have to be fully debriefed after the last psychological or biological measure has been obtained. It has proven helpful to have the two panel members come to the tested subject then (without the white lab coats now) and introduce themselves. They should explicitly explain that the test protocol required them to be nonresponsive and cold in the interaction with him or her.

Small variations of the standard TSST protocol are required when testing retired adults or children and adolescents between ages 7 and16 years. The variations pertain to the topic of the free speech task only. Test subjects of advanced age will be presented with a fabricated advertisement which calls for people willing to donate their time for working in a nonprofit organization (e.g., helping with experiments with elderly subjects in a psychology department). The experimenter asks the subjects to talk to the evaluation panel as a job applicant, presenting his or her personal strengths and positive characteristics. When testing children, the so-called TSST-C (Buske-Kirschbaum et al. 1997) protocol is used. Here, the experimenter reads the beginning of the story to the child and asks him or her to continue and finish the story as interesting and suspenseful as possible. All other aspects of the standard TSST protocol are also used in the elderly and young study populations.

Responses to the TSST

A wide range of psychological and biological response parameters have been studied in the past 15 years of TSST research (Kudielka et al. 2007). The TSST typically induces moderate to large subjective and physiological responses that peak 1–30 min after cessation of the stressful procedure. Approximately 80–85% of all subjects tested show a substantial increase in the respective parameters from the resting (baseline) period to peak values. Self-reported negative mood changes and moderate increases in anxiety ratings are typical. Endocrine, immunological, and cardiovascular parameters increase by 50–300% over baseline. Table 1 provides an incomprehensive list of biological parameters, which are significantly changed in response to the TSST.

Repeated Exposure to the TSST

In many instances, a repeated stress exposure is the ideal study design for the investigation of specific treatment effects. For example, the potency of an ► anxiolytic drug

could be tested, or the efficacy of a psychotherapeutic intervention studied using a prepost challenge study design. The TSST can be used for such purposes. Careful attention should be paid, however, whether the crucial TSST response read-out parameter shows habituation effects. When parameters controlled by the sympathetic nervous system are the main read-out variables, the standard TSST protocol can be used repeatedly for the same subjects. ACTH or cortisol responses, however, decline upon the second TSST exposure already (Kirschbaum et al. 1995). HPA axis habituation can be circumvented by changing the test setting (novel rooms/labs, panel members, and experimenters) for each TSST.

Using the TSST as a Group Stress Protocol

Researchers have begun to evaluate a modified TSST protocol for use with groups of 2–6 individuals at the same time (Childs et al. 2006). This allows for investigations of complex interactions between members of a certain peer group, or serves as an economical way of stressing larger numbers of individuals within a brief period of time.

A "Placebo" Version of the TSST

When stressing individuals with the TSST, the researcher might want to differentiate between the specific effects of the social-evaluative stress ("distress") and the effort component involved (orthostatic responses, speech-induced physiological changes etc.). A simple no-intervention control session cannot provide such information. It is therefore required to contrast the TSST induced subjective and biological responses with responses observed under similar setting and effort conditions, however, without a distress component. Such a "► placebo" version of the TSST has been published most recently (Het et al. 2009).

Trimipramine

Definition

Trimipramine is a ► tricyclic antidepressant with atypical pharmacological properties. Trimipramine produces moderate enhancement of noradrenergic (NA), serotonergic (5-HT), and dopaminergic (DA) transmission by inhibiting reuptake of the neurotransmitters. It is also a potent antagonist of 5-HT_2 and α_1 adrenergic receptors. In addition to its antidepressant properties, trimipramine also has sedative-hypnotic and anxiolytic effects. Furthermore, due to its moderate effectiveness as a D_2 dopamine receptor antagonist, trimipramine has been evaluated as an ► atypical antipsychotic with some limited clinical effectiveness.

Clinically observable antidepressant effects of trimipramine usually become noticeable after 10 days to 4 weeks of treatment. Trimipramine has strong anticholinergic and anti-adrenergic side effects, including dry mouth, sweating, hypotension, and arrhythmias, as well as other effects such as fatigue, dizziness, drowsiness, confusion (especially in the elderly), anxiety, nightmares, increased appetite and, more rarely, hypomania, seizures, delirium, and hematological and hepatic problems.

As with other antidepressants, abrupt termination of therapy triggers withdrawal symptoms, including rebound depression, anxiety, insomnia, or mania.

Trophic Factors

Definition

The original definition of trophic (from the Greek) is "to nourish." The definition has been expanded to the growth and sustenance of cells and tissues. In biology, the term factor refers to substances (of known or unknown molecular identity) displaying specific actions on specific tissues or cells. The term neurotrophic factor is presently applied to a large number of well-characterized substances with specific actions over cells (neurons and glia) of the peripheral and central nervous system. They are classified in families according to similar molecular characteristics and related biological actions.

Tryptamines

Definition

Tryptamine is the general chemical name for a substance that possesses a bicyclic indole nucleus with an ethylamine moiety attached to the indole 3-position. Within this broad definition, tryptamines may be substituted on the indole ring itself, on the ethylamine side chain, or on the amino group. Molecules with any or all of these types of substitutions would still be generically referred to as tryptamines.

Tryptophan

Definition

Tryptophan is one of eight essential amino acids required by humans; these substances cannot be synthesized by the organism and must therefore be supplied in the diet. Tryptophan is metabolized via the rate-limiting enzyme tryptophan hydroxylase to 5-hydroxytryptophan (5-HTP), which is in turn converted into the major neurotransmitter serotonin (5-hydroxytryptamine; 5-HT). ► Serotonin is broken down to the inactive metabolite 5-hydroxyindoleacetic acid (5-HIAA), but can also be metabolized further to the neurohormone ► melatonin. Tryptophan is sold as a dietary supplement and has been investigated as a mild ► hypnotic and as an adjunctive agent to enhance the efficacy of ► antidepressant drugs; studies of such uses have been inconclusive. In the early 1990s, tryptophan was implicated in the pathogenesis of eosinophilia–myalgia syndrome (EMS), a potentially disabling autoimmune reaction; subsequent investigation suggested that impurities introduced during a flawed manufacturing process

were responsible, although some authorities have held that tryptophan itself is also implicated.

Tryptophan Depletion

Dietary tryptophan depletion; Rapid tryptophan depletion

Definition

Acute tryptophan depletion (ATD) is a technique designed to investigate directly the effects of low serotonin levels in humans. Participants in ATD studies ingest an amino acid mixture that is devoid of tryptophan. This lowers brain tryptophan and, therefore, brain serotonin synthesis.

Principles and Role in Psychopharmacology

Principles of ATD

Ingestion of an amino acid mixture containing all the essential amino acids except for tryptophan induces protein synthesis. As tryptophan is incorporated into protein its level in the blood and tissues declines. Because brain tryptophan hydroxylase, the rate-limiting enzyme on the pathway from tryptophan to ► serotonin (5-hydroxytryptamine, 5-HT), is not normally saturated with tryptophan this results in a decline in serotonin synthesis. ATD was originally developed to investigate the symptoms associated with low brain serotonin levels. It has also been used in conjunction with drugs (and nonpharmacological treatments) to see effects of the drug that are reversed by ATD. Reversal of the effect suggests that normal serotonin function is an important component of the drug effect. The assumption behind the ATD method is that decreased synthesis of serotonin results in decreased release of serotonin from neurons, i.e., decreased serotonin function. This assumption remains untested but presumably the extent to which changes in serotonin synthesis will change release of serotonin depends in part on the firing rate of serotonin neurons, which may vary depending on the exact experimental conditions used. Therefore, the question of whether changes in serotonin synthesis lead to changes in serotonin function is too simplistic. The relevant issue is whether there are circumstances in which it is possible to demonstrate that ATD leads to changes in aspect of brain function that seem to be mediated by serotonin. Furthermore, because the coupling between serotonin synthesis and serotonin function is not necessarily the same in humans and experimental animals, studies on the effect of ATD on extracellular levels of serotonin in rodents may not be relevant to human studies.

Methodology of ATD

The principles, methodology, and results of ATD studies have been discussed in a number of reviews (Hood et al. 2005; Neumeister 2003; Young and Leyton 2002). The most commonly used amino acid mixture is that of Young et al. (1985), which is based on the amino acid content of human milk (and therefore presumably optimized for human consumption) and contains 100 g of amino acids. The control mixture is usually the same except for the addition of 2.3 g L-tryptophan. Both control and active mixtures contain no ► glutamate, glutamine, aspartate, or asparagine to reduce the size of the mixture and to avoid any potential adverse effects of the ingestion of large quantities of these free amino acids. As they are not essential amino acids, this should not alter the ability of the tryptophan deficient mixture to lower tryptophan levels. Some researchers have used mixtures that omit more of the nonessential amino acids, while some have used 50 g of amino acids in the same proportion as in the 100 g mixture. The 102.3 g control amino acid mixture will tend to lower brain tryptophan levels somewhat, like most proteins, because it has lower levels of tryptophan than of the other large neutral amino acids that tend to inhibit tryptophan uptake into brain. While this could be seen as an advantage, as it is a conservative control, some researchers have used control mixture with higher tryptophan levels. There is little evidence from direct comparisons of different methods on the advantages and disadvantages of the various depletion and control mixtures.

Plasma tryptophan reaches its lowest level in about 5 h after amino acid mixture ingestion and experimental measures are usually performed 4–7 h after mixture ingestion. Depletions of plasma tryptophan are normally in the range 70–90%, with even greater lowering of serotonin synthesis as measured by positron emission tomography. Depletion of tryptophan is usually greater in women than in men. How large the depletion needs to induce

changes in mood is not clear, but the decline in plasma tryptophan probably needs to be more than 50% (Booij et al. 2002).

Effects of ATD

The majority of ATD studies have noted effects on mood, behavior, and cognition in drug-free participants. ATD has a wide range of effects on mood, depending on the characteristics of the participant undergoing the procedure. In general, effects are greater in those with a greater susceptibility to ▶ depression. For example, healthy never depressed males usually show no change in mood, but healthy never depressed males with a family history of depression show a modest lowering of mood. In keeping with the greater incidence of depression in women than in men, healthy never depressed women sometimes (but not always) show a modest lowering of mood. Formerly, depressed patients off medication occasionally show a dramatic lowering of mood into the clinical range that resolves quickly at the end of the study once brain serotonin synthesis is normalized. Effects in such patients are more likely to be seen with recurrent depressive episodes, female gender, and previous suicidal ideation or attempts. There is some evidence that supports the idea that the magnitude of the effect on mood after ATD may be a predictor of future depression, but more research is needed on this topic. Overall, studies in drug-free individuals suggest that low serotonin can contribute directly to lowered mood, but that it is not sufficient by itself to lower mood. The other neurochemical factors contributing to a susceptibility to lowered mood after ATD are not known.

Effects of ATD on ▶ anxiety in health individuals, when seen, are smaller than those on mood. ATD has no effect on untreated patients with panic disorder and has minimal effect on the response to panicogenic treatments. In keeping with the large animal literature showing that low serotonin increases ▶ aggression, ATD has been shown in several studies to increase the response in laboratory tests of both aggression and impulsivity. Results of the effect of ATD on cognition have not always been consistent, but there is some consistency in the findings that ATD has adverse effects on aspects of memory, particularly memory ▶ consolidation, while it can improve focussed ▶ attention. Effects on cognition have been seen in the absence of effects on mood.

ATD has been used to investigate the role of serotonin in a variety of ▶ antidepressant treatments. In newly recovered depressed patients who are on serotonin reuptake inhibitors, the majority of patients showed a marked lowering of mood, similar to that when they were depressed, which resolves when their serotonin synthesis is normalized. No such effect is seen in patients on norepinephrine reuptake inhibitors. These results suggest that, in the short-term, maintenance of serotonin function is necessary component of the antidepressant action of serotonin reuptake inhibitors, but not norepinephrine reuptake inhibitors. In a small number of studies ATD also reversed the antidepressant effect of bright light therapy and ▶ monoamine oxidase inhibitors, but not that of ▶ tricyclic antidepressants, lithium, electroconvulsive therapy, and cognitive therapy. While ATD reverses the therapeutic effect of serotonin reuptake inhibitors in patients with depression, results in anxiety disorders are not as clear-cut. ATD can enhance the response to panicogenic agents in patients with panic disorder who are on serotonin reuptake inhibitors, and reverse the therapeutic effect in patients with social anxiety disorder. It does not cause greater obsessive or compulsive symptoms in patients with ▶ obsessive-compulsive disorder (OCD), who have responded to treatment with a serotonin reuptake inhibitor. On the other hand, such patients may show lowered mood or enhanced anxiety, raising the possibility that the therapeutic effect of serotonin reuptake inhibitors in OCD may be due in part to effects on mood and anxiety rather than directly on the core symptoms of OCD.

Other studies have used ATD to look at the role of serotonin in the action of a variety of different drugs. The number of these studies is small and results must be considered tentative. ATD has little effect on symptoms in patients with ▶ schizophrenia treated with ▶ neuroleptics. It decreased the cocaine-induced high and desire for cocaine suggesting that serotonin release has a role in the action of ▶ cocaine. It blocked the analgesic effect of morphine in response to the cold pressor test in participants, who had not taken ▶ morphine previously. However, the relevance of this to a role for serotonin in the clinical analgesic effects of morphine are not clear. Finally, ATD decreases the release of prolactin in response to the serotonin releaser, ▶ fenfluramine, suggesting that fenfluramine releases primarily newly synthesized serotonin.

Ethical aspects of ATD

Given that low serotonin is associated with depression, aggression, and ▶ suicide, participants in ATD studies need to be monitored carefully. At the end of an ATD study, serotonin levels of participants should be restored to normal as quickly as possible. This is best done by administration of tryptophan, but has been done more often by allowing participants to eat high protein foods. In a study of ATD in recovered depressed patients, some of whom re-experienced depressed mood, the participants

had a positive opinion of their participation in the study. Common views were that participation in the study had changed their perception of their illness, that the study had helped them to gain more insight and facilitated acceptance of being vulnerable and had made them realize how much they had improved during treatment (Booij et al. 2005).

Limitations of ATD

From the practical point of view one of the limitations of the ATD method is the unpalatability of the amino acid mixtures, which often results in nausea and sometimes vomiting. Various strategies have been adopted to reduce these symptoms, including adding strong flavors such as chocolate to the amino acid mixtures and putting the more unpalatable amino acids in capsules, but they do not eliminate the problem. From the theoretical point of view, a limitation is that relating any effect of ATD to lowered serotonin function involves two main assumptions. First, the effect seen is due to decreased release of serotonin; and second, other mechanisms do not contribute to the effect. Amino acid imbalance can alter aspects of brain function. However, the effects of ATD are unlikely to be due just to nonspecific effects of amino acid imbalance as (1) ► acute phenylalanine/tyrosine depletion causes somewhat different effects from ATD, and (2) in one study the effects on mood seen with ATD did not occur when a positive control mixture deficient in lysine was used (Klaassen et al. 1999). ATD will tend to lower the levels of tryptophan metabolites in addition to serotonin. These include tryptamine, ► melatonin, kynurenic acid, and quinolinic acid. While a contribution of these compounds to the effect of ATD cannot be ruled out, given that the effects of ATD are consistent with other research on the role of serotonin, effects of the other compounds are unlikely. Finally, an important limitation in extrapolating from ATD studies to the role of low serotonin in psychopathology, or to the role of serotonin in drug effects, is the short duration of the effect of ATD on serotonin. Longer-term depletion of serotonin through repeated administration of amino acid mixtures is not advisable due to the effects such a strategy would have on protein synthesis and amino acid metabolism.

Two-Dimensional Gel Electrophoresis

Synonyms

2-DE; 2-D Electrophoresis; Gel electrophoresis

Definition

Two-dimensional gel electrophoresis is based on the separation of proteins in two dimensions based on differences in isoelectric point (pI), and size (molecular weight, Mw). The first dimension, isoelectric focusing (IEF), is usually performed using individual drystrips with immobilized pH gradients (IPG). A number of different pH ranges are available from wide range strips to more narrow-range drystrips. The second dimension in 2-DE is a traditional sodium dodecyl sulfate-polyacrylamide electrophoresis (SDS-PAGE) separation. A wide variety of protein detection methods are compatible with 2-DE such as Coomassie Brilliant Blue, silver staining, and fluorescent staining.

Definition
A specialized system in the cell for regulating the protein composition of cells. Degraded, misfolded, or aberrant proteins are tagged by ubiquitylation for removal by digestion at the cytoplasmic 20/26S proteasome enzyme complex.

Ultrasonic

Definition
Refers to sound energies having a frequency above the human hearing range. The highest frequency that the human ear can detect is approximately 20 thousand cycles per second (20,000 Hz).

Attachment bonds have been proposed to underlie a variety of social relationships, for example, parent–infant, filial, and pair (male–female) bond formation. These are all typically characterized by preferential proximity seeking and all involve a response to separation. These forms of attachment appear to be common to many species including humans, suggesting that the neural basis can be investigated in animal models. Emerging evidence suggests that the biology of attachment in its many forms may also be similar across species.

Ultrasonic Vocalizations

Definition
Ultrasound is a sound with a frequency greater than the upper limit of human hearing, which is approximately 20 kHz (20,000 Hz). Adult rats emit two types of ultrasonic calls: alarm (22 kHz) calls, in aversive and dangerous situations, and appetitive (50 kHz) calls, in appetitive or nonaggressive situations. Both mouse and rat pups emit high-frequency separation/distress calls when separated from their mothers. Adult mice produce ultrasonic vocalizations during nonaggressive situations, particularly during mating. These vocalizations can facilitate or inhibit social interactions.

Uptake

Definition
Uptake or reuptake consists in the reabsorption of a neurotransmitter by a transporter located on a presynaptic neuron, or another cell, after it has performed its function of transmitting the signal. Reuptake is necessary for normal functioning because it regulates how long a signal lasts, allowing the recycling of neurotransmitters, and regulating its normal levels in the releasing cell. The uptake process can be experimentally assessed as the incorporation of radiolabeled neurotransmitter by the target cell.

Vaccination

Synonyms

Active immunization

Definition

Repeated administration of an immunogen (e.g., vaccine) to the subjects being studied in order to stimulate the immune system to produce drug-specific antibodies. Primary advantages of vaccination are that it requires relatively few administrations to achieve high serum antibody concentrations that can persist for several months and it is relatively inexpensive. The main disadvantages are the delay (1–2 months) to reaching effective serum antibody concentrations and the inability to precisely control those concentrations. Marked variability in antibody concentrations is observed between subjects, with some not achieving required levels.

Immunotherapy

Definition

In the context of psychopharmacology, vaccines are drug–protein conjugates that stimulate a subject's immune system to produce drug-specific antibodies that can bind a drug of interest and alter its pharmacokinetics.

Pharmacological Properties

Background

Vaccines and drug-specific antibodies are currently being developed for the treatment of ► drug abuse. Most pharmacotherapies for drug abuse target the neuropharmacological processes that mediate a drug's dependence-related behavioral effects by binding to associated receptors in the CNS (► Nicotine dependence and its treatment, ► Opioid Dependence and its treatment). In contrast, vaccines target the drug itself rather than the brain. Vaccines elicit the production of drug-specific antibodies that bind drug in blood and reduce its distribution into the brain. By acting outside the brain, a primary advantage of vaccines is that they lack the CNS side effects associated with CNS receptor-based pharmacotherapies that can alter normal neural function.

Immunologic interventions such as ► vaccination or ► passive immunization were first suggested as a pharmacologic approach to treating drug abuse over 30 years ago, when it was shown that immunization against ► heroin could reduce the self-administration of the drug in monkeys (Bonese et al. 1974). Since then, vaccines and drug-specific antibodies that are effective in modifying the ► pharmacokinetics and behavioral effects of a wide range of drugs of abuse in animals have been developed, and vaccines against ► cocaine and ► nicotine are currently in clinical trials (Kosten and Owens 2005; Orson et al. 2008; Pentel et al. 2007).

Mechanisms of Action

Drugs of abuse act as reinforcers, and the pharmacokinetic properties of drugs are key determinants of their reinforcing effects (► Operant behavior in animals, ► Pharmacokinetics). The concentration of drug in the brain and the rate at which drug enters the brain are directly related to the strength of its subjective and reinforcing effects. In addition, the rate of elimination of drug is inversely related to the duration of its subjective and reinforcing effects. Vaccines and drug-specific antibodies target these key pharmacokinetic processes.

Ian P. Stolerman (ed.), *Encyclopedia of Psychopharmacology,* DOI 10.1007/978-3-540-68706-1,

The antibodies produced by vaccination against a given drug contain binding sites for that drug. In a vaccinated subject, these drug-specific antibodies are present in the bloodstream and extracellular fluid, but excluded from the brain because they are too large to cross the ► blood–brain barrier. When a vaccinated subject receives the drug, a substantial fraction of the drug is bound to antibody, sequestered in blood, and prevented from entering the brain. The binding of drug in serum also attenuates the normally rapid rise in brain concentrations of drug. In addition, the binding of drug by antibody may make it less available for elimination and prolong its elimination half-life (Orson et al. 2008; Pentel et al. 2007). Slower elimination may be a beneficial effect in some circumstances, as it has been associated with reduced cigarette smoking and enhanced smoking cessation rates.

The efficacy of a vaccine depends upon three key variables: the serum concentration, affinity, and specificity of the elicited antibodies. Because higher ratios of antibody to drug result in greater binding of drug in serum, vaccines must elicit high serum concentrations of antibody to be maximally effective. Higher affinity (strength of binding to drug) increases the bound fraction of drug. Specificity refers to the extent to which the antibodies bind the drug in preference to other compounds. Greater specificity reduces competition from other compounds (e.g., metabolites, endogenous compounds) for antibody-binding sites and reduces the likelihood of adverse side effects. However, in cases where the metabolites of a drug contribute to its behavioral effects (e.g., ► methamphetamine, heroin), antibodies that cross-react with those metabolites would be advantageous.

Although vaccines and receptor antagonists can produce similar attenuation of a drug's behavioral effects, they should not be considered analogous. Receptor ► antagonists block the binding of endogenous compounds (e.g., dopamine, acetylcholine) to receptors, while antibodies do not. In addition, drug-specific antibodies can have the additional effect of increasing the ► elimination half-life of drug, while receptor antagonists do not.

Formulation

Because drugs are typically too small to elicit an immune response, they are rendered immunogenic by linking the drug itself or a structurally related compound (i.e., hapten) through a short linker to an immunogenic carrier protein to form the complete immunogen, which is referred to as a conjugate vaccine. To enhance the immune response, these vaccines are typically combined with an adjuvant such as alum. Carrier proteins are foreign (nonhuman) proteins (Kosten and Owens 2005; Orson et al. 2008), but virus-like particles have also been used (Maurer et al. 2005).

Administration

Initial vaccination schedules in both animals and humans typically involve 2–6 injections at 2–4 week intervals. Periodic booster doses are then needed to maintain satisfactory antibody levels since exposure to the drug by itself, which is not the complete immunogen, does not elicit a booster response (Hatsukami et al. 2005; Martell et al. 2005; Maurer et al. 2005; Orson et al. 2008).

Animal Models

Pharmacokinetics: The effects of immunologic interventions on drug pharmacokinetics are generally similar across different drugs (Kosten and Owens 2005; Orson et al. 2008; Pentel et al. 2007). In rodents, vaccines or drug-specific antibodies produce increases in serum drug concentrations due to the binding and retention of drug in serum, and reduce brain concentrations of cocaine, ► phencyclidine, methamphetamine, morphine, and nicotine following an acute administration of clinically relevant doses. Importantly, some studies have shown that the early distribution of an acute dose to the brain continues to be reduced or slowed during chronic drug administration, even when total drug exposure exceeds the binding capacity of the antibodies (Kosten and Owens 2005; Pentel et al. 2007). This finding suggests that the initial subjective and reinforcing effects of a drug could still be suppressed in the context of ongoing drug use. Finally, immunization can markedly prolong the ► elimination half-life of some drugs because antibody binding restricts elimination to the unbound fraction of drug. For example, immunization can produce a twofold to sixfold increase in the half-life of nicotine and morphine in rats and rabbits, respectively (LeSage et al. 2008; Orson et al. 2008).

Behavioral effects: Animal studies have shown that vaccines and drug-specific antibodies can significantly reduce the behavioral effects of the aforementioned drugs in a wide range of behavioral assays, including seizure induction, acute locomotor activation, development of locomotor sensitization, responding under simple operant schedules of food delivery, and ► drug discrimination. Active or passive immunization against cocaine, methamphetamine, nicotine, and heroin have also been shown to attenuate the acquisition, maintenance, and reinstatement of self-administration of these drugs, which are key animal models of drug use and relapse in humans (► Reinstatement of drug self-administration, ► Self-administration of drugs, ► Addictive disorder: animal models, ► Operant behavior

in animals) (Kosten and Owens 2005; LeSage et al. 2008; Orson et al. 2008). Immunization can also decrease the ability of drug to relieve withdrawal symptoms that occur upon the cessation of drug exposure, yet it has not been found to elicit withdrawal signs when initiated during chronic drug administration (► withdrawal syndromes) (LeSage et al. 2008; Lindblom et al. 2005).

Clinical Trials

Immunogenicity and Safety: Clinical trials have been conducted with three nicotine conjugate vaccines (NicVax, NicQb, and TA-NIC) and one cocaine conjugate vaccine (TA-CD) (LeSage et al. 2008; Orson et al. 2008) (► Randomized controlled trials). Phase I/II trials have shown that these vaccines elicit drug-specific antibodies in a dose-dependent fashion, with marked variability between participants. All vaccines have been well tolerated with no serious adverse events. Antibody levels decrease slowly after the last vaccine injection of the initial immunization period (e.g., 50% decline over 6–8 weeks), but increase again when a booster dose is administered.

Potential Efficacy: Although no Phase III trials have been conducted to rigorously assess the efficacy of vaccination for nicotine or cocaine addiction, the Phase I/II trials mentioned earlier included drug use as either a primary or secondary endpoint to provide the preliminary assessment of efficacy. In general, these trials have shown increased abstinence and reduced drug use in participants receiving the highest vaccine dose or exhibiting the highest antibody levels (LeSage et al. 2008; Orson et al. 2008). Importantly, neither withdrawal symptoms nor compensatory increases in drug use to surmount the effect of vaccination have been reported (Hatsukami et al. 2005).

Conclusion

Taken together, both preclinical and clinical studies suggest that vaccines could have utility in the treatment of drug addiction. However, the lack of control over antibody levels and large variability between subjects is the primary limitation of all current vaccines. Because achieving the highest antibody levels possible will be essential to maximizing the efficacy of vaccination, methods of boosting immunogenicity need to be developed in order to address this issue. Toward this end, vaccine formulations that contain novel haptens, different adjuvants and/or carrier proteins, multivalent vaccines (simultaneous administration of two or more distinct drug–protein conjugates), and combinations of vaccination with passive immunization are being explored (Keyler et al. 2008; Kosten and Owens 2005). Although not explicitly tested, vaccines would not be expected to directly reduce drug ► craving or withdrawal, since these occur when drug levels are already low or absent. Combining vaccination with medications that address craving and withdrawal might therefore enhance their efficacy.

Definition
A simple branched-chain carboxylic acid that possesses antiseizure and mood-stabilizing properties is rapidly absorbed after oral administration, and exhibits 90% binding to plasma proteins, hepatic metabolism, and a half-life of approximately 15 h.

Valproic acid is used for the treatment of convulsions, migraines, and acute manic or mixed episodes associated with psychiatric disorders. Valproate exerts its effects by increasing the concentration of gamma-amino-butyric acid (GABA) through inhibition of enzymes catabolizing GABA: transferase and succinic aldehyde dehydrogenase. Valproic acid is also a histone deacetylase inhibitor, a property that might be responsible for its teratogenic effects. The side effects due to valproic acid include liver injury, pancreatitis, abnormal bleeding, and birth defects, drowsiness, dizziness, nausea, vomiting, indigestion, diarrhea, weight loss, and tremors. If taken during pregnancy there is a risk of harm to the offspring.

Definition
Varenicline is a nicotinic partial agonist developed specifically as a smoking cessation agent. As a partial agonist, it reduces ► cravings for and decreases the pleasurable effects of cigarettes and other tobacco products, and also attenuates effects of nicotine obtained by smoking. Through these mechanisms, it can assist some patients to quit smoking, where its efficacy appears greater than that for nicotine replacement therapies. Its primary action as a ► partial agonist is on the $\alpha4\beta2$ subtype of the ► nicotinic acetylcholine receptor. In addition, it acts on $\alpha3\beta4$ and weakly on $\alpha3\beta2$ and $\alpha6$-containing receptors. A full agonist effect has also been shown on $\alpha7$-receptors. Nausea occurs commonly in people taking varenicline. Other less-common side effects include headache, difficulty in sleeping, and abnormal dreams. Rare side effects reported by people taking varenicline compared to placebo include change in taste, vomiting, abdominal pain, flatulence, and constipation. There has been some concern about more serious neuropsychiatric symptoms.

Verbal and Non-Verbal Learning in Humans

Joachim Liepert

Synonyms
Associative learning; Motor learning; Novel word learning

Definition
Learning is the acquisition of a new ability. The most relevant areas are knowledge, behavior, and skills. In this chapter, non-verbal learning mainly focuses on motor functions and how this learning can be influenced by psychoactive drugs in health and disease. Verbal learning explicitly focuses on the use of language and how our ability to learn and recall new words is modified by psychoactive drugs.

Impact of Psychoactive Drugs

One major aspect of learning is the ability to encode and recall new material or a new function. A neurobiological correlate of learning and memory is ►long-term potentiation (LTP). In LTP, ►synaptic plasticity is evoked by repeated and synchronized firing of pre- and postsynaptic neurons. Thus, all substances that induce or enhance LTP might support or augment learning capacities. Several lines of evidence suggest that ►glutamate metabolism and in particular *N*-methyl-D-aspartate (NMDA) agonists facilitate LTP induction.

Animal experiments have also indicated other neurotransmitters that are presumably involved in learning. For example, in rats the acquisition of motor skills is improved by noradrenergic substances. Lesions of dopaminergic neurons can produce cognitive deficits and impair attentional processes which are relevant for learning abilities.

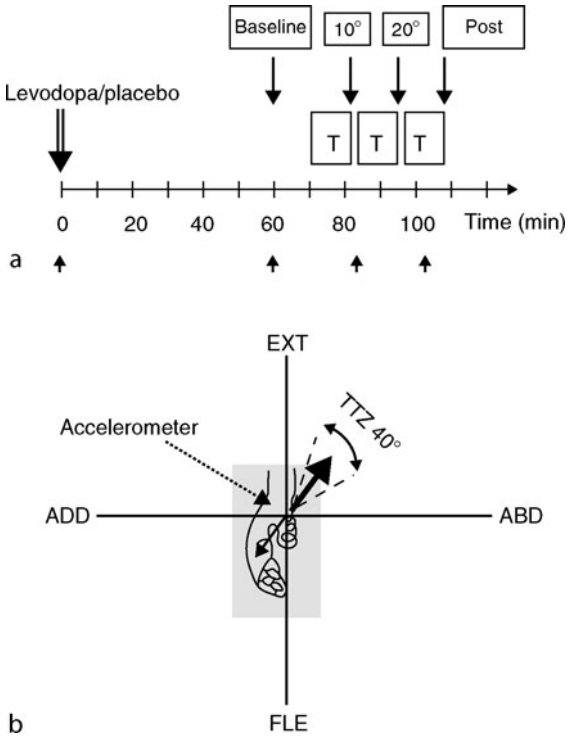
In some learning paradigms, e.g., the serial reaction time task, it is possible to follow the process of learning and to detect the development of implicit and explicit knowledge. In most paradigms, however, it is rather tested whether learning had occurred and whether the application of a psychoactive drug had been able to speed up the learning process or the amount of what had been learnt.

Non-Verbal Learning in Humans

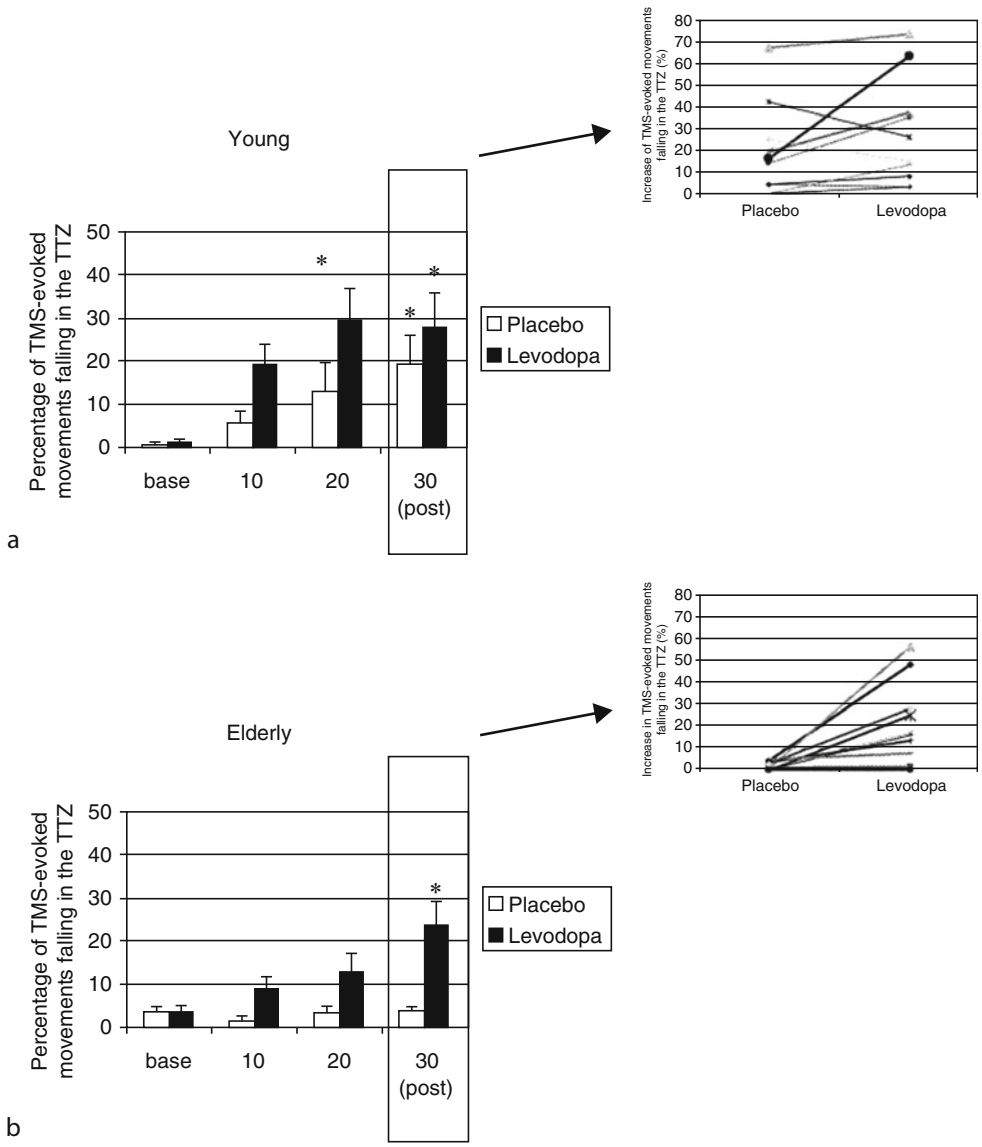
Dopaminergic Drugs

Healthy Subjects The application of a single dose of ►levodopa (100 mg) was able to improve a training-induced motor memory. The task consisted of practising of thumb movements in a different direction than thumb movements evoked by transcranial magnetic stimulation (TMS). After the training period, TMS induced thumb movements in the new, practised direction. In young subjects, the encoding process of this movement was accelerated by levodopa. Elderly subjects performed worse in this task but improved their motor memory encoding by intake of levodopa to levels present in younger subjects (Flöel et al. 2005a; Figs. 1 and 2). Presumably, older subjects have a subclinical dopaminergic deficit per se. Application of 300 mg levodopa induced a small, but significant improvement of motor functions even without training. This effect was only seen in elderly, but not in young subjects. In a study that used a tactile coactivation protocol to induce non-associative learning in the somatosensory system, tactile two-point discrimination was only improved after placebo, but not after levodopa application, suggesting that a potential beneficial effect of levodopa in the motor system is not necessarily generalized to other systems.

Patient Groups In stroke patients, several studies using multiple or single doses of levodopa have been published.



Verbal and Non-Verbal Learning in Humans. Fig. 1. (**a**) Experimental design. L-Dopa/placebo was administered at time 0 in each session, followed by determination of transcranial magnetic stimulation (TMS)-evoked thumb movement directions at baseline (60 min after drug intake) and after 10, 20, and 30 (post) min of training (*downward arrows*). Training consisted of three blocks of brisk thumb movements performed at 1 Hz in the direction opposite to the baseline TMS-evoked thumb movement direction (*T*). Fatigue, attention towards the training task, blood pressure, and heart rate were assessed four times during the experiment (*upward arrows*). (**b**) Diagram showing measurement of thumb movements with an accelerometer positioned on the distal interphalangeal joint (rectangle on the thumb). Baseline TMS-evoked thumb movements in this example fell in a flexion-adduction direction (*thin solid arrow*). Training voluntary thumb motions were performed in the opposite direction (extension-abduction, *thick solid arrow*). At the end of the training period, we measured the percentage of TMS-evoked thumb movements falling in the training target zone (TTZ), the end point measure of the study. (From Flöel et al. 2005a.)



Verbal and Non-Verbal Learning in Humans. Fig. 2. Percentage of ► transcranial magnetic stimulation (TMS)-evoked thumb movements falling in the training target zone (TTZ) in young (**a**) and elderly (**b**) healthy volunteers. In young subjects (**a**), training under placebo led to a progressive increase in TMS-evoked thumb movements falling in the TTZ that became significant after 30 min (A, 30 min [post], *white bar*). L-Dopa + training accelerated the development of this form of plasticity, which became significant after only 10 min of training (A, 10 min, *black bar*). In elderly subjects (**b**), consistent with previous results, training under placebo did not induce changes in TMS-evoked thumb movements falling in the TTZ (B, 30 min [post], *white bar*). L-Dopa + training substantially enhanced the response to motor training, which became significant after 30 min (B, 30 min [post], *black bar*), and that was comparable in magnitude with that identified in younger subjects under placebo and L-dopa (A, 30 min [post], *black* and *white bars*). Note that this effect was evident in five of the seven elderly subjects tested (inset). To illustrate the percentage change in the training + L-dopa versus the training + placebo condition, we summarize the mean change for each subject in each condition in the above insets (A, young; B, elderly). *$p < 0.05$. (From Flöel et al. 2005a.)

Results are inconsistent. In one study with repeated intake of 100 mg levodopa per day for 3 weeks, patients improved in their motor functions significantly stronger than the placebo group. This higher level of performance persisted even after termination of the drug intake period (Scheidtmann et al. 2001). However, a more recent ▶ placebo-controlled study with application of 100 mg levodopa per day for 2 weeks did not demonstrate a superiority of levodopa. Single doses of levodopa were effective in the encoding of a motor memory and in improving procedural motor learning (serial reaction time task) (Flöel et al. 2005b) but did not modulate more clinical aspects of motor functions (dexterity and strength) (Liepert 2008).

Undoubtly, levodopa reduces motor symptoms in patients with ▶ Parkinson's disease (PD). Astonishingly, its effects on cognitive functions and learning abilities are questionable and have even been shown to be detrimental. For example, PD patients treated with levodopa deteriorated in visual memory functions and motor sequence learning. It was suggested that levodopa effects depend on task demands and basal dopamine levels in distinct parts of the striatum.

Methylphenidate produces an increase in dopamine signalling through multiple actions. A trial with 21 subacute stroke patients indicated that the combination of ▶ methylphenidate with physical therapy over a period of 3 weeks improved motor functions and decreased depression. In patients with traumatic brain injury, the drug improved the speed of mental processing and had some effect on tests of ▶ attention and motor performance.

Noradrenergic Drugs

Healthy Subjects The noradrenaline re-uptake inhibitor ▶ reboxetine improved motor skill acquisition in a velocity-depending motor task (Plewnia et al. 2004).

D-amphetamine modulates not only noradrenergic, but also dopaminergic and serotonergic neurotransmission. In a paradigm with training of voluntary thumb movements, ▶ D-amphetamine facilitated use-dependent plasticity. However, in another study, the administration of D-amphetamine did not improve sensory functions in a tactile frequency discrimination training. There is some evidence that D-amphetamine exerts its effects in cognitive rather than motor networks. For example, D-amphetamine improved performance of ▶ selective attention tasks.

Patient Groups In chronic stroke patients, a single dose of reboxetine improved tapping speed and grip strength in the paretic but not in the non-affected hand.

Studies with D-amphetamine in stroke patients are inconclusive. In two studies, drug effects on motor recovery were found. In subsequently performed studies (n = 6), these positive results could not be replicated. A Cochrane review summarized that it is currently impossible to draw any definite conclusions about the potential role of D-amphetamine in motor rehabilitation (Martinsson et al. 2007).

Serotonergic Substances

Healthy Subjects There are no studies with serotonergic drugs for enhancement of learning in healthy subjects available.

Patient Groups The serotonin re-uptake inhibitor ▶ fluoxetine improved walking and activities of daily living in a group of subacute stroke patients. In eight chronic stroke patients, a single dose of fluoxetine improved motor functions of the affected hand. In another study, the more selective serotonin re-uptake inhibitor ▶ citalopram was used in chronic stroke patients. A single dose of citalopram was able to improve dexterity but not strength in the paretic hand. The effect was pronounced after 1 h of physiotherapy aimed at improving hand function (Zittel et al. 2008; Fig. 3). Taking these three studies together, results seem promising but one has to consider that only a very limited number of subjects have been studied so far.

Cholinergic Substances

This group mainly includes drugs that act as inhibitors of the enzyme acetylcholinesterase. This increases the amount of ▶ acetylcholine. Such drugs have been successfully tested in ▶ dementia and are recommended for patients with mild to moderate Alzheimer's disease.

Healthy Subjects In elderly healthy subjects, ▶ rivastigmine improved motor learning and visuospatial processes. In contrast the ▶ anticholinergic agent biperiden impaired these abilities. In another study ▶ donepezil was applied in elderly subjects and improved their memory performance. In addition, ▶ rapid eye movement (REM) sleep was enhanced, and the positive correlation between memory function and REM sleep duration suggested an interrelationship between these two factors.

Patient Groups There is only limited evidence regarding beneficial effects of ▶ acetylcholinesterase inhibitors in ▶ stroke patients. One case study and one ▶ open-label pilot study suggest that these drugs may enhance the recovery of motor functions, in particular in cognitively

impaired stroke patients. One study combining the application of donepezil with constraint-induced movement therapy only showed a trend towards stronger improvement in the drug-treated group.

Modafinil

This wake-promoting drug is approved for application in patients with abnormal sleepiness, e.g., ▶ narcolepsy and sleep disorders of shift workers. Some studies also suggest that it is helpful in patients with multiple sclerosis suffering from fatigue. A recent study demonstrated that ▶ modafinil blocks ▶ dopamine transporters and increases dopamine in the human brain.

Healthy Subjects Studies in healthy subjects are inconclusive. One study reported a drug-related improvement of several cognitive abilities including digit span, visual pattern recognition memory, spatial planning, and ▶ stop-signal reaction time. Another study suggested an effectiveness in monotonous ▶ working-memory tasks, in a third study modafinil was found to be equal to placebo regarding reaction time, dexterity and the d2 test.

Patient Groups In patients with ▶ Huntington's disease, modafinil increased alertness but did not improve cognitive functions. In contrast, deleterious effects on visual recognition and working memory were observed. In schizophrenic patients, improvements of ▶ executive functions and ▶ attention were found.

Verbal Learning

Dopaminergic Substances

Healthy Subjects Single doses of 100 mg levodopa improved verbal learning in young healthy subjects. Learning occurred faster and more successful, and the long-term retention of novel word learning was better than in the placebo-treated control group (Knecht et al. 2004; Fig. 4). A comparison between application of levodopa, D-amphetamine and placebo indicated a similar efficacy of levodopa and D-amphetamine and the superiority of both drugs compared to placebo. In contrast to beneficial effects of levodopa, the dopamine-receptor agonist ▶ pergolide impaired novel word learning. The authors suggested that this finding can be explained by the tonic dopaminergic effects produced by pergolide. Due to a much shorter ▶ half-life, levodopa rather exerts a phasic dopaminergic stimulation. Phasic stimulations might be more effective for associative learning.

Patient Groups A very recent ▶ placebo-controlled study in stroke patients indicated that levodopa induced a greater improvement of verbal fluency and repetition than ▶ placebo. This positive effect was particularly obvious in patients with frontal lesions.

▶ Bromocriptine, a dopamine-receptor agonist, has yielded inconclusive results. In one study, reading-comprehension, repetition, dictation and verbal latency

In addition, also shown are results in the subgroup (n = 10) receiving relatively higher doses of L-dopa because their body weights were below the group median. improved in chronic stroke patients with non-fluent aphasia, However, in another study bromocriptine was not superior to placebo in stroke patients with non-fluent aphasia.

Some preliminary evidence coming from an open-label study with four patients indicated that ► amantadine might be effective in non-fluent speech.

Noradrenergic Substances

Healthy Subjects Several studies have demonstrated that D-amphetamine facilitates verbal memory performance, improves information processing and enhances new word learning. These effects were independent of drug-induced increases of blood pressure and heart rate. It seems that there is an individual optimal D-amphematine dose, since an inverted U-shaped relationship was observed between amount of D-amphetamine and working-memory processing efficiency. This suggests that high doses of D-amphetamine can even impair memory processing. Another factor that influences the results of D-amphetamine application is the cognitive performance at baseline. The drug was effective in individuals with a low working-memory capacity, but deteriorated performance in subjects with high working-memory capacity at baseline.

Patient Groups Two studies performed in stroke patients with aphasia suggested a beneficial effect of D-amphetamine. However, when patients were re-evaluated 6 months later, the effect was gone.

Cholinergic Substances

Healthy Subjects There are no studies that explicitly investigate the effect of cholinergic transmission on verbal learning.

Patient Groups In one study with 26 stroke patients, donepezil reduced the severity of aphasia and improved picture naming to stronger degree than placebo.

Piracetam

The mode of action is unknown, but there is some evidence that ► piracetam enhances glucose utilization and cellular metabolism in the brain.

Healthy Subjects There are no studies available that investigated piracetam effects on verbal learning.

Patient Groups Placebo-controlled trials in subacute stroke patients (n = 203) indicated that application of 4.8 mg piracetam daily reduced aphasic symptoms as

evaluated by the Aachener Aphasie Test (Greener et al. 2001). Treatment duration was at least 6 weeks. A positron emission tomography (▶ PET) study demonstrated increased activity in speech-relevant brain areas as the left transverse temporal gyrus, Wernicke's area and Broca's area in the piracetam group, but not in the placebo group.

Conclusions

Currently, evidence is limited regarding a positive effect of psychoactive drugs that enhance neurotransmission or support cell metabolism. In healthy subjects, the most convincing and most consistent studies were found for the improvement of cognitive function and verbal learning by D-amphetamine and levodopa. Results obtained in elderly healthy subjects might suggest that ageing per se is associated with a subclinical reduction of neurotransmission and that substitution of dopaminergic, cholinergic (and potentially also serotonergic) neurotransmission can be more beneficial than in young subjects.

In patients, acquisition of new abilities or re-acquisition of old abilities is more difficult. We do not know enough about the consequences of brain lesions, e.g., stroke or traumatic brain injury, on neurotransmission. Therefore, it is still unpredictable who might benefit from which type of enhancement of neurotransmission. Hopefully, brain imaging techniques will help to develop hypothesis-driven concepts of specific neuropharmacological interventions. Until then, one can recommend piracetam for treatment of post-stroke aphasia and levodopa for recovery of motor functions.

Definition
Voltage-clamp recording is an intracellular recording modality where the apparatus controls the voltage across the cell membrane by injecting current as to maintain it at a fixed "command" voltage level. The injected current is the mirror of the ionic current flowing across the membrane at any one time and thus allows for its direct measurement.

Voltage-Gated Calcium Channels

Synonyms
VDCC; Voltage-dependent calcium channels

Definition
Voltage-gated calcium channels (VDCC) are a group of ion channels that permit the influx of calcium under conditions of changes in voltage (depolarization of the membrane). These channels can be particularly important as the influx of calcium into the presynaptic cell may be required for the release of transmitter substance into the synaptic cleft. Chronic exposure to ► alcohol can cause an increase in the number of these channels (i.e., upregulation). Increasing the number of these channels can lead to an increased or prolonged duration of transmitter release, which may in turn lead to an increased hyperexcitability in the neural circuit.

Voltage-Gated Potassium Channels

Definition
Voltage-gated K_V channels represent large family of membrane ion channels that are selectively permeable to potassium ions. Activation of these channels by changes in membrane voltage produces membrane hyperpolarization to control action potential repolarization, frequency, and firing patterns.

Volume of Distribution

Synonyms

Apparent volume of distribution; V_D

Definition

The volume of distribution (V_D) is the fictitious (theoretical) volume, expressed in liter or in liter per kilogram, in which a drug would have been distributed by supposing that its concentration is homogeneous, that is, the average tissue concentration is identical to that of the plasma. It is expressed as V_D = dose/C0 (initial concentration). For example, after intravenous injection of 100 mg of a drug whose initial concentration, C0, in plasma is 10 mg/L, the V_D is of 10 L.

Wakefulness

Definition

In humans, wakefulness refers to a periodic state during which a person is conscious and aware of the world around him or her. This definition cannot be applied directly to animal subjects, but analysis of its physiological characteristics provides objective measures that can be translated into definitions applicable to rodents and other animals. In the rat, wakefulness is characterized and defined by the presence of low-voltage fast waves in the frontal cortex, a mixed theta rhythm (4–7 Hz) in the occipital cortex, and relatively high electromyographic activity.

Water Maze

Synonyms

Morris water maze

Definition

The water maze task, originally developed by Richard G. Morris is one of the most commonly used paradigms to assess ► spatial learning and memory in rodents. In the typical paradigm, a rat or mouse is placed into a pool of opaque water that contains an escape platform hidden below the water surface. Distal visual cues are placed around the pool that the animal uses to guide its search for the hidden platform. When released, the rat swims around the pool in search of an exit while various parameters are recorded, including the time spent in each quadrant of the pool, the time taken to reach the platform (latency), and total distance travelled. The rat's escape from the water reinforces its desire to quickly find the platform, and on subsequent trials the rat is able to locate the platform more rapidly. Rats and mice typically learn to find the platform in an efficient manner after relatively few trials. In the classic version that assesses long-term ► spatial memory, the location of the platform remains in one location over the duration of testing. A ► short-term memory variation has also been used, whereby the location of the platform changes each training day and animals display substantial reductions in escape latencies and path lengths from the first to subsequent trials. A control version of the task uses a visible platform, so that animals can solve the task without the use of distal spatial cues.

Definition

A withdrawal syndrome that can be characterized both at the behavioral and the physiological level occurs when the use of a psychoactive substance that has been taken, usually for a prolonged period of time and/ or in high doses, is either stopped or reduced. The onset and course of the withdrawal syndrome are time-limited and related to the type of substance and dose taken previously. A withdrawal syndrome is one of the indicators of a drug-dependent state, which is very often paralleled by drug ► tolerance, both being due to adaptations within the body and the brain.

Impact of Psychoactive Drugs

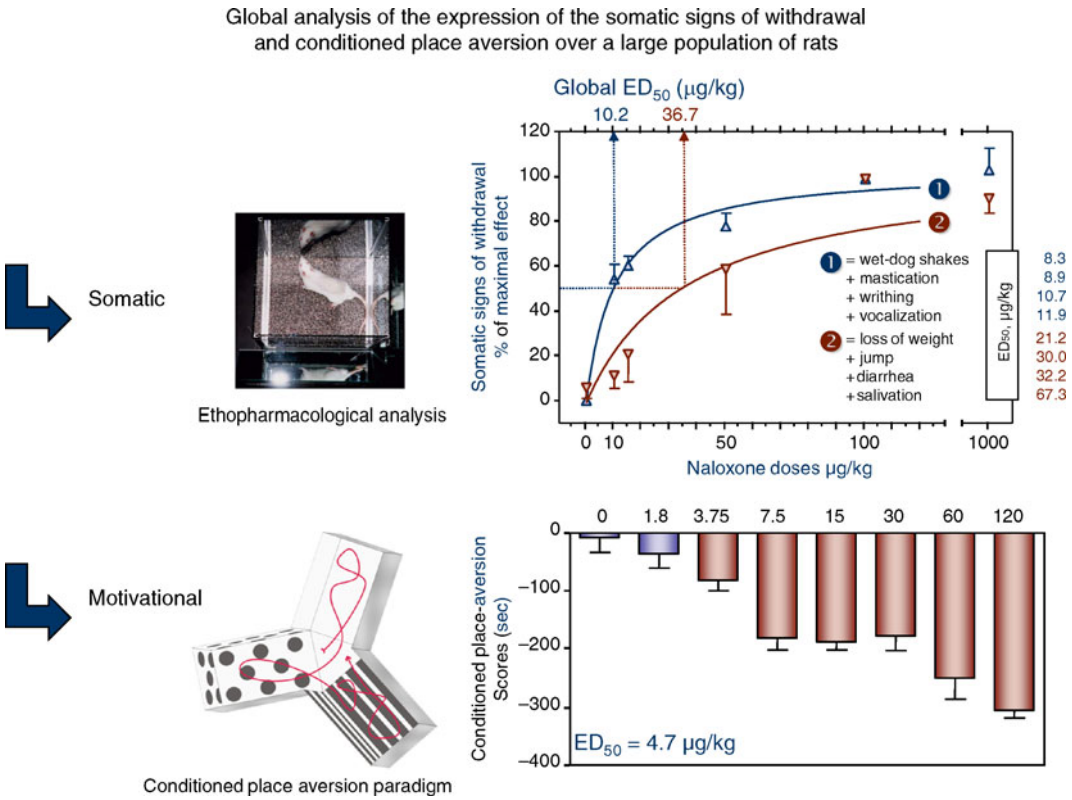
Withdrawal in Drug Addiction

Withdrawal is part of the ► drug addiction process and is a recurring feature of drug addiction because of the aversive state it engenders (► negative reinforcement theory). The symptoms defining withdrawal syndromes are rather well characterized in humans and appear in a time-dependent fashion (Jaffe 1990) depending on the drug being used (► heroin, ► cocaine, ► cannabinoids, ► nicotine, or ► alcohol). During the initial phase following drug discontinuation, a common feature for all drug abuse is that the individual is in a ► dysphoric state. No physical signs are observed at this stage though a strong motivation to use the drug again to relieve this discomfort is experienced. It has been suggested that drug withdrawal induces a motivational state that contributes to the maintenance of drug-taking behavior (Koob et al. 1989). If the drug is not provided, then as a continuum to the affective component of the withdrawal, several somatic symptoms of variable intensity emerge. In humans, the signs range from discomfort, ► anxiety, decreased appetite, sleep disorder, nightmares, irritability, nervousness, restlessness, sweating, aggressiveness, anger, shakiness, stomach pain, diarrhea and weight loss.

Animal models of drug dependence and drug withdrawal have been developed to study both the behavioral and the neurobiological targets of withdrawal. Usually animals are rendered dependent on a drug either through continuous exposure (► osmotic minipumps, ► drug pellets) or repeated exposure (non-contingent systemic administration or self-administered injections) to drugs such as morphine, heroin, cocaine, amphetamine, nicotine, alcohol, tetrahydrocannabinol (THC) or their analogs. A *spontaneous withdrawal* is observed when drug exposure is discontinued and the substance is slowly cleansed from the body. The signs of withdrawal appear quite slowly and become stronger as time passes, progressing from a negative affective state to the expression of somatic signs. A *precipitated withdrawal* is obtained through the administration of an ► antagonist of the receptors on which the drug acts (for instance ► naloxone for opiate dependence, ► mecamylamine for nicotine dependence, and CB1 receptor antagonist for THC dependence) though it should be mentioned that some cross-precipitation of withdrawal may occur (e.g., naloxone is able to induce both THC and nicotine withdrawal symptoms). When precipitated, the signs of withdrawal appear very rapidly and quite intensely due to the abrupt blockade of the receptors. Both affective and somatic components of withdrawal can be reproduced through the use of different doses of the antagonist (low doses induce only a ► negative affective state without somatic signs, whereas high doses induce somatic signs as well) (see Fig. 1 for an example of the different aspects of opiate withdrawal, depending on the dose of naloxone used).

Affective component of drug withdrawal: The negative affective component of withdrawal can be seen in various rodent behavioral models, including conditioned place aversion, conditioned suppression of operant response to food, increased threshold for intracranial self-stimulation, and anxiety measures. In ► the conditioned place aversion model (CPA), the negative affective state of withdrawal is repeatedly paired via ► classical conditioning with a specific environment. Subsequently, rats will avoid this environment and thus display conditioned place aversion, showing that the general negative affective state generated by withdrawal has been transferred to environmental stimuli (Frenois et al. 2005). Such conditioned stimuli have been shown to influence an animal's motivation towards the drug later on. The conditioned suppression model takes advantage of the interruption of an ► operant response (i.e., pressing a lever in order to obtain food). In this model, withdrawal is induced in dependent rats which are engaged in an operant response, and paired with the presentation of a stimulus (sound or odor for instance). The aversive state generated by acute precipitated withdrawal then interrupts the operant response. Thereafter, the simple presentation of this conditioned stimulus will also be able to interfere with the operant response. In the ► intracranial self-stimulation (► ICSS) model, animals learn to electrically self-stimulate a specific brain area – ► the medial forebrain bundle – until they reach a threshold of stable self-stimulation. In dependent rats, the induction of withdrawal produces an increase in *ICSS* thresholds, which is equivalent to a reduction in the ► reward sensitivity to the electrical stimulation of this brain area, indicating a withdrawal-induced ► dysphoric state. When withdrawal is paired with environmental stimuli, such stimuli are then able by themselves to generate an increase in ICSS thresholds. For instance, rats which were allowed to self-administer cocaine intravenously for prolonged periods of time showed elevated ICSS thresholds, the magnitude and duration of which were proportional to the amount of cocaine consumed. ► Anxiety and anhedonia are also components of early withdrawal: a decrease in time spent in the open arms of a ► plus maze or in the periphery of an ► open field has been repeatedly reported, as well as a decrease in the intake of natural rewards such as sucrose.

Physical component of drug withdrawal: The rating of the many physical signs of drug withdrawal in animals is based on the ethological quantification of a broad range of behaviors and somatic symptoms that may be very specific to the drug used. These rated behaviors may vary in intensity and quality depending on the drug used. The major signs in rodents are weight loss, jumping, writhing, body shake, diarrhea, teeth chattering, mastication, swallowing, salivation, chromodacryorrhea, ptosis, chewing, vocalization, eye twitches and rhinorrhea, scratching, facial rubbing, hunched posture, ataxia, irritability, abnormal motor responses, anxiety-like responses, decreased reward sensitivity, and seizures. For instance, opiate withdrawal symptoms are quantified by using the different scales found in the literature. According to the scale of Gellert and Holtzman (1978), some of these indices are quantified in a graded manner whereas others are quantal (either present or absent). Another method, the ethoscore described by Espejo et al. (1994) also makes it possible to obtain a global score for the appearance of somatic withdrawal signs, but is based only on the frequency of chewing and loss of weight. The scale of Gellert–Holtzman presents an asymptotic progression relative to increasing doses of naloxone (ceiling effect, see Fig. 1), whereas the ethoscore progresses linearly. Nicotine withdrawal symptoms are rated



Withdrawal Syndromes. Fig. 1. Global behavioral analysis of naloxone-precipitated opiate withdrawal. The upper panel (curves) shows the expression of two groups of somatic signs of withdrawal (means ± SEM) in response to naloxone injections at the following doses: 0, 10, 15, 50, 100 and 1,000 µg/kg. The first group is represented by the blue curve that fits the means of the signs showing an ED_{50} below 20 µg/kg (body shake, mastication, writhing, and vocalization). The second group is represented by the red curve that fits the means of the signs showing an ED_{50} above 20 µg/kg (weight loss, jumping, diarrhea, and salivation). The global ED_{50} values corresponding to the first and the second group of somatic signs were respectively 10.2 and 36.7 µg/kg. The lower panel (histogram) shows the expression of naloxone-induced conditioned place aversion using the following doses of naloxone during the conditioning phase: 0, 1.8, 3.75, 7.5, 15, 30 and 120 µg/kg. according to a scale designed by Malin et al. (1992). No scale exists for psychostimulants, as somatic symptoms from psychostimulants have not yet been reported.

Neural Circuits and Neurotransmitters Involved

The expression of a withdrawal syndrome is the consequence of neuroadaptations, which have been engendered by continuous/repeated drug exposure. These neuroadaptations can take place within the brain system on which the drug is acting directly (within system adaptations) and lead, for instance, to decreased or increased sensitivity and/or number of receptors, and increased or decreased release of the neurotransmitter, which activates these receptors endogenously. These neuroadaptations can also take place in systems different from the one on which the drug is acting directly (between system adaptations), which are often counteracting the drug effects. These within- and between-system adaptations might develop with very different kinetics and may follow one after the other. Some of them are directly responsible for the onset of the behavioral manifestations of withdrawal but others can be very long lasting and persist long after the drug is cleared and the overt signs of withdrawal have disappeared (Koob et al. 1989).

Using the different behavioral paradigms mentioned above, the neural substrates of withdrawal syndromes have been studied using different approaches such as brain site-specific injections of drug antagonist, c-fos imaging, and knockout mice (KO) for specific receptors. A brief

synthesis of the findings related to the neurobiological substrates of the withdrawal syndrome is given below.

Brain structures involved: One of the major findings related to drug withdrawal is the dissociation between the neural systems involved in the motivational and somatic components of withdrawal. In terms of brain structures, it has been shown that limbic structures encompassing the nucleus accumbens, amygdala, BNST and prefrontal cortex are involved in the negative affective part of withdrawal from drugs like opiates, cocaine, alcohol, and nicotine, whereas other structures such as the locus coeruleus and the periacqueductal grey (PAG) are involved in the somatic aspect of withdrawal. Using intracerebral injections of either ▶ opiate receptor antagonists (naloxone or methynaloxonium), ▶ nicotinic receptor antagonists (mecamylamine, and dihydro-beta-erythroidine), or ▶ cannabinoid receptor antagonists (SR141716A or AM251), negative affective states are produced and expressed, either by conditioned place aversion, increased anxiety, and increased threshold for ICSS (reviews, Koob et al. 1992 for opiates; Kenny and Markou 2001 for nicotine; Tanda and Goldberg 2003 for cannabinoids). However when the antagonists were injected in other structures such as the locus coeruleus (for opiates), somatic signs emerged even with low doses (Koob et al. 1992). These data were corroborated by c-fos imaging data showing that with low doses of antagonists, limbic structures were activated (among them the central nucleus of the amygdala has been shown to be activated with all drug withdrawal), whereas with higher doses leading to the expression of somatic signs, structures such as the locus coeruleus or PAG are activated (for example, see Frenois et al. 2005 for opiate withdrawal.).

Neurotransmitters and receptors involved: KO mice have been used for different types of receptors, showing that opiate mu-receptor KO mice do not show opiate withdrawal and cannabinoid CB1 receptor KO mice do not show THC withdrawal. Regarding nicotinic receptor KO mice, there is some evidence that some receptor subtypes are involved in the motivational component ($\alpha 4\beta 2$) while others are involved in the physical component ($\alpha 5\beta 4$) of withdrawal. However, available data are conflicting and there is at present no consensus over the role of receptor subtypes in nicotine withdrawal. Among neurotransmitters, ▶ corticotropin-releasing factors (▶ CRF) and ▶ dopamine have been repeatedly involved in the negative affective state associated with withdrawal. Peripheral administration of a CRF antagonist blocks the conditioned place aversion produced by either opiate withdrawal, nicotine withdrawal, or alcohol withdrawal. This effect takes place principally at the level of the central nucleus of the amygdale (CEA) where local CRF receptor antagonist administration (principally CRF1 receptor) diminishes the negative affective state of opiate- nicotine- and alcohol-withdrawal, using CPA, ICSS or anxiety measures (Koob 2008). Thus, intra-amygdala injection of CRF precipitates a negative affective state in opiate-, nicotine-, and alcohol-dependent rats. In rodents, during nicotine-, alcohol-, opiate- and cannabinoid-withdrawal, CRF neurotransmission is increased (review Koob 2008). This CRF neurotransmission involvement which has for long been related to the stress system and the stress response may participate in the anxiogenic aspect of withdrawal.

Dopamine release is decreased in the nucleus accumbens during withdrawal from cocaine, opiate, nicotine, alcohol, and cannabinoid. This reduced release of dopamine may explain the decreased sensitivity to rewards, as demonstrated using ICSS or sweet solution consumption. However, this might be over-simple as, for example, a lesion of dopamine neurons does not modify the affective and somatic aspects of withdrawal (Caillé et al. 2003).

Besides dopamine, other monoamines have also been involved. It has been suggested that noradrenergic functional antagonists can block some aspects of ethanol or nicotine withdrawal (Koob 2008 for alcohol). However, a noradrenergic lesion did not block opiate withdrawal, whereas clonidine (alpha2 agonist) abolished the negative affective state of opiate withdrawal and some (but not all) aspects of somatic withdrawal.

Other neurotransmitters have also been involved, though data are still incomplete. For instance, an increase in glutamatergic neurotransmission has been associated with opiate withdrawal and dynorphin neurotransmission has also been proposed to mediate the negative state of drug withdrawal (Koob 2008).

It is clear that our understanding of the behavioral and neurobiological effects of drug withdrawal is far from complete, though it is progressing rapidly. Using behavioral and neurobiological screening, systematic comparisons among withdrawal from different drugs should bring important information about potential therapeutic targets that can ameliorate withdrawal states and maintain abstinence.

Yale–Brown Obsessive–Compulsive Scale

Synonyms

Y-BOCS

Definition

The 10-item Y-BOCS scale, which evaluates the severity of obsessions and compulsions separately, is the standard scale used in treatment outcome studies of ► obsessive compulsive disorder (OCD) (Goodman et al. 1989a, b). The rater measures obsessions and compulsions in terms of the time occupied, how much they interfere with functioning, the patient's degree of distress, and his or her attempts to resist symptoms and the ability to control them successfully. To assess the patient's symptoms, the clinician may wish to use the Y-BOCS symptom checklist, which lists 40 obsessions and 29 compulsions. The 18-item Obsessive–Compulsive Inventory is a shorter alternative. The Y-BOCS scale and checklist along with instructions for their use are available at http://apple.cmu.edu.tw/_u901039/Rating-Scale-YBOCS.pdf. In clinical practice, some clinicians measure symptom change by simply asking the patient to estimate the amount of time taken by symptoms in an average day in the past week.

Yohimbine

Definition

Yohimbine is a naturally occurring alkaloid. By blocking α_2-adrenoreceptors while sparing a_1-adrenoreceptors, it increases ► noradrenaline release and produces sympathomimetic effects in some organs. It has stimulating properties and is purported to have aphrodisiac qualities.

Zaleplon

Definition

Zaleplon is a non-benzodiazepine sedative-hypnotic that potentiates gamma-amino-butyric acid (► GABA) neurotransmission by binding to the α-subunit of the $GABA_A$ receptor complex, with some selectivity for the α1-subunit. Zaleplon is effective the treatment for insomnia and has an extremely brief duration of action that makes it particularly suitable for treating difficulties in falling asleep (it decreases latency of sleep onset). This drug does not substantially alter the quality of sleep, has little or no residual hangover effects and the recovery from sedation is more rapid than with other ► hypnotics. Zaleplon has a similar side-effect profile to benzodiazepines and other non-benzodiazepine hypnotics although the adverse effects on cognition and psychomotor function are reduced because of the relative selectivity for the ω_1 receptor and the short half-life. Tolerance and dependence may develop with long-term use.

Zero-Order Elimination Kinetics

Definition

Sometimes a drug is absorbed at essentially a constant rate, called zero-order absorption. Zero-order kinetics is described when a constant amount of drug is eliminated per unit time but the rate is independent of the concentration of the drug.

Ziprasidone

Definition

Ziprasidone acts at multiple receptors but mainly as a potent $5HT_{2A}$ receptor antagonist. It is a second-generation antipsychotic with a benzothiazolyl-piperazine structure. The ► half-life is 4–10 h and it is metabolized by various CYP450 isoenzymes, most potently by 3A4. It has to be taken with food. Ziprasidone also inhibits noradrenaline and serotonin reuptake but the clinical relevance of these pharmacological effects has not yet been explored. It is also available as an acute intramuscular preparation. Among the newer antipsychotics, ziprasidone has a lower propensity to induce metabolic side effects.

Zolpidem

Definition

Zolpidem is a non-benzodiazepine sedative-hypnotic belonging to the class of imidazopyridines. It potentiates gamma-amino butyric acid (GABA) transmission by binding to the α-subunit of the $GABA_A$ receptor complex with some selectivity for the α1-subunit. It is commonly prescribed for short-term treatment of insomnia which should not exceed 2 weeks duration as the likelihood of tolerance, dependence, and rebound withdrawal symptoms increases with prolonged use. Like benzodiazepines, it also has anxiolytic, muscle relaxant, and anticonvulsant properties but these are very weak and require higher doses, which increase the severity of side effects. Clinical reports suggest that zolpidem may also be used to dramatically improve the condition of patients with some brain injuries. The side-effect profile of zolpidem is similar to that of other sedative-hypnotics and additionally includes symptoms such as hallucinations and delusions. Additionally, some patients report sleepwalking, migraine, subjective feelings of intoxication, manic reactions, and panic attacks. Tolerance and dependence may develop with long-term use.

Zonisamide

Definition

Zonisamide is a sulfonamide ► anticonvulsant. It is a ► GABA agonist that also reduces ► glutamate function and has a ► half-life of 63 h. It has been studied as an adjunctive treatment in various neuropsychiatric disorders ranging from migraine to ► bipolar disorder without leading to conclusive recommendations for its use beyond epilepsy.

Zopiclone

Definition

Zopiclone is a non-benzodiazepine sedative-hypnotic acting as an agonist at the benzodiazepine binding site on gamma-amino-butyric acid (► $GABA_A$) receptors. It is used for short-term treatment of insomnia, to improve both the initiation and maintenance of sleep. Common side effects include bitter metallic taste, disruption of REM sleep, drowsiness, nausea and vomiting, irritability, confusion, depression, and a lack of coordination. More severe side effects including headache, hallucinations, nightmares, and amnesia have also been reported but appear to be rare. Tolerance and dependence may develop with long-term use.

Zotepine

Definition

Zotepine is a second-generation antipsychotic that acts as a potent dopamine D2 and $5HT_{2A}$ antagonist. Chemically, it is in the dibenzodiazepine class. It has a plasma half-life of 21 h and is metabolized by 1A2 and 3A4 CYP450 isoenzymes. It also inhibits noradrenaline reuptake but the clinical relevance of this effect has not yet been explored.
