where example descriptors include the partition coefficient of a compound between a nonpolar solvent and water $P_{o/w}$, the electron-withdrawing or -donating ability of a functional group a, and the size of a functional group S. Many such models with different descriptors can be constructed and evaluated for their abilities to explain a set of experimental data. The mathematical relationship provided by the best models can then be used to estimate the activity of compounds not yet synthesized. The best models also give useful insight into which features may be important for biological activity, by examining which descriptors remain in the model. Such studies on quantitative structure–activity relationship (QSAR). pioneered by Hansch,[10] went further into 3D QSAR,[11] in which the 3D conformations of compounds are taken into account. Here, one needs to spend extra effort on determining optimal structure–property alignment of a number of active compounds, and descriptors such as the 3D electrostatic field surrounding these compounds can be used.

Methods based on quantitative modeling of molecular interactions

There are also methods that rely on quantitative descriptions of the interactions between drug candidates and receptors. For example, molecular docking programs attempt to determine where a compound may bind to a receptor using sampling techniques that explore an interaction potential energy surface. A potential energy surface is often represented by a simple analytical function, such as the following:

$$V = \sum_{bond} \frac{1}{2} k_b (b - b_o)^2 + \sum_{angle} \frac{1}{2} k_\theta (\theta - \theta_o)^2 + \sum_{dihedral} k_\phi [1 + \cos(n\phi - \delta)] + \sum_{improper} \frac{1}{2} k_\omega \times (\omega - \omega_o)^2 + \sum_{pairwise} \left[\frac{C_{12}}{r^{12}} - \frac{C_6}{r^6} \right] + \sum_{pairwise} \left[\frac{q_i q_j}{r} \right]$$

The term "summing over bonds" describes the energy costs in compressing or stretching bonds. A Hook's-law-type relationship is commonly used to model these costs, in which b is a bond length; b_o is its corresponding equilibrium value: and k_b is the force constant. A similar term "summing over angles" is used to describe angle bending, with θ a bond angle, θ_o its equilibrium value, and k_θ its force constant. A periodic function is used to describe rotational energy profiles about bonds. The sum over dihedral angles involves a periodic cosine function with $n\phi - 6$ its argument. Here. ϕ is a dihedral angle, n is an integer determining how many maxima and minima there are in a span of 360°, and 6 is a phase factor. A harmonic improper dihedral term, with the parameters k„, and ω_o, is also used to keep aromatic rings approximately planer. tetrahedral groups nearly tetrahedral. etc.[6–12] Lennard–Jones potentials, with the parameters C_6 and C_{12}, depend on the distance between two atoms r and are often used to describe the attractive forces between them due to electronic dispersion effects and to keep the two atoms from crashing into each other. Finally, Coulomb terms, which depend on the charges of two interacting atoms, q_i and q_j, are used to describe the electrostatic interactions between the atoms. When solvent molecules are not included explicitly to save coinputational time, their effects on electrostatics are modeled by introducing additional screening functions to the Coulomb terms. More sophisticated ways of modeling solvation effects such as those based on solving the Poisson–Boltzmann equation[1,2] and on generalizing the Born models[12] were also developed.

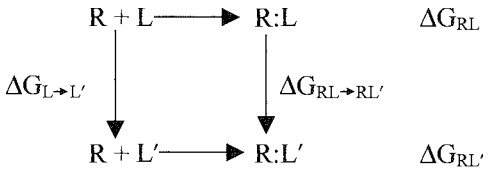
Once a model for the potential energy function is adopted, a conformational search algorithm can be used to move a ligand around in the receptor to find its most favorable binding site. The potential energy surface has a complicated landscape and requires an efficient algorithm to go over energy barriers during a conformational search. Simulated annealing Monte Carlo or molecular dynamics is one method with which to do it. This involves heating and cooling a system, while the system is evolving according to a Monte Carlo or molecular dynamics simulation algorithm. Genetic algorithms were also used. In such algorithms, one represents a ligand state—involving position. orientation, and conformation—with "genes," such as a series of bits that encode a particular conformation. One first starts with a random population containing a ligand in different states. The population is then allowed to evolve by selection, mutation. and gene crossing. A fitness function, which can depend on the potential energy function described earlier. can be used to determine which states fit better and survive after many generations. Autodock[13,14] is an example of a docking program that can utilize a simulated annealing Monte Carlo method or a genetic algorithm.

Quantitative calculations based on rigorous principles of quantum mechanics and statistical mechanics were also performed to discriminate strong inhibitors from weak ones.[6] Rigorous theories for calculating binding free energy were worked out.[15] A general approach not only accounts for ligand but also receptor flexibility. However; such approaches are expensive to use and are harder to apply to a large number of systems in a short time. Nevertheless, they provide more rigorous theoretical frameworks for evaluating approximations used in simpler models and can be applied in the later stage of a drug development process, when only a small number of potential drug candidates need to be investigated in further detail.

One approach is the thermodynamic cycle-perturbation method that allows one to compare the relative binding affinity of a number of similar ligands.[16] This approach recognizes the difficulty in simulating the absolute binding affinity ΔG between a ligand and its receptor:

$$\Delta G = G_{complex} - G_{receptor} - G_{ligand} \tag{2}$$

In principle. one can calculate the free energy of the receptor $G_{receptor}$, the ligand G_{lig^2} & and their complex $G_{complex}$ to obtain AG. However, it is usually difficult to carry out simulations long enough to obtain sufficiently good statistics for the free energies, which have large magnitude and statistical errors. and add them according to Eq. 2 to obtain ΔG with a much smaller magnitude. The thermodynamics cycle-perturbation method avoids this problem by focusing on comparing the free energy of binding among similar ligands. It makes use of a thermodynamic cycle to facilitate the comparison between two inhibitors:



Because free energy is a state function:

$$\Delta\Delta G = \Delta G_{RL'} - \Delta G_{RL} \tag{3}$$

which coinpares the binding affinity of two ligands, L and L', to a receptor R. it can also be obtained from

$$\Delta\Delta G = \Delta G_{RL\rightarrow RL'} - \Delta G_{L\rightarrow L'} \tag{4}$$

$\Delta G_{RL\rightarrow RL}$ and $\Delta G_{L\rightarrow L}$ are usually much easier to calculate, because each corresponds to the free energy difference between two similar systems. Moreover, methods such as Zwanzig's perturbation theory[17] can

be used to facilitate the calculations of $\Delta G_{\mathrm{RL}\rightarrow\mathrm{RL}}$ and $\Delta G_{\mathrm{L}\rightarrow\mathrm{L}'}$. For the Helmholtz free energy, Zwanzig's perturbation theory reads

$$\Delta A = -RT\ln\langle\exp(-\Delta H/RT)\rangle_r \quad (5)$$

where $\Delta H = H_p - H_r$, in which H_p and H_r are the classical Hamiltonians of the perturbed and reference systems, respectively; and $\langle\ldots\rangle_r$ represents an ensemble average over the reference state. By choosing the reference and perturbed systems to be those containing two similar ligands. the free energy difference between the two systems can be calculated directly rather than by first calculating the free energy of each and then taking their difference. Extensive efforts were also spent by a number of research groups to improve the range of applications of the thermodynainic cycle-perturbation method. These methods facilitate the calculation of a free energy difference when the direct application of Zwanzig's formula[17] gives poor statistics, such as when the two ligands are not sufficiently similar. Instead of changing a ligand into another in one step. the windowing technique introduces a number of intermediate steps, calculates the free energy difference between two adjacent intermediates, and sums the results to obtain the overall ΔA. Kirkwood's integration formula[18] utilizes a coupling parameter λ to change the classical Hamiltonian $H(\lambda)$ of one system into another. when λ goes from 0 to 1, and to obtain a free energy difference ΔG according to

$$\Delta G = \int_0^1 \left\langle \frac{\partial H(\lambda)}{\partial \lambda} \right\rangle_\lambda d\lambda \quad (6)$$

A recent derivation[19] showed that the free energy difference between two states can also be obtained by averaging the irreversible work in taking one state into the otl-ier, as follows:

$$\overline{\exp(-\beta W)} \equiv \int dW \rho(W,t)\exp(-\beta W) = \exp(-\beta\Delta G) \quad (7)$$

where W is the work associated with switching one system into another in a finite time t, β is the inverse of the product between the gas constant R and the absolute temperature T, and $\rho(W,t)dW$ is the probability of work found within the range W and $W+dW$. This formula was also evaluated experimentally by the mechanical unfolding of single RNA molecules.[21]

FASTER APPROXIMATE MODELS

Although the methods just described have firm theoretical bases. they are expensive to use. Faster approximate methods were developed to permit quick early evaluation of a larger number of potential drug candidates. One trick is to expand a binding free energy ΔA in terms of a Taylor's series of the model parameters λ_i, such as atomic partial charge and size of a lead compound:[15,16,22]

$$\Delta A = \sum_i \frac{\partial A}{\partial \lambda_i}\Delta\lambda_i + \frac{1}{2}\sum_{i,j}\frac{\partial^2 A}{\partial\lambda_i\partial\lambda_j}\Delta\lambda_i\Delta\lambda_j + \ldots \quad (8)$$

The key here is that analytical mathematical formulas can be worked out to calculate the derivatives: $\frac{\partial A}{\partial\lambda_i}, \frac{\partial^2 A}{\partial\lambda_i\partial\lambda_j}, \ldots$, and only simulation results involving the lead compound are required in calculating them. Once the expensive derivatives are calculated, they can be used in the Taylor's series expansion to predict the effects of making many different combinations of parameter change ($\Delta\lambda_i$) on the binding affinity. Because one usually only includes the first few order terms in the expansion, the parameter change cannot be made too large. However, thoroughly exploring a chemical space near the lead compound can point out useful compounds to synthesize. If some of the synthesized compounds are more active, similar calculations can be performed by using one or more of the new compounds as novel leads to gradually expand the chemical space. Sometimes, one can also obtain useful insights into inhibitor design simply by analyzing the derivatives, because they provide useful information about what parameter changes may improve activity. This approach was applied to study protein kinases, for example.[5] Other approaches that focus on examining a small chemical space near a lead compound to save computational time include the use of single-step perturbation methods. the Gaussian perturbation formula, and free energy perturbation calculations utilizing soft-core potentials.[6]

Another way to speed simulations is to use implicit rather than explicit solvent models. Solvent can play an important role in influencing binding, as both the ligand and the binding site of the receptor need to be desolvated before a receptor–ligand complex can be formed. Favorable binding can only occur when the gain in interaction energy upon binding can override the loss in solvation energy. Computational models need to account for solvation effects sufficiently well to be useful. Including a large number of solvent molecules surrounding a solute in a simulation provides a detailed molecular description of solvation effects. but this is very expensive. Recently. implicit solvent models became popular. Two major contributions of solvation effects are usually taken into account: electrostatic and hydrophobic. Different electrostatic models were introduced. Numerical solutions of the Poisson–Boltzmann equation,[1,2] taking into account the detailed shape of the solutes, are now used extensively.

Cheaper electrostatic models include various generalized Born models[12] and approaches that utilize screened Coulomb potentials.[23] The hydrophobic effects are most commonly modeled by using terms proportional to the surface area of a solute, as experimental results for simple alkanes suggest such a relationship.[24]

Another approximation commonly used to speed calculations is to assume the ligand and receptor to be rigid. This approximation may be crude, but calculations can be done on more hypothetical structures to identify promising ones for further computational and experimental explorations. This approximation can be partially relaxed by allowing only the smaller ligand to be flexible, with the receptor held fixed. Many molecular docking experiments were done with this approximation. Various approximate methods accounting for receptor flexibility are also being developed.[25] Some methods only allow side chains near the docking site to move. Others may take the receptor portions of crystal structures of different receptor–ligand complexes for docking, as these structures reflect the plasticity of the receptor when different ligands are bound. Snapshots of a receptor obtained from a molecular dynamics simulation can also be used. A traditional molecular dynamics simulation performed at a constant temperature may not be able to sample conformational space well enough in a short simulation, methods for improving conformational samplings can be put to use here. One inethod that became popular is the replica-exchange method.[26] In addition to simulating a system at the desired temperature, this method also simulates the system at higher temperatures and allows snapshots at different temperatures to exchange at regular intervals according to the Metropolis criteria. The runs at higher temperatures facilitate barrier crossing. and larger conformational switching can be realized at the lower desired temperature due to the replica exchange.

CONCLUSION

Computational chemistry can be used together with genomics information to aid in the design of selective drugs. Besides pointing out new targets for drug development. genomics information can also help in the design of more selective therapeutics. Computational chemists are beginning to be able to take many related targets into account so as to maximize the impact of a drug candidate on its intended target but not on the unintended ones.''' In addition. it should eventually be feasible to develop drugs that are tailored to the genetic traits of specific patients.

Computer-aided drug design is becoming more useful due to rapid improvement in computer speed, development of new algorithms, and rapid growth of experimental data that can be utilized in modeling studies. Here, we are able to introduce only some of the approaches being used and developed in the field. Other useful tools include diversity and similarity analysis methods that help in selecting a more manageable set of compounds for synthesizing, screening, and testing, methods that help to predict ADME (absorption, distribution, metabolism, and elimination) properties to aid in the design of molecules with good pharmacokinetic properties. and Web servers that provide useful databases and tools for modeling studies. Together with new developments in various experimental techniques, computer-aided drug design is playing its part in speeding the development of new pharmaceuticals. The rapid development of computer-aided drug design is fueled by the diligent work of many research groups. Due to limits in the number of citations that can be included here, we selected a short list of references that hopefully can lead readers to explore the works of a larger community.

Dye Inclusion Crystals

Bart Kahr
Sei-Hum Jang
University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

"Supramolecular chemistry" is of recent coinage. Therefore, it is no surprise that contemporary chemists rarely think of textile dyeing, a human occupation for thousands of years, as supramolecular chemistry. However, unlike pigments that color by the mechanical trapping of particles. genuine dyeing involves the tuning of equilibria of dye sorption on fibers in order to achieve a desired fastness. Dyeing, one of the oldest and most transforming of chemical technologies, is also a quintessential example of deliberate self-assembly. Dyeing, indeed, is supramolecular chemistry. broadly defined. Crystal growth from solution is another area of inquiry that is governed by the specificity of noncovalent interactions. Long shrouded in mystery, recent studies are beginning to specify relevant interactions between molecules or ions and growing crystal surfaces.[1] This article broaches the intersection of these two areas of supramolecular chemistry: dyeing and crystal growth from solution. Mere. we describe the process of dyeing crystals, whereby simple crystalline substances orient and overgrow chromophores during crystal growth from solution.

Compared with supramolecular chemistry, crystal dyeing is a comparatively old subject."' The crystallographic literature of the past 150 years contains examples of crystals stained by dyes that we call dye inclusion crystals (DICs). When dyes express different affinities for faces of growing crystals not related by symmetry, they produce strikingly colored,[3] dichroic polyhedra that captured the attention of generations of crystallographers, not only for their appearance but also for what they teach about crystal structure and crystal growth. How do dye molecules adopt oriented positions in otherwise close-packed lattices made from molecules or ions that bear no size. shape, or constitutional similarity to the dye molecules'! These mixed crystals were troublesome in the past. because they seemed to violate Mitscherlich's principle of isomorphism,"' the idea that host and guest molecules must "fit." Dyed crystals were studied in order to address a variety of other questions. including the nature of pleochroism, mechanisms of crystal growth, silver halide photosensitization, ceramics crystallization. colloid stabilization, habit modification. epitaxy, explosives preparation, and kidney stone inhibition.[2]

HISTORY

In 1854, Henri de Sénarmont (Fig. 1) contemplated whether pleochroism might analogously be imparted to an otherwise transparent crystal if a colored material present in solution should stain the crystal during growth. Sénarmont was satisfied by red, pleochroic crystals of $Sr(NO_3)_2 \cdot 4H_2O$ that he grew from a solution containing a natural red quinone called heinatein.

Retgers, motivated by the apparent violation of the principle of isomorphism in Sénarmont's salt, and appreciating the limitations of Sénarmont's singular study. attempted to produce a family of DICs by systematically adding dyes to solutions of three dozen simple salt crystals.[5] From some 1000 crystallizations, he observed only four mixed crystals that he thought were worthy of continued study. The paucity of successes suggests that the probability of staining an ionic crystal during growth with a randomly chosen dye is small.

Like Retgers, Lehmann was motivated to understand the limitations of the principle of isomorphism but focused his research on organic hosts, especially carboxylic acid derivatives.[6,7] Unlike Retgers, he obtained many dichroic crystals. illustrating a surprisingly general capacity of some crystalline substances to orient and overgrow organic dyes. Gaubert repeated many of Lehmann's studies. He was the first to describe the process of dyeing crystals with respect to specific crystallographic directions. For example. he clarified that methylene blue recognized the (021} growth sectors of phthalic acid[8,9] and the {101} growth sectors of poppy acid.[10]

Neuhaus[11–13] and France[14,15] were the first to use x-rays to study DICs. However. by and large. x-ray scattering[16] experiments were not informative, as minor components in single crystals (typically DICs contain 1 mole of dye to $10^3 - 10^5$ moles of host) are rarely manifest in the Bragg scattering. France determined that the lattice constants for pure and dyed alum crystals were the same within experimental error.

Fig. **I** Henri de Sénarmont.

Most scientists familiar with the process of dyeing crystals were first introduced to the subject by Buckley. who showed photographs of a number of DICs in his popular book. *Crystal Growth.*[17] In large measure. his work constitutes a reinvestigation of the previous studies of Gaubert. But, despite an extra generation of sophistication. he too was unable to interpret his results given the still-limited understanding of crystal structure and the conformations of complex dye molecules in the 1930s. Thereafter. contributions to the literature on DICs were incidental or highly restricted in scope and most often divorced from their antecedents, until recent investigations in the 1990s.[2]

Stained alums are suitable illustrations of DICs. They are appropriate in this context because of the important role that alum has long played in the dye industry. Dyes are often chemically fixed to textile fibers following adsorption; mordanting with alum is common. What if we chose alum crystals as the ground? In other words, can alum mordant a dye to itself, that is to an alum crystal? In this century, alum crystals were first dyed by France in 1928,[18,19] Milligan in 1929,[20] and Buckley in 1930,[21] using a variety of azo and triarylmethyl cation dyes. In Fig. 2, an alum crystal grown in the presence of the dye diamine sky blue that stained the {100} growth sectors only is shown. As small {111} faces were expressed, they eschewed the dye, thereby leaving behind the unstained "darts."

Potassium alum is structurally similar to NaCl; both crystals have two distinct planes, one checkerboard like [$(111)_{alum}$ and $(100)_{NaCl}$], and one with alternating layers of cations and anions [$(100)_{alum}$ and $(111)_{NaCl}$]. France believed that charged dye molecules would be more strongly attracted to faces comprised of like ions.[22,23] Buckley, nevertheless, found dyes that recognized both types of faces in K_2SO_4.[17] Moreover, Frondel found that the checkerboard {100} faces of NaF adsorbed a great number of ionic dyes.[24] Obviously. the process of dyeing crystals cannot be reduced to a few simple "rules." In fact; the entire range of noncovalent interactions determines the segregation of the dyes and their orientations and conforinations.

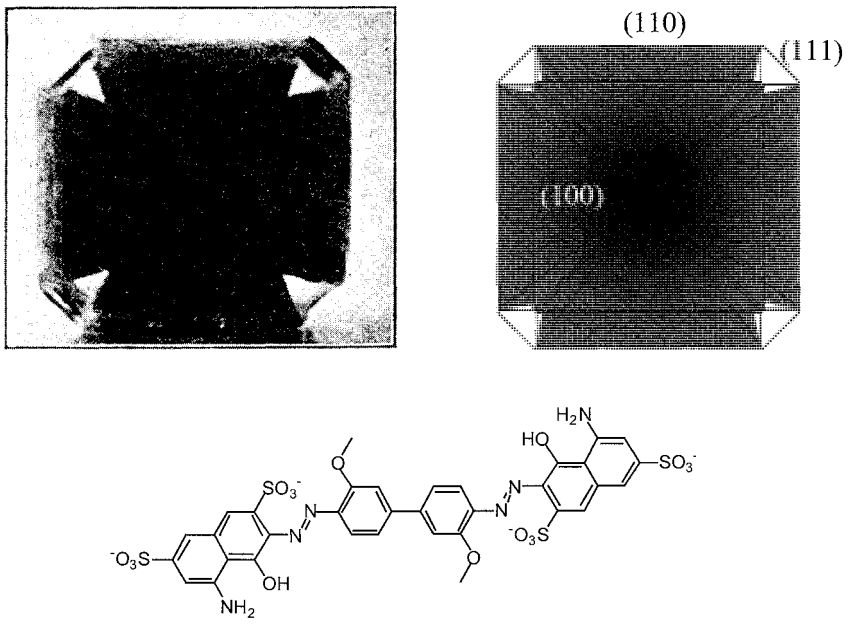

Fig. 2 France's photograph of a $NH_4AlSO_4 \cdot 12H_2O$ crystal stained by diamine sky blue in the {100} growth sectors. An idealized representation is shown on the right. (*View this art in color at www.dekker.com.*)

CHEMICAL ZONING

Additives interacting with growing crystals must discriminate between faces that are not symmetry related. Consequently: mixed crystals exhibiting more than one form will invariably display chemical zoning—the partitioning of impurities from one growth sector to another. While countless examples of such phenomena exist in mineralogy, as well as in the literature on dyeing crystals, a molecular-level understanding was first provided in a sweeping revision of the structure of solid solutions.[25,26] We explicitly designate this phenomenon intersectoral zoning. For example, many organic dyes. when included in saturated solutions of potassium hydrogen phthalate, give crystals in which the luminescence is confined to particular growth sectors (Fig. 3).[27] The orientations of the dye molecules can be ascertained by measuring the absorption spectrum in polarized light, so long as the electronic ctructures of the dyes are sufficiently well understood.

Organic impurities inhomogeneously deposit not only between growth sectors but also within single growth sectors depending on the crystal's surface topography. Surfaces of crystals grown in the lower supersaturation regime often propagate through dislocations that produce growth spirals or hillocks, shallow-stepped pyramids with single or multiple dislocations at the apexes. Polygonization of hillocks partitions faces into vicinal regions, each having slightly different inclinations. Impurity partitioning among vicinal slopes, intrasectoral zoning, results from the selective interactions of impurities with particular stepped hillock slopes. Tntrasectoral zoning, therefore, provides more detail about recognition mechanisms than intersectoral zoning, because the active growth surfaces at the time of incorporation can be more highly specified.

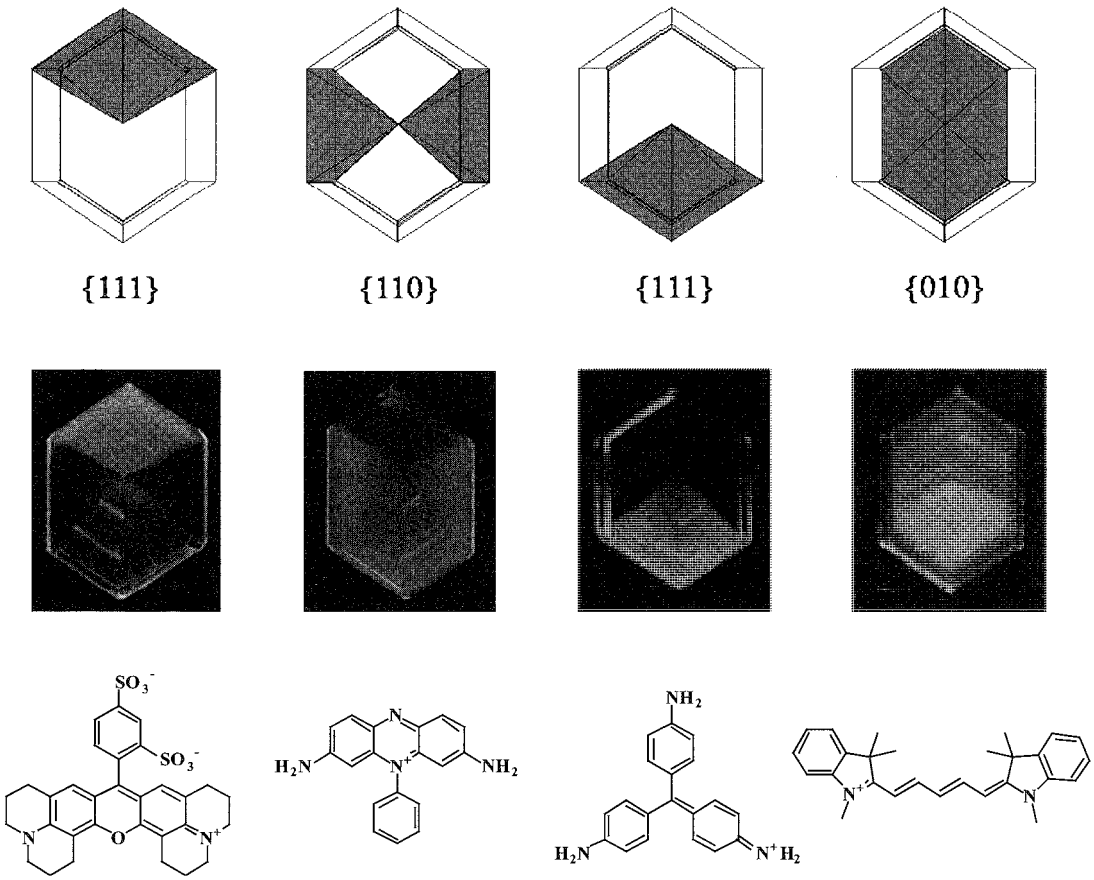

Fig. 3 Idealized representations of potassium hydrogen phthalate crystal habits viewed down [010] with growth sectors delineated. Red luminophores are included in each of principal growth sectors, as shown by the patterns of luminescence. (*View this art in color at www.dekker.com.*)

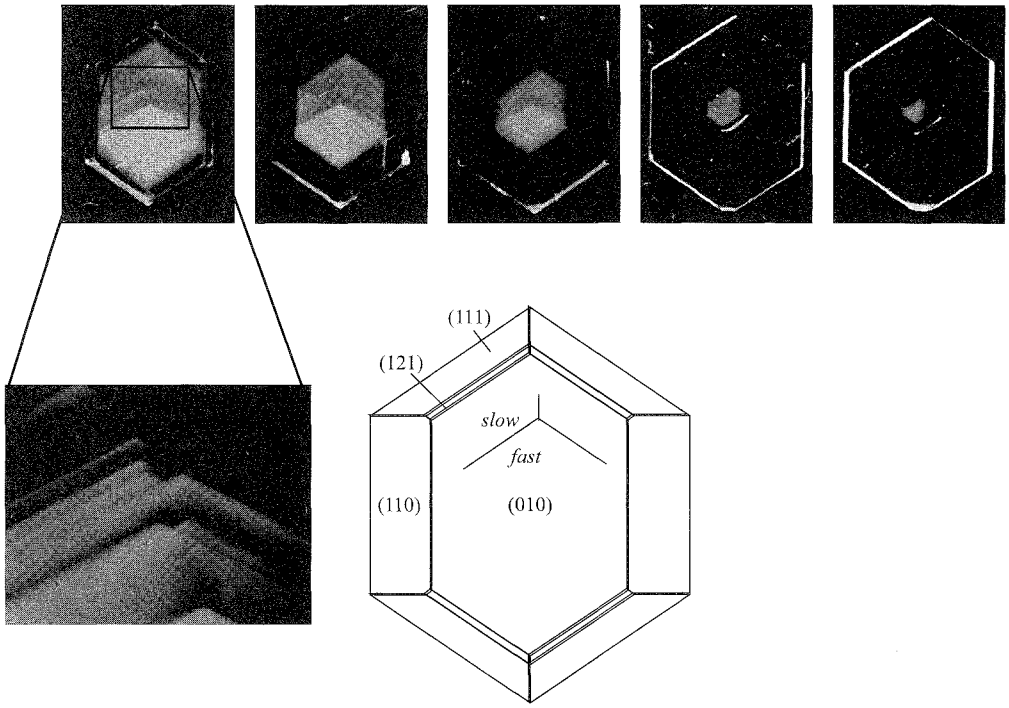

Fig. 4 Top row: Successive (010) slices (200 μ) of dyed potassium hydrogen phthalate crystals reveal the growth histories in their patterns of luminescence. Bottom row: The orientation of the fast- and slow-moving steps of a growth hillock are shown on the (010) face in a comparison of images made by differential interferencc contrast microscopy and fluorescence microscopy. (View this art *in color* at *www.dekker.com.*)

For example, the substructure in the luminescence from the crystal in Fig 4 results not only from intersectoral chemical zoning but also from intrasectoral zoning[28] on hillocks that arc manifest on these surfaces The dye recognizes the fast-growing steps in prcferencc to the slow-growing steps Other examples of the intrasectoral zoning of dyes were given by Zaitseva et al tor KH_2PO_4,[29] Gurney et al foi K_2SO_4,[28] and Kurtmoto et al for a-lactose monohydrate [30]

SUPRAMOLECULAR INTERACTIONS

We determined that the great range of host–guest interactions, including ionic forces, cation–π interactions, charge-transfer interactions, hydrogen bonding, and hydrophobic forccs are manifest in DICs. Of course, these categories are fuzzy at best. Cation–π interactions and hydrogen bonding could be considered charge-transfer interactions of a sort. Here, wc will not parse Coulomb's

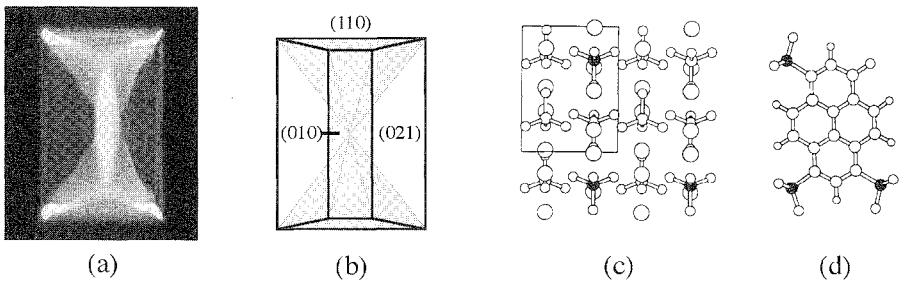

Fig. 5 Ionic forccs. (a) Fluorescence from K_2SO_4/pyranine. (b) Idealized representation of K_2SO_4/pyranine. K_2SO_4 (c) and pyranine (d) drawn to the same scale. law into separate sublaws and statutes. We will adhere to the meanings of the aforementioned terms as they are commonly given in the literature.

Ionic Forces

Potassium sulfate can be straightforward in the mechanisms by which it incorporates chromophores. Ionic forces drive the mixed crystal formation in most cases. Buckley long ago suggested that the stereoregular substitution of sulfate ions in the lattice by sulfonate substituents on the dyes were responsible for the formation of some DICs.[17] We prepared more than 100 intersectorally zoned K_2SO_4 DICs containing sulfonated synthetic dyes.[17] A typical example. shown in Fig. 5. is K_2SO_4 containing pyranine in the (110) and (010) growth sectors. The disposition of sulfate ions in the lattice closely matches the rigidly disposed sulfonate substituents and drives the mixed crystal forination. This mixed crystal model can be confirmed by measurements of absorbance with polarized light.[38]

Cation–π Interactions

Gurney et al. studied the excited state lifetimes and zero-field splittings of rooin-temperature phosphorescent *ortho*-arninosulfonated benzenes and naphthalenes, through which they found evidence of cation–π interactions.[28] A number of these DICs are highly subject to heavy atom effects. The triplet lifetime of *ortho*-aminobenzenesulfonate was shorter in Rb_2SO_4 as compared with K_2SO_4 (Fig. 6). Similarly, phosphorescent lifetimes of *para*-aminobenzoate were considerably shorter in barium acetate crystals as compared to sodium acetate trihydrate crystals.[28] it was demonstrated by optical detection of magnetic resonance that intersystem crossing rates for aromatic compounds are only affected by heavy atoms if they are interacting with the face of the π-system.[32,33] Thus, there is reason to assume that cation–π interactions are important in determining the properties of aromatic guests in ionic salt crystals.[34]

Charge-Transfer Interactions

As first demonstrated by Gaubert and Lehmann, phthalic acid orients a great variety of cationic dyes, especially in its {021} growth sectors.[35] Red shifts in the absorption spectra of the crystals indicated the possibility of hydrogen phthalateldye charge-transfer complexes. Such associations were confirmed in crystal structures of stoichiometric hydrogen phthalatelmalachite green cocrystals (Fig. 7). This crystal structure was used in the interpretation of the linear dichroism of the corresponding DIC.

(a) (b)

Fig. 8 Hydrophobic effects. (a) Dimerization of sulforhodamines in K_2SO_4. (b) K_2SO_4 dyed in {110} growth sectors viewed along [010].

Hydrophobic Effects

Hydrophobic effects are manifest in the aggregation of dyes in some crystalline hosts. For example, sulforhodamine B absorbs light of 537 nm in the (110) growth sectors of K_2SO_4. This absorbance has been blue shifted with respect to that in solution and has been attributed to dimers, as shown in Fig. 8.[36]

Hydrogen Bonding

It is self-evident that hydrogen bonding plays an important role in the dyeing of many crystals, such as KH_2PO_4, phthalic acid, and α-lactose monohydrate. However, specifying the active hydrogen bonds is difficult. One example that lends itself to interpretation is the dyeing of benzamide in the $\{10\bar{2}\}$ sectors with Nile red (Fig. 9). The horizontal polarization of the excitation is consistent with the preorganized hydrogen bonding of Nile red to three benzamide molecules in a crystal chain. The luminescence is consistent with H-bonding found in polar protic solvents, where the $-NEt_2$ groups are turned out of plane.[37]

(b)

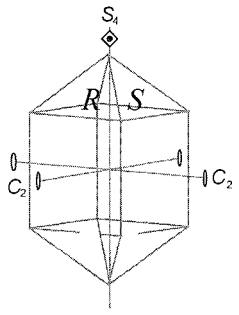
Fig. 10 Diastereoselectivity. Crystal spectra were interpreted as resulting from the incorporation of the asymmetric acid fuchsin diastereomer (a) in K_2SO_4 isomers. (b) The symmetric diastereomer.

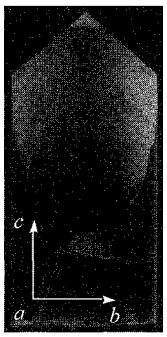
STEREOSELECTIVITY

In principle, distinct facets of a single crystal might express different affinities for guests that can exist in more than one conformation. Such is the case with acid fuchsin in the {110) growth sectors of K_2SO_4.[38] The breaking of symmetry evident in the shape of the absorption spectrum suggested that of the two predominant conformations of acid fuchsin, one with all three sulfonates pointing to the same side of the mean molecular plane and one with two above and one below, only the latter was evident in the process of dyeing. Conformational selectivity was also observed in K_2SO_4 crystals containing naphthylamines.[28]

The process of crystal dyeing can be enantioselective as well as diastereoselective (Fig. 10). Blattner et al.



(a)



(b)

reported that solutions of hematein stained the {100} growth sectors of KH_2PO_4.[39] Recent reinvestigation of their work revealed that hematein stains every other prism face.[40] Hematein is chiral: adjacent prism faces of KH_2PO_4 are mirror symmetric. The adsorption, therefore, must be enantioselective.

Recently, Kurimoto et al. observed a visible blue luminescence localized in the pyramidal {101} growth sectors of KH_2PO_4 grown from a solution containing adenosine triphosphate).[30] This is a common pattern of zoning of anionic dyes in KH_2PO_4.[41,42] Comparisons of the luminescence viewed through the *a* and b faces revealed that the (011) sector was considerably brighter than the (101) sector (Fig. 1I). As these sectors are mirror images of one another, the chiral nucleotides must also have recognized these faces enantioselectively.

CONCLUSION

Crystal dyeing is an easy,[43] colorful, and often dramatic way of obtaining definitive evidence for specific noncovalent interactions controlling crystal growth. Moreover. the applications of DICs are numerous. DICs can be used as unique hosts in single-crystal matrix isolation experiments with metastable excited states[...] and biopolymers,[44,45] for conforrnational analysis. for separations, to interrogate mechanisms in biomineralization[...] and in matrix-assisted optical[47] and mass spectrometric chemical analyses,[48] to identify growth-active surface structures on crystalline faces, and as optical reporters of phase transitions.[49] During the past decade, we barely scratched the surface of a subject that was barely scratched by crystallographers of past generations. It is likely that we will learn much more about the process of dyeing crystals. as varied methods of contemporary analysis—particularly high spatially and temporally resolved electronic spectroscopies—are brought to bear upon the subject in the future.

Electrochemical Sensors

James H. R. Tucker
University of Exeter, Exeter, United Kingdom

INTRODUCTION

There is considerable interest in electrochemical sensing within the field of supramolecular chemistry, and the topic has been identified as an important applicable area of host–guest chemistry.[1–3] This review covers developments in the area of supramolecular voltammetric/amperometric sensors. where current is measured as a function of applied potential. The area of supramolecular potentiometric sensors (e.g., ion-selective electrodes) is not covered here. and the reader is referred to a general review on electrochemical sensors that covers this topic.[1,2]

A number of methods for sensing or analyzing charged or neutral species in solution using voltammetric techniques have been identified.[1,2,4,5] So far. it is fair to say that many of the more successful approaches, in terms of applications and technological advances, have involved methods that fall outside the realm of supramolecular chemistry. particularly in the detection of electroactive (redox-active) species (e.g., the glucose biosensor).[4,5] This is not to say, however. that supramolecular receptors cannot be used to detect or respond to redox-active guests using electrochemical techniques.[6,7] However. it is no surprise that the electrochemical detection of non-redox-active species is less straightforward and requires an indirect method of detection. As far as voltammetric sensors are concerned. supramolecular chemistry can play an important role in this area with the use of redox-active receptors that can respond electrochemically to the cornplexation of a non-redox-active guest. This process is shown schematically in Scheme 1.

The complexation by a redox-active host. H. of a charged or neutral guest, **G**, imparts a change in its electrode potential that enables the binding process to be read out by an electrochemical technique. usually cyclic voltammetry. In the design of such a supramolecular sensor. the objectives are twofold; namely. guest selectivity and a significantly large redox response to complexation. This second aspect can be conveniently illustrated by the following square scheme (Scheme 2) and Eq. 1. Essentially. the change in the electrode potential (i.e., the redox response) of **H** upon complexation with **G** is related to the change in the host–guest binding constant upon its oxidation or reduction. In Eq. 1, $E_{\mathbf{H}}$ and $E_{[\mathbf{H-G}]}$ are the formal electrode potentials of **H** and the complex. **[H–G]**, respectively (each is usually approximated from the average of the anodic and cathodic peak potentials from cyclic voltammetry); K^+ and K are the binding constants in the oxidized and reduced form of the receptor, respectively: F is the Faraday constant; R is the universal gas constant, T is the temperature; and n is the number of electrons transferred (in Scheme 2, $n = 1$).

$$K^+/K = \exp[-nF(E_{[\mathbf{H-G}]} - E_{\mathbf{H}})/RT] \quad (1)$$

Therefore, a successful sensor will be selective for a particular target and bind it considerably more strongly in either its oxidized or its reduced form. The suitability of Eq. 1 for estimating the magnitude of the redox-switched binding enhancement from potential shifts has been examined in detail.[2,8] One finding is that the strength of the host–guest binding interaction appears to dictate whether cyclic voltammograms exhibit one-wave or two-wave behavior when adding aliquots of guest to the redox-active host.

The area of supramolecular electrochemistry and its relevance to sensing and redox-switched binding has been the subject of a book[1,2] and a number of reviews.[9–15] In

DOI: 10.1081/E-ESMC 120012784

a review by Gale, Beer, and Chen,[10] the different mechanisms by which complexation can impart a redox response. for example, via through-bond or through-space interactions, were discussed. In general, the proximity of the receptor site to the redox center and the charge density of the guest are important factors in determining the magnitude of the redox response and the effectiveness of the electrochemical read out. Here. an overview of the range of receptors designed for the binding and sensing of charged and neutral guest species will be given and will include examples of freely diffusing redox-active receptor species in solution and those immobilized at a surface.

RECEPTORS IN SOLUTION

In this section, freely diffusing receptors in solution will be discussed, in which the redox-active center or reporter group is, or is an integral part of. an inorganic or an organic group.

Inorganic Reporter Groups

Metallocenes

Ferrocene has been by far the most used redox-active group in a supramolecular sensor due its stability, its ease of functionalization and its well-understood and reversible redox chemistry. A host of ferrocene-containing compounds are now known that bind cations; anions, and neutral molecules. It can be argued that the first examples of redox-active receptors, for which the complexation of other species was demonstrated. were ferrocenyl crown ether compounds, as reported in the late 1970s and in 1980.[16–18] However, it was not until later that the structural. binding, and redox properties of these and related crown ether compounds were investigated in more detail.[19–28] Compounds such as **1**,[19] **2**.[20] **3**,[21] **4**,[22] and **5**[23] (Fig. 1), and related receptors containing two or more ferrocene centers, were found to bind and electrochemically respond to a range of hard (mainly Groups 1 and 2) metal cations in organic solvents, as well as. in some cases. ammonium ions[25] and ion pairs.[26] Almost without exception,[27] complexation imparts positive (anodic) shifts in the ferrocene-centered redox couples (Fc^+/Fc), as a result of the close proximity of the bound cation making ferrocene oxidation more difficult. Progress in this area has been reviewed extensively.[10,12] In addition to cyclic receptors, simple acyclic receptors have also been reported[29,30] (e.g., 6) that give a significant electrochemical response to the presence in solution of relatively charge-dense, hard cations.

Ferrocenyl receptors that bind and sense lanthanides.[31] as well as those that respond to a range of transition and soft metal cations, are now known. In the case of transition metal and soft metal cations; nitrogen-containing,[30,32–39] and to a lesser extent, sulfur-containing[40,41] ligands were used as receptor groups (e.g., Compounds 7–12. Fig. 2). A number of the aza-compounds can also bind anions, for example, Compound **9**.[35] As found with the crown ether derivatives, cation complexation generally imparts anodic shifts in the Fc^+/Fc redox couples of each receptor.

It is important that the factors responsible for generating a significant electrochemical response to complexation be fully understood if effective sensors are to be designed. In this respect, a detailed study by Plenio et al.[32] of transition metal complexation by a ferrocenyl molecule containing a cyclam ligand. 7, provided further

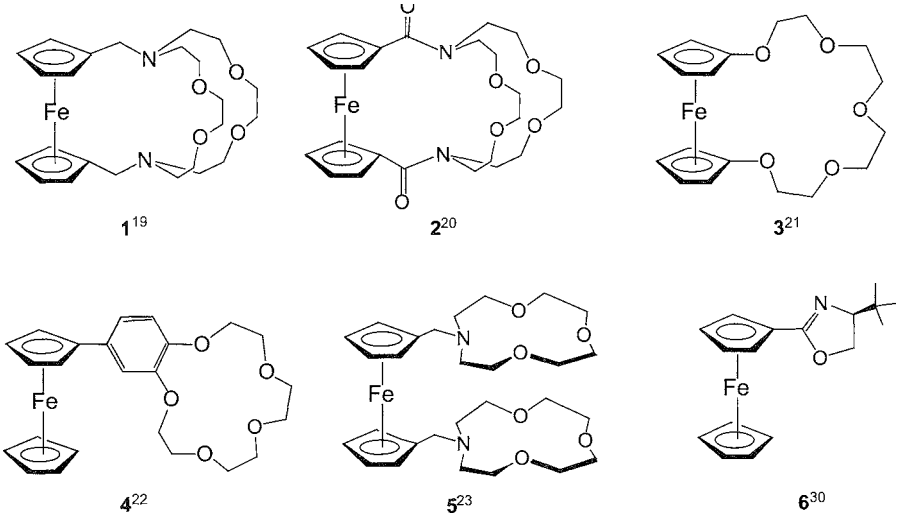

Fig. 1 Ferrocene receptors for hard metal cations

information on the iinportance of the Fe-metal distance and the solvent in governing the redox response to complexation. In particular. a linear dependence of the shift in the Fc^+/Fc couple upon complexation, AE, versus the intermetallic distance, 1/r, was found for the complexes $[M(FcCyclam)](CF_3SO_3)_2$ (M = Co. Ni. Cu, and Zn), which was clear evidence for a primarily coulombic, through space $Fe-M^{2+}$ interaction. Similar results were obtained previously. when the effect of protonation on the Fc^+/Fc redox couple of a series of tertiary amine derivatives was investigated.[''''] Found in other studies of the binding of hard metal cations by crown ether derivatives 1 and 2 were linear relationships between the shift in potential and either the charge/(radius)^2[19] or the charge/radius[20] of the bound cation. respectively. It was also shown by Plenio and Martínez-Mánez how the solvent can have a dramatic effect on the shift in potential, in that the complexation of $Zn(CF_3SO_3)_2$ by 7 imparted shifts ranging from + 280 mV in THF/CH_3CN (30:2 v/v) to + 409 mV in CH_3CN alone.[32] The expected trend toward larger shifts for solvents with lower dielectric constants was only observed for solvent mixtures of relatively high polarity. For solvent mixtures of relatively low polarity. the shifts were lower than expected due to ion-pairing effects.

There are now numerous reports of metallocene derivatives that bind and sense anions. Early work in this area was carried out by Beer, who first reported a redox-active anion receptor in 1989.[43] Beer published a number of cobaltocenium and fen-ocene anion receptors[10,11,43–48] some of which are shown in Fig. 3 (Compounds 13–16). In contrast to what is found with cations, the Fc^+/Fc redox couples undergo appreciable negative (cathodic) shifts upon complexation with inorganic anions in organic solvents. These negative shifts are consistent with a stabilization of the oxidized forms of each receptor by the negative charge of each guest. Beer found that amide receptors of this type (e.g., 13–15) bound anions through hydrogen-bonding interactions: with the cobaltocenium receptors binding anions more strongly due to the additional through-space electrostatic attraction between host and guest. Beer also developed sensors for organic anions,[45,46] for example; the cobaltocenium receptor 15 containing a calix[4]arene group that binds carboxylate ions selectively over halide ions. due to two rigidly held amide units on the upper rim of the calixarene that create an ideal site for bidentate coordination.

Beer and Martínez-Mánez also reported a number of fen-ocene-containing receptors that selectively bind and

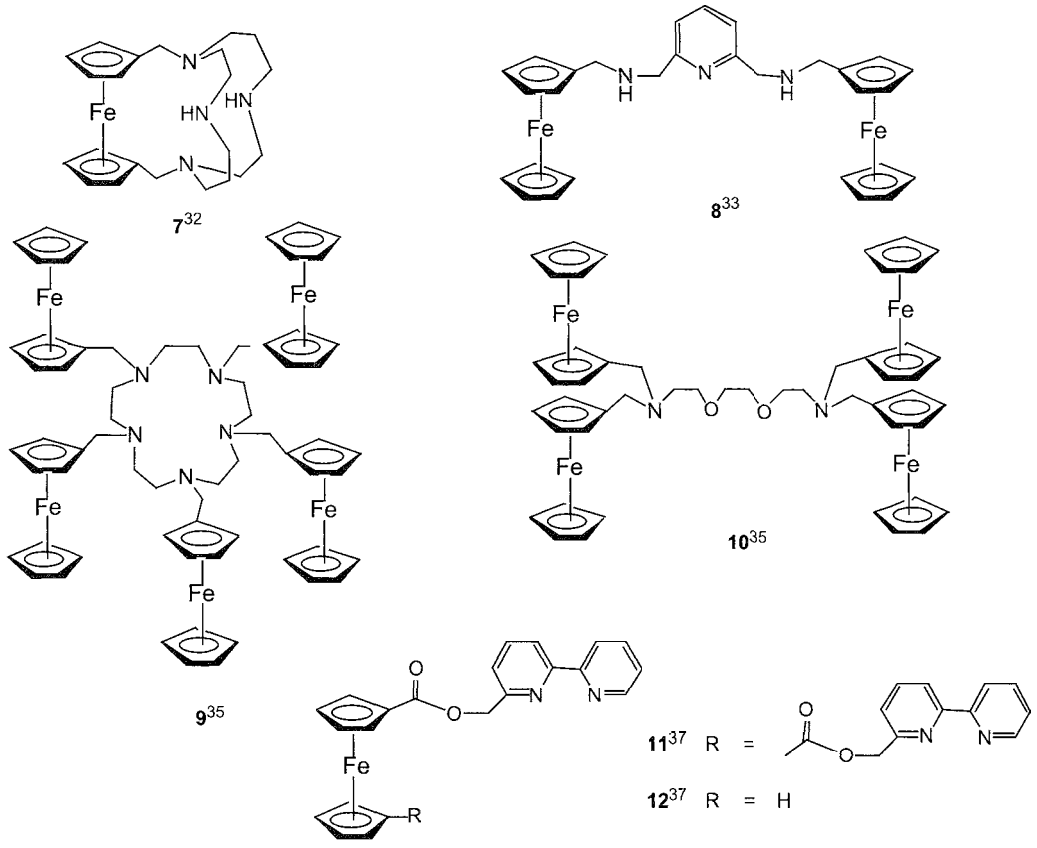

Fig. 2 Ferrocene receptors for transition metal and soft metal cations.

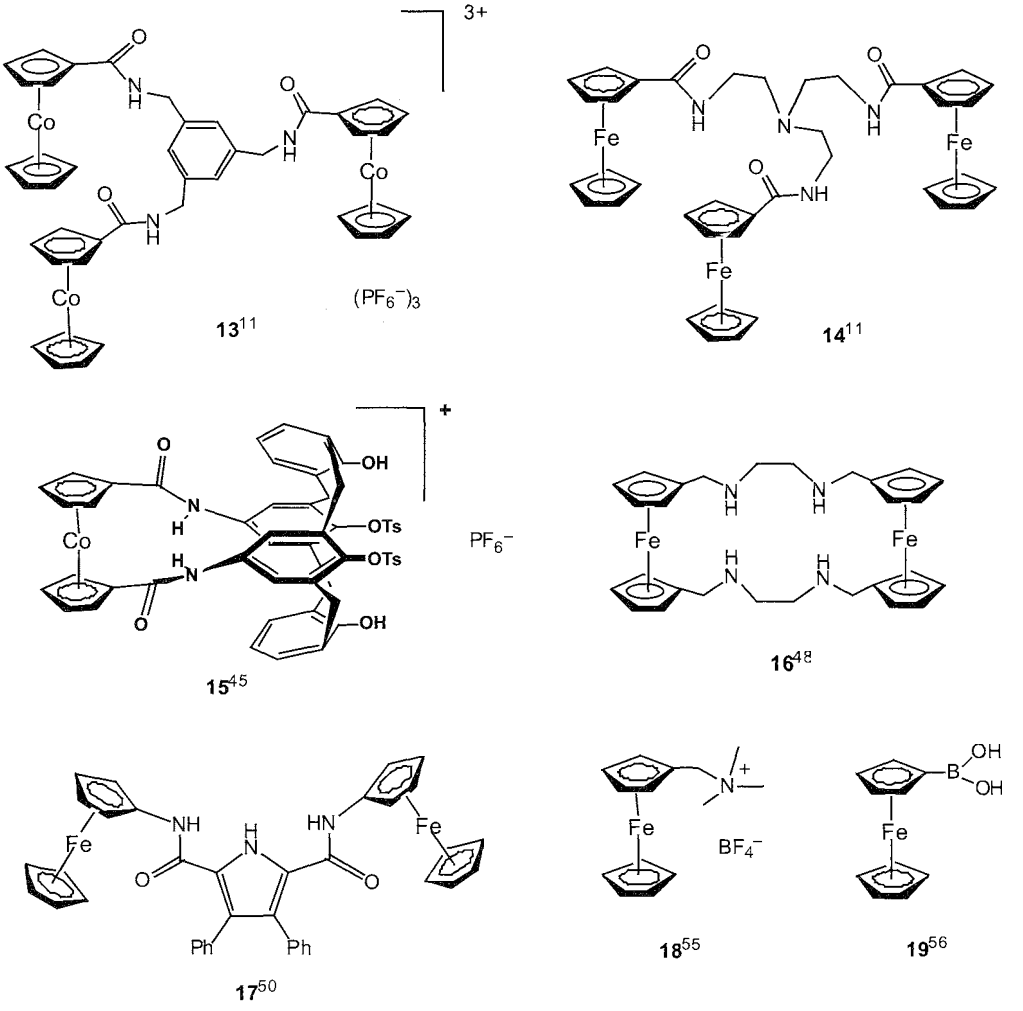

Fig. *3* Metallocene receptors for anions

sense oxoanions at a particular pH value. For example, at pH 4 in THF/water (70:30 v/v), ligand 16 selectively forms a 1:1 complex with sulfate in the presence of phosphate. with the Fc^+/Fc redox couple undergoing a shift of -54 mV upon complexation.[48] Under these conditions. all four secondary amines of the receptor are protonated. with the anion existing as HSO_4^-. The biological anion ATP can also shift the redox couple of **16** cathodically by up to -100 mV. depending on the pH of the medium.

Other groups reported a variety of ferrocene receptors for anions,[49–57] representative examples of which are shown in Fig. 3 (Compounds 17–19). Some of these are simple. for example, commercially available **18**, which can sense dihydrogen phosphate and ATP anions in organic media.[55] The large negative shifts of the Fc^+/Fc redox couple upon compiexation (e.g., $\Delta E = -470$ mV in CH_2Cl_2 upon addition of $H_2PO_4^-$) result from strong ion-pairing interactions between the anion and the double positive charge of the quaternary ammonium group and the oxidized ferrocenium ion. Another commercially available compound is ferrocene boronic acid. **19**,[56] one of a number of redox-active boronic acid and boronate receptors.[57–59] that recognizes fluoride selectively over a range of other halide ions and oxoanions in water. Cathodic shifts in the Fc^+/Fc redox couple of ca. -200 mV were observed upon the addition of excess amounts of fluoride. which forms an adduct with the Lewis acidic boron center. A study with a ferrocenyl *bis*(boronate) derivative demonstrated similar selectivity toward fluoride.[57]

In contrast to the recognition of cations or anions. the eiectrochemical sensing of neutral molecules by redox-active receptors is less common. A number of supramolecular ferrocene receptors for such species are now known,[59–67] but only a few are reported as undergoing significant electrochemical responses to complexation. As found with the anion receptors. complexation brings about a negative shift in the Fc^+/Fc redox couple. which is consistent with host–guest binding strength being stronger in the ferrocenium form. Beer utilized a neutral ferrocene-appended calix[5]arene to encapsulate and

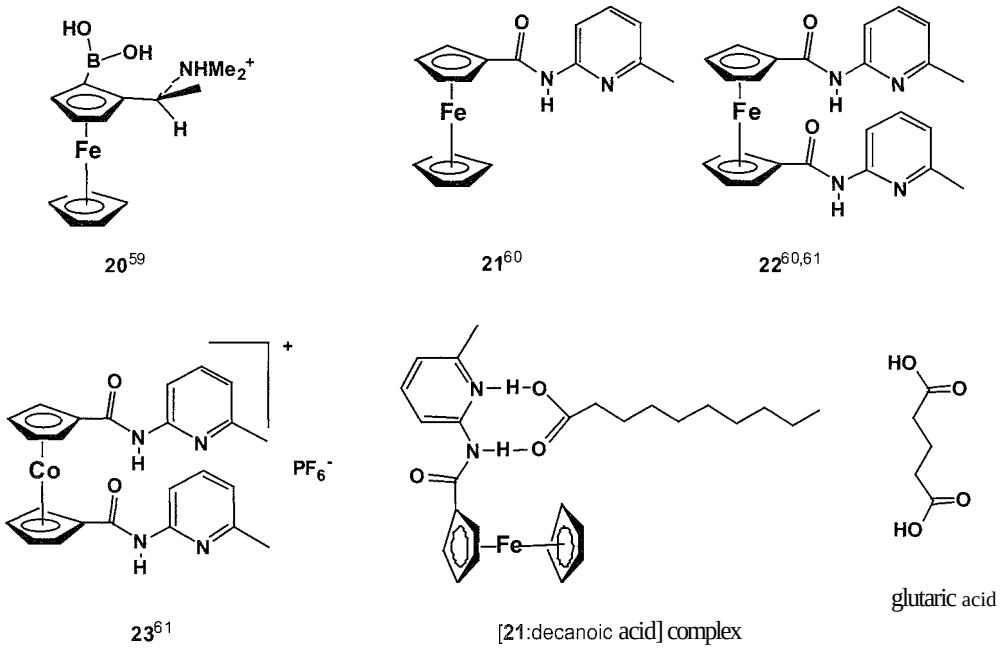

Fig. 4 Metallocene receptors for neutral molecules

sense the binding of polar organic molecules such as EtOH and DMF.[64] Electrocheinical studies revealed that inclusion of these molecules into the calixarene cavity induced small changes in the ferrocene-centered redox waves. Some other ferrocene compounds that electrochemically respond to neutral organic molecules are shown in Fig. 4.

The boronic acid 20 reported by Shinkai[59] is a rare example of an enantiopme chiral redox-active receptor." It was found to bind linear and cyclic sugars in aqueous solution at neutral pH due to the reversible reaction between the boronic acid moiety of the protonated ferrocene receptor and the sugar to form a boronate ester. Electrochemical studies revealed that complexation imparted cathodic (ca. -50 mV) shifts in the Fc^+/Fc redox couple. Interestingly, moderate enantioselectivity was observed in that (+) -1 bound the linear saccharide D-sorbitol more strongly than L-sorbitol (K_D/K_L = 1.4). However. differences in the electrochemical response to the binding of these enantiomers by 20 were not apparent.

Metallocenes 21–23 were found to bind mono- and dicarboxylic acids in organic solvents through complementary hydrogen bonds with their amide (N–H...O) and pyridine (O–H...N) groups.[60,61] Cyclic voltammetry studies in CH_2Cl_2 revealed cathodic shifts in the Fc^+/Fc redox couples, with the redox response to complexation of the monoacid decanoic acid by 21 and 22 (-25 mV and -55 mV, respectively) being approximately proportional to the number of hydrogen bonds in each complex (two and four. respectively).[60] Similar cathodic shifts were found in the complexation through hydrogen bonds of 3-aminopyrazole derivatives by ferrocene dipeptide receptors.[63] The binding of the dicarboxylic acid glutaric acid by metallocenes 22 and 23 in $CDCl_3$-0.5% DMSO. to give complexes of 1:1 stoichiometry. iinparted larger but identical cathodic shifts of -90 mV in the redox couples of each receptor. due to the guest being bridged between the Cp rings.[61]

Other inorganic reporter groups

A number of other metal-based redox-active centers have been incorporated into supramolecular receptors. representative examples of which are displayed in Fig. 5 (Compounds 24–28). Many of these receptors electrochemically respond to cations.[70–78] but species that respond to anions[58,79] and neutral molecules[80] are also known. A number of the cation binders are organometallic crown ether and metallocrown or metallothiacrown derivatives,[71–78] for example. Compound 24.[77] However, in many cases, the redox processes are not particularly reversible, and relatively small anodic shifts in the metal-centered redox couples are observed. A series of self-assembled [12]metallocrown-3 complexes. two of which are 25 and 26, were found by Severin to bind halide salts of small Group 1 metals strongly in organic solvents. with affinities similar to those of the cryptands.[71,72] X-ray crystal structures revealed that the metal cation was

"For two recent examples of electrochemical sensing by homochiral redox-active receptors. see Refs. [68,69].

bound in the center of the cavity, coordinated by three oxygen atoms of the metallocrown and the halide counterion. No detectable complexation of KCl was observed due to the small size of each cavity. These receptors were found to respond electrochemically to complexation, with shifts in oxidation peak potential of more than + 300 mV observed upon addition of LiCl and NaCl to 25. The $LiBF_4$ complex of 26 was also found to electrochemically sense fluoride anions in organic solvents.[72] A cathodic shift of −203 mV was observed upon the addition of excess NBu_4F, as a result of the fluoride anion forming an unusual molecular Li–F bond.

Transition metal bipyridine[79] and terpyridine[58] complexes were used as redox reporter groups for anions. The bimetallic receptor **27** was found to respond to chloride anions in CH_3CN, as evidenced by a cathodic shift of −110mV in the ligand-centered reduction couple of the two *bis*-substituted bipyridine groups.[79]

Organic Reporter Groups

There are numerous examples of organic redox-active reporter groups that have been incorporated into supramolecular receptors over the past 20 years. Many of these date to the 1980s and early 1990s. when Gokel and coworkers reported a number of crown ether and cryptand derivatives containing redox-active centeres. Much of this work has been reviewed.[2,13] A number of macrocylic receptors containing reducible redox-active groups are now known,[81–92] representative examples of which are shown in Fig. 6 (Compounds 29–33). Crown ethers and cryptands containing quinone/anthraquinone,[81–86] azobenzene,[87,88] and nitrobenzene[8,89] units sense Groups 1 and 2 metal cations through anodic shifts in reduction potential, as a result of the reduced forms binding these positively charged guests more strongly. The zinc(II) cyclen complex 30 was found to electroche~nicallydetect the DNA base thymidine in aqueous solution at physiological pH. This was possible through cathodic shifts in the anthraquinone reduction potential, as a result of π–π stacking interactions between host and guest decreasing upon anthraquinone reduction.[85]

A number of other reducible organic redox-active groups were used in receptors that can bind species through the formation of hydrogen bonds. However, most of these were used for i-edox-switched binding purposes rather than for electrochemical sensing.[9,93]

Some examples of receptors containing oxidizable organic groups that respond electrochemically to cat-i$_{ons}$[**–102] are depicted in Fig. 7 (Compounds 34–38). The tetrathiafulvalene (TTF) unit. which can undergo two reversible oxidations. is one of the most common redox-active groups to be incorporated into a supramolecular sensor over the past few years. The groups of Becher, Sallé. and Bryce are prominent in this field, publishing

receptors with cation binding sites located at the end of (e.g., **34**), or across (e.g., **35**), the TTF unit.[94–99]

TTF receptors are known for binding hard or soft metal cations, depending upon the type of donor atom used in the receptor unit, although hydrogen-bonding TTF receptors for neutral molecules[97] are also known. In general, cation binding produces a positive shift in the first TTF oxidation potential, with the second being largely unchanged, which is attributable to the expulsion of the bound cation from the positively charged cavity. Recent progress involved the preparation of a TTF receptor **36**[98] containing two pyrrole units that makes it devoid of the *cis*/*trans* isomerization found in 35. This compound can electrochemically sense Pb^{2+} and Ba^{2+} ions in organic solvents; with unprecedented large shifts observed in the first TTF oxidation potential.

RECEPTORS IMMOBILIZED AT A SURFACE

In order to assess the commercial viability of the supramolecular approach to voltammetric sensing. it is important for freely diffusing receptor species to be attached to a surface to assess whether changes in redox properties observed upon complexation in a homogenous system can still be observed once the receptor is immobilized. Accordingly, examples of thin filins of redox-active receptors on surfaces (e.g., chemically modified electodes. CMEs) are becoming increasingly common, as exemplified by a recent review.[6] The most common methods of iinmobilizing a receptor onto a surface involve the formation of either a polymer film or a self-assembled monolayer (SAM). An overview of both approaches, with appropriate examples, is given below.

Polymer-Based Electrochemical Sensors

Polymer-based materials are of immense interest to supramolecular chemists working in a number of fields. The area of polymer-based sensing is vast and was reviewed by Swager in 2000.[103] As far as electrochemical sensors are concerned, a number of approaches have been identified,[6] but they generally fall into two main categories. The first involves using a system in which the receptor site is simply attached to the electrode-immobilized polymer (e.g., polypyrrole or polythiophene) through covalent bonds, with the redox-active polymer film acting as the redox probe (e.g., Fig. 8, Compounds 39–41).

This approach was fairly popular in the past,[6,103] especially for the sensing of metal cations using crown ethers (e.g., Compound **39**[104]) or nitrogen-containing ligands.[105] More recently, calixarene-based polymers were shown to be effective voltammetric sensors for such species.[103,106] However, other charged or neutral species can also be sensed if an appropriate receptor group is used. For example. Fabre reported that a conjugated polymer film formed from the anodic oxidation of boronate-substituted pyrrole. 40, can selectively sense millimolar concentrations of flouride in an H_2O–CH_3CN solvent mixture.[107] Likewise, redox-active thiophene polymers covalently linked to hydrogen-bonding units were found to recognize complementary DNA base derivatives (e.g., Complex **41**).[108,109]

The second approach involves using a separate redox-active group as the reporter group, with the polymer merely providing a convenient means for immobilizing the receptor onto an electrode surface (e.g., Compounds 42–44, Fig. 9). Thus, a more defined and controlled redox response to complexation can be envisaged, and a direct comparison with the performance of freely diffusing receptors is possible.

The group of Moutet and coworkers published a number of reports on the sensing of Group 1 and Group 2 metal ions using ferrocenyl crown ethers in polypyrrole films."[10] In a recent study, a polypyrrole film was grown on a Pt electrode from the corresponding pyrrole-substituted monomer 42. A sole redox process corresponding to the Fc^+/Fc redox couple was observed in CH_3CN solution. The transfer of this film to a solution containing Ba^{2+} ions resulted in the immediate appearance of a new redox wave. anodically shifted by 0.12 V. The free receptor could be regenerated by holding the film at a positive potential in Ba^{2+}-free electrolyte or by soaking in an aqueous EDTA solution. Interestingly, the magnitude of the redox response and the selectivity pattern toward different cations were comparable to that of an analogous freely diffusing receptor.

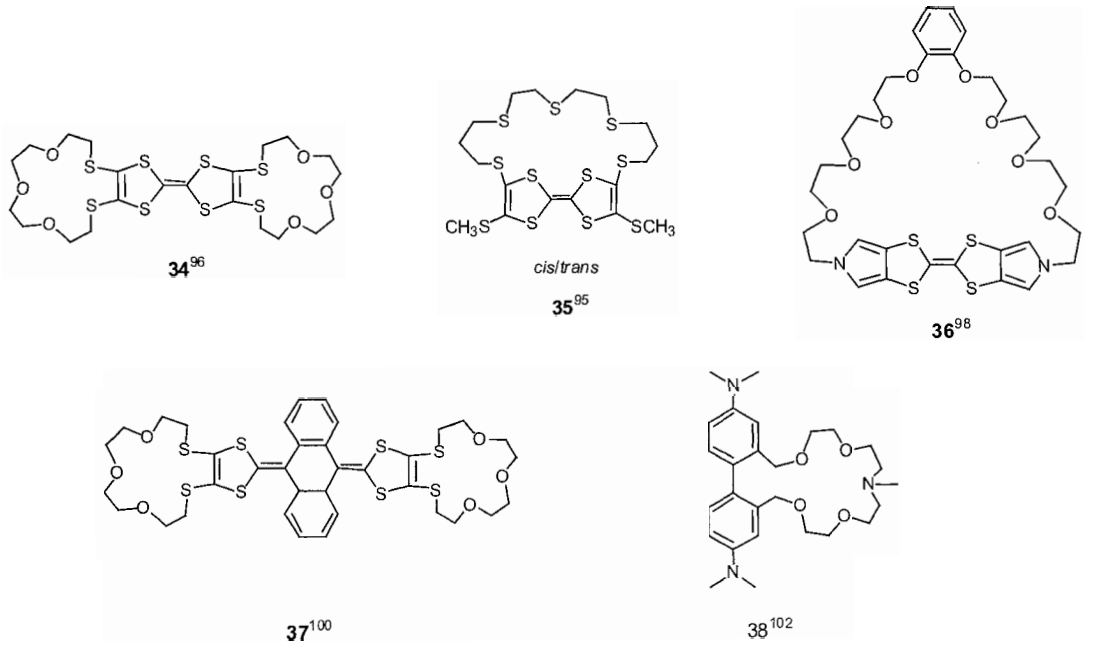

Fig. 7 Redox-active receptors containing oxidizable organic reporter groups.

Similar approaches were used by others to detect of anions and neutral molecules. For example, the cobaltocenium compound 43 was immobilized onto an electrode surface by electropolymerization.[111] The presence of submillimolar amounts of $H_2PO_4^-$ in CH_3CN caused a cathodic shift in the cobaltocenium$^+$/cobaltocene redox couple as well as the appearance of a new redox wave at more negative potentials. The film was selective toward this anion over HSO_4^- and halide ions. as was the monomer in homogenous solution. Smith built on previously described studies of hydrogen-bonding interactions in solution[93] with the synthesis of a phenanthrenequinone (PQ) pyrrole 44, which was electropolymerized at a glassy carbon disk electrode.[112] Electrodes derivatized with this polymer were found to be reasonably stable in organic solvents. The electrode was placed in CH_3CN solutions of various urea compounds. such as 1-phenyl-3-propylurea. As observed previously in solution phase studies, urea complexation through two compleinentary hydrogen bonds resulted in anodic shifts in the $PQ^{0/-1}$ redox couple, indicating a strong interaction between the surface-confined quinone radical anion and the urea. Interestingly. the surface-confined receptor was found to be more selective than the analogous compound in solution. with only aromatic ureas causing a significant shift in reduction potential.

SAM-Based Electrochemical Sensors

The use of self-assembled monolayers (SAMs) for Investigating the binding properties of redox-active groups at a surface has been explored over the pact few years by a number of research groups [13 14.113–117 119–123] Some examples of redox-active receptors that form monolayers and respond electrochemically to complexation are shown in Figs 10 and 11 (Compounds 45–49) An early example

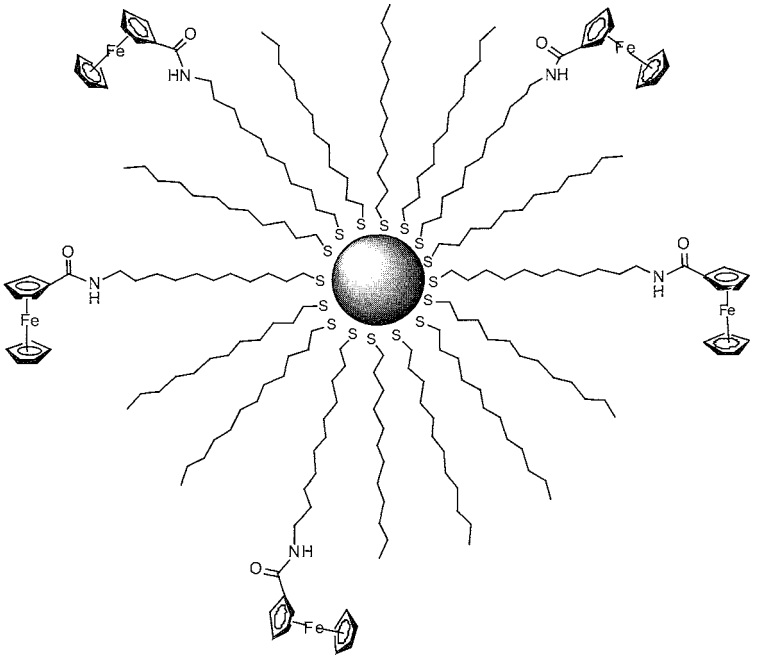
involved the disulfide 46, which formed a inixed monolayer with decanethiol on a gold electrode.[113] Micromolar concentrations of catechol and indole could be detected by shifts in the reduction potential of the viologen groups. More recently. a related viologen-based receptor[114] was found to bind and sense a series of ferrocene derivatives.

Ferrocene-containing SAMS have been used in a number of examples of molecular recognition processes at a surface. Kaifer and Gokel successfully used such species to probe the binding of β-cyclodextrin derivatives through shifts in ferrocene-centered oxidation potentials.[115] More recently, ferrocene-containing SAMS on spherical surfaces (gold colloids)[116] and planar surfaces



45[116]

Fig. 10 A gold colloid containing mixed dodecanethiol and amido(ferrocenyl) undecane thiol ligands

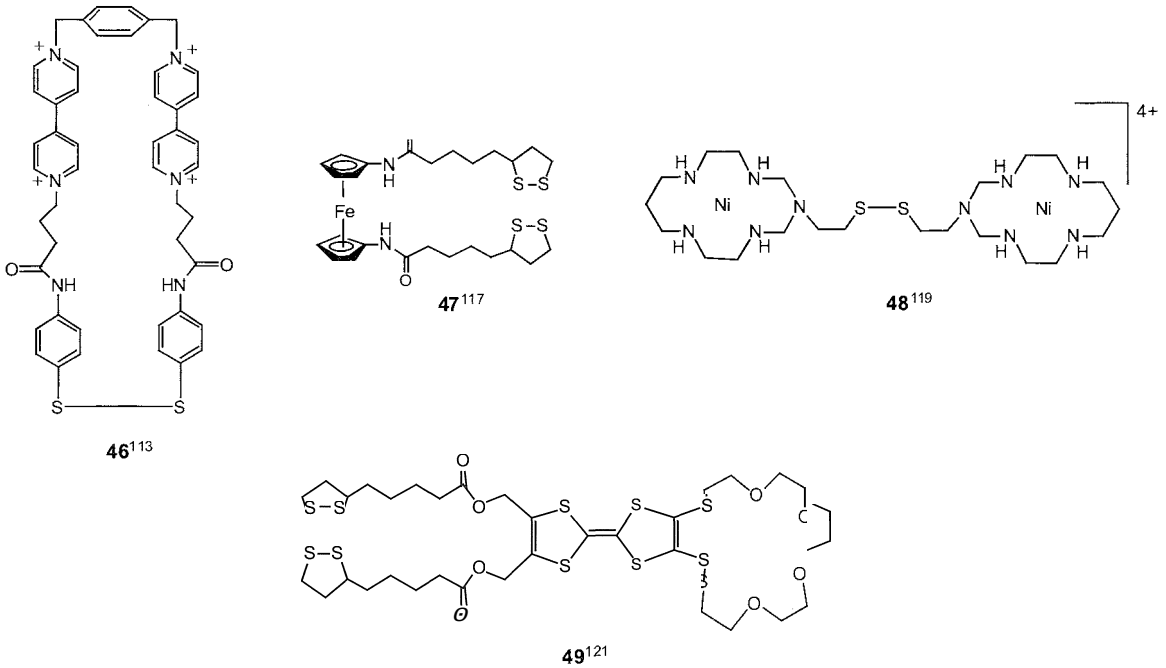


Fig. 11 *Redox-active receptors* that *form self-assembled monolayers* (SAMs) *on electrode* surfaces

(gold electrodes)[117] were *used to sense anions. Functional assemblies on gold colloids have been identified by Willner as potential nanostructured sensing* devices.[118] Astruc *synthesized a series of* mixed *monolayer gold colloids such as 45 (containing 39 ferrocene branches) that responded to anions* in CH_2Cl_2.[116] *Cyclic* voltammetry *studies revealed that the addition of* $H_2PO_4^-$ *to a solution of 45 induced the* formation *of a new ferrocene-centered* redox *wave that was cathodically shifted by* −220 mV *from the original couple that corresponded to the oxidation of the* unbound redox *sites.* An *electrochemical titration revealed that each ferrocene branch formed a 1:1 complex with the anion. Interestingly, the shifts in the* redox *couple were much less with* HSO_4^- *(−30* mV), *with no significant changes observed with nitrate or with the halide anions* Cl^- *or* Br^-.

Beer and Davis *reported* Compound **47**, *which formed a* 1:1 *complex* with $H_2PO_4^-$ *in organic* solvents.[117] *The addition of an excess amount of this anion to a monolayer of* **47** *on a gold electrode in* CH_2Cl_2–CH_3CN *brought about a large cathodic shift in the* Fc^+/Fc redox *couple of* −300 mV. *This shift was significantly larger than the response for the same compound as a freely diffusing species* (−210 mV), *which was indicative of a surface sensing* amplification *effect. As for other anion sensors, a SAM of a* dinickel(II) *complex 48 was found* to *electrochemically respond to a range of anions in aqueous solution. including ATP, as evidenced by cathodic shifts in the* Ni(III)/Ni(II) couple.[119] The *results were consistent with axial coordination of the nickel center by either one or two anions, but* only *in the* +3 *oxidation state.*

Cations can also be sensed by SAMs *containing* redox-active TTF[120,121] *or* calix[4]quinone[122] *moieties. The first example of a TTF-containing SAM that responded to cations was reported by Moore and* coworkers.[96,120] *Anodic shifts in the TTF-centered* redox *couple the surface-bound receptor were observed* in *the presence of Croup 1 and Group 2 cations and also* Ag^+. *Echegoyen reported a related dithia-crown ether, 49, containing two* disulfide *arms, that forms particularly stable monolayers and responds to Croup 1 cations* in *a similar* fashion.[121]

CONCLUSION

The objective of this review has been to show how supramolecular *chemistry has made, and is continuing to make. an important contribution to the area of electrochemical sensing. From an applications point of view, future developments will continue to be directed toward recognition and read out at a surface. so that robust voltammetric sensors that are viable alternatives* to *other sensors* (e.g., *biosensors) can be produced. However, fundamental studies are required to further our understanding of how to maximize substrate selectivity. while maintaining an effective electrochemical response to* complexation. *Switchable* ''on/off'' *binding processes,*[9,124,125] *where* complexation *strength can be closely controlled by* redox *processes. are likely to become increasingly important. Recent developments in molecular recognition and sensing using redox-active* dendrimers[126–129] and nanoparticles[116,118,123,130] *are*

likely to widen interest in this area even further, as will the continuing development of novel electrochemical methods[131–134] for the detection of a range of species.

E

Electron Paramagnetic Resonance Spectroscopy

Gunnar Jeschke
Max Planck Institute for Polymer Research, Mainz, Gerrnany

INTRODUCTION

Structures on length scales between 0.3 and 10 nm and dynamics on time scales between approximately 10 ps and 1 ys can be characterized by electron paramagnetic resonance (EQR) spectroscopy if a suprainolecular system contains native paramagnetic centers. such as free radicals or transition metal ions, or if stable free radicals can be introduced as spin probes or labels. Probe concentrations as low as 10 $\mu mol \cdot L^{-1}$ and sample volumes down to *5* µl may be sufficient for recording continuous-wave (CW) EPR spectra at conventional frequencies of 9–35 GHz. Such experiments provide details on the reorientation dynamics of small molecules or paramagnetic side groups that are. in turn, related to weak interactions between molecules. For high-field EPR at frequencies of *95* GHz, sample volumes of 100 nL may suffice. while more sophisticated pulse techniques. such as pulse electron electron double resonance (ELDOR) and electron nuclear double resonance (ENDOR) at *9–35* GHz, require concentrations and sample amounts that may be *5–10* times larger than for CW EPR. The latter techniques can yield pair correlation functions corresponding to specific sites in a supramolecular system and can directly prove contact between different molecules or between molecules and inorganic surfaces. The highly selective addressing of sites of interest by probes or labels combined with the vast amount of information accessible by a broad arsenal of techniques makes EPR spectroscopy an attractive tool for studying complex suprarnolecular systems that lack long-range order.

SCOPE OF EPR SPECTROSCOPY

Native Paramagnetic Species

Paramagnetism is related to single occupation of molecular orbitals. Systems with an odd number of electrons are, thus, necessarily paramagnetic, while the more abundant systems with an even number of electrons have a diamagnetic low-spin state and paramagnetic high-spin states. For most stable molecules. the ground state is diamagnetic. and short-lived excited paramagnetic stales are accessible only by absorption of UV or visible light. In the absence of strong light irradiation, such species do not give rise to EPR signals. For this reason, EPR spectroscopy is not a generally applicable method for structure determination. On the other hand, the rareness of paramagnetic centers greatly enhances the resolution in the spectra and simplifies the assignment of the lines in applications to complex materials such as supramolecular assemblies.

A few stable molecules, notably NO and NO_2, have an odd number of electrons and are accessible to EPR spectroscopy. The most important class of such molecules is comprised of the nitroxide stable free radicals.[1,2] In the solid state. where diffusion is slow, dilute radicals may be metastable for long times, in particular, when the unpaired electron is strongly delocalized over a system of conjugated bonds. Further molecules and macromolecules have a high-spin ground state.[3] Some can be detected directly by EPR. while others, such as O_2 with an extremely fast-relaxing ground-state triplet enhance relaxation and thus broaden lines of other paramagnetic species.[4] Solid inorganic networks have structural discontinuity at their surface that often gives rise to so-called dangling bonds. For particle sizes in the nanometer to micrometer range, the specific surface and thus the concentration of such dangling bonds may be sufficient for detection by EPR spectroscopy.

Among transition metal and rare earth metal ions, there is a sizeable number of stable species with an odd number of electrons, prominent examples being Ti^{3+}, VO^{2+}, Cr^{3+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Cu^{2+}, Ce^{3+}, Nd^{3+}, Dy^{3+}, and Er^{3+}. Most of these species are catalytically active, and a number of them were studied in zeolite-type materials.[4] For these ions. a low-spin ground state with total electron spin $S=1/2$ is attained due to electron pairing in strong ligand fields. Complexes with weak ligand fields may have high-spin ground states; for instance, $S=3/2$ for Co^{2+} ($3d^7$), and $S=5/2$ for Fe^{3+} ($3d^5$). This is significant. as high-spin species tend to have more complicated spectra and shorter relaxation times and are thus more difficult to study. However, transition metal ions with an even number of electrons can only be studied in their high-spin states. the low-spin states being diamagnetic. These species have integer spin and transitions that are observable only at high fields and frequencies,[6]

Encyclopedia of Supramolecular Chemistry

unless symmetry is high enough to cause degeneracy of two states at zero field (cubic symmetry or at least one rotation axis C_n with $n \geq 3$).

Stable Free Radicals Suitable as Probes or Labels

The structures and dynamics of supramolecular assemblies are usually complex and cannot be completely characterized by a single technique. This is particularly true for functional systems, which require a minimum size of a few nanometers and a certain balance between flexibility and rigidity to allow for reproducible changes of their states. The difficulties in characterizing such systems are readily apparent for a natural class of supramolecular systems, namely, membrane proteins that are functional when embedded in a lipid bilayer and tend to be extremely difficult to crystallize. To understand structure-dynamics-function relationships of such systems, many pieces of information on length scales between 1 Å and several nanometers and time scales between picoseconds and milliseconds have to be assembled and interpreted. The samples are often macroscopically disordered systems, and the conformation of the molecules is distributed to some extent. Techniques for local characterization of structures and dynamics at selected sites are required to reduce the complexity of the problem.

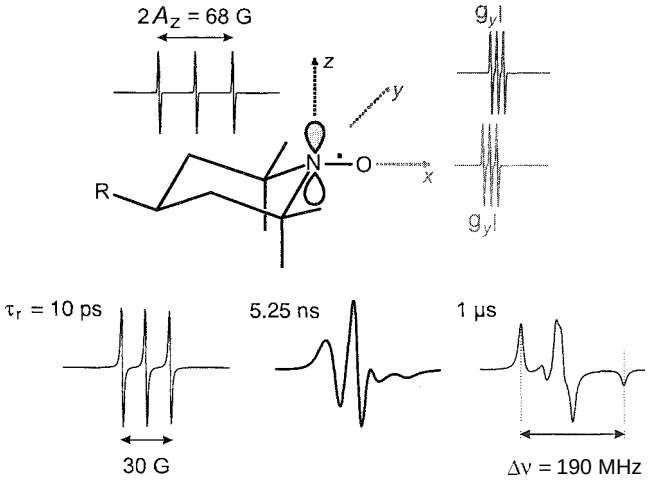

Fig. 1 Orientation dependence of nitroxide spin-probe EPR spectra and dynamical effects on line shapes (simulations). Maximum hyperfine splitting A, is observed along the lobes of the singly occupied molecular orbital (z direction). Within the xy plane, spectra at X band frequencies differ only slightly due to g anisotropy. Dynamic spectra are shown for rotational correlation times τ_r corresponding to the fast limit (10 ps), slow tumbling ($\tau_1 = 1/\Delta\nu = 5.25$ ns), and the rigid limit (1 ys). (*View* this *art* in *color* at *www.dekker.com.*)

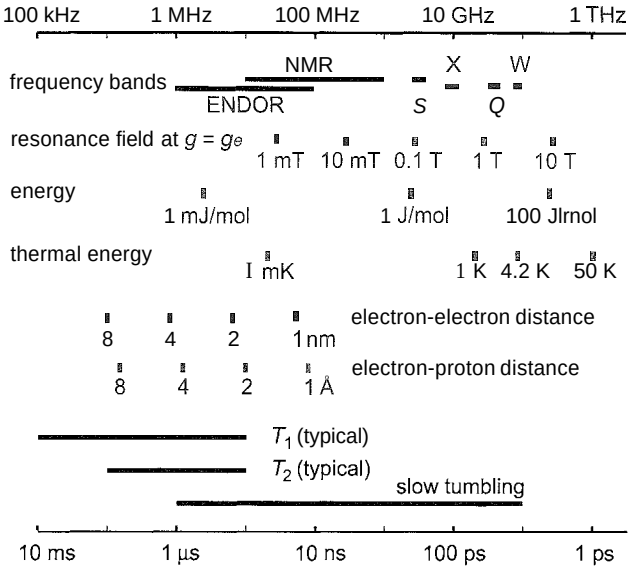

Fig. 2 Frequencies, magnetic fields, energies, length scales. and time scales relevant in EPR spectroscopy (logarithmic scale).

These factors represent the rationale for using probes, which mimic certain constituent parts of the system, or site-selective labels. In a spin probe (in the following, this term includes labels). the electron should be well localized to allow for measurements with high spatial resolution. Furthermore, a moderate anisotropy of the spin interactions is favorable, as this introduces information on reorientation dynamics of the probe into the spectra. Finally. probes should be as small as possible to avoid undue interference with the observed system. Nitroxide-free radicals (Fig. 1) nicely fulfill all the requirements and are available with a broad range of additional functional groups.[1,2,7] The spin is almost equally distributed between two p orbitals on the N and O atoms of the nitroxide group, with little spin density on adjacent carbon atoms. The anisotropies of the hyperfine coupling to the nitrogen nucleus and the g tensor correspond to widths of the powder pattern of a few 10 mT at typical EPR frequencies between 9.5 and 95 GHz (see Fig. 2 for designations of EPR frequency bands). The N–O group and the neighboring groups, which prevent dimerization by sterical hindrance, roughly fit into a rotational ellipsoid with an extension of 0.7 nm x 0.5 nm. Probes such as TEMPO (2,2,6,6-tetramethyl-piperidine-1-oxyl) are soluble with the required concentrations of approximately 1 mM in a broad range of solvents. including for instance toluene and water. as the molecule as a whole is largely unpolar, while the slightly polar N–O group can take part in hydrogen bonds.

Transition metal ions are less widely applicable as spin probes but may be convenient for addressing ionic clusters or ligand moieties[8] or for substituting diamagnetic ions.

For substitution of diamagnetic Mg^{2+} ions by paramagnetic Mn^{2+} ions. the perturbation of the system is almost not perceptible, as evidenced by some metalloproteins that function with both of these ions.

Sensitivity

In general. sensitivity of spectroscopies increases with frequencies of the photons that excite the transitions. EPR spectroscopy ($\sim 10^{10}$–10^{11} Hz) is thus significantly less sensitive than optical spectroscopy ($\sim 10^{15}$ Hz) and vibrational spectroscopy ($\sim 10^{13}$ Hz) and significantly more sensitive than NMR spectroscopy ($\sim 10^{7}$–10^{9} Hz). Typical concentrations of paramagnetic centers in EPR spectroscopy are between 50 μM and 2 mM. In this range, the whole arsenal of CW[9,10] and modern pulsed EPR methods[11] can be applied. Usually. CW EPR spectra of good quality can be acquired for concentrations as low as 10 μM, and free radicals can be detected at least down to concentrations of 1 μM. Typical sample volumes with standard equipment are 150 μl at X-band frequencies, which can be decreased to 5 μl using loop-gap resonators. A sample amount corresponding to 2.5 nmol paramagnetic centers is thus sufficient for a broad range of techniques at X band, while CW EPR can be performed down to sample amounts of approximately 0.1 nmol. As spectra of transition metal ions are broader, 5–10 times higher concentrations may be needed for those species.

The required sample volume in EPR spectroscopy roughly scales with the cube of the wavelength. A sample volume of 100 nL is sufficient for all experiments at W-band frequencies. Despite a moderate decrease in concentration sensitivity when going to frequencies higher than 35 GHz. high-frequency EPR can thus deal with minute amounts of paramagnetic centers.

RELATION OF SPIN INTERACTIONS TO STRUCTURE AND DYNAMICS

Spins are magnetic dipoles that interact with magnetic fields imposed externally or locally by other spins.[9–11] As the dipole–dipole interaction scales with the inverse cube of the distance between the two dipoles (Fig. 3), information on the spatial distribution of the spins in solids can be inferred. For electron spins, the apparent local magnetic field is influenced by the spatial distribution of the unpaired electron and modified by spin-orbit coupling, so that there is also information on the singly occupied molecular orbital (SOMO).

For spin quantum numbers larger than $^1/_2$, spins have an electric quadrupole moment that interacts with electric field gradients. For electron spins, this interaction is again related to the spatial distribution of the unpaired electron and modified by spin-orbit coupling. For spins of nuclei involved in covalent bonds, the quadrupole interaction is related to the type and specifics of bonding. For nuclear spins in ionic materials, it is related to the distribution of point charges in the vicinity of the nucleus.

The separation and analysis of all interactions can thus provide a detailed picture of the geometric and electronic

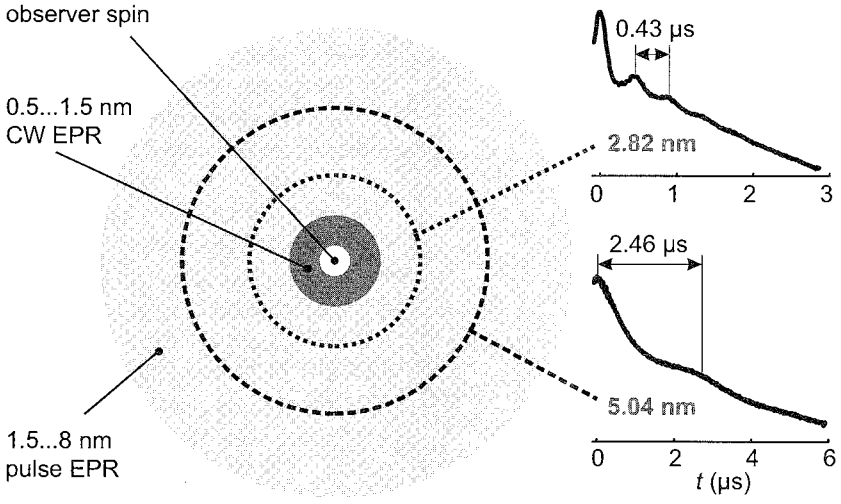

Fig. 3 Distance measurements between paramagnetic centers by EPR spectroscopy. Below 0.5 nm. distance estimates are unreliable: for $0.5<r<1.5$ nm. CW EPR is the method of choice; for $1.5<r<8$ nm, pair correlation functions can be obtained from pulse EPR data: and spins at larger distances (up to 40 nm) contribute only to background. Well-defined distances in shape-persistent molecules can be directly computed from the dipolar oscillation frequency (right). (View *this art in color at www.dekker.com.*)

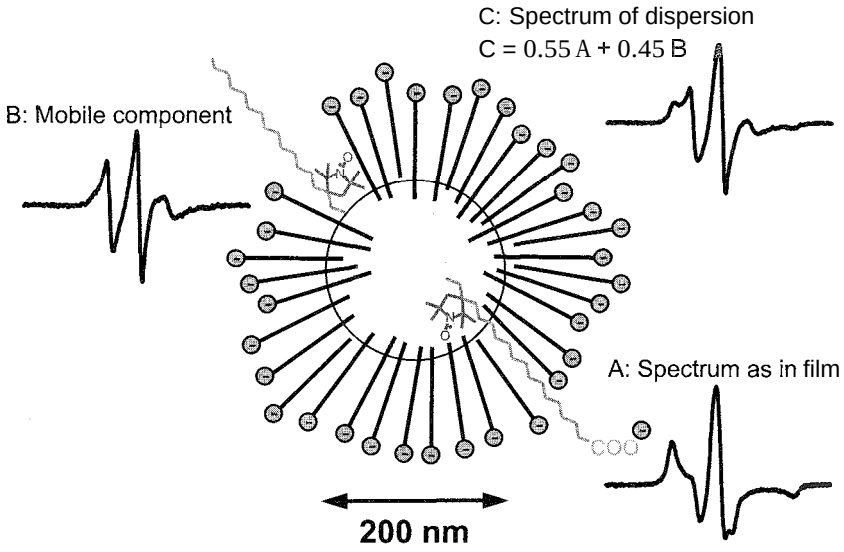

Fig. **4** Dynamical contrast between two surfactant sites in a colloidal polymer dispersion [poly(butylmethacrylate)]. Surfactant spin labels anchored with their tail end in the polymer particle exhibit a rigid limit line shape (A), while surfactants not anchored are more mobile (B). The total spectrum C of the dispersion is a superposition. with the fraction of the mobile component decreasing with decreasing water content (data taken from S. Cramer. Ph.D. thesis. University of Mainz, 2000). (*View this art in color at www.dekker.com.*)

structures of the system under investigation. Such a complete analysis can rarely be performed on the basis of only the CW EPR spectrum. The ENDOR, ELDOR, and electron spin-echo envelope modulation (ESEEM) techniques may be required to separate interactions.[11,12] Even with such a broad method arsenal, a full analysis is not usually undertaken. After the interactions of interest in a given context are identified. one tries to separate and measure them with the required precision and collects supporting information necessary for their unambiguous interpretations. The intricacies involved in this approach are discussed below. An overview of the interactions and their typical energies is given in Fig. 2.

The EPR, ENDOR, and ELDOR spectra are sensitive to dynamic processes that change electronic or geometric structures (chemical reactions, phase transitions. diffusional encounter of paramagnetic centers among each other or with macromolecules or surfaces), lead to a change in resonance frequency for a given structure (reorientation of centers with anisotropic interactions), or influence spin relaxation (fluctuation of interactions due lo reorientation, vibrational dynamics, Heisenberg spin exchange). The most reliable results on dynamics are usually obtained for spin probes with electronic and geometric structures that are well known. Dynamical contrast. i.e., differences in rotational dynamics, between probes located at different sites or in different domains of a complex material can be used to infer the distribution of the probes between the sites or domains (Fig. 4).

Geometric Structure—interactions Through Space

Dipole–dipole interaction between electron spins—The nanometer range

The dipole–dipole interaction between two electron spins $S=^1/_2$ with $g=g_e$ has a magnitude of 52 MHz or 1.9 mT at a distance $r=1$ nm. It scales with distance as r^{-3} and is proportional to the product of the two g factors (Fig. 3). Line splitting or broadening due to this interaction is significant in CW EPR spectra up to a distance of approximately 2 nm. For larger distances, broadening due to proton hyperfine couplings usually dominates. For distances below 0.5 nm, anisotropic contributions of exchange coupling may become significant, and distance estimates based on electron–electron coupling may become unreliable. Line-shape analysis of CW EPR spectra or related techniques can thus provide distance estimates in the range between 0.5 and 2 nm.[7,13]

Pulse EPR methods can measure dipole–dipole couplings with precision to 0.5 MHz for most paramagnetic centers. which corresponds to a distance range up to 5 nm.[13–15] If transverse electron spin relaxation caused by proton spin diffusion is slow, a precision of 0.1 MHz corresponding to a distance of 8 nm can be achieved. This is possible for materials that do not contain methyl groups or water or when the bulk of the material is perdeuterated. If part of a supramolecular system exhibits

a distribution of conformations, distances between sites may not be well defined but instead broadly distributed. Such situations can be addressed by direct conversion of pulse EPR data to a spin-to-spin pair correlation function.[14]

Anisotropic hyperfine interaction—The Angstrom range

The dipole–dipole interaction between an electron spin $S=1/2$ with $g=g_e$ and a proton has a magnitude of 79 MHz at a distance of 1 Å. It scales with distance as r^{-3} and is proportional to the product of the electron and nuclear g factors. Only in exceptional cases are splittings due to this interaction resolved in EPR spectra. Usually. ENDOR or ESEEM techniques are applied that measure nuclear transition frequencies with a sensitivity roughly comparable to an EPR experiment.[11] The resolution of the measurements is determined by the static NMR line width, which is typically up to 100 kHz for protons in solids and less for other nuclei. This indicates that distances up to 8 Å between an electron spin and a proton can be measured. The precision of the distance measurement is not usually limited by the precision of the frequency measurement but rather by the spatial distribution of the unpaired electron. For a paramagnetic center with known structure, the latter contribution can be estimated by quantum-chemical computations of the hyperfine coupling and can thus be corrected.

The direct relation between the anisotropic part of the hyperfine coupling and the electron-nuclear distance is spoiled when there is spin density in orbitals other than *s* orbitals on this nucleus. Except for protons, alkali. and earth alkali ions, this is usually expected. In this situation. a quantum-chemical computation is mandatory before any attempt can be made to relate the hyperfine splitting to a distance.

Electronic Structure—Singly Occupied Molecular Orbital and Interactions Through Bonds

The *g* tensor

Orbital angular momentum of the electron spin is usually quenched in the ground state, but due to relativistic effects. there is an admixture of excited states that manifests itself as spin-orbit coupling and. in turn. as a deviation of the g value from g_e. Often the deviation is anisotropic and has to be described as a g tensor. This tensor reflects point symmetry at the site of the paramagnetic center and can be considered a characteristic for the global distribution of the unpaired electron. In other words. the principal values of the g tensor can often be used as the fingerprint of a certain type of paramagnetic center.

For characterizing supramolecular interactions, it is of interest that g tensor principal values are sensitive to the polarity of the environment and are influenced by hydrogen bonding to an atom with significant spin density in a p orbital.[16] For nitroxide spin probes. it was demonstrated that the two effects can be separated by correlating g_{xx} to A_{zz}.[17]

Exchange interaction

Two electron spins interact through Heisenberg spin exchange when their wave functions overlap. Such an exchange can proceeed along a network of bonds (overlap of two molecular orbitals of the same molecule) or through space or through a matrix. Exchange through space or through an isolating matrix is isotropic and is negligible compared to the dipole–dipole interaction at distances longer than 1.5 nm.[7] Exchange through a network of conjugated bonds or in a conducting material can be significant at distances up to at least 5 nm. In solutions, exchange broadening of spectral lines occurs through short-time overlap of the wave functions of colliding paramagnetic species. It is thus related to the local concentration of these species (Fig. 5).

Exchange coupling is related to ferromagnetism (antibonding overlap) and antiferromagnetism (bonding overlap) and to the rate of electron transfer between the two centers. The EPR measurements are useful in studies of molecular magnets. in order to probe their inner structures and to separate intramolecular and intermolecular contributions to the exchange interaction.[18]

Isotropic hyperfine interaction

Spin density in *s* orbitals of an atom with a magnetic nucleus results in an isotropic hyperfine coupling (Fermi contact interaction of electron and nuclear spin). Proton *s* orbital spin densities are usually caused by spin polarization and are proportional to the spin density on the directly bound neighbor atom.[9] Isotropic hyperfine couplings are thus related to the delocalization of the SOMO.

Hyperfine couplings to nuclei of strongly electronegative elements are sizeable. even for the extremely low-spin densities transferred from a paramagnetic center to neighbor molecules. For instance, in the case of ^{19}F, a hyperfine splitting of 0.5 MHz corresponds to a spin density as low as 10^{-5}. Detection of such couplings can thus prove spatial proximity between different molecules.

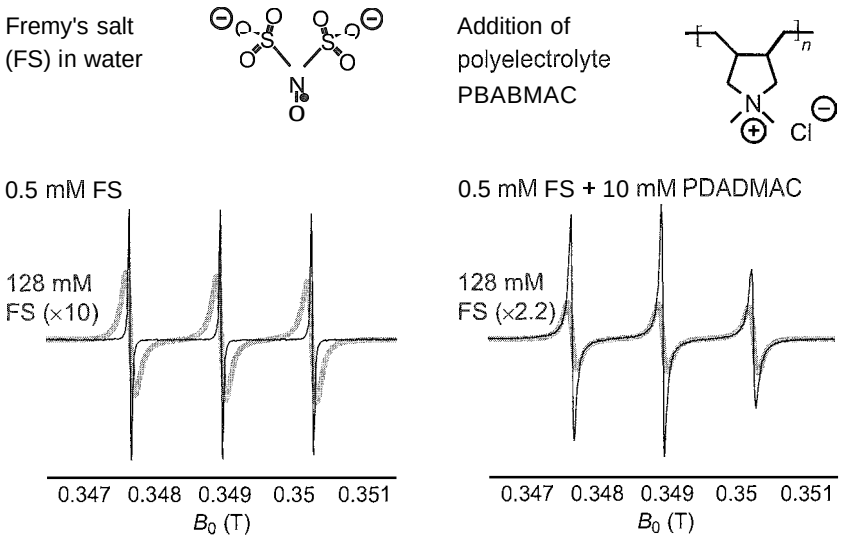

Fig. 5 Exchange broadening and slow down of rotational diffusion by dynamic electrostatic attachment of counterion spin probes to a polyelectrolyte. Left panel: Effect of exchange broadening on the spin probe EPR spectrum. Right panel: The broad wings of the center line indicate strong enrichment of counterions close to the polyelectrolyte. Broadening of the low-field and high-field lines cornpared to the center line stems from a slow down of the reorientation of the probe and is caused by formation of contact ion pairs with a subnanosecond lifetime (data provided by D. Hinderberger).

Dynamics—Anisotropy and Fluctuation of Interactions

Rotational dynamics and small-angle libration

Due to the anisotropy of g and of the hyperfine interaction, resonance frequencies of EPR transitions depend on the orientation of the paramagnetic center with respect to the magnetic field (Fig. 1). Hence. if rotational diffusion of the molecule or dynamics of a spin-carrying side group change this orientation on the time scale of the EPR experiment, spectral changes are observed. Such dynamics is observable up to rotational correlation times τ_r that are comparable to the transverse relaxation time T_2 of the electron spins (typical range 100 ns–10 μs). For $\tau_r \gg T_2$, the rigid limit is attained in which the spectrum of a macroscopically disordered sample is the superposition of the spectra of all orientations. The lower limit of τ_r for dynamics to be observable depends on the total anisotropy $\Delta\nu$ of the spectrum. Strictly speaking, $\Delta\nu$ is the largest possible frequency change of a single EPR transition during reorientation. however, the total width of the EPR spectrum in the rigid limit is usually a good approximation. For nitroxide spin probes at X-band frequencies, $\Delta\nu$ is well approximated by $2A_z \approx 200$ MHz, where A_z is the ^{14}N hyperfine coupling along the z direction (Fig. 1). For $\tau_r \ll 1/\Delta\nu$, the East limit is attained in which the anisotropy is averaged and the spectrum is characterized by narrow lines with frequencies that are determined by the isotropic averages of g and of the hyperfine splittings. For nitroxides, this requires rotational correlation times shorter than 10 ps.

For correlation times in between the rigid and fast limits (slow tumbling regime). spectral line shapes depend on τ_r and on specifics of the motion.[1,19] It is usually possible to decide whether rotational diffusion is isotropic (nearly spherical molecules) or has to be characterized by a rotational diffusion tensor (molecules with prolate or oblate shape). Spectral line shapes are also sensitive to reorienting potentials as they occur in microscopically ordered phases such a liquid crystals or lipid membranes. It is thus possible to recognize microscopic order in EPR spectra of macroscopically disordered samples.[19] Furthermore, restricted side-group motion is manifest in line shapes that are different from the line shapes for unhindered rotational diffusion. Sensitivity of the EPR spectra to all these details of reorientation dynamics is optimum at $\tau_r \approx 1/\Delta\nu$. In many supramolecular systems. this optimum can be attained by temperature variation. Restricted motion, such as small-angle libration. can be recognized by line-shape changes at the edges of the rigid limit that are induced by partial averaging of the anisotropy. Such motion can be characterized by pulse EPR experiments.[11]

Chemical exchange and Heisenberg spin exchange

The spin Hamiltonian changes suddenly when a paramagnetic molecule changes its conformation, undergoes chemical reaction. or exchanges spin with another para-

magnetic tnolecule. All of these processes cause changes in transition frequencies and are thus observable in EPR spectra. Detailed information can be obtained by time-domain experiments at time scales between approximately 10 ns and 1 ms.[11] Slow processes with characteristic times in the range of seconds to hours can be conveniently characterized by CW EPR spectroscopy.

Heisenberg spin exchange occurs upon collision of paramagnetic molecules in solution due to temporary overlap of the wave functions of the two unpaired electrons.[20] This process causes line broadening in the spectra. It can be noticed, even for collisions of like molecules, if hyperfine splittings are resolved in the EPR spectrum, because in that case, the two molecules may differ in their nuclear magnetic spin quantum numbers and thus in the local fields at the electron spins. Furthermore, even if one of the species is unobservable due to electron-spin relaxation that is too fast. collisions still cause line broadening in the spectrum of the other species. Generally, EPR spectra broadened by Heisenberg exchange contain information on the rate of collisions and their effectiveness in spin exchange. The rate of collisions, in turn, depends on the diffusion coefficients of the molecules and on their local concentrations, while their effectiveness can be described by a steric factor. A quantitative analysis of collisions between nitroxide radicals and transition metal ions ligated by crown ethers provides a good introduction to this topic.[21]

SPIN LABELS AND SPIN PROBES—ACCESS TO DIAMAGNETIC MATERIALS

Site-Directed Spin Labeling

Paramagnetic centers can be directly attached to the site of interest via covalent bonds. Such methodology is particularly well developed for proteins. where the amino acid residue of interest can be converted to a cysteine residue by site-directed mutagenesis, and a thiol-reactive spin label can be attached under mild conditions.[22] If a peptide or protein is synthesized, the nonnative spin-labeled amino acid TOAC can be incorporated directly into the chain.[23] In other synthetic systems. nitroxides can be conveniently attached via ether. ester, or amide bonds,[24] an approach that is also viable for labeling ceramic and metal oxide surfaces.[25] The complexity of supramolecular systems that can be investigated by this approach is exemplified by a study on the interaction between spin-labeled starburst dendrimers and DNA.[26]

Probing Weak Supramolecular interactions

The high sensitivity of the spectra to subtle changes in probereorientation dynamics combined with a concentration sensitivity in the 10 $\mu mol \cdot L^{-1}$ range and the large variety of commercially available nitroxide spin probes[1,2,7] makes CW EPR a valuable tool for studying weak interactions between molecules. Instructive application examples include the adsorption of inorganic[27] and organic molecules on zeolites,[28] hydrogen bonding between small additive molecules and epoxy polymers,[29] formation of surfactant layers on clay particles in a poly(acrylamide)/bentonite composite,[30] detection of dynamic electrostatic attachment of counterions to polyelectrolytes in solution.[31] and study of lipid–protein interactions.[32]

CONCLUSION

As a local method for characterization of dynamics at faster time scales and structures at longer distances than are accessible by NMR spectroscopy, EPR spectroscopy is a valuable technique for studying supramolecular systems. The absence of any background signals in most cases and the possibility to address sites of interest by a variety of relatively small spin probes allows for applications to complex materials. Weak interactions between molecules, such as electrostatic interaction, physisorption, and hydrogen bonding, can be detected in solutions, soft matter, and on large internal surfaces by simple, fast, and sensitive CW EPR measurements. While the principles of applying EPR spectroscopy to suprarnolecular systems were proved and impressive results were achieved on biological systems, the broad arsenal of existing techniques still appears to be underutilized in studies on synthetic materials.

Emergence of Life

Pall Thordarson
The University of Sydney, Sydney, New South Wales, Australia

INTRODUCTION

How life emerged has occupied the thoughts of mankind for millennia. Life, of course, can be defined in a number of ways.[1] but here the NASA definition is the most appropriate. stating that: "Life is a self-sustained chemical system capable of undergoing Darwinian evolution."[2] Chemistry. together with biology and other disciplines of science. have now come a long way in explaining how life could have emerged from the once sterile primordial earth (or for that matter, elsewhere in the universe) to reach the complexity we now see around us. Evolutionary science and biology can trace the roots of modern lifeforms back to the "last common ancestor,"[1,3] while prebiotic chemistry"' gave us insight into how the building blocks of life (nucleotides, amino acids, etc.) could have been formed under the conditions that prevailed before life emerged. It is, however. what happened in the gap from the time the building blocks of life were formed until we had the first primitive lifeforms (the last common ancestor), that remains a challenge for modern science. Supramolecular chemistry is likely to play a major role here, as the key questions are how simple molecules can interact noncovalently in such a fashion to give rise to more complicated superstructures. in a hierarchical fashion. that eventually lead to living identities. The topics that (supramolecular) chemists have so far tried to cover in their quests to answer these questions range from self-replication, chiral amplification and templated synthesis. to temporal thermodynamics, self-reproduction. and *emergence*.

TIMELINE FOR THE EMERGENCE OF LIFE

Our solar system and the Earth are thought to be about 4.6 Ga (4.6 billion or 4.6×10^9 years) old (Fig. 1). Meteorite bombardment made the surface of our planet a rather inhospitable place during the first few hundred years after its formation, however. isotopic patterns in sediments from Greenland indicate that life already existed as early as 3.8 Ga ago.[5] The upper limit for the emergence of life is set by the intense bombardment of the Earth between 3.9–4.1 Ga ago, which without doubt sterilized it, e.g., by boiling off the oceans.[1] destroying the prebiotic matter (the prebiotic soup) that is necessary for life to emerge. Only when this heavy meteorite bombardinent ceased, about 3.8–3.9 Ga ago."' could life have started to evolve. Thus; it appears that life evolved from the prebiotic soup within the span of 100–200 million years.[1] A window as narrow as 10 million years was suggested for life to emerge.[6] There are, broadly speaking, two strategies that can be used to try to understand what happened during this period. They are the "top-down" biological strategy and the .'bottom-up" biogeochemical strategy."' Prebiotic bioorganic chemistry, and in particular, prebiotic supramolecular chemistry. clearly belong to the latter (Fig. I).

PREBIOTIC CHEMISTRY

As the famous Miller–Urey experiment showed,[7] many of the building blocks of life can be obtained under experimental conditions that resemble (as far as we know) conditions on primordial Earth. There is controversy about whether the early atmosphere of Earth was reducing or not,[1] but assuming it was so (i.e., a mixture CH_4, NH_3, H_2, and H_2O), one can obtain important prebiotic feedstock molecules like $HC{\equiv}N$, $CH_3C{\equiv}N$, $HC{\equiv}C{-}CN$, and HCHO. From these initial feedstock molecules, a range of amino acids, purines, pyrimidines, and sugars were obtained under prebiotic conditions. which upon further reaction can afford nucleosides. nucleotides, and activated amino acids. eventually leading to oligomers of these building blocks.[4,8] The prebiotic synthesis of other important building bloclcs such as lipids[9] and riboflavins[4] was demonstrated. however. under a cloud of considerable controversy.[1]

Calculations also showed that about 4 Ga ago, more carbon was delivered to Earth in less than a few million years by interplanetary dust particles than the current amount of organic carbon in the biosphere, or about 6×10^{14} kg.[10] Analyses of interstellar dust clouds and heavenly bodies found on Earth, such as the Murchison meteorite, showed the presence of a variety of important prebiotic compounds. such as amino acids. ureas. alcohols. aldehydes, purines. polycyclic aromatic hydrocarbons (PAH), and organic acids,"'' highlighting the significance of extraterrestrial carbon delivery to Earth.

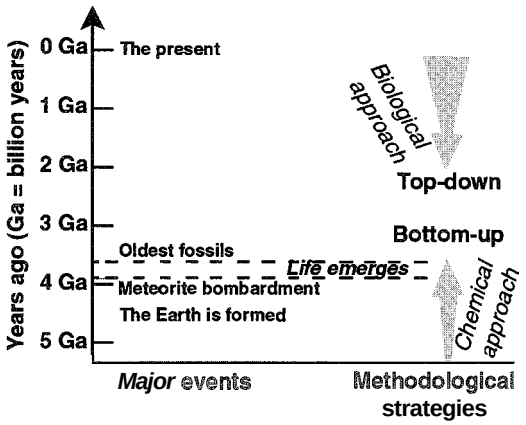

Fig. 1 A hypothetical timescale for the emergence of life. The dotted lines indicated the window within which life is thought to have emerged. On the right. the two main methodological approaches according to Lahav[11] are shown in relation to the timescale. (*View this art in color. at www. dekker.com.*)

Thus, it appears that most of the compounds necessary to form life were available. even abundant. in the "prebiotic soup" some 3.8–3.9 Ga ago, whether they were formed on Earth or were of extraterrestrial origin. How these then assembled to eventually beget life is less clear, but before going into the details, it is worthwhile to consider the thermodynamic aspects of forming complex systems such as those that make life possible.

THERMODYNAMIC CONSIDERATIONS FOR THE EMERGENCE OF LIFE

The first (conservation of energy) and the second (entropy of the universe is increasing) laws of thermodynamics are universal and, thus, will apply to the processes that led to life. Because energy can easily change from one form to another (e.g., light to electrical to chemical as in the photosynthetic reaction center). it is possible to explain how prebiotic (spontaneous) chemistry could have taken place without violating the first law. One might find it harder to see how life and living identities (and therefore the origin of life) can possibly obey the second law, as life seems to be characterized by a decrease in entropy. The answer is that the second law applies to a closed system (e.g., the universe). while life is an open system in which exchanges of energy and matter with its surroundings cause a net increase in the total entropy of life and its environment as a whole. But as every chemist understands, these two laws are related, and what really matters for the study of chemical processes is the free-energy (Gibbs) or more precisely the free-energy change ΔG within a given system, where $\Delta G = \mathrm{AH} - \mathrm{TAS}$ (AH= enthalpy change and AS = entropy change). Thus, processes that are unfavorable for the system in terms of entropy can be driven forward by enthalpy (energy input).

When it comes to considering these factors in a possible scenario for the emergence of life. it is useful to consider the level of organization at different stages in relation to energy flow.[12] On the first level is energy (such as electrical discharge and UV light) necessary to drive the synthesis of prebiotic molecules, like cyanides, nitriles, and formaldehyde. On the next level are concentration mechanisms necessary to gather dilute solution of potential building blocks. Here. the energy might come from adsorption to mineral surfaces, simple drying, or molecular self-assembly in the forms of films and vesicles. On the third level, energy input is required to drive polymerization reactions in "nonliving" assemblies. On the fourth level. these assemblies would grow using internal energy sources based on photosynthesis or metabolism, eventually leading to cellular life.[12] On the latter two levels, a variety of possible scenarios were postulated: from the energy of simple dehydration and heating, to redox properties of minerals, through to geothermal energy, light energy capture by primitive pigments, and ion gradients across lipid bilayers.

When the thermodynamics of self-assembly and the emergence of life are discussed, one critical factor is often overlooked—namely. time. Life is. after all, dynamic; and it is difficult to overlook the importance of energy flux in all living processes. Most of our understanding of self-assembly comes from examining static systems. Fortunately, this is now changing, and studies'into dynamic self-assembly are gaining increased popularity.[13] Within thermodynamics there is even a theory of "temporal hierarchies?" which, broadly speaking, states that supramolecular structures on one particular hierarchical level (j) that arise because of self-assembly of lower-hierarchy structures ($j-1$). have a lifetime inversely related to the level of hierarchy. i.e., $\tau_j \gg \tau_{j-1}$ (τ = lifetime of structure).[14]

TEMPLATED SYNTHESIS

Templaied synthesis plays a central role in any discussion about the emergence of life. This is because it was certainly involved in two stages of the evolution of life—self-replication and translation (protein synthesis)—and possibly in the third, polymerization of monomers or shorter oligomers of amino acids and nucleotides into peptides and (longer) oligonucleotides. The role of templated synthesis in supramolecular chemistry is ubiquitous and well documented.[7,9] Before going further, it is

useful to define it in the words of Busch: "A chemical template organizes an assembly of atoms with respect to one or more geometric loci; in order to achieve a particular linking of atoms."[16] The template is. therefore, distinguished from a reagent by its ability to interfere with the macroscopic geometry of the reaction rather than the intrinsic chemistry.[15] In the complicated case of protein synthesis. *messenger*-RNA (m-RNA) acts as a template for the assembly of amino acids linked to the *transfer*-RNA (t-RNA), leading to one combination of these amino acids only, instead of the many other possible combinations of amino acids that could form a peptide in the absence of the m-RNA template. Likewise, self-replication is nothing but a subclass of templated synthesis restricted to the template used being the same as the product.

Although it was demonstrated that montmorillonite clay particles can catalyze the condensation of nucleotides,[17] it is unclear if the surface shape of these clays can template a specific sequence or shape of the oligomers formed. Many other theories of how clays and minerals could have played a templating role or been used as compartmentation agents[1,8] were proposed, but all remain to be confirmed by experiments.

SELF-REPLICATION, CHIRALITY, AND MUTATION

The transition point in the evolution of life was the emergence of a molecule that was capable of replication." It should be noted that the DNA molecule does self-replicate. however, at present, only with the aid of several enzymes. What researchers are looking for is a molecule that can self-replicate without the aid of any (or many) complex cofactors, like enzymes. The "chicken–egg" paradox[11] that comes from DNA being synthesized by enzymes while enzymes are synthesized by instructions stored in DNA but mediated and cocatalyzed by RNA. led many researchers to suggest that RNA or a WNA-like molecule was the first self-replicating molecule. the so-called "RNA world" theory.[1] This is because RNA can function as a catalyst (ribozymes) and as a carrier for genetic information (retroviruses), offering a possible solution to the "chicken–egg" paradox. According to the "RNA world" theories, the formation of self-replicating RNA (RNA replicase) predates the formation of a primitive ribozyme RNA capable of protein synthesis.

It is not surprising that many researchers spent their time designing and synthesizing self-replicating systems." These efforts show that self-replication is possible, however, it is a complicated issue to study. One has to be careful here to define self-replication, as it is merely a subset of autocatalytic reactions (such as acid-catalyzed hydrolysis of esters, which in turn, makes more acid). Self-replicating molecules are selfish catalysts, i.e., they will only catalyze their own formation.[18] This also means that information is transferred during the reaction; in other words, molecular recognition between the product(s) and reagent(s) plays a major role in templating the reaction.

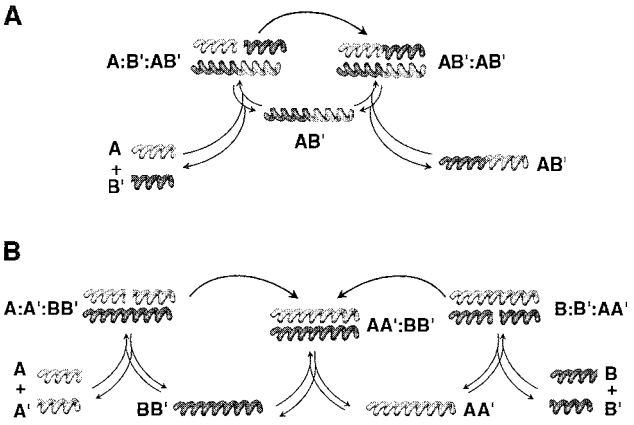

Fig. 2 *(A)Self-replication versus (B)cross-catalysis. according to* von *Kiedrowski et al. (Ref.* [19]). *A. A'. B. B' stands for oligomeric fragments that can combine to form the templates (AA',AB'. BB').* (*View this art* in *color at www.dekker.com.*)

Self-replication can occur through autocatalysis with a self-complementary template (Fig. 2A) or by cross-catalysis with a complementary template (Fig. 2B). In the latter case, two complementary units catalyze each other's formation. This is significant: as modern DNA is made up of two complementary strands that replicate in a cross-catalytic manner. Studies on a simple nonenzyinatic DNA system capable of competing auto- and cross-catalysis. show that in the absence of an initial template, both pathways are equally as likely, but that in the presence of a seeding template, the cross-catalytic route is more efficient.[19]

The self-replication of peptides was also demonstrated in the laboratory,[20] raising the question of whether peptides were the first molecules to self-replicate in the evolution of life. Whether this was the case or not. various interesting phenomena were demonstrated using self-replicating peptides. including dynamic error correction[21] and chiroselective amplification.[22] Both are significant in discussing the emergence of life. The dynamic error correction experiment is based on introducing two mutants to the system. The system as a whole was shown to be robust enough to suppress the formation of these mutants and capable of using the mutants to produce more of the nonmutated template.[21] Thus, small "errors" in

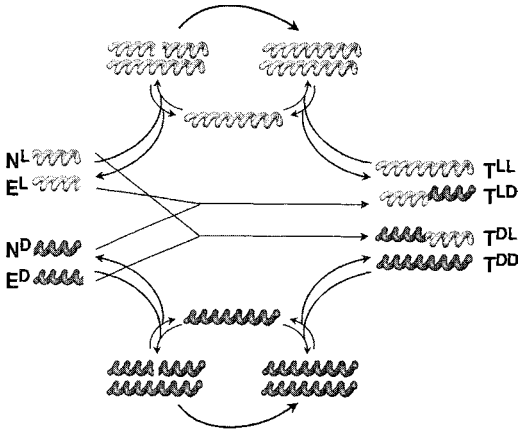

Fig. 3 Chiroselective amplification according to Saghatellan et al. (Ref. [22]). The potential ternplates T are formed by reacting nucleophilic *N* and electrophilic E peptide fragments together. The superscripts (L and D) indicate the different chiralities of the amino acids that rnake up the peptide fragments. *(View this urt in color at \vww.dekker.com.)*

the replicating system can be corrected again toward the native template. In the case of chiroselective amplification (Fig. 3), a similar correction mechanism was observed. More importantly, it was also observed that a chiral peptide template is capable of amplifying homochiral products from a racemic mixture of shorter fragments.[22] For instance. starting from a racemic mixture of the shorter peptide fragments, more than 70% diastereomeric (de) excess of the homochiral (template) versus heterochiral peptide was obtained under the conditions used. The origin of homochirality in biopolymers is still one of the great mysteries in the quest to understand the origin of life,[1] but these experiments help us understand how chirality can be amplified once an initial enantiomeric imbalance is established and indicate that self-replication of biopolymers might have played an important role.

TRANSLATION AND PROGRAMMED TEMPLATED SYNTHESIS

At least as important as the self-replication of information (DNA) is the ability of a living organism to carry out programmed templated synthesis of proteins using RNA. At the center of this system is the codon–anticodon recognition between m-RNA and t-RNA. This is the genetic code, as m-RNA is synthesized by complementary templated synthesis from a DNA (the genetic material) single-strand sequence. The t-RNA molecules carry a specific amino acid and. according to the anticodon they possess, form a compleinentary complex with a codon on m-RNA inside the ribosome, where the amino acid is added to the growing polypeptide chain. In modern organisms, this system is complex, but it is obvious that it must have been a lot simpler closer to the origin of life. How it evolved is one of the most contested topics in the whole discipline; some favor a graduai change from RNA-replication to RNA-coded protein synthesis (RNA-world), while others suggest a ''coevolution'' of RNA and catalytic peptides and proteins that eventually merged into one system.[1] The simulation or mimicking of this remarkable programmed templated synthesis system has. to date, not been attempted by wholly synthetic analogues, which is not surprising considering its complexity.

It should also be noted that the genetic code is twofold, with the second being the recognition between individual t-RNA anticodons and the specific ainino acids they stand for. This adds some weight to the theory that peptides were the first carriers of genetic information. or the coevolution theory.[1] This kind of template switching, or a transition between two different (albeit related) genetic systems, has been demonstrated, between RNA and PNA (peptide nucleic acid) oligomers.[23]

LIPIDS, MEMBRANES AND SELF-REPRODUCTION

Important but often overlooked players in the origin of life scenario are lipids. Lipids, and amphiphiles in general, can self-assemble into structures such as micelles, vesicles, and importantly. membranes. Their most important role in living organisms today is compartmentalization, but they also play a vital role in metabolism, respiration, and photosynthesis, to name a few examples. Normally, it is assumed that they play a passive role in these processes. However, the recent ''lipid world'' theory suggests that lipid-like molecules played a much more active role in metabolism[12,24,25] arid in the early stages of evolution, and even acted as information carriers.[24,25] The latter suggestion conies from the observation that cell membranes are always created by growth and division and not de novo and, thus. are direct ancestors of the first living cells.[24]

Another important observation in this context is that micelles are capable of self-reproduction. that is, the amphiphiles (fatty acids) within the micelles are capable of catalyzing the hydrolysis of fatty acid esters. causing the micelle to grow and eventually split into two new ones.[26] The term reproduction is used to distinguish it from self-replication as discussed above, as it is not limited to discrete (linear) molecular structures but rather is confined in geometry. Because each new micelle

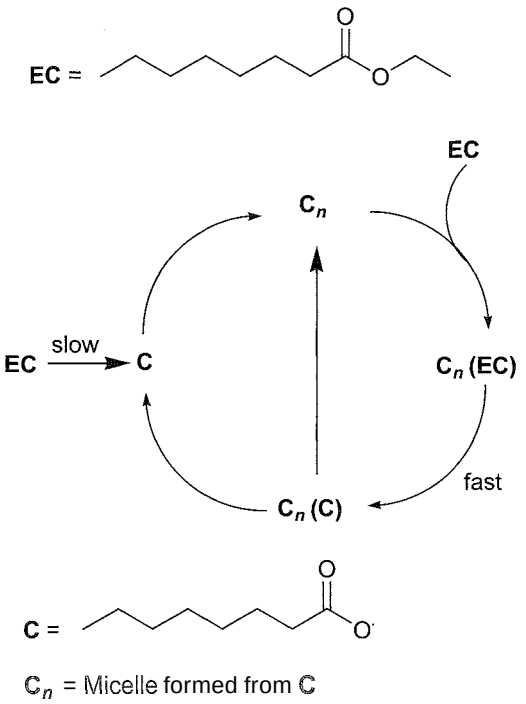

Fig. 4 Self-reproduction of a micelle according to Bachmann et al. (Ref. [26]). The ester *EC* is hydrolyzed slowly to C outside the micelles (indicated with C_n) but much quicker inside, and as the micelles grow. they generate new ones.

formed is capable of binding and then hydrolyzing about five ester molecules, the micellar growth is explosive once the first is formed from the very slow noncatalytic hydrolysis of fatty acid esters (Fig. 4). Although micelles are obviously too small and unstable to have played a significant role in the evolution of life, they are closely related to vesicles. which could more easily have served as envelopes for protocells.[26,27]

HIERARCHY, *EMERGENCE*, AND SYNTHETIC LIFE

Until now. the discussion was limited to how individual components of life might have developed. But living organisms, even as simple as the "last common ancestor",[1,3] are multilevel complex assemblies. A closer look reveals that biological self-assembly of complex structures can be explained based on a few simple principles.[28] One of the most important of these is that self-assembly occurs in an hierarchical fashion, i.e., it is a modular process by which stable subassemblies are formed before they assemble into a more elaborate structure. Hierarchical assembly was put into practice by supramolecular chemists: an early example concerns the formation of an helical stack from a chiral phthalocyanine where. in turn, two of these stacks form a superhelix.[29] This, and other examples of hierarchical assemblies, show that information within one molecule (e.g., chirality) can be transferred through several levels of hierarchy, forming very large structures that still contain that piece of information (a superhelix is chiral). As pointed out above, the lifetime of a particular superstructure seems to be linked to the level of hierarchy for that structure.[14] Therefore, as the complexity of prebiotic assemblies increased in a hierarchical fashion, the longer their lifetimes became. This could have ensured a smooth transition toward cellular life, once all the basic components were in place.

Another tool that could turn out to be helpful in comprehending how life reached its complexity is the concept of "*emergence*" (it should be stressed that this is a much broader term than used in the phrase "emergence of life"). *Emergence* as a concept can be defined in a number of ways, but often the statement "the whole is more than the sum of the parts" is used. Another definition would be that it describes how novel properties arise (emerge) on one particular level of hierarchy *(j)*,

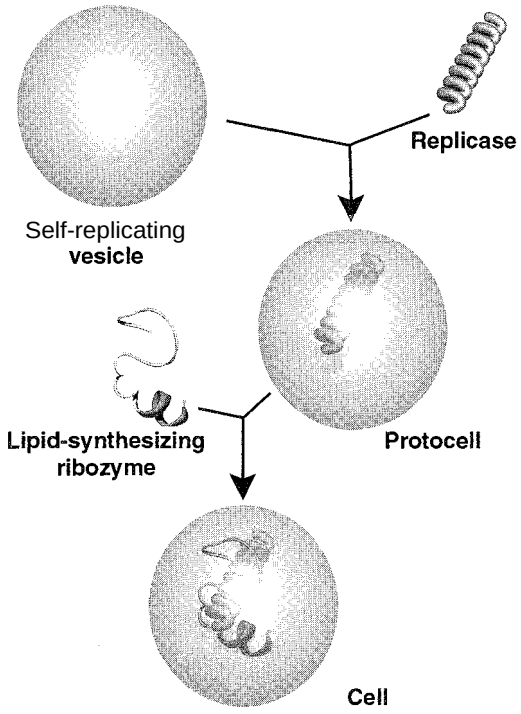

Fig. 5 A hypothetical pathway to a synthetic cell. according to Szostak et al. (Ref. [27]). ***(View** this art in color at www.dekker.corn.)*

when that was formed from the next hierarchical level $(j-1)$ below it. This concept clearly plays a major role in chemistry, despite having gone almost unnoticed until recently.[30] In the emergence of life, novel properties (self-replication, metabolism, etc.) arose as more complex assemblies formed. *Emergence* will undoubtedly help us to better understand the origin of life. An illustration comes from ambitious plans to make a minimal synthetic cell.[27] The plan is based on combining an RNA replicase and a self-replicating vesicle, forming a protocell. Incorporation of a lipid-synthesizing ribozyme would complete this minimal cell (Fig. 5). It is anticipated that novel properties will arise as complexity increases, providing major insights into the origin of life.

CONCLUSION

The problem of understanding how life emerged is as complex as it is fascinating. It is. however, impossible to travel back in time to actually observe how it happened. Therefore, we can only speculate how it could have happened and then test those theories in the laboratory. Supramolecular chemistry has already, and will certainly continue: to play a major role in this quest. Studies into self-replication, templated synthesis, and micellar replication, to name a few topics covered here, already gave valuable insight into how life might have emerged. Hierarchical assembly, *emergence*, and other more novel areas within supramolecular chemistry are also set to do the same. Practical applications, such as programmed templated synthesis of polymers. could also result from these studies. Synthesis of "living" cells was targeted, and other ambitious plans are likely to follow. Prebiotic supramolecular chemistry is therefore set to be a thriving field in the twenty-first century.

INTRODUCTION

In recent years; considerable effort has been devoted to elucidating the pathway of energy transfer in supramolecular assemblies. The impetus for this work stems from the fact that electron transfer reactions are endemic in biosynthesis. Such critical and well-known cellular activities as respiratory oxidative phosphorylation[1] and photosynthesis[2] rely on electron transfer processes. Most of these are mediated via protein–protein interactions. Currently, it remains uncertain whether a specific pathway is required for a given biological electron transfer event.[1,3–5] The study of synthetic donor–acceptor systems held together by noncovalent interactions resembling those found in proteins, nucleic acids, and other biological inacromolecules is thus being pursued with the goal of better understanding the full range of natural electron transfer processes. The aim of this chapter is to summarize recent advances in the area of electron and energy transfer model studies. with the focus being specifically on synthetic supramolecular model systems that are held together via hydrogen bonds. reported after 1998. This choice of emphasis, designed to be illustrative of how supramolecular approaches can help shed light on current problems of interest, is, of course, arbitrary. Indeed, it is important to appreciate that supramolecular assemblies based on hydrophobic interactions. salt bridges, aromatic π-stacking, van der Waals forces, etc., have been produced, and that they also have an important role to play in the area of electron and energy transfer modeling. The reader is directed to many excellent reviews for examples of these kinds of model systems as well as of early hydrogen-bond-derived ensembles.[6–9]

THEORY

Traditional transition state theory does not hold for long-distance electron transfer reactions. Due to weak electronic coupling between donor and acceptor moieties, formation of a transition state does not necessarily lead to an electron transfer event. Thus, electron transfer rates (k_{ET}) must be described by Fermi's golden rule. which has its basis in nonadiabatic quantum mechanical perturbation theory (Eq. 1). Here. T_{DA} is an electronic coupling factor that reflects the electronic structure of the donor. acceptor, and bridging groups." The second term is the Franck–Condon factor (FC), the weighted density of states that can be calculated using classical Marcus theory[10] or. more precisely, using its many quantum mechanical corrections.[11,12] Detailed in Eq. 2 is the FC factor in the high-temperature regime predicted by Marcus. In this equation, λ=reorganization energy, and ΔG^0=standard free energy for the reaction. When $-\Delta G^0 \approx \lambda$. the electron transfer rate reaches its maximum value and is dependent solely on T_{DA} (Eq. 3), where $|T_{DA}|_0$=electronic tunneling matrix element when the donor and acceptor are at van der Waals contact distance, r_0, and β=decay constant.

$$k_{ET} = \frac{2\pi}{\hbar}|T_{DA}|^2(FC) \quad (1)$$

$$(FG) = \frac{1}{\sqrt{4\pi\lambda kT}}\exp[-(\Delta G^0 + \lambda)^2/4\lambda\kappa T] \quad (2)$$

$$k_{ET} = \frac{2\pi}{\hbar}|T_{DA}|_0^2\exp[-\beta(r - r_0)] \quad (3)$$

Marcus theory deals with the first-order electron transfer rate constant for a donor-acceptor system presuming fixed separation. However, there are often systems that do not undergo Marcus behavior and have to be treated using the Rehm–Weller formalism.[13] Here. the second-order diffusion-mediated electron transfer rates are calculated using Eq. 4, where ΔG^*=free energy of activation for

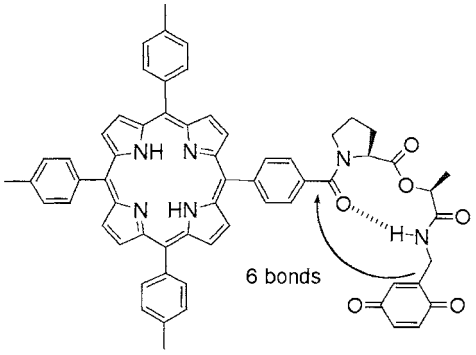
"Some authors use H_{AB} instead of T_{DA}. Strictly speaking. these terms differ in that H_{AB} is the electronic coupling matrix element. and T_{DA} is defined as the electronic tunneling matrix element. However. this subtle difference in meaning is unimportant as far as the mostly qualitative conclusions of this review are concerned. Thus, T_{DA} is used throughout.

the electron transfer and is defined by Eq. 5, where ΔG^*_0=free energy of activation when there is no standard free energy for the reaction (i.e., $\Delta G^0=0$). The greater complexity associated with the study of systems that must be treated in accord with Eq. 4 has provided an impetus to make and study systems where the distance between the donor(s) and acceptor(s) are well defined. To date, this has largely been accomplished via the synthesis of covalently linked systems. Often these systems have proved hard to prepare. By contrast, a prime attraction of synthetic hydrogen-bond-mediated assemblies is that they allow donor and acceptor complexes to be placed at various preselected distances and orientations while providing systems that would allow the importance of noncovalent interactions to be assessed by experiment. Not surprisingly. therefore; such systems have attracted considerable attention of late.

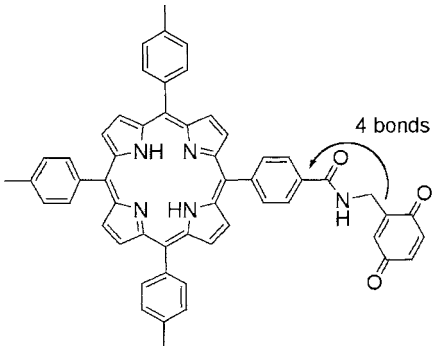
$$k_{ET} = \frac{20 \times 10^9}{1 + 0.25[\exp(\Delta G^*/RT) + \exp(\Delta G^0/RT)]} \quad (4)$$

$$\Delta G^* = \frac{\Delta G^0}{2} + \left[\left(\frac{\Delta G^0}{2}\right)^2 + (\Delta G_0^*)^2\right]^{1/2} \quad (5)$$

Ensemble 1



Ensemble *2*



MODULES WITH A SINGLE TETHERING HYDROGEN BOND

Appropriate combinations of well-known functional groups such as amines. phenols. and carboxylates are known to assemble through one-point hydrogen-bonding motifs. Such combinations are thus attractive in the context of energy and electron transfer model construction. Unfortunately. supramolecular assemblies preorganized solely via a single H-bond have low association constants. While increasing the number of hydrogen bonds in a cooperative manner dramatically enhances the stability of supramolecular assemblies and abets their formation, analyses of photoinduced electron transfer events in ensembles tethered via a single H-bond are of considerable interest, because interprotein electron transfers are often mediated via a single H-bond. With these considerations in mind. Williamson and Bowler designed and synthesized a linked porphyrin-*p*-benzoquinone donor–acceptor dyad (Ensemble 1), in which the shortest bond electron transfer pathway requires electronic coupling through a hydrogen bond.[14] The authors chose a depsipeptide bridge that forms a β-turn due to an intramolecular hydrogen-bonding interaction. Temperature-dependent ^{1}H-NMR, ROESY ^{1}H-NMR. and FTIR spectroscopic measurements confirmed the presence of the β-turn in the predominant conformation. Time-resolved fluorescence studies of Ensemble 1 showed a biexponential fluorescence decay in dichloromethane [τ_1=0.85 ns; τ_2=8.76 ns]. The shorter lifetime was assigned to the conformation containing the β-turn, wherein electron transfer is found to be competitive with intrinsic fluorescence decay. In contrast, the longer lifetime is attributed to various non-β-turn conformations. From these lifetime values. the electron transfer rate in the hydrogen-bond-containing conformer was determined to be $k_{ET}=(1.1 \pm 0.1) \times 10^9$ s^{-1} in dichloromethane. This rate compares well with that of a covalent analog reported by Bolton and Archer (Ensemble 2)[15] for which $k_{ET}=(8.0 \pm 0.4) \times 10^8$ s^{-1}, thus illustrating the efficiency of electron transfer *via* the single hydrogen bond present in Ensemble 1. As part of their studies, Williamson and Bowler found that the coupling decay factor, ε_{hb},[b] was 0.8 ± 0.4, a value that correlates well with the theoretically predicted value of 0.36.[16]

[b] ε_{hb} is a decay factor representing the electronic coupling through a hydrogen bond. This factor is somewhat analogous to β; however. β refers to a decay through a homogeneous electronic coupling medium. while ε_{hb} is defined specifically for through-hydrogen-bond orbital interactions.

MODULES CONTAINING TWO HYDROGEN BONDS

Despite the relatively low enthalpy gain associated with using two hydrogen bonds to generate a supramolecular ensemble. numerous examples of photoinduced electron transfer in models linked via two-point hydrogen bonds have been reported. Part of the reason for this is that many polar groups containing H-bond donor and acceptor sites tend to self-associate. For instance, Gopidas and colleagues have taken advantage of the dimerization ability of carboxylic acid groups to generate systems wherein the rate of electron transfer between various donor and acceptor units could be studied.[17] In these models, the edge-to-edge distance between the donor–acceptor pairs was kept constant at 9.40 Å (Chart 1b, where $n=m=1$ and both m and n are the number of methylene units). The dependence of the electron transfer rate on driving force was then determined by systematically varying the redox potentials of the quenches molecules (Chart la). Fluorescence quenching experiments yielded k_{ET} values between [(1.9 + 0.19) x 10^7 s^{-1} and (144.0 + 14) x 10^7 s^{-1}]. The authors proposed two types of electron transfer mechanisms: intraensemble electron transfer, which obeys the Marcus equation; and bimolecular electron transfer. where an inverted region is not observed. The latter mechanism can be treated by the Rehm–Weller formalism (Eqs. 4 and 5) and is associated with diffusion in a regime where the driving force is moderately large ($\Delta G^0 \geq -1.5$ eV). Furthermore. Gopidas and coworkers realized that dyads PA/1 and **PA/2** (where PA dimerizes with **1** and **2**, respectively) fall into the Marcus normal and inverted regions, respectively. Subsequent experiments involving studies of distance on the electron transfer rates within dyads **PA/1** and PA/2 were made by varying the number of connecting methylene units (Chart 1b, where $m+n \leq 6$).[18] These studies confirmed the expected exponential decrease with increasing distance in the normal region. However, in the inverted region, the predicted increase in rate at larger distances was not seen. Novel experiments incorporating rigid linkers may be needed to further elucidate the role that distance plays in the inverted region of these two-point H-bond-mediated systems.

Taking advantage of a different kind of hydrogen bond interaction, Tanaka and colleagues assembled several cofacial p-benzoquinone-posphyrin systems that are tethered via two amide-quinone hydrogen bonds (Ensemble 3).[19] The authors ascribe the stability of the system to these interactions. However, x-stacking interactions could also be serving to stabilize Ensemble 3. Such interactions also serve to complicate interpretations of intraensemble electron transfer events, making these elegant systems less useful than they otherwise would be.

Arimura and coworkers were able to overcome the problem of x-stacking by using a calix[4]arene linker between the porphyrin unit and the quinone (Ensemble 4).[20] In this system, it is proposed that two-point hydrogen bonds between the two phenolic hydroxyl groups on the calix[4]arene and the oxygen atom on the p-benzoquinone

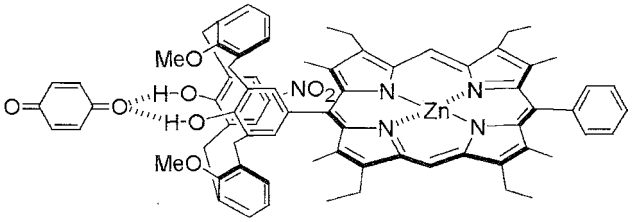
Ensemble 4

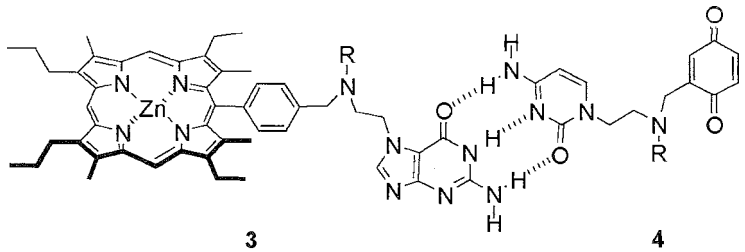


link the system. Further, the directionality of the H-bonds and the exo-cyclic nature of the OH groups are thought to preclude π-π porphyrin-quinone interactions. In point of fact, neither ^{1}H-NMR nor UV-Vis spectral shifts corresponding to n-stacking were observed. Proton-NMR binding studies in $CDCl_3$ gave a weak association constant [(70 a 10) M^{-1}] for the interaction between the quinone and the rest of the ensemble. Time-resolved fluorescence measurements indicated two lifetimes, τ_1=30 ps and τ_2=1.3 ns that are ascribed to intraensemble quenching and to diffusional quenching, respectively.

ENSEMBLES BASED ON THREE HYDROGEN BONDS: CYTOSINE-GUANINE MOTIFS

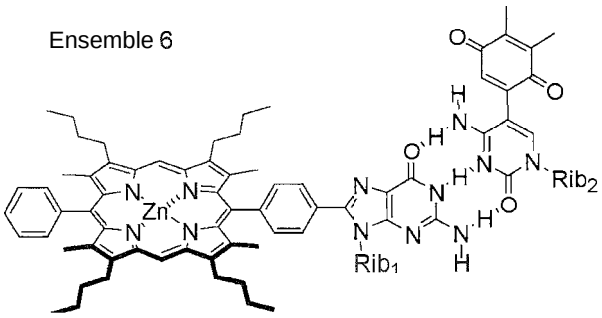
Watson–Crick hydrogen bonds between nucleic bases are ubiquitous in living systems. Their directionality and cooperativity renders them essential in the transfer of biological information. Similar considerations have made the cytosine-guanine (CC) base pair attractive for energy and electron transfer model studies. It possesses three hydrogen bonds and two attractive and two repulsive secondary interactions (referred to as DDA•AAD couples in the language of supramolecular chemistry, where D=donor and A=acceptor). Sessler and coworkers were the first to use CG base pairing to generate a redox-active supramolecular scaffold. In a first series of studies. a zinc porphyrin and a free-base porphyrin, tethered via flexible linkers were linked in a supramolecular sense via CG base pairing. Second-generation guanine-cytosine assemblies. designed to study electron-, as opposed to energy-, transfer processes, were then synthesized incorporating a porphyrin donor and a quinone acceptor into a GC-linked motif (Ensemble 5).[21] Proton NMR binding studies in CD_2Cl_2 gave an association constant (K) for the formation of Ensemble 5 of 3100 a 470 M^{-1}. Time-resolved fluorescence experiments involving subunit 3 alone gave a single exponential decay, which became biexponential upon the addition of 4. The associated lifetimes were found to be τ_1=(1.5 a 0.2) ns and τ_2=(0.94 a 0.07) ns, respectively. Here, τ_1 is the lifetime attributed to the uncomplexed porphyrin 3, while τ_2 (the shorter-lived decay) is ascribed to electron-transfer-derived quenching of the excited state of 3 by quinone 4. The derived rate constant was (4.2 ± 0.7) x 10^8 s^{-1}. The authors concluded that electron transfer was taking place as the result of the three-point hydrogen bond bridge, because no quenching was seen when a small quantity of ethanol (2% v/v), sufficient to break up the CG hydrogen bonds, was added.

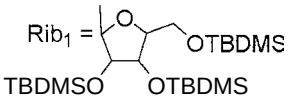
Ensemble 5

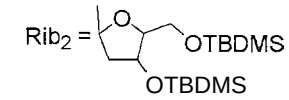


3 4

R = 
Ensemble 6







TBDMS = -SiMe$_2$^{t}Bu

Ensemble 5 is tethered via flexible linkers. This means that many conformations are possible even after formation of the sought-after hydrogen-bonded assembly. This leads to problems in defining the exact electron transfer pathway. To circumvent this problem, Sessler and coworkers synthesized systems containing rigid linkers (Ensemble 6).[22] The use of these latter models allowed the authors to calculate electron transfer rates and to conclude that the most probable electron transfer mechanism occurs through the hydrogen bond network. Ensemble 6 also has a larger association constant (8990 ± 600) M^{-1} as compared to Ensemble 5. Time-resolved fluorescence studies indicated two lifetimes: τ_1=(1.8 ± 0.2) ns and τ_2=(740 ± 90) ps, where the latter lifetime is ascribed. as in the case of Ensemble 5, to electron-transfer-mediated fluorescence quenching within the Watson–Crick defined complex. The rate of electron transfer was calculated to be $-8 \times 10^8\ s^{-1}$.

To gain further insight into the electron transfer properties of Watson–Crick linked donor–acceptor assemblies, the authors of the present chapter synthesized several dimethylaniline-anthracene electron transfer dyads (Ensembles 7 and 8).[23] The association constant for Ensemble 7 was found to be 38,500 ± 1300 M^{-1}. The large binding constant seen for this system is attributed to its increased rigidity relative to earlier CG ensembles. In this ensemble, the driving force for the initial photoinduced charge separation and the subsequent charge recombination processes were estimated as $\Delta G^0_{CS} = -0.41$ eV and $\Delta G^0_{RC} = -2.5$ eV, respectively. Fluorescence quenching experiments revealed substantial quenching of the anthracene chromophore 6 upon the addition of the dimethylaniline-guanosine donor ***5***. Further control experiments, using a masked donor: wherein the exocyclic amino group on 5 was protected, revealed little quenching, thus providing support for the idea that three-point hydrogen bonding is necessary for the observed photophysical process. Transient absorption spectroscopic studies were also carried out. Following irradiation with a 150 fs 417 nm laser pulse, two strong

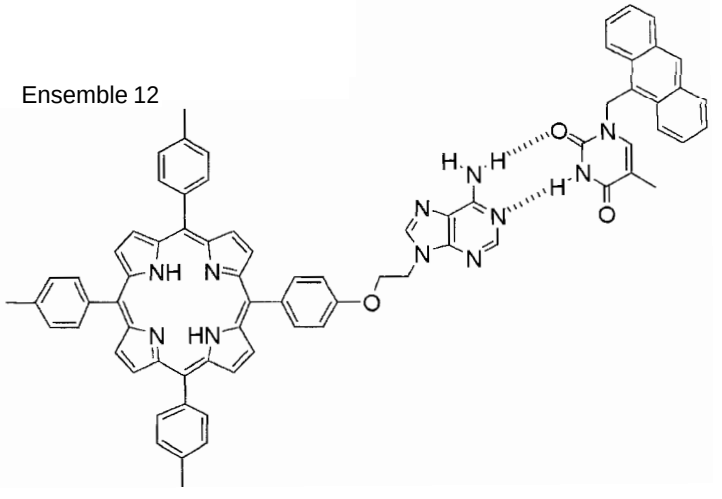
absorption bands, at 590 and 480 nm, were seen. The higher wavelength band is dominant 15 ps after photoexcitation and is ascribed to the $S_n \leftarrow S_1$ transition of the anthracene acceptor 6. From an analysis of the absorption band at 590 nm, A_{590}, as a function of time, a rate constant of $(2 \pm 0.5) \times 10^{10}\ s^{-1}$ was calculated for this forward electron transfer process. In contrast to what is seen at 590 nm, the absorption band at 480 nm is seen to rise and then decay in a monoexponential fashion after photoexcitation. Such a finding is consistent with the formation and disappearance of the presumed dimethylaniline cation. This latter absorption band was thus used to determine the charge separation and charge recombination rates, with values of $k_{CS} = (3.5 \pm 0.03) \times 10^{10}\ s^{-1}$ and $k_{CR} = (1.42 \pm 0.03) \times 10^{9}\ s^{-1}$ being calculated, respectively. These transient absorptions experiments are considered important, because they provided the first direct evidence for charge separation in a Watson–Crick-type model system under simple solution-phase photoexcitation conditions.

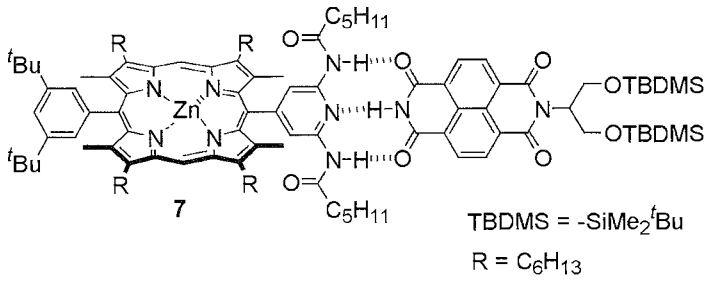
In spite of the apparent structural similarity, photophysical studies on the reverse Ensemble 8 revealed behavior that was different from that observed for Ensemble 7. In fact, fluorescence analyses of Ensemble 8 revealed the formation of an exciplex in dichloromethane. Subsequent experiments in toluene using time-resolved emission and transient absorption methods provided no evidence of quenching. These results illustrate the sensitivity of electron transfer processes toward the orientation of donor–acceptor moieties in a given intraensemble system.

Ward and coworlters extensively studied energy transfer between metal polypyridyl complexes preorganized via complementary Watson–Crick base pairing.[124] Ensemble 9 has an association constant of $5 \times 10^{7}\ M^{-1}$ in CD_2Cl_2, and the k_{EN} for the Ru → Os energy transfer

Ensemble 12



Ensemble 13



within the resulting dyad was calculated to be k_{EN} = 29.3 x 10^7 s^{-1} on the basis of time-resolved luminescence measurements. Ensuing studies by the authors[25] led them to conclude that the Ru → Os energy transfer process within the constrained Ru-G/C-Os-C Ensemble 10 is of the Forster type, implying that the role of the guanine–cytosine couple is merely structural. However. replacing the C-Os-C couple with a fen-ocene (Fc-C) moiety (Ensemble 11) gave experimental results consistent with a Dexter mechanism, a finding that implicates an electronic mediation role for the H-bonds.

Interestingly. Ward and his coworkers were unable to study the energy transfer properties of the analogous adenine–thymine linked systems. In this case, the less favorable two-point hydrogen bond interactions give rise to low association constants (i.e., K ~ 10^2 M^{-1} in CD_2Cl_2). Maiya and Sirish also reported an adenine–thymine linked system (Ensemble 12). where the donor is an anthracene and the acceptor is a porphyrin.[26] Here the authors attempted time-resolved fluorescence measurements but only observed a monoexponential decay. They suggest that there exists a short-lived component due to the foldover conformers. However; the lifetime of this component is too short to be measured. Another explanation for the lack of a biexponential decay may be due to the possibility that the lifetimes of the complexed (Ensemble 12) and uncomplexed forms (free anthracene–thymine unit) are similar. Be this as it may, it is clear from these studies that the use of adenine–thymine bridges provides electron transfer model systems that are harder to study than their guanine–cytosine counterparts.

ABIOTIC MOTIFS LINKED BY THREE HYDROGEN BONDS

Synthetic systems with three primary hydrogen bonds and four repulsive secondary interactions, ADA•DAD motifs in the supramolecular vernacular. are among the best known of all noncovalent host–guest systems. Although not generally as stable as the previously mentioned DDA•AAD system (because they have four repulsive secondary interactions, while the DDA•AAD models possess two attractive and two repulsive interactions), they have been widely used for electron transfer model construction. The naphthalene diisnide interface is one ADA system that is especially attractive, due to its distinct transient absorption properties when reduced. Furthermore, it serves as an efficient electron sink for excited zinc posphyrins. Hence, Mataga and Osaka recently reported a 2,6-diacylaminopyridylporphyrin-napthalene diimide complex (Ensemble 13).[27] The presence of the complex was confirmed by ^{1}H-NMR spectroscopic binding studies in C_6D_6 (K=2.8 x 10^2 M^{-1}). The rate of forward electron transfer (k_{CS}=4.1 x 10^{10} s^{-1}) was obtained from an analysis of the time profile of the transient absorption spectrum (λ_{ex}=532 nm) at 458 nm, where the main absorbing species was the S_1 state of the zinc porphyrin 7. Unambiguous evidence for the proposed electron transfer across the hydrogen-bonding interface within the supramolecular Ensemble 13 came from transient absorption spectroscopic measurements. The transient absorption spectrum of Ensemble 13 recorded 20 ps after laser excitation at 532 nm revealed absorption bands at 474 and 655 nm that correspond to a diimide radical anion and zinc porphyrin radical cation, respectively. The rate of back electron transfer (k_{CR}=3.7 x 10^9 s^{-1}) was calculated from the lifetime (τ=270 ps) of the transient species. Comparison of Ensemble 13 with a related covalent system[27] indicated similar forward and

backward electron transfer rates. a finding that underscores the efficiency of hydrogen-bond-mediated electron transfer within (at least) ensembles such as this.

Sessler and Brown also studied a system wherein a naphthalene diimide moiety is linked via a three-point hydrogen bond to a rigid chlorin (see Ensemble 14).[28] The edge-to-edge distance was calculated to be 7 A. Proton NMR binding titrations in $CDCl_3$ gave an association constant. $K = 364 + 47\ M^{-1}$. Subsequent photoirradiation studies, carried out with excitation effected at 573 nm. allowed for various spectroscopic analyses. For instance. from single-photon counting studies, the electron transfer rate was determined to be $7.6 \times 10^8\ s^{-1}$. These studies, also revealed a biexponential decay, indicating two lifetimes ($\tau_1 = 13$ ns and $\tau_2 = 1.25$ ns), with the latter lifetime being characteristic of intracomplex photoinduced eiectron transfer. Unfortunately, in this system, no evidence for a diimide-derived radical anion was obtained, presumably as a consequence of rapid back electron transfer.

MODULES WITH MULTIPLE H-BONDS

In recent years. research has focused on the exploration of motifs with multiple hydrogen-bonding sites. Like the ensembles described earlier in this chapter. these systems can serve as models for photoinduced electron transfer. However, by virtue of possessing a greater number of hydrogen bonds, these newer systems offer the promise of increased preorganization and enhanced stability. As one example of a system with a high degree of self-complementarity, Isied and coworkers recently reported a new barbiturate-*bis*(2,6-diacylaminopyridine) template-mediated $*Ru^{II}$ or $*Os^{II}G \rightarrow Ru^{III}$ or $Os^{III}H$ (where *G* and *H* are defined as the guest and host. respectively) electron transfer model system (Ensemble 15).[29] Here. the barbiturate moiety allows for a six-point H-bonding array that contains the diacylaminopyridine unit. As a consequence, the donor ($M^{II}G$) and acceptor (HM^{III}) units assemble in CD_2Cl_2 with high affinity ($K = 2-5 \times 10^{n}\ M^{-1}$) as judged by steady-state fluorescence and 'H-NMR spectroscopic titrations. Upon laser excitation. in all cases, the excited singlet state is observed to decay in a biphasic manner. with the shorter lifetime corresponding to the intramolecular electron transfer across the 18 ± 1 A H-bond-linked donor–acceptor gap. The forward electron transfer rates from $*M^{II}G$ to $M^{III}H$ in dichlorornethane were calculated from the difference in fluorescence lifetimes of the complexed and uncomplexed components. Furthermore, the rate of thermal back electron transfer (charge recombination) was determined by transient absorption spectroscopic techniques. The results generated from the studies are suinmarized in Table 1. The authors were also able to fit the experimental electron transfer rates using classical Marcus theory (Eqs. 1 and 2), thereby obtaining both the electronic coupling matrix element T_{DA} ($1.2\ cm^{-1}$)[a] and the reorganization energy λ (1.2 eV).

The use of multiple hydrogen bonding also allows for the assembly of higher-order supramolecular structures that begin to mimic the complexity of biological arrays. In the bacterial photosynthetic system. many antenna

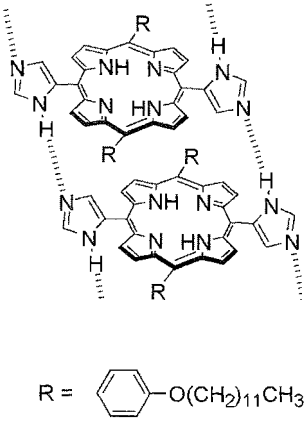
pigments are located around the reaction center; these pigments serve to absorb and transmit light into the reaction center. Generating noncovalent analogues of these antennae has stood as an important challenge to the supramolecular chemist. Kuroda and colleagues made important progress toward this goal. They reported a novel synthetic porphyrin suprarnolecular assembly that illustrates the principle of the antenna effect. Their system

Ensemble 17



contains one energy acceptor porphyrin and four pairs of antenna porphyrins. Each dimeric antenna porphyrin pair is self-assembled via eight hydrogen bonds between carboxylic acid moieties (Ensemble 16a).[30] Absorption and fluorescence titrations indicate binding between 8 and 9 in a 1:4 ratio. The four individual binding processes are independent. and the association constants are identical ($K = 4$ a 1 x 10^7 M^{-1}). The free-base porphyrin 8 in the absence of 9 exhibits a weak emission. By contrast, Ensemble 16b shows a strong fluorescence emission. Using a best-fit analysis for the absorption spectrum, the authors calculated the efficiency of energy transfer from the zinc porphyrin 9 to the free-base porphyrin 8 at 82% for a process that takes place over a range of 16–21 Å. These results are consistent with the conclusion that the fluorescence of 8 is enhanced 18-fold. thereby achieving the proposed antenna effect.

Kobuke and coworkers also built a supramolecular system that mimics light harvesting arrays via an antenna effect (Ensemble 17).[31] Were, a polymeric complex is assembled through cooperative hydrogen-bonding interactions involving imidazole subunits and via slipped cofacial π-stacking interactions. In studying their systems, the authors used chloranil and tetraphenylporphyrinato-Mn(III) chloride (MnTPP·Cl) as external energy acceptors. It was found that chloranil and MnTPP·Cl quenched the fluorescence of the complex (Ensemble 17) 2.9 times faster than they did that of the monomer (porphyrin lacking the imidazole hydrogen-bonding sites). An explanation for these findings put forward by the authors is that the excitation energy is delocalized through the polymeric complex and can be quenched by an acceptor from any one of the monoineric components.

CONCLUSION

Investigations of electron and energy transfer processes in supramolecular model systems preorganized through hydrogen-bonding interactions have advanced our understanding of noncovalent assembly construction and electron- and energy-transfer theories. Among the most important take-home lessons are that the rate of electron transfer in ensembles tethered via hydrogen bonds is often comparable to what is seen in comparable covalent analogs. and the orientation and rigidity of the donor–acceptor pairs within a given intramolecular system can profoundly affect the nature of the electron transfer process. Yet another important finding is that working antenna systems can be generated by tethering multiple photoacceptors to an appropriate acceptor through multiple hydrogen-bonding interactions. Still. in these and all other cases, the models remain but oversimplified reflections of the natural systems they are designed to imitate. Thus, there remains a need to prepare yet more elaborate model systems that can provide further insights into why certain biological electron transfer pathways are favored over others.

Enzyme **Mimics**

Anatoly K. Yatsimirsky
Universidad Nacional Autónoma de México, Mexico City, Mexico

INTRODUCTION

Biomimetic chemistry attempts to improve the performance of chemical reactants and catalysts by imitating enzymatic processes.[1] One may consider as enzyme mimics catalysts of a different nature, which use principles of enzyme action, such as an initial binding interaction between the substrate and catalyst, polyfunctional activation of the bound substrate by properly positioned organic catalytic groups or metal ions, transition-state stabilization and others.[2] Enzyme mimics are designed mainly for practical applications as artificial enzymes and less for understanding enzyme mechanisms, which is one of the goals of enzyme modeling. Although in some instances even simple organic molecules[3] or metal complexes[4] work as enzyme mimics, only more sophisticated supramolecular systems discussed in this article show an enzyme-like performance. A general feature is the presence of a host that recognizes the substrate and the reaction transition state, providing increased reactivity and selectivity. Several books[5,6] and reviews[2,7,8] may be recommended for general reading on this subject.

SURFACTANT AGGREGATES AND SYNTHETIC POLYMERS

Surfactants aggregate above so-called critical micelle concentration, forming spherical or cylindrical micelles, bilayers. vesicles, and other aggregates; depending on surfactant structure and conditions. Synthetic polymers. e.g., polyethyleneimine or polyvinylpyridine, modified (usually by quaternizaiton) by long-chain aliphatic groups behave similarly, forming intramolecular micelles already at low concentrations. All of these aggregates possess a hydrophobic interior or core made from surfactant hydrocarbon tails covered by a hydrophilic, usually ionic, surface layer made from surfactant head groups, reminiscent of the structural organizations of globular proteins and biological membranes. For this reason, reactivity in such aggregates was studied for a long time and represents. perhaps, the oldest suprainolecular imitation of enzyme catalysis.[9]

Surfactant aggregates serve as primitive hosts, due to their ability to incorporate apolar organic molecules into the hydrophobic core and to attract counterions to the surface layer. The origin of catalysis in micelles and other aggregates is principally the concentration effect: the partitioning of reactants between aqueous and micellar pseudophases leads to increased concentrations of reacting species in the micelles and, consequently. to an increased rate.[10] Remarkably, this simple effect explains large rate enhancements of up to 10^6 times.[11] Simple inert surfactants typically catalyze bimolecular reactions between a neutral organic molecule bound to micelles by hydrophobic interactions and an ionic species charged opposite to the micellar surface charge and bound electrostatically. For example, cleavage of 4-nitrophenyl carboxylates by deprotonated aryl oximes is accelerated 10^3–10^4 times in the presence of micelles of cationic surfactants. The acid hydrolysis of acetals is accelerated ca. 10^2 times by micelles of anionic surfactants.[10,11]

More successful enzyme mimics are aggregates with functionalized surfactants. In this approach, a functional group (a nucleophile, a metal complex, or an enzyme cofactor, e.g., nicotinamide or cobalamine) is attached to a long-chain molecule that has surfactant properties or can be incorporated into aggregates of an inert surfactant.[7,9] As an example of such a system, shown in Fig. 1 is a mechanism proposed for cleavage of a chiral ester of C-phenylglycine by a lipophilic chiral alkoxide Cu(II) complex incorporated into *n*-hexadecyltrimethylammonium bromide micelles.[12] The metal cation facilitates deprotonation of the ligand alcohol group and binds the substrate via coordination of the α-amino group. In comparison with a nonmicellar complex of similar structure, but with an N-methyl instead of an N-dodecyl group, the micellar catalyst is 140 times more active and shows much higher enantioselectivity (the ratio of the rate constants for cleavage of S and R enantiomers increases from 1.2 to 11.6). The nonmicellar catalyst uses coordinated hydroxide anion as a nucleophile, but the micellar environment favors formation of a stronger alkoxide nucleophile, which in addition, reacts more stereospecifically. Positive micellar charge and hydrophobic binding of the ester to micelles also contribute to catalysis and enantioselectivity. Incorporation of the

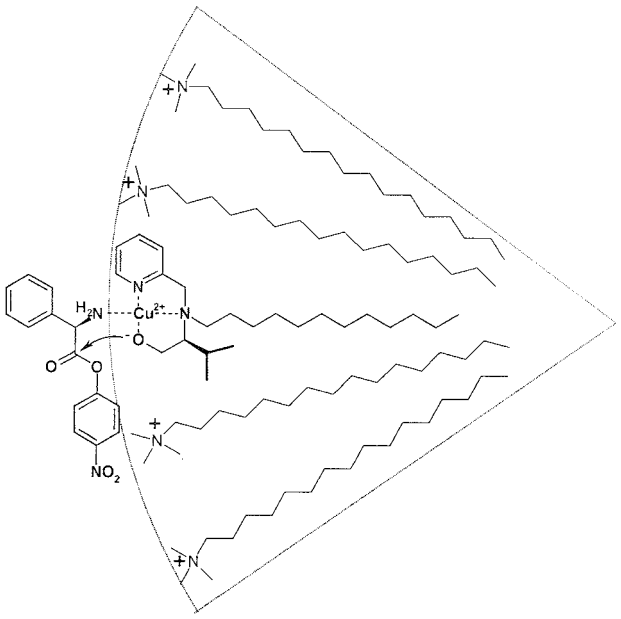

Fig. I Cleavage of an α-amino acid ester by a lipophilic Cu(II) complex incorporated into micelles of a cationic surfactant. A sector of a spherical micelle with incorporated ligancl is shown schematically. (From Ref. [12].)

same lipophilic complex into cationic bilayers leads to a further increase in enantioselectivity, probably due to the more rigid structure of bilayers as compared to spherical micelles.

Functionalized polymers behave similar to surfactant aggregates[9] but have some advantages for practical applications. Surfactant aggregates have low stability and exist only in solution at sufficiently high concentrations. Surfactant polymers have an advantage of being stable at any concentration. and they can easily be incorporated into, e.g., filters or other devices for analytical or biomedical applications. For example; polymeric surfactants. which are glutathione transferase mimics. were designed for such applications.[13]

CYCLODEXTRINS

Cyclodextrins (CDs) are useful components for biomimetic systems. They form well-characterized inclusion complexes with many organic compounds via hydrophobic interactions and possess a large number of alcohol groups that can serve as cataiytic groups or can be used to attach other functional groups. A large number of biomirnetic catalytic reactions using native or modified CDs were described.[14]

An important area of application of CDs as enzyme mimics involves hydrolysis of activated esters and amides via nucleophilic attack of a deprotonated secondary hydroxyl group of CD on the carboxyl group of the bound substrate. The enzyme-like Michaelis–Menten kinetics, turnover, and a mechanistic similarity of CD-catalyzed reactions to serine hydrolases were demonstrated in earlier studies with simple acetate and benzoate esters as substrates.[''' Further investigations guided by molecular modeling of CD-substrate and CD-transition-state complexes revealed the importance of the specially designed acyl part of the substrate for the efficiency of CD catalysis.[14] Thus. the rate enhancement by β-CD in the hydrolysis of 4-nitrophenyl acetate is only six times, but the hydrolysis of ferroceneacrylate esters is accelerated by ca. 6×10^6 times in the presence of β-CD. Binding constants for both substrates are similar. Therefore. the stronger catalysis for ferroceneacrylate esters is due to better complementarity of CD cavity to the reaction transition state.

For a long time, the hydrolase activity of CDs was restricted to activated substrates. such as aromatic esters, because CD hydroxyl groups are not basic enough to force out a poor leaving group. such as aliphatic alcohol. from the tetrahedral addition intermediate. Recently, successful catalytic hydrolysis of an unactivated aliphatic ester was achieved by using a *bis*-CD derivative with a Cu(II) bipyridine complex as the active site (Fig. 2).[15] The rate enhancement for this system is 1000-fold, and the attacking nucleophile is the coordinated hydroxide ion rather than a CD hydroxyl group.

Numerous biomimetic reactions catalyzed by CDs carrying catalytic or reactive functional groups, such as nucleophiles (imidazole. oxime, and amine). enzyme cofactors (pyridoxamine, thiazolium. nicotinamide, cobalainine, flavin), metal complexes. etc.. were reported.[14] Typically, enzyme-like kinetics and improved performance of a catalytic group, as compared to a simple analog lacking CD. are observed.

Besides enhanced reactivity, a higher selectivity may be achieved by using CDs. For example. chlorination of

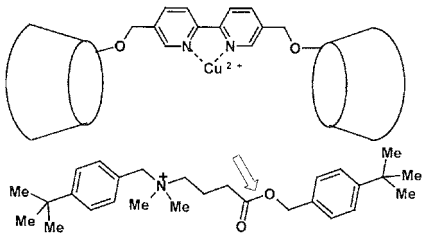

Fig. *2* Catalytic hydrolysis of an unactivated aliphatic ester by a Cu(II) bipyridine complex with two attached CDs. (From Ref. [15].)

anisole by hypochiorous acid in the presence of α-CD proceeds faster and exclusively in the *pal-a* position of the substrate.''' Also, the regioselectivity of the Diels–Alder reaction may be improved by CDs.[14]

Supramolecular catalysts that involve two or more CD units are especially promising. The presence of several CD units strongly increases binding constants for substrates. which can bind to two CD cavities. Binding constants exceeding 10^{10} M^{-1} were reported for CD dimers and guests, like 4-$(CH_3)_3C$–$C_6H_4COO(CH_2)_3$-$OOCC_6H_4$–$C(CH_3)_3$-4, while binding constants of typical organic guests to CDs are in the range of 10^2–10^4 M^{-1} only.[14] High activities and high selectivities were reported for catalysts of this type. Illustrated in Fig. 3 is the application of a cytochrome P-450 mimic based on a Mn(III)–porphyrin active site with three attached CD units for selective hydroxyiation of steroids.[16] The catalyst contains fluorinated phenyl groups that protect the porphyrin from oxidative destruction, three CDs for substrate complexation, and a pyridine group required for catalytic activity as an axial ligand stabilizing the active Mn=O species. In the first step, androstan-3,17-diol was modified by esterification with two fragments carrying bulky hydrophobic groups for binding into CDs cavities and sulfonate groups for solubility in water. Then, the modified steroid was hydroxylated by iodosobenzene in the presence of the enzyme mimic, and the ester groups were removed by hydrolysis. The only product was the 6α-hydroxy derivative. and the catalyst did the oxidation with 2000 turnovers. In a control experiment, a similar substrate, but lacking terminal *tert*-butylphenyl groups. was not oxidized. This remarkable selectivity is in line with results of molecular modeling that predict that bound to two CDs, the steroid diester is positioned above the posphyrin plane. and only the α-hydrogen at C-6 can be reached by reactive Mn=O species. A similar approach was successfully applied to mimic carotene dioxygenases: selective 15,15′ double-bond scission of β,β-carotene was achieved with a Ru(II) porphyrin with two CDs attached to opposite sides of the

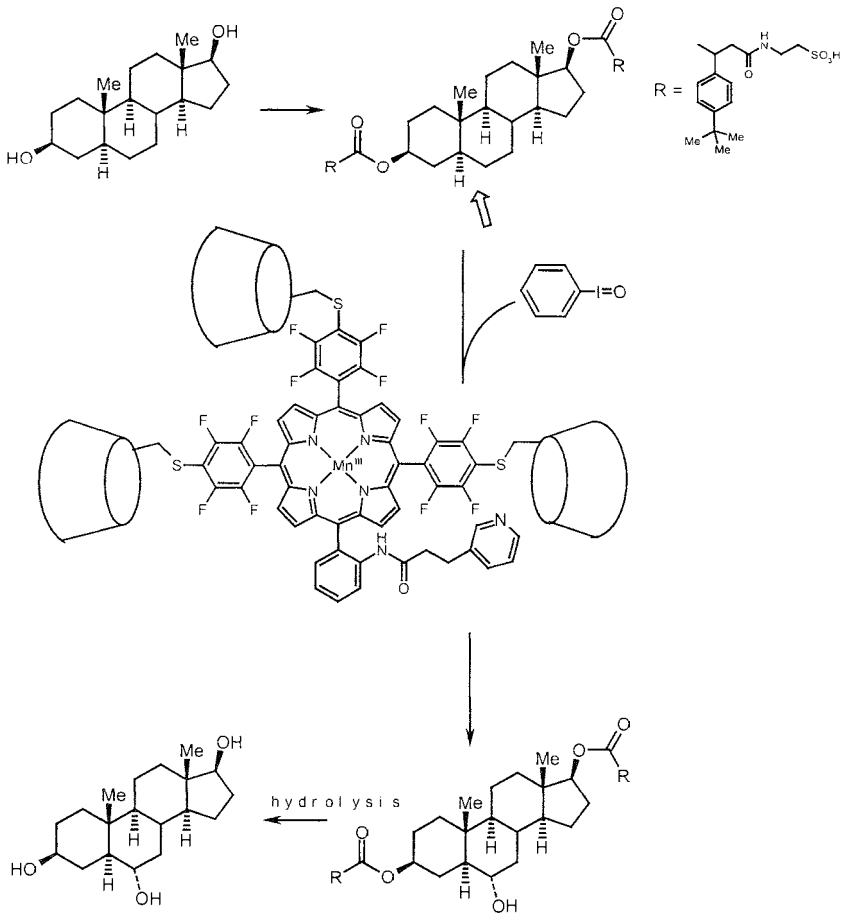

Fig. *3* A cytochrome P-450 mimic for selective hydroxylation of steroids. (From Ref. [16].)

porphyrin ring.[17] Other examples can be found in the literature.[7,8 14]

SYNTHETIC MACROCYCLES

Crown Ethers and Macrocyclic Polyamines

The ability of crown ethers to bind primary ammonium groups was used to achieve an enzyme-like cleavage of activated amino acid esters by attachment to the macrocycle nucleophilic group. Inclusion of the protonated amino group of the substrate into the crown ether approximates the ester group and the nucleophile, inducing significant rate enhancements.[2] Such systems were proposed to accelerate peptide synthesis by using dithiole crown ether derivatives like 1 (Fig. 4).[18] Both thiole groups of 1 are acylated by activated esters of amino acids, and then intramolecular aminolysis leads to formation of the dipeptide as the thioester at one thiole group and liberation of another thiole group. that again may be acylated.

Partially protonated macrocyclic polyamines possess a high positive charge that may attract and activate negatively charged substrates. This type of catalysis is illustrated by catalysis of H–D exchange in the malonate dianion in the presence of a tetraprotonated macrocyle (2; Fig. 4) that imitates enolase enzymes.[19] In addition, amino groups of the macrocycle, which remain unprotonated, may act as nucelophiles toward an anionic substrate bound to the protonated cationic part of the macrocycle. This type of catalysis operates in the ATP hydrolysis by the same macrocycle (3: Fig. 4).[20]

Cyclophanes

Guest-binding properties of cyclophanes resemble those of CDs. Nonfunctionalized cyclophanes with large cavity sizes may catalyze bimolecular reactions by bringing together two reactants.[2] Many cyclophanes carrying functional groups (nucleophiles and some enzyme cofactors) were prepared as enzyme mimics.[2,7,8] In Fig. 4 (Structure 4), one of the most successful cyclophane enzyme mimics, a flavo-thiazolio-cyclophane imitating the action of pyruvate oxidase,[21] is shown. The host 4 catalyzes oxidation of 2-naphthaldehyde to methyl 2-naphthoate in methanol. The reaction kinetics is of the Michaelis–Menten type. A similar, but not macrocyclic, compound reacts much slower and does not show any saturation upon variation of substrate concentration. The results show the importance of the macrocyclic binding site. The recycling of the flavin is possible by electro-

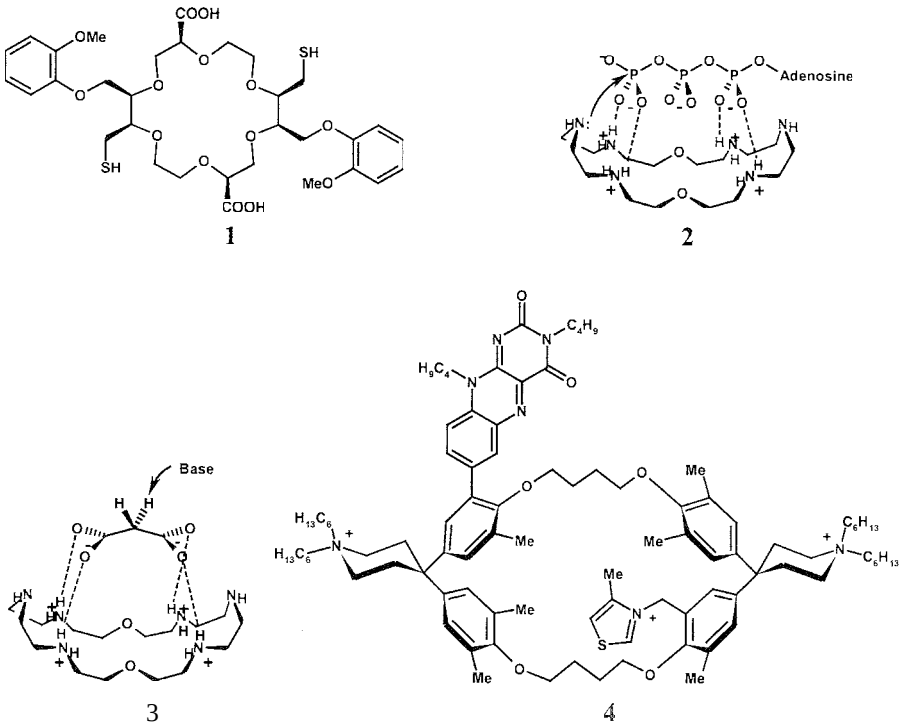

Fig. 4 Some synthetic macrocycles used as enzyme mimics

chemical reoxidation of the cofactor. and up to 100 cycles can be performed on a preparative scale.

MOLECULARLY IMPRINTED POLYMERS

Transition-state stabilization by complementary noncovalent binding to the active-site functional groups is the central idea in interpretating the remarkable activity and selectivity of enzymes.[2] From this point of view, a synthetic receptor designed as an enzyme mimic should recognize reactants in the transition rather than in the ground state. The most successful approach to such receptors is the development of catalytic antibodies (abzymes), discussed in a separate article. The general idea of this approach is to use a stable analogue of the transition state for a given reaction as a hapten (a small molecule that can stimulate antibody formation when combined with a protein) to induce production of antibodies. which will have combining sites capable of specifically interacting with the transition state. In chemical systems. this idea was realized (with much lower efficiency. however) by using molecularly imprinted polymers.[22]

Schematically shown in Fig. 5 is the preparation of an enzyme mimic for the hydrolysis of ester 6 by molecular imprinting.[22] Phosphonate 5 is an analog of the transition state for the alkaline hydrolysis of Ester 4. It was used as a template for polymerization with two equivalents of the binding-site monomer *N,N'*-diethyl-4-vinylbenzamidine. Amidinium groups were chosen, because they can interact electrostatically with the side carboxylate group as well as with the anionic transition state of the alkaline hydrolysis, thus achieving substrate recognition and transition-state stabilization. Polymerization of the preassembled binding-site monomer with the template (Fig. 5A) followed by template removal (Fig. 5B) leaves a cavity that acts as transition-state receptor for the ester substrate (Fig. 5C). The imprinted polymer accelerates the hydrolysis of 6 more than 100-fold compared to the reaction at the same pH in buffer solution without the polymer. The reaction kinetics is of the Michaelis–Menten type. A polymer obtained with amidinium benzoate as a control, with a statistical distribution of amidinium groups. is ca. one order of magnitude less active in the hydrolysis of 6.

Another often applied approach to enzyme mimics is imprinting a polymer containing catalytically active groups with a substrate analogue. For example, a polymer containing Co(II)–imidazole complexes imitating the active site of the phosphotriesterase enzyme was designed

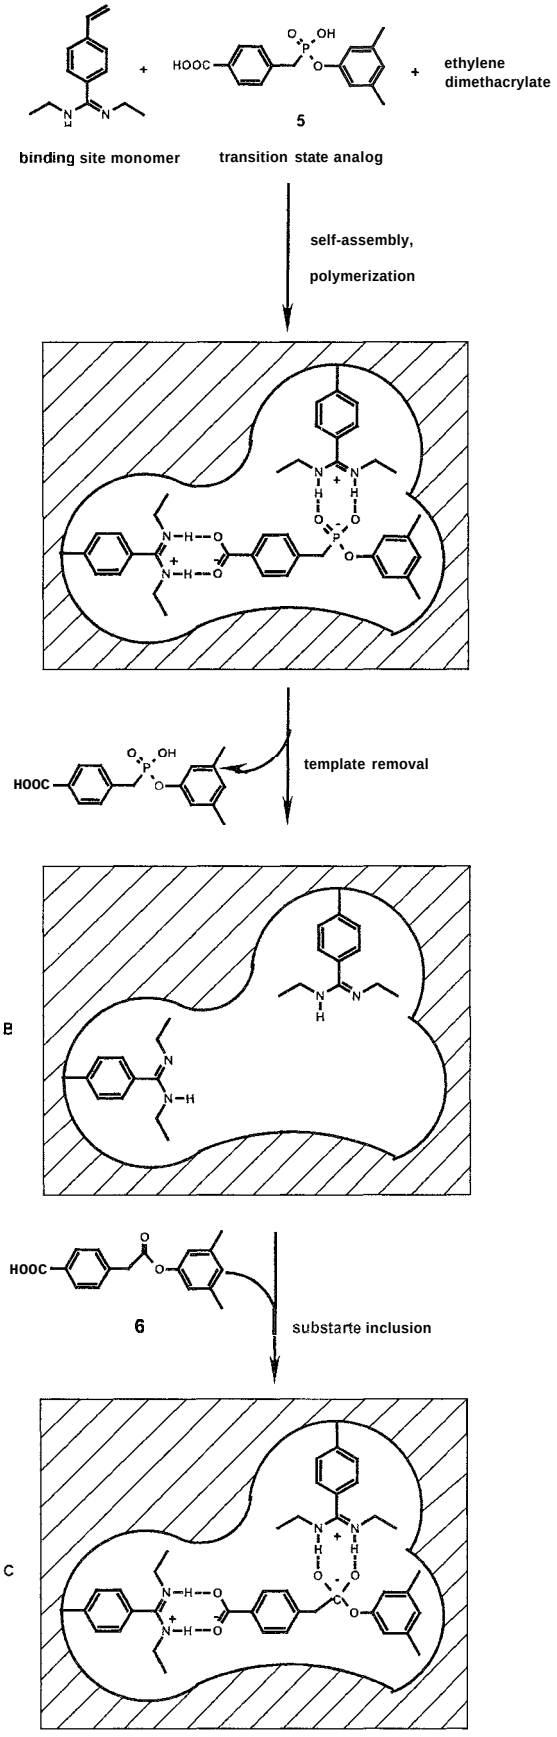

Fig. 5 Preparation of an enzyme mimic for the ester hydrolysis by molecular imprinting. (From Ref. [22].)

for the hydrolysis of paraoxon [$(EtO)_2P(=O)OC_6H_4$–NO_2-4)].[23] Imprinting this polymer with a substrate analogue stable toward hydrolysis [$(EtO)_2P(=O)CH_2$-C_6H_4–NO_2-4)] noticeably improved the catalyst activity. Catalytically active imprinted polymers were prepared, using both approaches discussed above, for many other reactions. such as elimination, carbon–carbon bond formation, oxidation. and hydrogen transfer.[22]

Bioimprinting is a more recent approach that employs a biological polymer for the imprinting.[18,22] Thus. a glutathione peroxidase mimic was prepared by imprinting egg albumin with *N*,*S*-*bis*(2,4-dinitrophenyl)glutathione and by having subsequent chemical modification.[24] The protein was denaturated and allowed to interact with the glutathione derivative. Then the new protein conformation was fixed by cross-linking with glutaraldehyde, the template was removed by dialysis, and protein serine residues were converted to selenocisteines. The resulting enzyme mimic was only seven times less active than the native glutathione peroxidase.

SOLID-STATE **ENZYME MIMICS**

The microporous structure of some solid materials makes possible incorporation of active species, e.g., metal complexes inside them, and these systems may show the shape-selective catalysis and an enzyme-like kinetics that allows one to consider them as enzyme mimics.[25]

The most important class of solid-state enzyme mimics is based on zeolites. Zeolites are solid materials composed of SiO_4 or AlO_4 tetrahedra linked at their corners, affording a three-dimensional network with small pores of molecular dimensions. They possess a unique feature of a strictly uniform pore diameter. In particular, zeolites with encapsulated metal complexes are used as inimics of cytochrome P-450.[26] An efficient enzyme mimic was obtained by encapsulating an iron phthalocyanine complex into crystals of zeolite Y, which were, in turn, embedded into a polydimethylsiloxane membrane acting as a mimic of the phospholipid membrane.[26] With t-butylhydroperoxide as the oxidant, the system hydroxylates alkanes at room temperature: with rates comparable to those for the enzyme. It shows similar selectivity (preference oxidation of tertiary C–H bonds) and a large kinetic isotope effect of nine.

Enzyme-like behavior was observed for electrocatalytic oxidation on Nafion/lead-ruthenium oxide pyrochlore chemically modified electrodes.[27] Nafion is loaded with lead(II) and ruthenium(III) cations by ion exchange, and then their oxides are prepared by in situ precipitation in such a way that the catalytically active sites remain

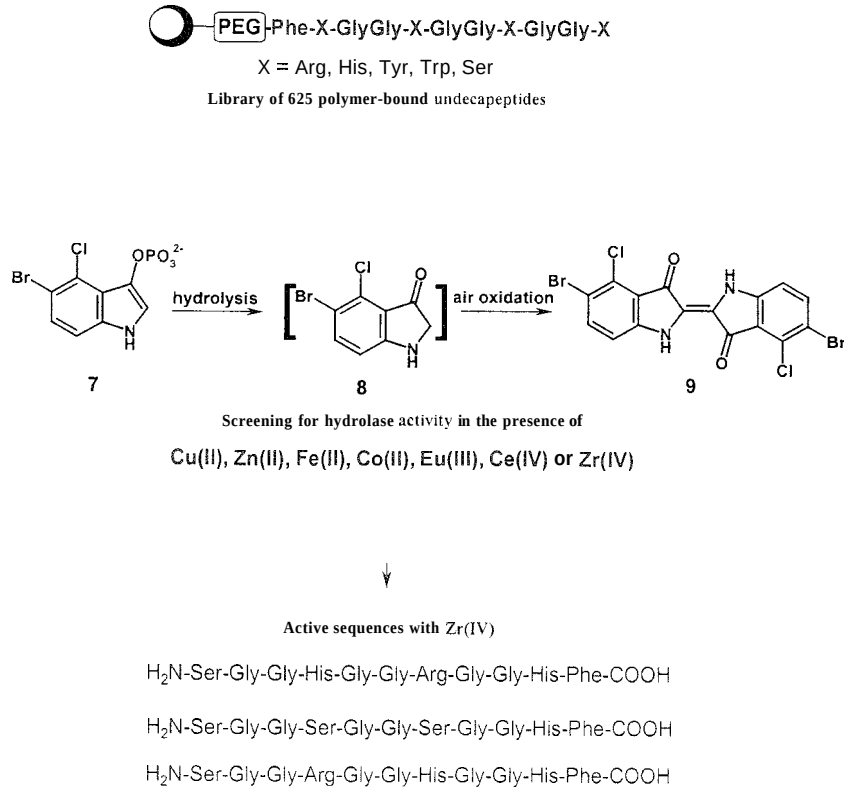

Fig. *4* Combinatorial development of phosphatase mimics on the basis of a peptide library. (From Ref. [30].)

covered with a hydrophobic core of the polymer. The electrooxidation of many biological compounds follows the Michaelis–Menten mechanism. Electrodes of this type were used as chemical sensors.

OTHERAPPROACHES

Using peptides in the design of enzyme mimics received increased attention. For example, nuclease mimics were prepared by incorporating lanthanide(III) cations into chimeric peptides composed of helices from the DNA-binding protein Engrailed and the binding turn from the Ca protein Calmodulin.[28] These 33- and 34-residue peptides were expected to possess metal-binding and DNA-recognition properties. They showed high affinity for Eu(III) [dissociation constant of the Eu(III)–peptide complex is 3 μM] and higher activity than free Eu(III) cation in the hydrolysis of supercoiled plasmid DNA. In another instance, attachment of a 14-residue peptide to a Mn(III) porphyrin complex allowed size-selective oxidation of alkenes.[29]

Impressive progress in combinatorial chemistry led to a new approach to the development of catalysts by the activity selection principle. A discussion of this aspect related to combinatorially developed enzyme mimics can be found in Ref. [8]. In Fig. 6. this approach is illustrated with an example of combinatorial development of phosphatase mimics on the basis of a peptide library.[30] In the first step. a library of 625 polymer-bound undecapeptides with five variable amino acids and three constant GlyGly spacer fragments was prepared. Variable amino acids were chosen on the basis of their possible ability to recognize anionic substrates (Arg). coordinate metal ions (His, Tyr). participate in π–π stacking interactions with aromatic groups of the substrate (Trp), and serve as a nucleophile (Ser). Screening for hydrolase activity was performed by using a specially designed phosphate monoester Substrate **7**, which affords, after hydrolysis, a deeply colored insoluble Product **9** via the air oxidation of the Intermediate 8. In the screening experiments, I mM solutions of different metal cations were added to approximately 2500 polymer beads, and in the case of Zr(IV), about 20 of these beads showed a typical turquoise color of 9. Peptide sequences shown at the bottom of Fig. 6 were determined for three intensively colored beads. Resynthesized peptides with these sequences mixed with Zr(IV) show catalytic activity in 4-nitrophenyl phosphate (a typical phosphatase substrate) hydrolysis in solution. Another original combinatorial approach to the development of phosphatase mimics is based on random functionalization of polyallylamine by potential metal coordinating and nucleophilic groups.[31]

CONCLUSION

Introducing the ideas and methodologies of supramolecular chemistry to the development of enzyme mimics allowed new catalysts to be obtained. which usually follow enzyme-like kinetics and show relatively high efficiency. Artificial enzymes are still inferior to natural enzymes in catalytic activity and selectivity.[2] Nevertheless, enzyme mimics already have practical applications, e.g., in the development of electrochemical sensors with solid enzyme mimics[27] or in organic synthesis with metal complexes of modified cyclodextrins.[32] Future progress in this area may be expected from more efficient designs of transition-state receptors,[2] improvement of the catalytic activity–selection approach based on combinatorial methodology,[8] and general progress in development of specific receptor molecules.

Enzymes: Characteristics and Mechanisms

Nicholas C. Price
Adrian J. Lapthorn
University of Glasgow, Glasgow, United Kingdom

INTRODUCTION

Enzymes are remarkable catalysts. With a high degree of specificity, they can bring about rate enhancements greater than 10^{12}-fold for simple reactions, such as the hydrolysis of amide bonds or phosphate esters. The vast majority of the enzyme-catalyzed reactions in living systems do not occur on any reasonable time scale in their absence. In addition to the specificity and catalytic power, the third remarkable property of enzymes is that their activities can be regulated by a variety of mechanisms. thereby allowing the complex metabolic network of chemical reactions in organisms to be controlled. In short. enzymes provide the essential underpinning to life in organized systems.[1–4] Because of these remarkable properties, the application of enzymes to industrial processes attracted increasing attention, and a number of ways in which the obvious disadvantages of enzymes. such as high cost and ability to work over a limited range of experimental conditions, are being successfully overcome.[5] Over the last 20 years or so, it was recognized that certain RNA molecules can act as catalysts; these molecules were termed ribozymes.[6]

The purpose of this article is to explain the principal characteristics of enzyme catalysis and to focus on the approaches used by enzymologists to answer current questions. Over the last decade. developments in recombinant DNA technology that have led to high levels of expression of enzymes and provided the ability to mutate amino acid residues, coupled with those in structural characterization and bioinformatics over the same period. have led to a renaissance in enzymology. In the next decade. we will see the harvesting of the fruits of the genome sequencing projects.[7]

THE CLASSES OF ENZYME-CATALYZED REACTIONS

As of 2002, over 4000 different chemical reactions were characterized as being enzyme-catalyzed. The Enzyme Commission, established by the International Union of Biochemistry (now known as the International Union of Biochemistry and Molecular Biology), in consultation with the International Union of Pure and Applied Chemistry in the 1950s. proposed the basis for enzyme classification and nomenclature that is still in use.[8]

Reactions are divided into six classes:

Class	*Type of reaction*	*Category of enzyme*
1	Redox	Oxidoreductase
2	Group transfer	Transferase
3	Hydrolysis	Hydrolase
4	Elimination (to form a double bond)	Lyase
5	Isomerization	Isomerase
6	Ligation (joining molecules at the expense of any energy source. e.g., ATP)	Ligase (synthetase)

Enzymes are classified on the basis of the reaction catalyzed, not on the source from which they were isolated or on the precise details of the mechanism of the reaction. Each enzyme is then given an Enzyme Commission (EC) number consisting of four parts (A.B.C.D); this number serves as an identifier for interrogating databases. A is the Class number. i.e., it can take values from 1 to 6: B and C denote more precise descriptions of the type of reaction and substrate(s) acted on: and D is a serial number within the sub-subclass. Each enzyme is given a systematic name (usually too cumbersome for everyday use) and a common name. For example. lactate dehydrogenase is EC 1.1.1.27, and chymotrypsin is EC 3.4.21.1. Further details can be found in Ref. [8].

HOW MANY DISTINCT ENZYMES ARE REQUIRED BY AN ORGANISM?

Although well over 4000 different types of chemical reactions are now known to be catalyzed by enzymes, these do not all occur in every organism. In the well-studied enteric bacterium *Escherichia coli* K-12, the results of genome sequencing[9] indicate that 4288 different proteins can be coded for. and of these. 2656 (62%) are

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012683

characterized. (The others are regarded as hypothetical, unclassified, or unknown.) Of the characterized proteins. 1701 (64%) are enzymes. This is likely to represent a reasonable estimate of the number of reactions required to sustain a simple free-living organism. In higher eukaryotic organisms such as mammals. this figure is likely to be five- to 10-fold higher. Of course, not all enzymes are equally abundant in the cell, and it is estimated that the 20 or so enzymes that catalyze the steps in the major energy-yielding pathways of glycolysis and the tricarboxylic acid cycle make up nearly 60% of the total number of actual enzyme molecules in the E. coli cell.[10]

WOW CAN ENZYMES BRING ABOUT CATALYSIS?

In order to achieve catalysis of so many different types of chemical reactions, enzymes have, at their disposal. an enormous variety of chemical weapons. Enzymes are proteins. i.e.. chains of amino acids Iinked by peptide (amide) bonds. There are 20 different amino acids, providing side chains with a variety of characteristics:

- Nonpolar (Ala, Val, Leu, Ile, Phe, Cys, and Met).
  Charged (Lys. Arg, Glu. Asp. and His).
- Nucleophiles (Cys, Lys. Tyr, and Ser).
  Proton donors/acceptors (His, Asp. and Glu).
  Hydrogen-bond donors/acceptors (Asn. Gln. Ser. and Thr. in addition to charged residues).
- Metal ion coordination (His, Asp, Glu, and Cys).

A number of amino acids display composite properties. For example. Lys is a charged amino acid due to a prinary amine group in the side chain; however. this group is at the end of an aliphatic chain $-(CH_2)_4-$, which can allow the residue to be significantly buried in a nonpolar environment.

Other side chains play important structural roles, e.g., Pro (an imino acid) disrupts regular secondary structural elements. stabilizes the conformation of exposed loops, and, although hydrophobic in nature. is often found surface-exposed at turns. Similarly, Gly is found performing a number of functions because of its small size, which allows it to adopt conformations that are sterically inaccessible to other amino acids. Gly is therefore critical to the correct folding of many proteins. can form hinge regions between domains (folded units), and can be necessary for the correct positioning of functional groups. which are all crucial roles for catalysis. Cys is the only amino acid residue that can form covalent cross-linking of the peptide chain by forming a disulfide linkage to another suitably positioned Cys under oxidizing conditions. This cross-linking provides significant stability to folded proteins but is not usually considered necessary for acquisition of the correct folded structure.

In addition to the repertoire of amino acids, a significant proportion (of the order of 30%) of enzymes exploits the properties of metal ions to assist catalysis; these metals include Zn to act as a Lewis acid and polarize bonds, Mg to neutralize charges on anions, and Cu and Fe to act as redox centers. The last role is especially important, because only one of the naturally occurring amino acids (Cys) has any significant redox chemistry: although it should be noted that certain redox cofactors such as TPQ (2,4,5-trihydroxyphenylalanine quinone) in E. coli amine oxidase can be formed by posttranslational modification of Tyr side chains.[11] Several other metals (Na, K, Ca, V, Mn, Ni. Co, Mo) also assist catalysis in specific cases. Biological systems generate a number of organic compounds with specific chemical functions, which are essential components (cofactors) of many enzymes. These cofactors include pyridixal-5'-phosphate (involved in elimination and replacement reactions of amino acids), biotin (involved in CO_2 fixation and carboxylation reactions), lipoic acid (involved in acyl transfer reactions), and heme (which is critical in monooxygenase reactions).[1–3]

The range of chemical functionalities available to enzymes means that an almost limitless range of environments for the correct binding: mutual orientation, and activation of reacting molecules can be created. The mechanisms by which catalysis can be achieved are discussed in a later section.

For a number of enzyme-catalyzed reactions, it is clear that nature evolved a number of distinct answers to the same chemical problem. Thus; for example, in the cases of 3-dehydroquinase[12] and phosphoglycerate mutase,[13] two distinct types of enzyme are known in each case. In the case of proteases, there are four main types of enzymes, each of which displays a distinct solution to the problem of breaking the (relatively stable) amide bond.[1,2] To illustrate the range of possibilities involved, the nucleophile attacking the electrophilic carbon of the carbonyl bond can be a Ser or Cys side chain or a water molecule activated by an Asp side chain. The polarization of the carbonyl bond is enhanced by a Zn ion or by hydrogen bonding. and the proton donor to the leaving (amino) group can be His or a dyad of carboxyl (Asp) side chains. These different types of enzymes presumably represent the outcomes of independent, parallel, evolutionary processes.

In comparison with proteins, the smaller variety of chemical functionalities available in nucleic acids (only four bases compared with 20 amino acids) restricts the range of structures they can adopt. It is therefore not surprising that ribozymes appear to catalyze a more

limited range of reactions (mainly those of phosphodiester transfer). While it is clear that the active site of the peptidyl transferase activity in ribosomes contains only RNA, some precise details of the catalytic process remain to be elucidated.[14]

THE THREE-DIMENSIONAL CONTEXT OF ENZYME CATALYSIS

The three-dimensional structures of enzymes provide the context within which the chemical functionalities are depioyed to bring about catalysis. The three-dimensional structure not only brings the individual functions into the correct spatial relationship. but also allows modulation of these functions. Thus. the effect of the microenvironment can be to alter the pK_a of a given side chain in an enzyme by several units from its value in model compounds: examples include the side chain of Glu 35 in lysozyme (pK_a raised to 6.2[2]) and Asp 32 in pepsin (pK_a lowered to <3[2]). In the case of the ''serine'' proteases. such as chymotrypsin. trypsin. and thrombin, a precise geometrical arrangement of three side chains (Ser...His...Asp) known as the "charge relay system'' serves to increase the nucleophilicity of the catalytic Ser by several orders of magnitude.[1,2] It is now appropriate to give a short overview of enzyme structure.

The Structures of Enzymes

Enzymes consist of polypeptide chains from about 100 to over 2000 amino acid residues in length. The three-dimensional structures of several thousand enzymes were determined, predominantly using the technique of X-ray crystallography, while NMR continues to be an important technique for determining the structure of smaller. often flexible; enzymes (<30 kDa). Advances such as the routine freezing of crystals to 100 K to prolong their lifetime, brighter synchrotron X-ray sources with tunable wavelengths to permit structure solution from a single crystal. and charged couple devices (CCD) detectors to speed up data collection times by an order of magnitude have revolutionized X-ray crystallography. These developments alongside those in the overexpression and purification of proteins resulted in faster structural characterization. From the large number of enzyme structures determined. we have a better understanding of enzymes than ever before. Databases such as SCOP[15] and CATH[16] attempt to catalog protein structures into a hierarchy of folds, superfamilies, and families of proteins (Fig. 1). These proteins can be further divided into motifs of secondary structural elements; for example, the ferredoxin-like fold is composed of two repeats of the common β-α-β motif. Although both databases highlight the potential diversity of enzyme folds. it must be stressed that many proteins share common folding architectures e.g., $(\alpha/\beta)_8$ or TIM barrel, which is estimated to represent 10% of all enzyme folds.

There are 58 classes of small proteins identified so far, which are dominated by disulfide bridges. metal ligands. or hemes; however, few can be considered enzymes. The small proteins consist of enzyme inhibitors, toxins, hormones, and discrete folded units or domains of larger proteins. The smallest enzymes (approximately 100 amino acid residues in length) include the bacterial ribonucleases and thioredoxins. At around 400–500 residues. enzymes such as cyiochrome P450s and the aminodeoxyisochorismate (ADC) synthase subunit are unusual in forming a single large globular protein. It is more common for proteins of this size and larger to be composed of a series of smaller folded domains joined by short and often flexible linker regions. This is clearly advantageous in terms of simplifying the folding of the protein as well as generating hinges between protein domains that permit the large conformational changes necessary for catalysis. For example, lactate dehydrogenase is a 330 amino acid polypeptide chain separated into two domains of approximately 160 amino acid residues in length (see "Lactate Dehydrogenase" later in this article). One domain is involved in binding NAD^+ and has a characteristic (Rossmann) fold, the other binds lactate. The two domains close together on binding both substrates to form the catalytically competent conformation of the enzyme. This pattern is found in other members of the dehydrogenase family.

Flexibility in the protein is often key to the functioning of the macromolecule as a catalyst. Regions of flexibility are often identified from crystallography by high thermal parameters and from information such as NMR relaxation times. rates of hydrogen exchange, and fluorescence polarization.[2,17] In some enzymes. such as adenylate kinase, multiple X-ray structures of the enzyme in the presence and absence of ligands precisely defined the hinge regions of the protein and the extent of conformational changes that occur during the catalytic cycle.[18]

Large enzymes are rarely cornposed of a single polypeptide chain but form larger syminetricai arrangements via self-assembly processes. This quaternary structure of the enzyme is often necessary for the formation of active protein, as the catalytic active site is often formed at the interface between subunits. Given that proteins are chiral molecules. almost all possible symmetrical arrangements of subunits were observed, from the simple 222 symmetry of the tetramer of various dehydrogenases such as lactate dehydrogenase to the cubic 23 symmetry of the Type II dehydroquinase dodecamer. The role of

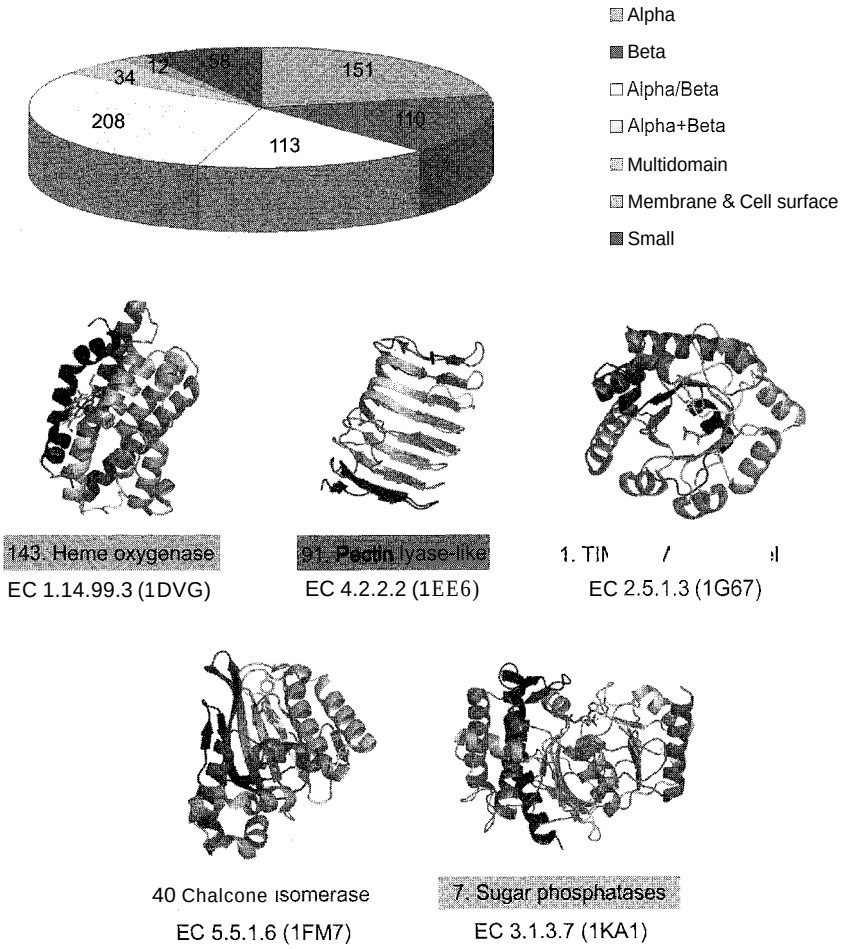

Fig. 1 The number of fold families identified from structural studies of proteins based on data obtained from SCOP.[15] Representative structures are shown from each of the classes of protein fold, e.g., alpha or beta, that include enzymes. The proteins are represented as ribbons. colored from blue at the N-terminus through to red at the C-terminus. Cofactors and inhibitors are colored according to atom type and are represented in stick. For example. the alpha fold of Heme oxygenase is fold 143 out of 151 in the classification. a multihelical bundle containing two structural repeats of three-helical motif. The enzyme is an oxidoreductase EC 1.14.99.3 and is represented by the crystal structure of rat heme oxygenase-1 (HO-1) protein data bank acession code IDVG. (*View this art in color at www.dekker.com.*)

oligomerization is not completely understood, but it is believed to contribute to increased stability of the protein,[19] as well as to offer possibilities of regulation of activity.[20] Oligomerization of multiple enzymes allows for the coordination of sequential steps in a metabolic pathway and the containment of potentially toxic intermediates.[21,22]

DETERMINATION OF ENZYME MECHANISMS

Understanding the mechanism of an enzyme requires the structural characterization of the various enzyme-containing complexes involved in the transformation of substrates to products. as well as the rates at which these complexes are interconverted. It follows that information from a variety of experimental approaches must be integrated.

Kinetic Aspects

Kinetic data (steady-state and rapid reaction) can be used to identify the sequence of enzyme-containing complexes as substrates are converted to products, and to identify the rates of some or all of the elementary steps in the overall reaction. For instance, in a two-substrate reaction such as that catalyzed by lactate dehydrogenase (lactate+ $NAD^+ \longleftrightarrow$ pyruvate+NADH), it can be shown that the

reaction proceeds via a ternary complex (E-NAD^+-lactate), which is formed in an ordered fashion. with binding of NAD^+ preceding that of lactate. Other two-substrate reactions, such as that catalyzed by creatine kinase (creatine + ATP $\longleftrightarrow$ phosphocreatine + ADP). proceed via a random ternary complex mechanism in which either substrate can bind first. A third group of two-substrate enzyme reactions proceed via enzyme substitution (or "ping-pong") mechanisms in which the first substrate combines with the enzyme to produce the first product and a modified enzyme (E*). In the second step, E* reacts with the second substrate to give the second product and regenerate enzyme. An example of an enzyme substitution mechanism is provided by nucleoside diphosphate kinase, where the first substrate (NTP, N=any nucleoside) transfers a phosphate group to an His side chain in the enzyme. The techniques involved in assigning a given enzyme to a particular mechanistic category have been described in detail.[1,23,24]

In addition to determining the sequence of complexes. kinetic studies provide fundamental parameters of the enzyme. For most enzymes, the dependence of rate (velocity. v) on substrate concentration ([S]) follows a hyperbolic saturation curve known as the Michaelis–Menten equation. i.e., $v = V_{max}[S]/(K_m + [S])$. The dependence is characterized by the parameters V_{max} (the maximum or limiting velocity at infinite substrate concentration) and K_m (Michaelis constant, corresponding to the concentration of substrate required for the velocity to reach half V_{max}). For reactions involving two or more substrates. the same general principles apply, although the equations are more complex. For some enzymes. particularly those with multiple polypeptide chains that play key roles in metabolic regulation. the dependence of rate on substrate concentration does not follow the Michaelis–Menten equation. and more complex mathematical descriptions are required to account for the kinetics. These involve interactions between the multiple active sites in the molecule.[1,2]

The parameter V_{max} can be converted to a turnover number or k_{cat} by taking account of the molar concentration of enzyme present in the assay mixture. The values of k_{cat} of enzymes are generally in the range of 10^2–10^6 s^{-1}.[2] This means that the catalytic events on the enzyme occur in the time range of milliseconds or less. In order to characterize such steps. it is necessary to employ rapid reaction techniques such as stopped-flow, which has a dead time of approximately 1 ms. Continuous-flow mixing techniques can have shorter dead times but make much greater demands in terms of quantities of sample required. The value of k_{cat}/K_m provides not only a quantitative measure of the specificity of an enzyme for a given substrate.[2] but it can also be used as a measure of cataiytic efficiency.[2]

Structural Aspects

The detailed three-dimensional picture of an enzyme obtained by techniques such as X-ray crystallography is effectively a time- and space-averaged view of a single conformation of a protein stabilized by the crystallization conditions. Protein crystals typically contain 50% (w/w) solvent. and. as a result. have large solvent channels running through them. In many cases. the enzymes are still capable of catalyzing reactions within the crystal. albeit at a somewhat reduced rate. The ideal approach with which to examine events at the active site would appear to exploit X-ray crystallography by diffusing substrates into enzyme crystals and thereby defining the side chains involved in substrate binding and the structural changes that occur during catalysis. Freezing techniques and complete data collection in microsecond or shorter time scales in the late 1980s seemed to hold great promise of time-resolved structural studies on enzymes.[25] However. technical difficulties associated with loss of order in the crystals during catalysis as a result of the spatial averaging necessary for the diffraction experiment, among other reasons, made this approach technically challenging. Success stories include the use of lasers to initiate a light-sensitive reaction, followed in real time by the use of Eaue diffraction in photoactive yellow protein,[26,27] and the use of conventional X-ray methods with a single-crystal spectrophotometer to identify stable highly populated intermediate states in amine oxidase[11] and cytochrorne cd_1 nitrite reductase.[28] These methods. together with traditional X-ray data collection using cocrystallization (often in preference to soaking of crystals) with poor substrates, transition state analogues. competitive inhibitors. catalytically compromised enzymes (by site-directed mutagenesis), or individual components of multisubstrate reactions, provided structural perspectives on many enzyme mechanisms.[29] In addition, conformational changes essential for catalysis were also characterized in much greater detail than was previously possible.

WOW CAN WE UNDERSTAND THE SPECIFICITY OF ENZYME-CATALYZED REACTIONS?

The term specificity is widely used in connection with enzymes but has a number of aspects.[1,2] Most enzymes are highly specific in the nature of the substrates they utilize and the reaction catalyzed. There are enzymes with relatively low specificities (bond specificityj. e.g., peptidases and phosphatases, which will act on a wide range of substrates provided they contain the requisite chemical band (peptide or phosphate ester. respectively). Low

specificity is commonly observed with degradative enzymes but rarely with biosynthetic enzymes. Hexokinase is an enzyme showing group specificity: it acts on a variety of sugars provided they are aldohexoses. A number of enzymes show absolute or near-absolute specificity and will work effectively on only one substrate or substrate combination; urease is an example of this type of enzyme. These classifications of specificity become more difficult when macromolecular substrates are considered. For example, restriction endonucleases catalyze the breaking of DNA chains at a recognition sequence of four to six base pairs in DNA. Any DNA molecule containing this sequence will be acted on: in this case, the specificity is for that portion of the substrate in immediate contact with the active site of the enzyme. A further aspect of specificity is the stereospecificity exhibited by enzymes: thus, a given dehydrogenase using the NAD(P)H/NAD(P)$^+$ redox pair will abstract only one of the two hydrogens (A-side or B-side) at the C4 of nicotinamide ring of NAD(P)H.[11] The precise mode of binding of the NAD(P)H substrate to the enzyme will dictate which hydrogen is available for transfer to the other substrate in the reaction.

A further aspect of specificity has become recognized in recent years. namely, proofreading.''' The accurate replication of DNA during cell division is an event of crucial importance to an organism. DNA polymerases catalyze this process with an error rate of as little as 1 in 10^{10}. This is achieved by a combination of Watson–Crick base pairing (error rate of the order of 1 in 10') in combination with a proofreading step in which checks are made after the addition of each base to the 3' end of the growing DNA chain that the correct pair was formed. Any incorrectly added bases are removed by a 3'–5' exonuclease activity that occurs at an active site distinct from the polymerase site.

Specificity can be understood in terms of the complementarity of interactions between enzyme and substrate. In addition, the binding of the substrate will generally bring about a conformational change in the enzyme, so as to bring the amino acid side chains necessary for catalysis into the correct spatial relationship. The adjustment of the structure accompanying complex formation has proven to be a complicating factor in the application of computer programs that ''dock'' the enzyme and substrates or other ligands.

HOW CAN WE UNDERSTAND THE CATALYTIC POWER OF ENZYMES?

From studies of the rates of organic reactions. several factors were identified that could be relevant to understanding the mechanism of enzyme-catalyzed reactions. More complete discussions of the importance of these have been given.[1,2,30]

The factors include the following:

- *Proximity and orientation effects*
  The binding of substrates at adjacent sites on an enzyme in the correct orientation for reaction leads to a reduction in the entropy of activation. It was estimated that for a bimolecular reaction, each factor could contribute approximately 10'-fold to rate enhancement.
  Acid–base catalysis
  The addition or removal of a proton can promote electron flow. i.e., bond formation and breakage. during the reaction. As far as enzymes are concerned. only general acid or base catalysis can occur. because enzymes have no means of concentrating H^+ or OH^- ions. A number of amino acid side chains can act as proton donors or acceptors, and in many Zn-dependent enzymes, such as carboxypeptidase. the metal ion acts as an effective Lewis acid to enhance polarization of the carbonyl moiety of the amide bond. Among the amino acids; His (which has a pK_a generally close to 7) plays an especially important role in enzyme catalysis. because at neutral pH, there is a good balance between its protonated and deprotonated forms. In most cases, enzymes have suitably positioned pairs of side chains to provide push and pull of electrons.
- *Covalent catalysis*
  Reactions can be accelerated by the formation of intermediates, provided that such intermediates are rapidly formed and broken down. This then provides a new reaction pathway of lower activation energy. Many enzyme-catalyzed reactions proceed via covalent catalysis. involving side chains such as Cys, Ser, Eys. or His acting as nucleophiles in the formation of intermediates such as acyl-enzymes or Schiff bases.
  Changes in environment
  The rates of many reactions involving polar species are low in water because of the energetic cost of desolvating the reactants. Such reactions can be accelerated drainatically by switching to dipolar aprotic solvents such as dimethylsulfoxide. Enzymes are capable of providing nonpolar environments for reactions in which water is essentially removed. In addition. charges that develop during the reaction can be effectively stabilized in a medium of low dielectric constant by appropriately positioned charged side chains.
- *Distortion of substrate/transition state stabilization*
  In model reactions, it was demonstrated that distortion of a reactant so as to make it more closely resemble the postulated transition state of the reaction can lead to dramatic acceleration. In a number of enzyme-catalyzed reactions. there is evidence for such strain or

distortion, but the quantitative effect of this on the rate of reaction was not always clear. In order to act as a catalyst. an enzyme must make more favorable interactions with the transition state than with the substrates or products. From this. it follows that a compound that resembles this state in terms of geometry and electronic structure should bind to the enzyme. Such tight binding transition state analogues were developed for many different types of enzymes. Apart from helping to confirm ideas about the nature of the proposed catalytic mechanism of a reaction, they offer scope as potential selective inhibitors for therapeutic intervention.

It is clear that in a qualitative sense, the factors outlined in this section help us to understand the origin of enzyme catalytic power. However. it is not clear that for any given enzyme we can yet account quantitatively for the magnitude of its rate enhancement.

Given recent developments in computer modeling of chemical reactions. there is considerable interest in attempting to develop a mathematical understanding of enzyme catalysis. The sheer complexity of enzymes means that at present, it is possible to apply a strict quantum mechanical approach to only a limited region, such as the active site, and classical molecular mechanics are used to describe the remainder of the molecule. This combined approach had some success in modeling some aspects of enzyme-catalyzed reactions. such as the importance of particular side chains in the catalytic process.[31] However, a complete mathematical description of enzyme catalysis remains a considerable way off.

Constraints on the Rates of Enzyme-Catalyzed Reactions

For a number of enzymes. such as triosephosphate isomerase. fumarase, and catalase. the value of the k_{cat}/K_m ratio approaches a value of 10^8 M^{-1} s^{-1}.[2] This is close to the diffusion limit. i.e., the enzyme cannot work any faster because the rate is limited by the rate at which substrate diffuses to the active site. Enzymes of this type were described as having achieved catalytic perfection in evolutionary terms.[32] However, it should be noted that "evolutionary perfection" may not always imply a high value of k_{cat}. In the case of aldose reductase. for example. the enzyme was considered perfectly evolved for its role as a detoxification catalyst with a broad specificity by developing high affinities for the redox substrates NADPH/$NADP^+$ in such a way that the equiiibrium is shifted in the direction of product formation. These properties thus achieve saturation of the enzyme at all times under cellular conditions and effective rapid removal of toxic aldehydes.[33]

In some enzymes. it appears that the upper limit of k_{cat} is set by the rate of structural changes that accompany the catalytic events. For example, in the cases of lactate dehydrogenase[34] and triosephosphate isomerase,[35] it was shown that the catalytic rate matches the movement of flexible loops that close over the active site to allow catalysis to occur. Because of the scarcity of data concerning the rates of catalytically relevant structural changes in enzyme, it is difficult to know how widespread this effect might be; however: the structural data indicate that substrate-induced conformational changes occur in many enzymes. In kinases (enzymes that catalyze ATP-dependent phosphorylation reactions), formation of the catalytically active complex requires closure of the two domains. preventing access of water to the active site. In large assemblies such as the motor systems of ATP synthase and the actin–myosin system, the linkages between the structural changes and the reaction catalyzed underpin their function in coupling H^+ movement to ATP synthesis and ATP hydrolysis to muscle contraction. respectively.[2]

EXAMPLES OF ENZYME MECHANISMS

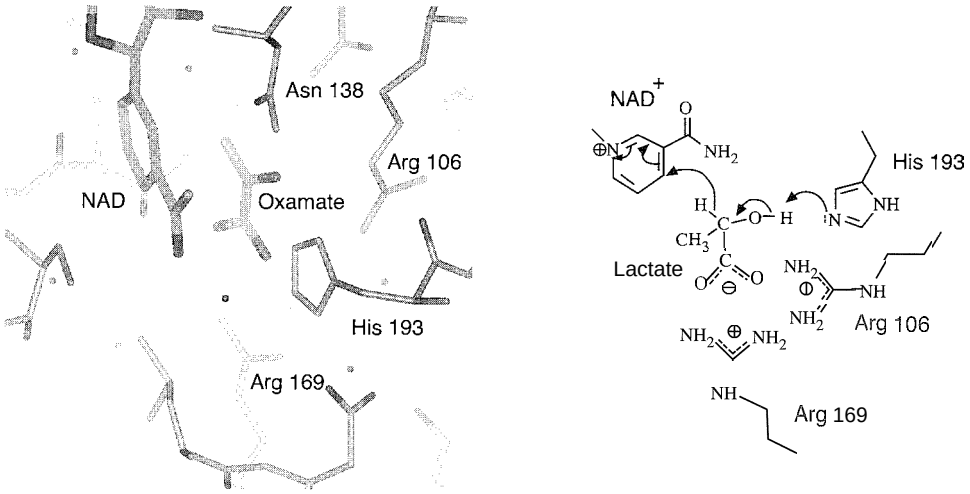
In this section, the mechanisms of two enzymes will be outlined in order to illustrate the way in which the various experimental approaches were integrated to provide an understanding of enzyme mechanisms. For further examples. see Refs. [1–3].

Lactate Dehydrogenase

Lactate dehydrogenase (EC 1.1.1.27) catalyzes the reaction lactate+NAD^+⟷pyruvate+NADH, which in the reverse direction represents the last reaction of anaerobic glycolysis. The enzyme consists of four identical polypeptide chains (subunits), each of molecular mass about 35 kDa. For a summary of this work, see Ref. [1].

X-ray crystallographic studies of the enzymes from dogfish and pig muscle and from *Bacillus stearothermophilus*[36,37] show that the enzyme belongs to the α/β class of proteins, with about 40% of the amino acids in α helix and 23% in β structure (Fig. 2a). In the N-terminal domain. there is a six-stranded parallel β-sheet with interconnecting helices. This motif is found in all $NAD(P)^+$-dependent dehydrogenases and is referred to as the Rossmann fold. Binding of NAD^+ to lactate dehydrogenase involves a large number of interactions with different side chains, including hydrogen bonds. electrostatic bonds, and hydrophobic interactions. The mode of binding explains why $NADP^+$ is not a substrate and also why lactate dehydrogenase is an A-side dehydrogenase.

a)



b)

Fig. 2 Lactate dehydrogenase: a) a ribbon representation of the tetramer of the B. *stearothermophilus* enzyme with each peptide chain depicted in a different color. The cofactor and oxamate inhibitor are colored according to atom type. as is fructose bisphosphate. which is an allosteric regulator of the enzyme. b) On the left is a detailed view of the enzyme active site as seen in the crystal structure. The ligand is highlighted in green and key amino acid residues are labeled. This is compared with the traditional two-dimensional representation of the enzyme mechanism on the right. Note that the residue numbers differ slightly from those of the muscle enzyme discussed in the test. (*View this art in color at www.dekker.com.*)

The structure of the catalytically active complex was deduced by the use of competitive inhibitors in abortive complexes (e.g., E.NADH.oxamate and $E.NAD^+$.oxalate). On this basis, the lactate is predicted to bind between the nicotimamide group of NAD^+ and the side chain of His 195 (which is close enough to form a hydrogen bond to the hydroxyl group of the lactate). The side chains of Arg 109 and Arg 171 are thought to anchor the carboxylate group

of lactate. (Note that these numbers are for the muscle enzyme and differ slightly from the corresponding residues in the *B. stearothermophilus* enzyme shown in Fig. 2).

Of key importance are the structural changes that accompany formation of the active, ternary complex. A flexible loop, consisting of Residues 98 to 120, which in the absence of substrates extends into solution, moves down in the ternary complex so as to exclude water from the active site. The side chain of Arg 109 moves some 1.4 nm: a smaller movement (0.15 nm) of the side chain of His 195 occurs to bring this into the correct position with respect to lactate.

As stated previously. kinetic studies showed that the enzyme-catalyzed reaction follows an ordered ternary complex mechanism in which the binding of NAD^+ occurs prior to that of lactate. and release of pyruvate precedes that of NADH. The use of rapid mixing methods allowed rates of many of the individual steps in the reaction sequence to be elucidated. including the hydride ion-transfer step in the catalytically active ternary complex.

The overall chemistry of the reaction involves the side chain of His 195 acting as a general base, abstracting the proton from the hydroxyl group of lactate and promoting electron flow in the direction of the positive charge on the nicotinamide ring of NAD^+ (Fig. 2b). The crucial features of the catalytic process are the correct positioning of the substrates. the conformational changes that aligned the appropriate side chains for reaction and binding. and the role of the side chain of His 195 as a general base.

Lactate dehydrogenase was subjected to extensive enzyme engineering studies using site-directed mutagenesis to explore the roles of a number of side chains in catalysis. to examine the nature of the rate-limiting step in the catalytic cycle. and to alter the specificity of the enzyme.[1,38,39] To examine the nature of the rate-limiting step, Gly 106 in the flexible loop was replaced by Trp. and the other Trp residues (80. 150. and 203) were replaced by Tyr, which has a much lower fluorescence. The mutant enzyme had similar catalytic activity to the wild-type. but essentially, only a single fluorescent group located within the flexible loop (Residues 98–120). Changes in the fluorescence of Trp 106 could be used to monitor the rate of structural changes associated with formation of the catalytically active complex. From this work. it was possible to conclude that the rate-limiting step in the catalytic cycle corresponded to the rate at which the flexible loop closed over the active site.

The active site of lactate dehydrogenase could be redesigned to convert it to a malate dehydrogenase. (It was already known that the tertiary structures of the two enzymes were similar.) To take account of the increased size and additional negative charge of malate, the volume of the active site was increased (Thr 246 replaced by Gly), and the basic character of the active site was enhanced (Asp 197 replaced by Asn, and Gln 102 replaced by Arg). The effect of these mutations was to change the ratio of the lactate/malate rates from 50011 to 1/1000. i.e., over 10^5-fold change in specificity. In further experiments. the active site of lactate dehydrogenase was altered to allow a broad range of bulky hydrophobic ketoacids to act as substrates, though at the expense of a significant reduction in the value of k_{cat}.[37]

Type II 3-Dehydroquinase

The dehydration of 3-dehydroquinate to 3-dehydroshikimate catalyzed by 3-dehydroquinase (EC 4.2.1.10) is common to two metabolic pathways, the inicrobial biosynthetic shikimate pathway and the catabolic quinate pathway. This reaction is catalyzed by two completely different enzymes: either a Type I enzyme that catalyzes a *syn* elimination: or a Type II enzyme that catalyzes an *anti* elimination.

The Type II 3-dehydroquinase is made up of 12 identical 16.5 kDa subunits of approximately 150 amino acid residues, which are arranged as a tetramer of trimers. The protein adopts a flavodoxin-like fold (i.e., belongs to the α/β class of proteins), with a parallel five-stranded β-sheet flanked on both sides by α-helices (Fig. 3a). The active site is located at the carboxyl end of the β-strands as in other α/β proteins, in the crevice produced by the specific topology of the β-sheet.[40] The loops from the P-strands 1 and 2 connect to helices in one direction. while those of β-strands 3, 4. and 5 connect to helices on the opposite face of the β-sheet. Between Strands 1 and 3, a crevice is formed, and this is where the active site is located (at least partially) in all α/β proteins. It should be noted that locating the active site of an enzyme is not as straightforward in the other classes of protein folds shown in Fig. 1.

Before the structure of the enzyme was determined, chemical modification experiments (using proteolysis and mass spectrometry to identify the modified residue) and site-directed mutagenesis were used to identify Arg 21, Tyr 28, and a His as catalytically important side chains.[41,42] Substrate and solvent ^2H isotope effects. proton inventory studies. and the pH-dependence of the kinetic parameters V_{max} and K_m were used to identify the enzyme mechanism[43] as an E_1CB elimination reaction proceeding via an enolate intermediate, with the initial proton abstraction as the rate-limiting step. The unusual sharp increase in k_{cat} and K_m above pH 9 was interpreted as the effect of an active-site Arg side chain on the basicity of a His.[43]

In the first crystal structure obtained for a Type II 3-dehydroquinase,[12] Arg 21 and Tyr 28 were disordered

in a loop region of the structure. However, based on the conserved amino acid residues within the active site, His 106 was suggested as the residue involved in proton abstraction, with its basicity elevated by the neighboring side chain of Glu 104. Further structural characterization was made possible by the synthesis of a series of transition-state analogue inhibitors.[47] Four crystal structures including the catalytically compromised mutant enzyme in which Arg 21 was replaced by Ala in complex with the product dehydroshikimate and the wild-type enzyme with 2,3-anhydro-quinic acid bound (Fig. 3b) defined unambiguously the active site of the enzyme and the role of key amino acid residues and provided snapshots of the catalytic cycle.[45] Surprisingly, Tyr 28 is involved in the initial proton abstraction step rather than a His, its pK_a being lowered by the proximity of Arg 113. The absence of a residue to stabilize the negative charge of an enolate and the presence of a conserved water molecule strongly suggests that the reaction proceeds via an enol intermediate. The His 106–Glu 104 pair instead is involved in the elimination of water, with His 106 acting as an acid, not a base. Despite having identified the various catalytically important amino acid residues and the probable enzyme mechanism, several questions still need to be addressed. including the following: 1) is Tyr 28 present as a phenolate ion and. if so, how is this maintained in a flexible loop; and 2) what is the role of Glu 104, if any, in the enzyme mechanism? Different combinations of techniques will undoubtedly be needed to answer these and further questions.

CONCLUSION

In this article, we showed how the application of structural and kinetic methods allowed enzyme action to be understood at the atomic level. Higher-resolution definition of reaction intermediates together with computational methods will give increasing insights into the processes of bond breakage and formation as substrates are converted to products. Using exquisitely sensitive spectroscopic and mechanical methods, it is now possible to study the action of single-enzyme molecules.[46] It is expected that the application of these methods to enzyme systems catalyzing complex biosynthetic reactions will lead to the successful exploitation of enzymes for the manufacture of compounds of commercial and medical importance. The range of applications of enzymes is already wide[17] and is being extended by developments such as the generation of catalytic antibodies[14] and the directed evolution of enzymes.[49] Progress in the attempts to redesign enzymes has been reviewed.[50] The coming decade will be a rewarding one for enzymologists.

Fluorescence Sensing of Anions

Kihang Choi
Andrew D. Hamilton
Yale University, New Haven, Connecticut, U.S.A

INTRODUCTION

Fluorescence is one of the most sensitive methods for converting molecular events to photophysical phenomena that can be easily detected using relatively simple devices and techniques. The powerful technique of fluorescence spectroscopy has been used for the analysis of many chemical and biological samples, especially when the quantity of the analyte is limited. Another key advantage of fluorescence sensing is that it is nondestructive; the analyte does not need to be isolated from its original environment as long as there is no background fluorescence blocking the detection of the signal.

Fluorescence sensors are usually constructed by conjugating a receptor (synthetic or biological) to a fluorophore.[1] The fluorescence properties of a fluorophore, such as emission intensity and wavelength. can be affected by the binding of an analyte to the receptor recognition domain. These changes can be monitored to determine the presence or. in a more quantitative way, the concentration of a given analyte. Effective connection of an analyte-binding domain to a fluorophore is important to produce a sensitive sensor with a significant fluorescence change. Many fluorophores with a wide range of excitation and emission wavelengths are available, and their fluorescence properties, such as excitation/emission mechanisms, decay processes; and excited state reactions are well characterized. Sensors using the chemical and physical properties of certain analytes to alter one of these fluorophore properties could give highly specific responses.

In this article. we will describe different approaches to the design of fluorescence sensors for anions that exploit distinctive mechanism-based concepts. In most case, synthetic receptors are used for anion binding and induce specific responses from the appended fluorophores, leading to selective and sensitive sensing.

LANTHANIDE COMPLEXES

An obvious approach to anion sensing would be to use cationic species as the anion-binding sites. In addition, some metal ions have well-characterized luminescent properties that can be utilized for sensing purposes. For example, the lanthanide f–f transition is forbidden. which makes direct excitation of the lanthanide ion difficult but also leads to slow radiative decay from the excited state.[2] The long-lived emission lifetime ranges from micro- to milliseconds. and by using time-gating detection methods, this can be distinguished from background short-lived emissions; which are common in biological systems. As a result: sensitive luminescence fluorophores can be obtained using this property.

Parker and coworkers showed that lanthanide complexes can be used as selective anion sensors.[3] Because lanthanide emission is quenched effectively by metal-bound water molecules through vibrational energy transfer to OH oscillators. displacement of water molecules by an anion changes the extent of vibrational quenching and can be signaled by increases in the intensity and lifetime of emission (Fig. 1). Macrocyclic heptadentate ligands containing aromatic chromophores were used to make coordinately unsaturated complexes of Eu and Tb ions. These in-built chromophores act as antennas to transfer energy from the chromophore excited state to the metal excited state. This indirect excitation solves the problem of direct excitation, and the excitation wavelength can be changed by using different chromophores. In aqueous solution; empty coordination sites are filled with one or two water molecules that can be replaced by certain anions with emission changes. When a chiral macrocyclic ligand was used, as in **1.** anion binding also induced changes in emission polarization.[4] HPO_4^{2-}, F^-, and SO_4^{2-} displaced one water molecule. while HCO_3^-, citrate, and lactate displaced two water molecules and formed chelated adducts. In particular. HCO_3^- binding was studied in a competitive anion background simulating an extracellular environment.

Another lanthanide-based anion sensor 2 exploits a bipyridine phosphine oxide derivative as a pentadentate ligand to coordinate Eu cation.[5] As anions bind to this complex, emission intensity was increased. presumably again due to the displacement of ligated water molecules.

RU(II) POLYPYRIDINE COMPLEXES

Another class of transition metal-based anion fluorescence sensors is based on ruthenium(II) *tris*(bipyridyl)

DOI: 10.1081/E-ESMC 120012885

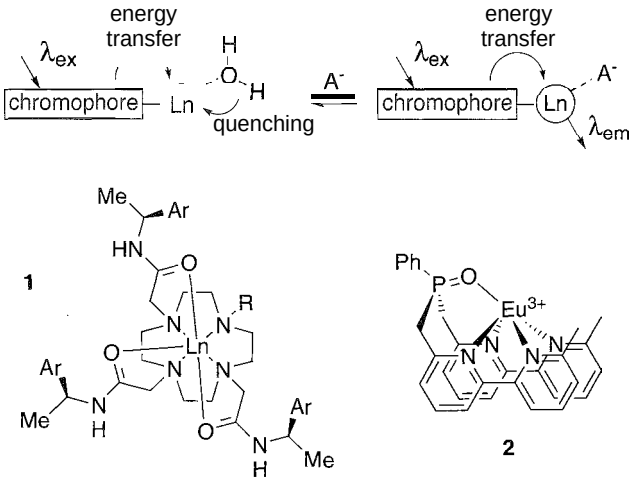

Fig. 1 Lanthanide complex sensors,

complexes. The electrochemical and photophysical properties of $Ru(bpy)_3^{2+}$ are well characterized[6] and are applied in the design of many sensors. The lowest excited state of the complex derives from a metal-to-ligand charge transfer (MLCT), so its nature can be controlled by the choice of ligands. The easy synthetic accessibility of the heteroleptic complex $Ru(L_2L')^{2+}$ is another advantage of this sensor system, as it allows ready incorporation of the anion recognition domain into one of the ligands.

Most sensors in this class, reported mainly by Beer and coworkers. have 4,4′-dicarboxamide-2,2′-bipyridine derivative as the anion-binding ligands (Fig. 2).[7,8] The two amides and additional binding groups on side-chain R constitute the anion-binding site. Negative charge develops on the ligand after photoinduced MLCT. and the charge interaction with a bound anion leads to a relative destabilization of this excited state. As a result, the emission shows a blue shift, which is usually accompanied by an increase in intensity. The anion is postulated to restrict the conformational flexibility of the receptor and. consequently, inhibit nonradiative decay processes.

When a metal complex like osmium(II) *tris*(bipyridyl) or a metallocene, as in compound **3,** is appended to the ligand, the MLCT excited state is quenched by energy transfer to the adjacent metal center. The rate of this quenching decreases as an anionic substrate binds between the two metal complexes. A similar switching mechanism is seen in the calix[4]diquinone-appended complex, 4. In this case. the fluorescence emission is quenched via an intramolecular electron transfer to the quinone. Anion binding between the Ru complex and the quinone blocks the quenching process, and the emission intensity is significantly recovered.

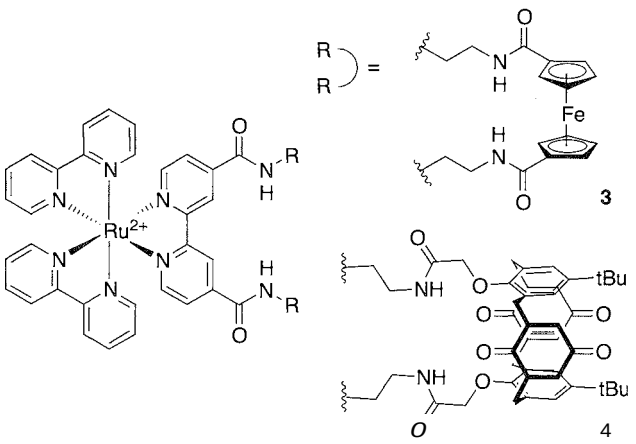

Fig. 2 Ru(II) polypyridine complex sensors.

PHOTOINDUCED ELECTRON TRANSFER

The fluorescence properties of aromatic alkylamines are critically dependent on the energy level of the amine functionality. After local excitation of the aromatic ring. electron transfer can occur from the amine nitrogen to the aromatic ring, preventing radiative decay of the excited state. This photoinduced electron transfer (PET) is suppressed by analyte binding to the amine functional group that lowers the energy of the nonbonding orbital, and as a

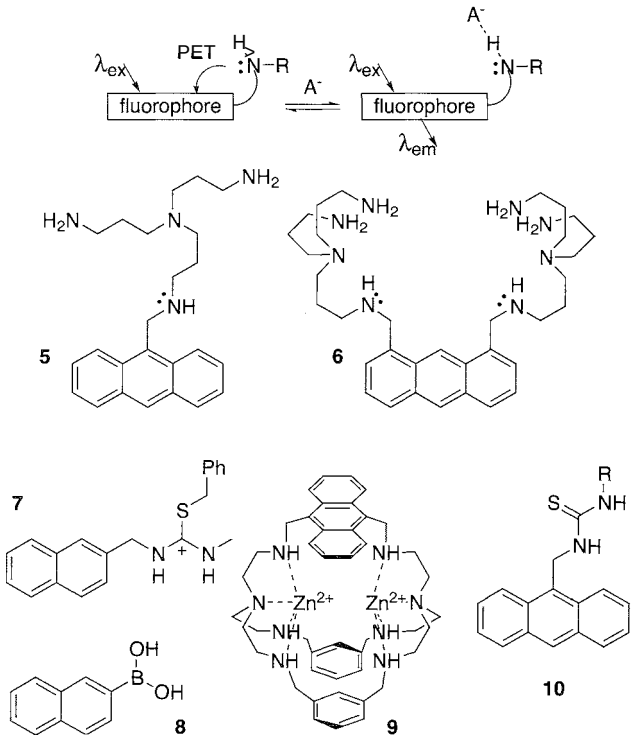

Fig. 3 PET sensors

result, enhanced emission intensity is observed (Fig. 3). This simple on–off switching mechanism and the undemanding chemistry of polyaromatic fluorophores led to extensive development of PET-based sensors for the detection of diverse analytes.

Czarnik and coworkers developed the first fluorescence anion sensor based on the PET mechanism using a polyamine as the anion-binding domain.[9] The polyamine-appended anthracene **5** showed enhanced emission upon HPO_4^{2-} binding in neutral aqueous condition. The anion interacts with the benzylic amine group, rendering the nitrogen electron pair unavailable for PET, probably by a proton transfer. and fluorescence of the anthracene is switched on. A closely related system was devised for pyrophosphate sensing.[10] Compound 6 has two polyamine chains attached to the I- and 8-positions of anthracene. These two arms effectively discriminate between pyrophosphate and phosphate at neutral pH. Thiouronium **7**. synthesized from the corresponding thiourea, also showed an increase in the maximum emission intensity after anion binding, with good selectivity for AcO^- over dialkylphosphate.[11]

There are several examples of the reversal of the PET mechanism being used for anion sensing. In these cases, anion binding enhances PET, leading to a reduction in the maximum emission intensity. Arylboronic acids. widely used for carbohydrate recognition, can also act as Lewis acids and bind to F^- to form the tetrahedral boronate. For example. F^- binding to Compound **8** quenches the fluorescence of the attached naphthalene ring due to increased PET from the boronate anion.[12] No fluorescence change was observed on addition of Cl^- or Br^-. Bis-zinc(II) Complex **9** selectively coordinates linear N_3^- over other anions, and the emission of the anthracene fluorophore is quenched through intracomplex electron transfer from the bound N_3^-.[13] Recently, neutral PET anion sensor **10** with a thiourea group linked to anthracene was shown to undergo significant fluorescence quenching on addition of F^-, AcO^-, and $H_2PO_4^-$.[14] The authors proposed that electron transfer from the anion–thiourea complex to the anthracene excited state is increased. because the reduction potential of the thiourea group is enhanced by anion binding.

EXCITED STATE COMPLEXES

Pyrene is an example of a ciass of fluorophores that form complexes with themselves. A concentration-dependent fluorescence behavior occurs due to intermolecular interaction between the flat hydrophobic surfaces in the dimer. A highly structured emission from the monomer is dominant at low concentration. but as the concentration increases; a long-wavelength emission from the excited state dimer, called an excimer. begins to appear. Shifting the monomer-to-excimer equilibrium can be exploited to develop ratiomeric fluorescence sensors. By measuring the intensity ratio of monomer-to-excimer emissions. analyte concentrations can be determined independently of sensor concentration or other artifacts that might affect emission intensity.

A guanidinium-functionalized pyrene was shown to assemble into a dimer, directed by pyrophosphate anion complexation (**11** in Fig. 4).[15] Characteristic emission of the pyrene excimer was observed from this anion-templated, self-assembled complex, and the concentration of pyrophosphate was measured by ratiomeric titration. The addition of phosphate did not cause any significant emission change. A closely related Compound 12 was also an effective ratiomeric anion sensor.[16] The emission of this thiourea-functionalized pyrene monomer was quenched by anion binding due to the increased PET from the thiourea group to the pyrene ring. The long-wavelength emission. however, was not significantly affected, and the ratio of two emission intensities showed ideal behavior as a function of changing anion concentration. The authors assigned the long-wavelength emission to an intramolecular exciplex formed between the pyrene ring and the thiourea group.

Cornpound 13 bearing four pyrene rings was recently reported as a selective phosphate sensor.[17] The pyrene rings. connected through amide bonds, undergo hydrophobic collapse and form an intramolecular pyrene exciplex. In the presence of phosphate anion; the intensity of the long-wavelength emission was reduced with simultaneous increase of pyrene monomer emission. Presumably. pyrene exciplex formation is inhibited by anion binding to the amide groups between fluorophores. The selectivity for phosphate was explained by the pseudo-tetrahedral arrangement of the hydrogen bond donating amide NH groups.

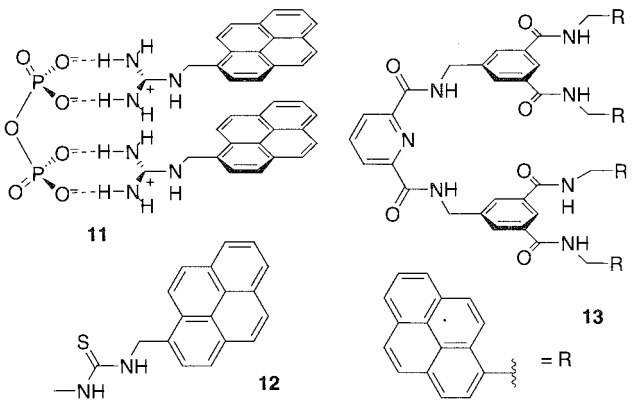

Fig. 4 Excimer/exciplex sensors.

SENSING ENSEMBLE

Competitive titration is another powerful method for anion fluorescence sensing. In this technique, the fluorophore and anion recognition domain are not linked together. Instead. changes in the fluorescence properties of the fluorophore are induced by its displacement from a noncovalent association with the recognition domain (the sensing ensemble) by the target anion. Sensing selectivity comes partially from the structural similarity between the fluorophore and the analyte, because these two molecules act as competitive guests for the receptor. A calibration curve, obtained by monitoring emission changes over a range of analyte concentrations. is used for quantification of the analyte. Several biologically important anions, including citrate, carbonate, and inositol triphosphate. were detected in a range of solvent mixtures using this method.

Many chemosensor ensembles were reported by Anslyn and coworkers.[18] Compound 14, with three guanidinium groups displayed in the same direction (Fig. 5). binds to the citrate tricarboxylate anion. Anionic fluorophore 5-carboxy-fluorescein **15** binds with modest affinity to this receptor and shows increased fluorescence intensity due to the decreased pKa of its phenol group. As citrate is added, the fluorophore is displaced from the receptor, and the emission intensity diminishes. The same fluorophore was used in another sensing ensemble for inositol-1,4,5-triphosphate (IP_3), an important second messenger involved in many cell regulatory functions. The fluorophore bound to positively charged hexa-guanidinium receptor **16** is displaced by added IP_3, and the fluorescence intensity decreases.

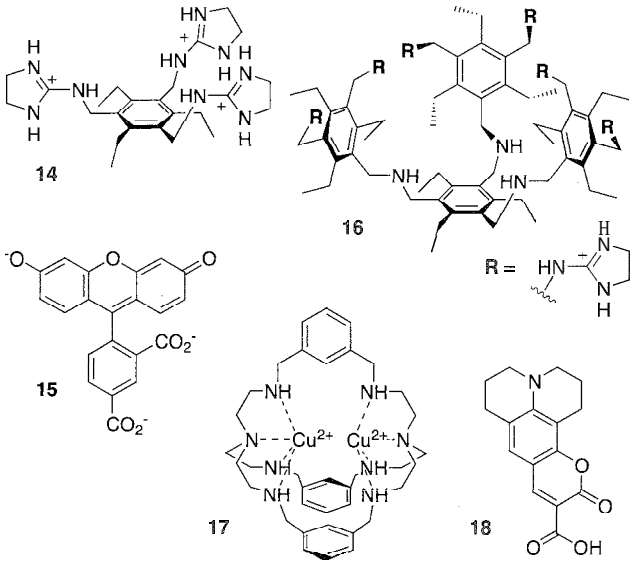

Fig. 5 Sensing ensembles.

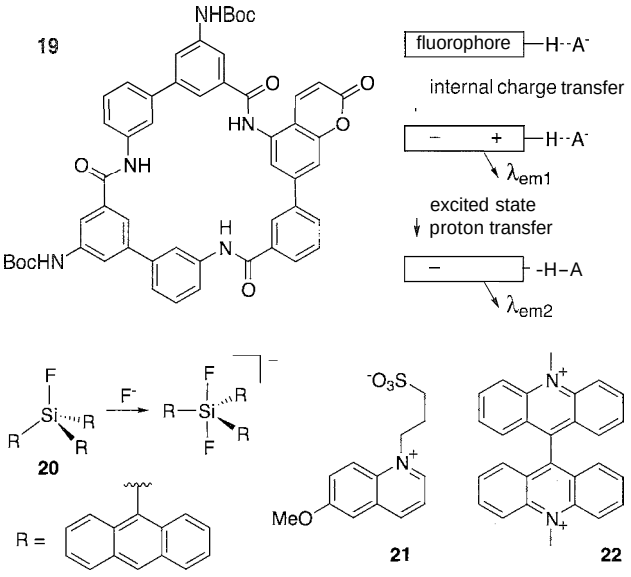

Fig. 6 Other anion chemosensors.

A coinpetitive method for carbonate sensing is based on dicopper complex **17** and coumarin 343 as anion receptor and external fluorophore, respectively.[19] The fluorophore 18 coordinates to the copper atoins through its carboxylic group. and energy transfer between coumarin ring and copper atoms quenches the fluorescence emission. Carbonate showed strong binding to the metal complex and coupled the displacement of the bound fluorophore with concomitant recovery of the coumarin emission. This ensemble showed selective response to carbonate over phosphate or carboxylate.

OTHER CHEMOSENSORS

We explored the strategy of linking an anion receptor to a fluorophore that exhibits emission from an internal charge transfer (ICT) excited state. This allowed us to obtain a high dynainic range of emission response, and in one case, the resulting design functions as a dual channel
In sensor **19** (Fig. 6), an aminocoumarin tluorophore is integrated into the binding domain of a macrocyclic receptor such that it is directly involved in hydrogen bonding to the anion. Anion binding caused an increase in intensity and red shift of the fluorescence emission of the coumarin. The red shift is due to stabilization of the ICT excited state relative to the ground state by electrostatic interaction with the bound anion. The intensity enhancement likely results from conformational restriction of the fluorophore that would otherwise lead to nonradiative decay through rotatory inotion of the amide group of the fluorophore. The most remarkable change was the

appearance of a second emission band at longer wavelength upon addition of anions like $H_2PO_4^-$. The increased acidity of the fluorophore after excitation facilitated proton transfer to the bound anion. and the second fluorescence emission channel was opened through intermolecular excited state proton transfer (ESPT).

Tri(9-anthryl)fluorosilane **20** was used for fluorescence sensing of fluoride anion.[21] The organosilane derivative binds with F^- to form a penta-coordinated organosilicate, and this hypercoordination changes the structure from tetrahedral to trigonal bipyramidal. Through-space interaction between the anthryl groups is reduced, and the emission intensity of the anthracene fluorophore increased significantly.

N-Alkyl-6-methoxyquinolinium and N-alkylacridinium derivatives like **21** and **22** were used to detect chloride anion in biological samples.[22,23] These simple derivatives are commercially available and, unlike the other sensors discussed so far, they detect Cl^- via collisional quenching of the fluorophore excited states. No molecular recognition event is involved in the sensing mechanism. Other halides. such as Br^- and I^-, and SCN^- are also efficient quenchers, but physiological concentrations of these anions do not significantly affect the fluorescence.

BIOSENSORS

Biosensors represent additional useful tools for fluorescence anion sensing. In this approach, an anion-binding protein is used as the recognition domain. and a fluorophorc is covalently linked to the region where conformational changes are expected after analyte binding. Variation of the microenvironment around the fluorophore is detected through changes in its spectroscopic properties.

E. coli phosphate-binding protein (PBP) is a monomeric protein that associates strongly and selectively with inorganic phosphate. The anion binds into a cleft between two domains of PBP and induces a large conformational change in the protein. One alanine residue at the edge of the binding cleft was replaced with cysteine. and the mutant protein was reacted with a thiol-reactive diethylaminocoumarin derivative.[24] On binding phosphate, the fluorophore-labeled protein exhibited a Slue shift and intensity increase in its fluorescence emission. The aminocoumarin is postulated to be constrained in a highly fluorescent conformation due to the reduced local flexibility of the phosphate-bound form of PBP.

A similar strategy was employed for an IP_3 biosensor.[25] Pleckstrin homology (PH) domain of phospholipase C (PEG) δ_1, which binds IP_3 with a submicromolar affinity. was mutated to incorporate a cysteine residue next to the anion-binding site. Labeling with thiol-reactive fluorescein or aminonaphthalene derivatives gave anion sensors that showed large fluorescence changes in response to IP_3, with good selectivity over other phosphates.

Mutants of yellow fluorescent protein (YFP), an engineered variant of green fluorescent protein (GFP). were developed as biosensors for Cl^-. YFP autocatalytically generates its own fluorophore. and its mutant YFP-H148Q showed decreased fluorescence in response to many anions. Crystallographic analysis confirmed that the anion is bound close to the protein fluorophore and increases its pKa, inducing fluorescence suppression.[27] To improve the halide anion selectivity. random mutants of YFP-H148Q were generated. and some variants with increased affinity and selectivity for C l and I were identified.[28]

CONCLUSION

Design of a receptor molecule that can bind to a target anion with high affinity and selectivity remains a challenging task. The properties of the target anion and the nature of its possible interactions with a receptor in different environments must be considered in the design. The key additional element in the design of a fluorescence sensor is the fluorophore. The interactions of a fluorophore with a receptor or an analyte before and after their binding determine the fluorescence behavior of the sensor. It is not enough to simply connect a receptor with a fluorophore to achieve sensitive and selective sensing. The anion fluorescence sensors described in this article provide good examples of how tluorophores can be coupled with selective anion-binding receptors to convert a molecular recognition event to fluorescence changes. Fluorophore properties such as the energy of the excited state. the extent of nonradiative decay. and the opening and closing of transfer processes can be modulated by direct interaction with an anion or by indirect changes in the receptor after binding an anion. Designs based on fluorescence mechanisms led to many sensors. The growing number of synthetic anion receptors suggests that in the future. more selective and sensitive anion sensors will be developed for diverse applications.

Fluorescent Sensors

A. Prasanna de Silva
Gareth D. McClean
Thomas S. Moody
The Queen's University of Belfast, Belfast, Northern Ireland

INTRODUCTION

Following a brief introduction and justification, the design of fluorescent sensors is summarized. Three popular photochemical designs are highlighted. Then, with some examples, we will show how suitably selective receptors can give rise to excellent sensor systems. Cases showing considerable success in cellular physiology and in medical diagnostics are included among these examples. To conclude. a glance at the future will be taken.

WHY DO WE NEED FLUORESCENT SENSORS?

It is a truism that our environment exerts as much control over us as our genes. It is no wonder that most societies lay considerable emphasis on monitoring human environments. In practice, this means that such surveillance must extend to many chemical constituents of our external environment as well as those that exist within ourselves. The ideal spies for such operations must be small enough to enter the various spaces of interest and cause minimum disruption to the sensitively poised steady states existing therein.[1,2] In addition. such spies must be able to communicate their findings to human observers. Such tough criteria for the ideal spy are most satisfactorily met by fluorescent molecular sensors.[3–9]

HOW ARE FLUORESCENT SENSORS DESIGNED?

The bare essentials[10] of a fluorescent sensor molecule are as follows: 1) a means of temporarily capturing chemicai targets, i.e., a receptor: 2) a means of long-range communication with the observer/controller, i.e., a light absorber/emitter or a fluorophore; and 3) a means of shorter-range communication between the receptor and the fluorophore so that capture of a chemical target causes a light signal.

Several elaborations of Point 3 exist. The oldest of these[1,11] ensures receptor–fluorophore communication by simply overlapping the two units so that their x-electron systems merge (Fig. 1). Such x-systems are particularly useful if they show electronic push–pull character. These give rise to internal charge transfer (ICT) excited states that are significantly perturbed when the receptor captures its target species.[2] A color change in excitation or emission is the usual experimental outcome that can be of considerable value in physiological investigations.[12]

Another approach to implementing Point 3 has become particularly popular. In this method. the fluorophore and the receptor are forced to cominunicate through a short σ-bond spacer. Photoinduced electron transfer (PET) is a single-electron process that can cross this bridge with ease if the thermodynamics are right.[13,14] Naturally. the PET thermodynamics are substantially altered upon target capture by the receptor.[1] The experimental outcome can be a switching on or off of fluorescence (Fig. 2). Such a result creates considerable drama when compared to most laboratory experiments. and it may account for the rapid uptake of this design. However, PET is not the only process that can be profitably arranged within fluorophore–spacer–receptor systems. Electronic energy transfer (EET)[15] can also be useful in cases where the target possesses a rather low-energy excited state. The emission from the fluorophore is then switched off upon target capture.

A third way to tackle Point 3 is to arrange for the fluorophore and the receptor to be associated by means of one supramolecular interaction or another.[1,16] Such an association can mimic the situation discussed in the previous paragraph. Or else the proximity of the receptor to the fluorophore can disturb the emission properties of the latter.[17] Target capture by the receptor liberates the fluorophore so it can emit normally again.

ILLUSTRATIVE EXAMPLES OF FLUORESCENT SENSORS

There are literally hundreds of fluorescent sensors[2] that would merit discussion in a general introductory review of this kind. Many of these were already featured in the review literature.[1–10] For the present purpose. we allowed

Encyclopedia of Supramolecular Chemistry

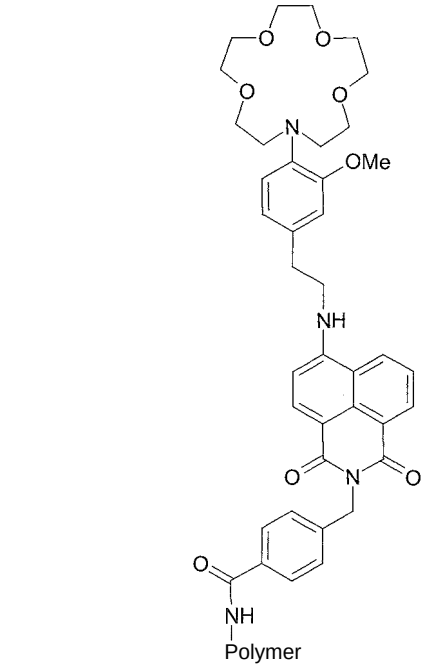
our choice to be dictated by the selectivity of cheinical target recognition as well as by the diversity of photochemical mechanisms.

A Fluorescent Sensor for Ma'

Tusa, keiner, and their colleagues at Roche Diagnostics Corporation produced a commercially successful diagnostic system for blood electrolytes and gases in critical care and point-of-care situations.[18] Its design platform is PET, with fluorescent sensors for each blood constituent being equipped with an adequately selective receptor. The case for Na^+**1**[19] is highlighted here. The *N*-(2-methoxyphenyl)monoaza-15-crown-5 ether picks out extracellular Na^+ (normally 1.5×10^{-1} M) from K^+ (normally 5×10^{-3} M) and a myriad of other species. Monoaza-15-crown-5 ether has similar preferences for binding Na^+ and K^+. besides sufficient attraction toward H^+, to be heavily protonated at the pH value found in the extracellular matrix (normally 7).[20] The fusion of the phenyl unit with an azacrown nitrogen essentially destroys the attraction toward H^+ under these conditions. The 2-methoxy substituent on the phenyl ring presents a ligating oxygen to supplement the NO_4 donor set as they confront Na^+. The three-dimensional pseudocryptand environment now shows higher selectivity[21,22] toward the size-complementary Na^+ than the larger K^+. All these selectivity aspects were considered and tackled previously by Tsien[12,23] during his groundbreaking program for imaging intracellular constituents. We subsequently constructed fluorescent PET sensors with Tsien's Na^+ receptor.['' importantly, receptors like that within **1** display clear conformational changes upon binding Na^+ which decouple the electron systems of the 2-methoxyphenyl unit and of the nitrogen atom.[24] This has important ramifications in a PET sensing context. because the oxidation potential of the receptor jumps from 0.8 V (versus SCE) to >1.2 V upon Na^+ binding.

Rational discussion of PET thermodynamics now cues the entry of the fluorophore. The 4-amino-1,8-naphthalimide was introduced by us into the field of PET sensors some time ago.[25] Its particular attractions for the present application are its complementarity with visible light-emitting diodes as excitation sources and its robust thermal stability. The oxidation potential of this fluorophore is 1.1 V. A molecular orbital diagram (Fig. 3) collects these oxidation potentials and their relationship to the sensory behavior of **1**. Excitation of the fluorophore leaves a hole in the highest occupied molecular orbital (HOMO) that can be filled by an electron from HOMO' but not by an electron from HOMO". where the Na^+ exerts its influence. So de-excitation of the excited fluorophore via fluorescence is only possible when Na' is present (Fig. 3b), i.e., "off–on" signaling of Na^+.

The dimethylene spacer between the fluorophore and the receptor is short enough to permit PET at a sufficient rate (when thermodynamically feasible. i.e.,



1

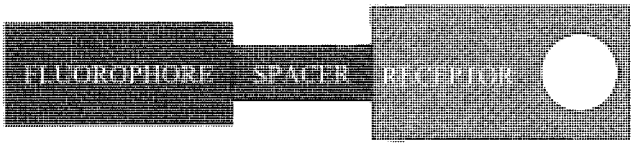


Fig. 2 Modular fluorophore–spacer–receptor format. where PET or EET processes can deactivate the excited state (either before or after capture of the target). (*View this art* ***in color*** *at www.dekker.com.*)

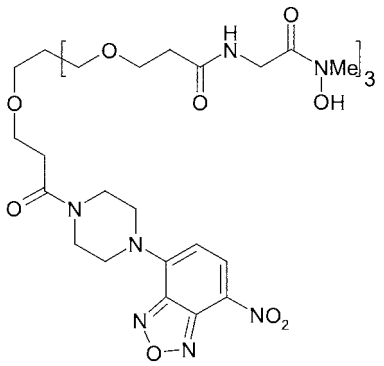
in the absence of sufficient Na^+) *to overwhelm the competing process* of *fluorescence. Nevertheless,* it *is long enough to preserve the* modularity *of the fluorophore and the receptors. Besides these three photochemically essential components,* 1 *also contains an anchor to iink with a water-insoluble polymer. to* complete *the medical device.*

Fluorescent Sensors for Fe^{3+} and MoO_4

Siderophores are naturally honed to pick up Fe^{3+} with *excellent selectivity. without which many microorganisms would fail to achieve their essential iron* intake.[26] Some *of these siderophores are also* excellent *at recognizing* MoO_4^- *(see Fluorescent Sensing of Anions).*[27] *So it* is *natural that* such *receptors were incorporated into* fluo*rophore–spacer–recepcor* systems *without* compromising *their coordination properties.* It *is equally natural to design such systems* to *be intrinsically fluorescent, because targets such as* Fe^{3+} *and* MoO_4^- *will be* redox*active and, therefore. switch off the fluorescence via PET upon binding. As* mentioned *previously, the fluorescence quenching can also arise via EET for these colored targets, though this pathway appears to* be *experimentally ruled* out *in the cases to be* examined *here.*

Shanzer's team *uses a tris-*hydroxamate *motif within 2 to target* Fe^{3+}, *as the latter is transported into Pseudomonas putida* bacteria.[28] *On the other hand, a catecholcarboxamide serves as the receptor for* Fe^{3+} *and* MoO_4^- *within* 3 *designed by* Duhme-Klair, *Perutz, and* coworkers.[29] The Fe^{3+} *recognition by* **3** *can be* suppressed *by artificially adjusting the* pH *to 5.7, even though such action disqualifies it from* many in vivo *studies. Nevertheless, this leaves us with 3 as a brilliant assay* for MoO_4^-. *Both 2* and **3** *employ* fluoro*phores with solid track records: 4-amino-7-nitrobenzo-*2-oxa-1,3-diazole *(widely used as a biochemical label) and tris*bipyridylRu(II) *(the* most *famous metal* complex *in* photochemistry/physics).

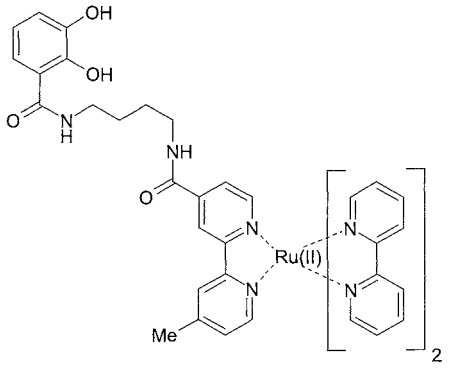


2

The relatively long spacers in 2 and **3** *again assist in maintaining modularity. Nevertheless, the spacers are short enough to* permit *rapid PET and switch fluorescence off* when *required. There is no significant (rate of) PET* in *the target-free 2 and 3. Poor* redox *activity of the hydroxamic acid receptor* in *2 is to be expected;* but *the* same *cannot be said of the catecholcarboxarnide receptor in 3 without more careful consideration. In fact, this receptor will undergo PET to the fluorophore if deprotonated. However, the* redox *activity of the receptor remains insufficient if the pH was pegged at acidic enough* values *(5.7) to prevent deprotonation. The arrival of targets* Fe^{3+} *and* MoO_4^- *into 2 and 3. respectively. causes clear fluorescence quenching. Proof of the PET nature of the quenching is seen in the case of 3: freezing of* **3**.MoO_4^- *solutions resurrects fluorescence. This is because PET changes the charge states of the receptor and the fluorophore. Such charge* changes require *reorientation of solvent dipoles, which. of course, cannot occur in a* frozen *glass.*

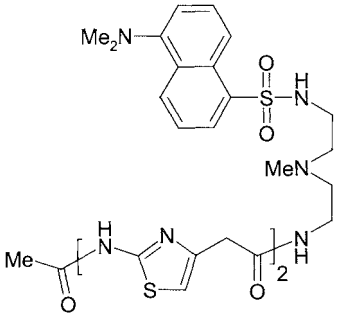
Fluorescent Sensors for Cu^{2+}

A feature common to a number of receptors showing *good* Cu^{2+} *selectivity is the presence of one or* more *primary*



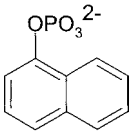
3

amide moieties that appear to lose the amide proton during the complexation process. Naturally, the complex is bolstered by the availability of other ligating units in chelating configurations. Sensor 4, due to Bhattacharya and Thomas, contains a receptor unit that illustrates these generalities.[30] It picks up micromolar concentrations of Cu^{2+} at neutral pH values. The fluorophore employed within 4 is 5-dimethylaminonaphthalene-1-sulfonamide (dansylamide), the common biochemical label. It seems that the fluorophore stands clear of the receptor-Cu^{2+} complex, even though the spacer component is flexible. The experimental upshot of all this is a clear switching off of the fluorescence of 4, though the off state is still emissive: upon encountering Cu^{2+}. Such a limited degree of switching off is probably caused by the relatively large separation between the fluorophore and the complexed Cu^{2+} center. Cu^{2+} shares several key properties, like redox activity and color, with Fe^{3+}, so the mechanistic arguments considered in the previous section are equally relevant here. Nevertheless, several studies, including a one by Prodi and coworkers,[31] find that Cu^{2+}-induced fluorescence quenching is not prevented by freezing. In other words, EET rather than PET is the likely channel of fluorescence switching.

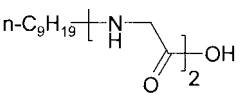


4

As indicated in the design section. supramolecular assembly of a fluorophore and a receptor creates a pseudointramolecular situation in which effective quenching via PET or EET becomes possible. Tecilla and Tonellato's team apply fluorophore 5 and receptor 6 in this way to selectively target Cu^{2+}.[16] Receptor 6 fits the generalizations opening the previous paragraph. However. 6 contains something else—a long hydrocarbon chain. This is the clue to the supramolecular assembly process of 5 and 6. In fact, there is a third species with a similar chain — cetyltrimethylammonium bromide (CTAB)—that supramolecularly assembles with many copies of itself in aqueous solution to form micelles. Receptor 6 naturally incorporates into CTAB micelles while locating its peptide/acid units in the micellar head-group region. Fluorophore 5 also locates in this region, owing to its dianionic nature being attracted to the cationic micellar surface, beside a modicum of hydrophobic association. Addition of Cu^{2+} causes fluorescence switching off, as seen with 4, even though the cationic micelle surface would somewhat hinder the approach of the target.



5



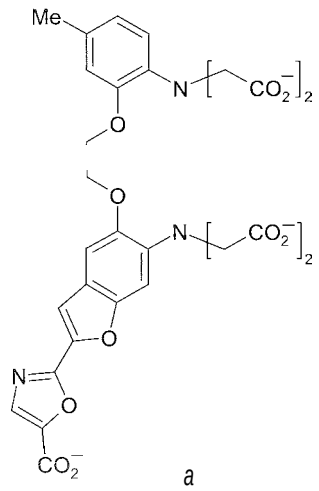
6

The study with 5, 6, and CTAB expose two advantages of general significance. Assembling rather than synthesizing a fluorescent sensor can be a big convenience, especially if the components can be obtained "off-the-shelf." Furthermore, 5, 6, and CTAB can be replaced by other pretenders and evaluated for their degrees of success as judged by the efficiency of fluorescence switching off in the presence of Cu^{2+}. However, self-assembled fluorescent sensors of this type have an Achilles' heel: they are not robust enough to be used within multi-compartmental environments. because each component may localize in a different environment.

A Fluorescent Sensor for Ca^{2+}

It is rare to have an opportunity to report on the birth of a revolution, but this is one such time. Tsien's 7,[32] though

not the first.''' supplied the molecular spy to enlighten physiologists about the Ca^{2+} *traffic within* living *cells.''' Prior to this, spying for ions within living cells was regarded as a hazardous occupation.* ''How *does the spy observe its target* amidst *a jungle of chemical species?''* was *the frequently asked question. In the case of* Ca^{2+}, *the spy* must look *for* 10^{-7} M concentrations *of its target,* while H^+ *lurks at* 10^{-7} *M.* Mg^{2+} *at* 10^{-3} M, Na^+ *at* 10^{-3} *M.* K^+ *at* 10^{-1} M, *and a myriad of others. Excellent selectivity of* Ca^{2+} *reception* is *called for. The receptor part of 7 discriminates against the monovalent cations as well as anions by* flaunting its *tetra-anionic cavity. It discriminates against* Mg^{2+} *by exploiting the spacious cavity.*



a

Being nonmodular, 7 *does not* employ *a popular* fluorophore. Rather, *the n-electron system of one of the* 1-amino-2-alkoxy *benzene moieties was extended by fusion with a* furan *ring and by further addition of an oxazole ring. This* extended *n-electron* system *is adequate for the* purpose at *hand, though the excitation wavelengths are short.* An example *is* 7, *showing an* ICT *excited state. Upon optical excitation. the* electron *density shifts away* from the *tertiary amino group toward the* furan *and oxazole heterocycles. The resulting* δ^+ *charge on the tertiary amino region will naturally suffer destabilization* upon *entry of* Ca^{2+} *into the cavity. So. a blue shift of the* emission *and excitation spectra of 7 would be the simple prediction.* In *practice;* the Ca^{2+}-induced *emission shift is nullified in 7 and* many *(but* not *all) of its relatives because of* Ca^{2+} *decoordination. The latter is a natural* consequence *of the* Ca^{2+} *being placed near the* δ^+ *charged tertiary amino group.* However, the *excitation shift is clearly observed. and the revolutionary is born.*

Suddenly. the life processes of the cell as reflected by the Ca^{2+} *traffic are visualized in every square micrometer and at every millisecond. Not surprisingly. bioresearchers have* taken *to the general approach in their thousands. As evidence, we offer a statistic:* Ref. [32] *was cited in over* 13.000 *publications at the time of writing.*

CONCLUSION

The previous discussion indicated how adequately *selective receptors for a given target species can be developed into typically* useful *fluorescent sensors. PET, EET, and* ICT *are the photochemical mechanisms underlying the sensing behavior. The road* immediately *ahead is likely to yield a broadening of the target set that* can *be practically sensed.* Sensor *families where each member goes after a given range of target concentrations are also set to emerge. Mechanistic consolidation of PET, EET,* and ICT *types can also be expected, though other designs''' will gather momentum.* Sensory *data transmission* from *specific* microenvironments *even below the* limit *of visual resolution will be encountered.* In *fact, the forerunners of this class are already with us. Small spaces adjoining detergent* micelle *surfaces and resin beads are the focus of* H^+-selective *fluorescent* PET *sensors 8 and 9, respectively. Our 8 is just one member of* a family *that maps the* H^+ *distribution* in *the Gouy–Chapman region bounded by the membrane with electric* and *dielectric* influences.[34] Copeland *and Miller's 9, when covalently linked to the* polymer *substrate, serves to signal local* H^+ *generation if a coresident on the bead serves as a catalyst for an* acid-*forming reaction.''''* It *seems that fluorescent sensors are heading for many problem areas looking for molecular or* supramolecular *solutions—and to a rosy future.*

Fullerenes as Encapsulating Hosts: Preparation, Detection, and Structures of Endohedral Fullerenes

Alan L. Balch
University of California, Davis, California, U.S.A.

INTRODUCTION

The prototypical fullerene, C_{60} consists of a closed icosahedral cage of 60 carbon atoms that enclose a small void space. and it is natural to expect that atoms may be trapped within this space. Indeed, shortly after C_{60} was discovered, Kroto, Smalley. and coworkers reported the detection of La@C_{60} by mass spectrometry and proposed a structure in which the lanthanum atom resided inside the fullerene cage.[1] Fullerene cages with varying numbers of carbon atoms are known, with the empty cages C_{60}, C_{70}, C_{76}, C_{78}, and C_{84} particularly abundant in normal fullerene preparations. Consequently, it is expected that there will be a variety of cage sizes available as intriguing hosts for the encapsulation of a variety of individual atoms or collections of atoms. Moreover. if the atom entrapment occurs during fullerene formation, the trapping procedure can produce new fullerene cages that are not generally found in conventional empty-cage fullerene preparations. Throughout this article, we will use the symbol A@C_n to indicate that an atom of element A is encapsulated within a cage of n carbon atoms to form a particular endohedral fullerene. In the alternative, but less widely adopted IUPAC nomenclature, one would use the symbol iAC_n for the same species.

What atoms are found within fullerene cages? Shown in Fig. 1 is a periodic table that highlights the atoms found in some type of fullerene cage. Moreover, endohedrals with two, three, and four atoms (not necessarily all of one kind) were detected. As seen in Fig. I, a wide range of atoms. including unreactive noble gas atoms, highly reactive and rarely encountered atomic nitrogen. electropositive metal atoms including alkali metals, alkaline earth metals, and lanthanide atoms, were found encapsulated in carbon cages. Representative examples include He@C_{60},[2] N@C_{60},[3] La@C_{82},[4] Sc_3N@C_{80},[5] and Sc_2C_2@C_{84}.[6] It is notable that there are few reports of transition metal atoms beyond Sc, Ti, Y. and Lu bound within fullerene cages, and those generally involve single studies that were not replicated in other laboratories.

In the following sections. we will consider in more detail some of the types of atoms and molecules that are found confined within the curved walls of carbon cages of various sizes. In many cases. these species were detected by a combination of spectroscopic methods as minor components in mixtures of fullerenes. Further work on separation and purification produced small quantities of isolated endohedrals.

NOBLE GAS ATOMS AS GUESTS

Noble gas atoms can be physically trapped within fullerene cages of various sizes.[1] An example is shown in Fig. 2. In these species. the interaction between the fullerene and the noble gas atoms largely involves van der Waals forces. How are they made? The conventional arc synthesis of empty cage fullerenes uses an electric arc between two graphite rods to vaporize graphite. This procedure is usually conducted under 0.2 atm of helium. Under these conditions, helium atoms may be trapped inside the fullerene as it is assembled from smaller carbon fragments starting with C_2 units. As a consequence, one atom of ^{3}He is present in every 880,000 molecules of C_{60}, and one atom of the less abundant ^{4}He is found in every 10^{12} C_{60} molecules formed in the conventional arc process. Sensitive mass spectrometric methods were utilized to detect the release of helium from these filled cages.

Enrichment of these endohedral species can be obtained by heating the intact solid fullerene under 3000 atm of a noble gas at 650°C.[2] Under these conditions, helium. neon, argon, krypton, and even xenon can be forced into the cavity within C_{60}. This process is believed to occur via a window mechanism in which a C—C bond of the fullerene breaks to provide a window through which the noble gas atom enters the fullerene. Subsequent reformation of the C—C bond can trap the noble gas atom inside the cage.[1] Recent work on creating orifices in C_{60} through chemical modification produced an interesting model system in which entry and exit of both He and H_2 can be monitored, as shown in Fig. 3.[7]

Because ^{3}He has a spin of 1/2 and a high gyromagnetic ratio, ^{3}He-NMR spectroscopy of fullerenes and chemically modified fullerenes containing helium atoms produces useful information in regard to the electronic and

†† alone and with metals.

Fig. 1 The periodic table, with those atoms that were reported to be trapped within fullerene shown in boldface.

geometric structures of these molecules.[8] For example. the spectrum of $^3He@C_{60}$ consists of a single line with a chemical shift of −4.4 ppm (relative to dissolved ^3He at 0 ppm), while the spectrum of $^3He@C_{70}$ shows a single resonance at −28.8 ppm. The chemical shift of the ^3He nucleus monitors the magnetic field experienced by the ^3He atom within the fullerene and is a sensitive indicator of that environment. The large difference in chemical shift between $^3He@C_{60}$ and $^3He@C_{70}$ was ascribed to differences in the aromatic ring currents within these different cages. Thus, C_{70} shows a much larger diamagnetic ring current and has a greater aromatic character. Demonstrated in Fig. 4 is how useful ^3He-NMR spectroscopy can be in detecting individual species in a mixture of higher fullerenes.[9] Resonances of different isomers with varying cage geometries for C_{76}, C_{78}, and C_{84} are clearly differentiated.

However. the purification of endohedrals containing noble gases is challenging. Generally, only minute quantities of purified endohedrals like $Kr@C_{60}$ were separated. and this separation was accomplished only after using tedious sequential high-pressure liquid-chromatographic steps. Nevertheless, a sample containing 9% $Kr@C_{60}$ and 91% C_{60} is sufficiently enriched to allow the structure of this endohedral to be obtained by single-crystal x-ray diffraction.[10] The structure is shown in Fig. 2. In $Kr@C_{60}$, the krypton atom is found at the center of the fullerene cage. and the average Kr to C separation is 3.540 Å.[3] For comparison, the sum of the van der Waals radii for carbon (1.70 Å) and ksypton (2.02 Å) is 3.72 Å, so the krypton atom is tightly confined within the C_{60} cage. However, at the level of crystallographic refinement. the dimensions of the C_{60} cage are not significantly altered by the presence of the entrapped ksypton atom.

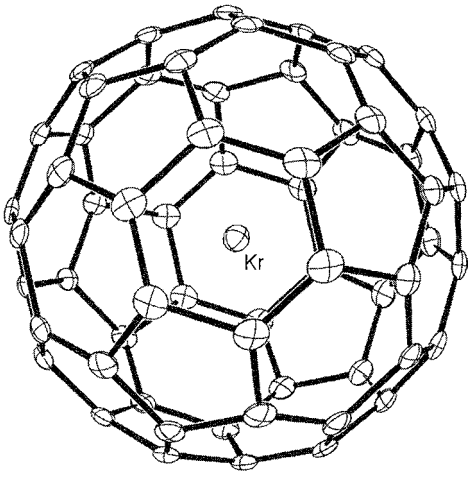

Fig. 2 The structure of $Kr@C_{60}$ as determined from a single-crystal x-ray diffraction study of $(0.09\ Kr@C_{60}/0.91\ C_{60})\cdot Ni^{II}$(octaethylporphyrin)·2 (benzene) from data in Ref. [10].

ATOMIC NITROGEN AND MOLECULAR N_2 WITHIN C_{60}

Bombardment of C_{60} with nitrogen ions from a plasma discharge source or sublimation of C_{60} in a nitrogen glow discharge produces a mixture of neutral $N@C_{60}$ and empty C_{60}.[3,11] The presence of $N@C_{60}$ can be readily detected by electron spin resonance (ESR) spectroscopy, which shows an isotropic three-line spectrum for ^{14}N (with a weaker doublet due to lower abundant ^{15}N) that is characteristic of a paramagnetic nitrogen atom with three unpaired electrons (i.e., $S=3/2$). The ESR spectrum of $N@C_{60}$ strongly resembles that of the free nitrogen atom. However, unlike atomic nitrogen, $N@C_{60}$ is stable in the atmosphere. Samples containing $N@C_{60}$ can be dissolved in toluene and handled as any other stable endohedral species. In $N@C_{60}$, the three nitrogen p orbitals are degenerate, but chemical modification of the icosahedral C_{60} cage should destroy the degeneracy of these nitrogen p orbitals. Consequently, the series of adducts $N@C_{60}\{C(COOEt)_2\}_n$, with varying numbers (n) of cycloprophyl groups on the exterior of the fullerene cage. show additional features in their ESR spectra that reflect the different symmetries of each abduct.[9,11] These studies clearly demonstrate that the inside of the fullerene cage is chemically unreactive, unlike the outside of the cage, which readily undergoes a variety of addition reactions.

Not only can individual nitrogen atoms be trapped within C_{60}, but also N_2 (as well as CO) molecules were inserted into C_{60} cages.[13] The methodology for this follows the techniques for inserting the noble gases—heating the fullerene to 650°C under 3500 atm of N_2. Again, the ratio of empty to filled cages (200011) in the product is high, but the presence of $N_2@C_{60}$ can clearly be detected by mass spectrometry.

ELECTROPOSITIVE METAL IONS IN FULLERENES

Macroscopic amounts of a metallofullerene, $La@C_{82}$, were first obtained by the Rice group in 1991 through laser vaporization of a composite of La_2O_3 and graphite.[4] Although $La@C_{60}$, $La@C_{70}$, and $La@C_{82}$ were detected in the sublimed product of the reaction. only $La@C_{82}$ could be extracted into toluene and purified. The presence of $La@C_{82}$ is readily detected by ESR spectroscopy, and the observed hyperfine splittings were interpreted to indicated that the encapsulate metal is present as La^{3+}.[14] Consequently, the fullerene cage must bear a 3− charge, which is consistent with the observations that fullerenes

can readily accept electrons through a series of stepwise one-electron reductions. Many other metal-containing fullerenes were prepared through the laser vaporization of graphite in the presence of a metal salt or the conventional arc synthesis, in which graphite rods doped with metal oxides are vaporized in a low-pressure helium atmosphere. The resulting endohedrals can be detected by mass spectrometry in the soot that is generated, sublimed for an initial stage of purification, extracted into organic solvents, and purified by chromatographic techniques. In the process. fullerenes of various sizes can be produced. The components present can control the types of fullerene cages formed. For example, laser vaporization of a graphite-UO_2 composite rod produces the small cluster $U@C_{28}$, in which a uranium atom stabilizes a C_{28} cage with tetrahedral symmetry.[15] The mechanism of formation of these endohedral fullerenes received relatively little attention, but polycyclic polyene rings with metal atoms appended were detected during the gas-phase self-assembly of endohedrals.[16] Several reviews cover the progress made in the isolation and in the rudimentary characterization of these endohedrals.[17–19]

In order to illustrate the progress in separation and structural identification of endohedral metallofullerenes, we will focus our discussion on one such molecule, Isomer 1 of $Er_2@C_{82}$.[20,21] Three isomers of $Er_2@C_{82}$ were separated through high-pressure liquid chromatography and characterized by their chromatographic retention time, mass spectrometry, and UV/Vis spectroscopy. Isomer I has the shortest retention time. In characterizing the structure of such an endohedral, there are two main issues: the specific geometry of the fullerene cage and the locations of the metal atoms within that specific cage. Generally, empty-cage fullerenes obey the isolated pentagon rule (IPR), which requires that each pentagon be surrounded by five hexagons.[1,22] For the C_{82} cage, there are nine isomeric forms (three different C_2 isomers, three C_S isomers, two C_{3v} isomers, and one C_{2v} isomer) that obey the IPR. Small amounts of the empty-cage C_{82} were isolated and purified. Analysis of the ^{13}C-NMR spectrum of a mixture of these isomers reveals that the dominant isomer present has C_2 symmetry, while two other fullerenes are present in minor amounts.[23] Theoretical calculations indicate that the stability of the C_{82} cage isomers depends markedly upon the negative charge that resides on the cage,[24] and that there is no requirement for the endohedral coinplexes involving C_{82} cages to have the same symmetry as those of the empty cages.

The structure of Isomer 1 of $Er_2@C_{82}$ was identified through a low-temperature (113 K), single-crystal x-ray diffraction study of a crystalline complex [$Er_2@C_{82}$ Isomer $1 \cdot Co^{II}(OEP) \cdot 1.5$ (benzene). 0.3 (chloroform)], in which the endohedral was cocrystallized with cobalt-(II)octaethylporphyrin.[25] The structure of the endohedral is shown in Fig. 5. In Fig. 5A, a drawing of the C_{82} cage is shown, which is one of the three C_s isomers (82:6) that obey the isolated pentagon rule. In Parts B and C of Fig. 5, the entire endohedral from two different perspectives is shown. The two erbium atoms are disordered and distributed over 23 different sites, with fractional site occupancies ranging from 0.35–0.01. These erbium sites reside near the walls of the fullerene. with the closest Er–C distances in the 3.3–3.4 A range. Moreover, the erbium sites cluster near a band of 10 contiguous hexagons that encircle the carbon cage. This band is highlighted in Parts A and B of Fig. 5 by the use of solid lines to connect the carbon atoms within that band. Each of the two other isomers of C_{82} [C_{3v}(82:8) and C_{2v}(82:9)] has a similar band of 10 contiguous hexagons, and it was speculated that the other two known isomers of $Er_2@C_{82}$ involve these C_{82} isomers with their analogous bands of 10 hexagons.

HETERONUCLEAR ASSEMBLIES WITHIN FULLERENES, $Sc_3N@C_{80}$ AND RELATED MOLECULES

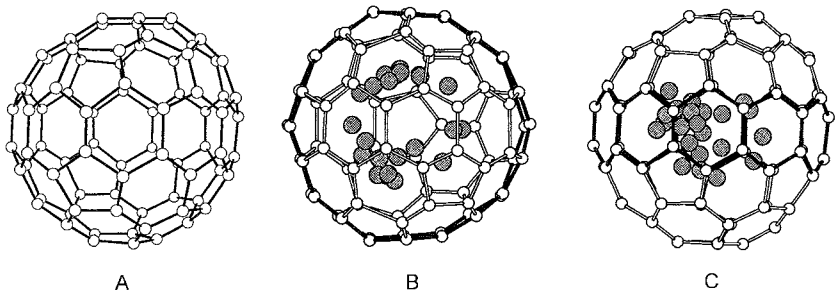

Fig. 5 The structure of Isomer 1 of $Er_2@C_{82}$ as determined from a single-crystal x-ray diffraction study of $Er_2@C_{82}$ Isomer $1 \cdot Co^{II}(OEP) \cdot 1.5$ $(C_6H_6) \cdot 0.3$ $(CHCl_3)$ from data in Ref. [25]. (A) The C_{82} cage alone. (B,C) The endohedral from two different perspectives showing the *23* fractionally occupied Ersil.

to helium, results in enhanced production of a new family of endohedral fullerenes: $Sc_3N@C_{80}$, $Sc_3N@C_{78}$,[26] and the novel $Sc_3N@C_{68}$[27] (with relative yields of 8:1:1). The fullerene cages in $Sc_3N@C_{68}$ [and in Sc_3C_{66}[28]] must violate the isolated pentagon rule, because there are no cages that can obey the IPR for C_{62}, C_{64}, C_{66}, or C_{68}. Significantly, $Sc_3N@C_{80}$ is more abundant than C_{84} (the third most abundant of the empty cage fullerenes after C_{60} and C_{70}). These endohedrals, which contain the planar tetraatomic Sc_3N unit within variously sized carbon cages, were isolated via three stages of high-pressure liquid chromatography. The structures of $Sc_3N@C_{80}$ and $Sc_3N@C_{78}$ as determined by low-temperature x-ray diffraction are shown in Fig. 6. The $Sc_3N@C_{80}$ consists of a C_{80} cage with icosahedral symmetry that encloses the planar Sc_3N unit.[5,27] Because the ^{13}C-NMR spectrum of $Sc_3N@C_{80}$ at 25°C consists of only two lines (as required by the I_h symmetry of the cage only, the Sc_3N unit must be freely moving inside the carbon cage.[5] The $Sc_3N@C_{78}$ consists of a C_{78} cage with D_{3h} symmetry, with the planar Sc_3N unit located in the horizontal mirror plane.[26]

The isolation of milligram quantities of pure $Sc_3N@C_{80}$ allowed its chemical reactivity to be explored. The icosahedral C_{80} cage of $Sc_3N@C_{80}$ lacks the usual sites (6:6 ring junctions between two pentagons) for addition reactions that are found to occur in all other fullerenes investigated so far, and hence, its reactivity will follow new patterns. Thus, it is significant that the first addition product involves a Diels–Alder reaction at a 5:6 ring junction.[30] The structure of the product $Sc_3N@C_{80}$-$C_{10}H_{12}O_2$ shown in Fig. 5 reveals that the scandium atoms are not near the site of addition, and that the Sc_3N portion retains its planar structure.[31]

The recent identification of $(Sc_2C_2)@C_{84}$, which was originally thought to be $Sc_2@C_{86}$, presents another example of a fullerene that encapsulates a combination of metal and main group atoms.[6] In this case: an acetylenic C_2 unit is believed to have two scandium

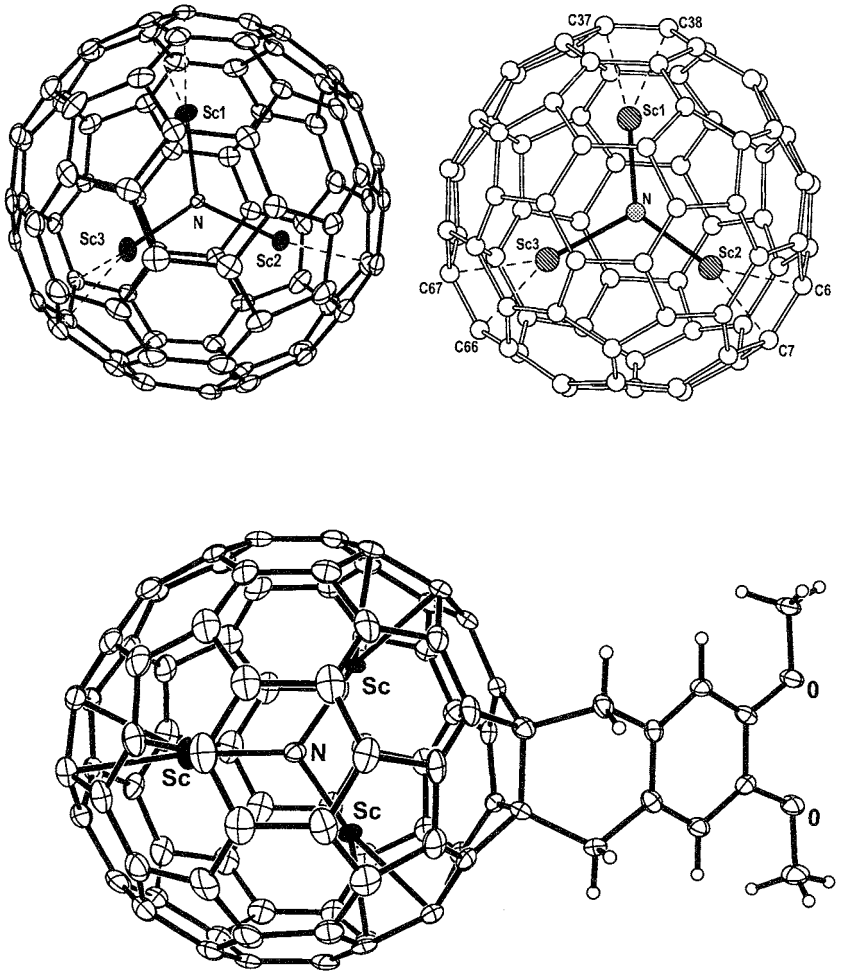

Fig. 6 The structures of $Sc_3N@C_{80}$ [in crystalline $Sc_3N@C_{80}\cdot 5(o\text{-xylene})$, Ref. [29]], $Sc_3N@C_{78}$ [in crystalline $Sc_3N@C_{78}\cdot Co(OEP)\cdot 1.5\ (C_6H_6)\cdot 0.3\ (CHCl_3)$, Ref. [26]], and the Diels–Alder cycloadduct $Sc_3N@C_{80}$-$C_{10}H_{12}O_2$ (Ref. [30]), as determined from single-crystal x-ray diffraction studies.

atoms located perpendicular to the C—C portion, which is then surrounded by a C_{84} cage. Further examples of fullerene cages containing complex combinations of electropositive metals and main group elements are likely to be created.

CONCLUSION

As seen in Fig. 1, fullerenes can encapsulate a variety of atoms from different parts of the periodic table. One to four atoms can be accommodated in cages of varying sizes. The interior face of the fullerene cage is remarkably inert toward the very reactive nitrogen atom, but the carbon cage can accept electrons when an electropositive metal atom is encapsulated. To date, most research focused on the preparation, identification, and characterization of these unusual molecules. However, applications for these novel molecular containers (which have low toxicity due to the inert carbon cages) are anticipated, including radioisotope delivery for imaging and diagnostic and therapeutic radiochemistry.[32] For example, recent work showed that polyhydroxylation of $Gd@C_{82}$ produces Gd-fullerenol that has an exceptionally high relaxivity and acts as an effective MRI (magnetic resonance imagining) contrast agent.[33]

Gels

Jan H. van Esch
Ben L. Feringa
University of Groningen, Groningen, The Netherlands

INTRODUCTION

Everyone knows what a gel is. but from a scientific point of view, the term "gel" encompasses chemically diverse systems. Already in 1926, Jordon Lloyd wrote that ''A gel is easier to recognize then to define,''[1] however, an exact definition of a gel is still a problem. Perhaps the most general definition is given by Flory, who described gels as dilute mixtures of at least two components, in which both components form a separate continuous phase throughout the system.[2] This definition includes not only gels composed of a solid phase and a gas phase (so-called aerogels, in which the solid phase often consists of silicates)[3] but also gels consisting of a solid-like phase and a fluid phase. In most gels, the solid-like phase is the minor component that forms a network structure in the fluid phase. Because of the coexistence of a network structure with a liquid phase, a gel behaves like an elastic solid at low stress values. but above a finite yield stress, they turn into a viscous liquid. This was described by Tanaka as follows: "the solid network structure prevents the fluid from flowing, whereas the fluid prevents the solid from collapsing.''[4]

Gels can be divided into two groups depending on the types of interactions that hold the network structure together. Chemical gels are formed through covalent cross-linking of dilute solutions of polymers or inorganic oxides, and because of the covalent nature of the network, their formation is thermally irreversible.[3] Chemical gels can. nevertheless, have many interesting properties and applications. Smart gels. for example. are hydrogels from cross-linked polymers that can reversibly swell and shrink in response to a physical or chemical stimulus (Fig. 1A), and are of great interest for novel drug delivery systems or artificial muscles.[4] Opposite to the chemical gels are the physical gels.'" In physical gels, the network structure is built up from smaller subunits, which are held together by noncovalent interactions. Many gels formed by polymers, proteins, surfactants. small organic molecules, and even mineral clays, belong to this class. Despite the different natures of their constituents. they all exhibit a characteristic thermally reversible gel–sol phase transition at moderate temperatures. because the strengths of the noncovalent interactions are comparable to the thermal energy (Fig. 1B).

Also, certain low-molecular-weight organic molecules ($M_w \sim 300$–1000 Da) are capable of forming physical gels. Gelation of a solvent by low-molecular-weight organic molecules is the result of self-assembly of the compound into elongated fibers. which then form an entangled network within the solvent (Fig. 1B). In these networks, the fibers consist of infinite arrays of small molecules that are solely held together by noncovalent interactions. The focus of this article will be on gelation phenomena by low-molecular-weight organic molecules, because this is a striking macroscopic manifestation of self-assembly and supramolecular structure formation.

SMALL-MOLECULE GELLING AGENTS

Survey of the Literature

The gelation of liquids by small organic molecules is a phenomena known for a long time, and in 1921. Bradford considered gelation by small organic molecules as a kind of incomplete crystallization.[6] However, until 60 years ago, gel formation was not consistently reported as such, either because the gel state was not recognized or because the gelling agents were named after their main applications, for instance, as lubricants or thickeners. A fine introduction into the older literature was given by Beginn.[7] From 1940 onward. many cases of gel formation by small organic molecules were reported, and these gelaror systems were summarized in reviews by Terech and Weiss and van Esch and Feringa.[8,9]

Unfortunately, even nowadays, searching for literatme on low-molecular-weight gelators among the enormous number of papers on gels, is like searching for "a needle in a haystack." The main reason is that up to now, there were no generally accepted keywords with which to discriminate between the various types of gels or gel-forming substances. Because low-molecular-weight gelators were most frequently used for the gelation of organic solvents, the term "organogel" (as opposed to ''hydrogel") became more popular, but it is not clear whether it denotes the gelling agent or the liquid phase. and it becomes even more confusing when the small-molecule gelling agent is used to turn water into a ''hydrogel.'' Therefore, we propose to use the more accurate term

Encyclopedia of Supramolecular Chemistry

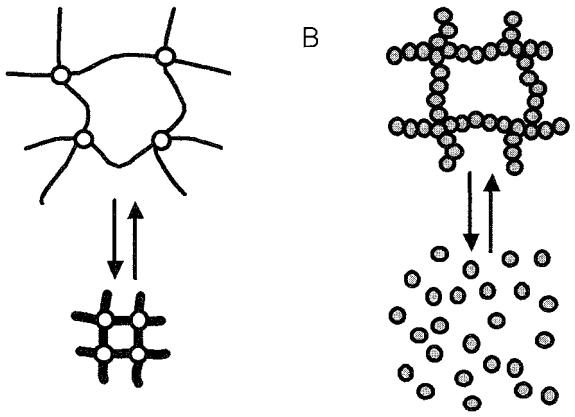

Fig. 1 A change of the environment can cause the reversible shrinking or swelling of a chemical gel, but the network structure remains intact (A). whereas a physical gel can undergo a reversible gel–sol phase transition (B).

"low-molecular-weight gelators" (LMWGs) for future reference.[8,10]

Structural Features of LMWGs

The LMWGs have in common the property that they self-assemble into fibrous aggregates; a process that can be driven by different noncovalent interactions like coulomb interactions, hydrogen bonding, π–π interactions, van der Waals forces, and solvophobic effects. For most of the early examples of LMWGs, the gelation properties were, however, discovered by accident, e.g., during attempts to crystallize the compound, and the diverse structures of the gelator molecules makes it difficult to identify the common structural features responsible for the gelation ability.

In some cases, the gelator structure bears a clear resemblance to surfactants. and one can distinguish a solvophobic part and a solvophilic part. The solvophobic part is prone to aggregate in a particular solvent, but this favorable contribution is opposed by the solvophilic part. Probably the best example is the gelation of aliphatic hydrocarbons or perfluorinated solvents by the perfluoralkane-perhydroalkane block compounds **1** (Fig. 2), which is believed to be caused by the immiscibility of either the perfluorocarbon or perhydrocarbon chains with the solvent.[9,11] In most other cases, specific interactions between (part of) the gelator molecules favor aggregation into fibers. The gelation of aliphatic solvents by the *bis*(alkyloxy)anthracene 2 is, for instance, driven by favorable π–π interactions between the aromatic moieties.[12] The gelation of apolar solvents by surfactant **3** is caused by electrostatic interactions between the ion pairs in the aggregates.[13] Many salts of fatty acids or phosphates were reported as potent gelators for organic solvents, an example being 12-hydroxystearic acid (12-HSA. 4) and especially its lithium salt.[14] For this compound, the clear distinction between the solvophilic and solvophobic part faded, and detailed investigations revealed that hydrogen bonding between the hydroxyl groups and electrostatic interactions between the head groups contribute to the stability of the fibrous aggregates.

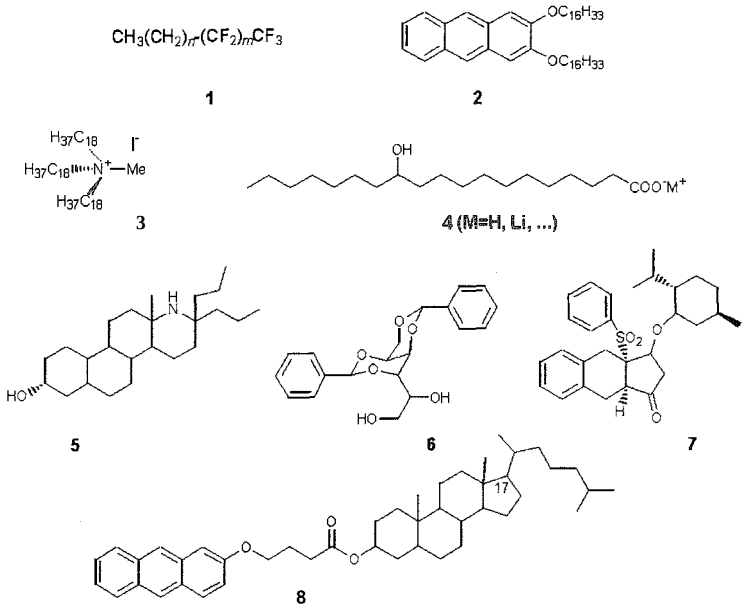

Fig. **2** Examples of well-known gelling agents for organic solvents.

Compounds 5–7 are also potent gelators for organic solvents. but for these compounds, it is less obvious which structural features contribute to their gelation ability. Gelator 5 is an example of a steroid-like compound that is able to gel saturated hydrocarbons.[15] Other steroids were also reported as efficient gelators,[8] and it was suggested that this gelation ability is related to the anisotropic aggregation properties of the rigid steroid skeleton, which is usually associated with their ability to form liquid crystalline mesophases.[16] Other gelators are also built around a rigid skeleton, like dibenzylidene-D-sorbitol (DBS. 6), which was known since 1942 as an efficient gelator,[17] and menthoxyfuranone derivative 7.[18] The broad scope of solvents, ranging from cyclohexane to ethylene glycol, that are gelated by enantiomerically pure DBS suggests that different intermolecular interactions like hydrogen bonding or π–π interactions contribute to its gelation ability, depending on the nature of the solvent.[19] However, racemic 6 does not show gelation ability, and the gelation ability of menthoxyfuranone 7 is susceptible to minor structural changes and stereochemical modifications. This sensitivity of the gelation ability to structural modification. solvent, number, and nature of intermolecular interactions. and stereochemical aspects is a common phenomenon among LMWGs.

In one approach to identify some of the molecular features that favor gelation. Weiss and coworkers systematically varied the structure of anthracene-steroid 8. which is an effective gelator for a large variety of organic solvents (Fig. 2).[20] It was found that some structural modifications are allowed, as long as the rod-like shape of the molecule is preserved, which emphasizes the importance of the inolecular shape. The dibenzoyl cysteine gelators **9a** and related compounds. which are potent gelators for water, represent another interesting case (Fig. 3). Guided by the crystal structure of ditoluoyl cysteine 9b, Menger and coworkers studied the relationship between gelation ability and molecular structure in detail and found that in addition to the capability to form an infinite hydrogen-bonded network, the kinetics of gel fonnation and the solubility are also crucial for gelation ability and stability of the gels.[21]

However, for most other gelators. the supramolecular arrangement in the gel fibers is still not known in detail; and in many cases, the explanation for the presence or absence of gelation ability remains speculative. It should be noted that the above-mentioned examples are only a selection of the many known gelling agents. and for an extensive overview, the reader is referred to the review by Terech and Weiss.[8]

Design of Small-Molecule Gelling Agents

The scientific challenges associated with the gelation phenomena by LMWGs together with the quest for robust gelators with tunable properties or additional functionality considerably stimulated research on organogelators and, in recent years, led to remarkable progress in the design of new LMWGs.

One approach to develop new gelling agents is to make use of one or more structural moieties that are known for their self-assembly or gelation properties, as building blocks (''tectons'')[23] for the construction of new gelators. Inspired by the anthranyl-cholesterol gelators 8, Shinkai and coworkers exploited the cholesterol moiety as a covalently attached tecton to turn peptides, carbohydrates, and even functional units like azobenzenes, crown ethers, and porphyrins into efficient gelators for organic solvents.[24] It was proposed that the cooperative effect of the anisotropic association properties of the cholesterol and the intermolecular interactions provided by the attached functional moiety leads to the gelation ability. because the separate units as single molecules do not display gelation behaviors. The structure of the powerful

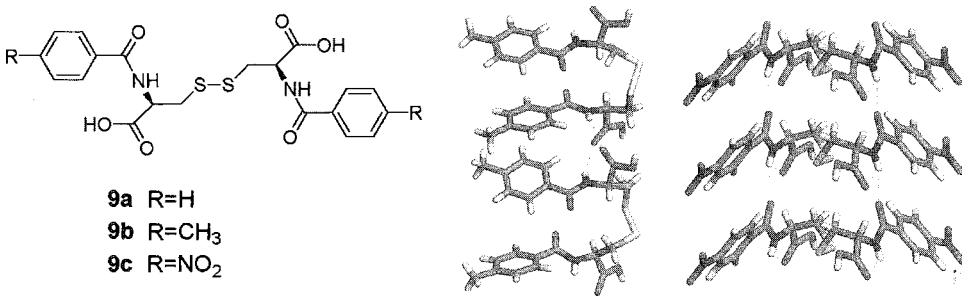

Fig. *3* Dibenzoyl cysteine family of gelators (9) and crystal structures of 9b (middle) and 9c (right). Compound **9a** is an excellent gelator for water, whereas the closely related compounds 9b and 9c form two-dimensional (0-network) and one-dimensional (α-network) arrays of hydrogen bonds, respectively, in the crystalline state. (From Refs. [21,22].) *(View this art in color at www. dekker.com.)*

gelator *dibenzylidene sorbitol clearly inspired Shinkai and coworkers to investigate the gelating properties of a* family *of saccharide gelators,* which *consists of a rigid molecular skeleton, with one or more hydrogen-bonding hydroxyl groups connected to* it.[10] *The well-defined molecular architecture with little conformational freedom and the large library of carbohydrates allowed for the evaluation of* gelation *properties in relation to* molecular *conformation and supramolecular arrangement in the crystal and gel states. The outcome of these studies confirms the presence of strongly anisotropic intermolecular interactions as a prerequisite for* gelation *(vide infra).*

In a different approach, new gelator *molecules were designed, starting from criteria derived from the events and intermolecular interactions that occurred during the* gelation process.[25] *Important guidelines for the design of new gelators that* emerged *from these studies are the presence of strong self-complementary and unidirectional interactions to enforce one-dimensional (1D) self-assembly; the control of fiber-solvent interfacial energy to tune solubility* and *prevent crystallization; and the presence of some factor to induce cross-linking of the fibers and* form *a network.*

Hydrogen-bonding groups appear to offera particularly useful self-assernbly motive *for the rational design of new gelators because of their strength and directionality. One of the earliest* examples *is the two-component system consisting of triaminopyrimidine- and barbituric acid derivatives. which self-assembles into linear tapes, whereas crystallization is prevented by the presence of the aliphatic side chains (Fig.* 4).[26] *The apparent preference for ID tape formation is sensitive to interactions between the substituents at the triaminopyrimidine and barbituric acid molecules. and slight changes in the nature of the substituents can shift the preference from* 1D *tapes to the formation of cyclic hexameric* assemblies.[27] *The problem of polymorphic self-assembled structures is not directly apparent with cyclic dipeptides and his-urea-based gelators, because in both types of compounds. all of the hydrogen-bonding groups are directed along a single molecular axis (Fig.* 4).[28,29] *These compounds are accessible and can* gelate *a wide range of solvents. and moreover. the hydrogen-bonding core can be used as a "gelating scaffold" to which other* functional *moieties can be attached without losing* gelation *ability.*

It *should be noted that these designs are not yet perfect, because they are mainly based on the concept of* 1D *self-assembly and do not include factors that would limit the diameter of the fibers.* In *most gels, the fibers are composed of* multiple *strands of molecules, and the fiber diameters show a broad distribution. It was proposed that fiber formation takes place via nucleation–growth*

processes, similar to that of crystal formation, and kinetic factors play an important role in restricting the fiber diameter.[30,32] Furthermore, many gel systems suffer from instability due to the growth of small crystals (vide infra) with much lower aspect ratios than the original fibers. Gelators designed to form fibers with a finite diameter are the wedge-shaped amphiphilic carbohydrates 12 (Fig. 5).[31] A consequence of the wedge shape of the molecules is that an optimal packing can only be realized in columnar aggregates; and the observed structures show the presence of thin fibers with a discrete diameter. However, many thicker fibers can also be observed, indicating that there is still a significant driving force for the formation of multicolumnar fibers.

These studies clearly showed that the rational design of LMWGs became reality. and in recent years, these insights were exploited in the development of functional gelators for specific applications (see the section entitled "Applications." below). The design approach established that unidirectional intermolecular interactions are a prerequisite for gelation by LMWGs, but it remains a challenge to control, at the supramolecular level, other aspects of gel formation. like the fiber length and diameter, cross-linking of the fibers, and prevention of crystallization.

CHARACTERIZATION AND PROPERTIES OF THE GELS

Gels from LMWGs usually display a gel–sol phase transition at a characteristic temperature that depends on the nature of the solvent and the structure of the gelator as well as its concentration. Gels can, therefore, easily be prepared by crossing the gel–sol phase boundary by cooling or by adding a poor solvent. Significant supercooling is. however, often necessary, because gel formation is, in most cases, a kinetically controlled process that resembles in many aspects the nucleation and growth stages of crystallization.[30,32] On the other hand, the gel–sol equilibrium is maintained during melting of the gels if the heating rate is sufficient low. The gel–sol phase-transition temperatures (T_{GS}) can be determined by a number of different methods in which one monitors. for instance. the viscoelastic properties or a specific spectroscopic or optical feature as a function of the temperature.["] Particularly convenient are the "dropping ball" and "tilted tube" methods, which allow visual observation of the gel–sol transition (Fig. 6).

Gels from low-molecular-weight organic compounds can have remarkably high melting temperatures. even up to 150°C, despite the fact that the gels are solely held together by noncovalent interactions.[34,35] The gel–sol phase transition occurs through dissolution of the fibrous network. Analogous to the dissolution of crystals in ideal solutions, the variation of T_{GS} with the concentration usually obeys the van't Hoff or Schrader relation. from which one can calculate the gel–sol phase-transition enthalpy (ΔH_{GS}).[16,33] The melting enthalpy of a gel can also be measured by calorimetric methods, like differential scanning calorimetry, although the sensitivity is often a problem. More importantly, the ΔH_{GS} obtained from T_{GS} measurements and calorimetric methods can

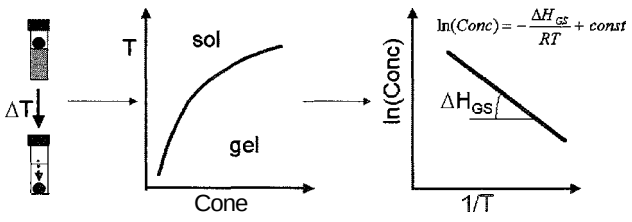

Fig. 6 In the dropping ball method, one records the temperature (T_{GS}) at which the gel can no longer bear the weight of the ball (left). The experiment is repeated at different concentrations. and from the variation of the T_{GS} with the concentration, one can construct the phase diagram (middle) and calculate ΔH_{GS} (left) using the van't Hoff equation.

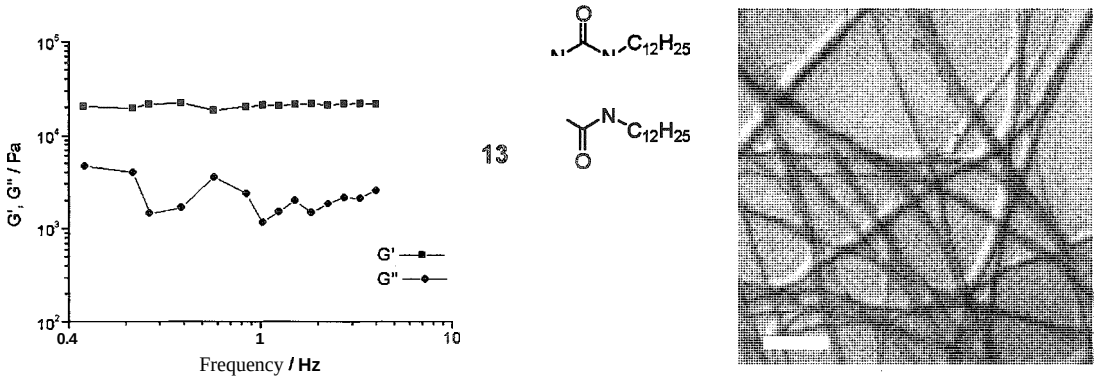

Fig. 7 Typical viscoelastic behavior of a strong gel. in this case, of his-urea gelator **13** in 1-hexanol (left). The TEM micrograph of this gel is shown at the right and reveals that the minimum width of the fibers amounts to 15–20 nm. which is still an order of magnitude larger than the molecular dimensions of **13**. (Scale bar is 500 nm. reproduced from Ref. [37].)

differ significantly, which is most likely due to the assumptions made and nonideal behaviors of the gels. It should be noted that in the long-term, many organogels tend to transform to crystals, most likely through Ostwald ripening, and this instability toward crystallization clearly indicates that the gel state is metastable.[30]

One of the most prominent features of a gel is its specific viscoelastic properties. The solid character of organogels at low stress values. for instance, provides a convenient test for gelation. because gels resist gravitational flow. This and other viscoelastic properties of organogels are direct consequences of the presence of a network structure. Therefore, rheological studies of the viscoelastic properties are. in the ideal case, complemented by characterization of the fiber and network morphology. Pioneering work in this area by Terech showed that most orpanogels can be classified as "strong" gels, but there are also few documented examples of ''weak'' organogels.[36]

Strong organogels are usually composed of a network of cross-linked fibers. The diameters of the fibers are at least an order of magnitude larger than the size of a single gelator molecule, and cross-linking of the fibers into the network structure occurs through entanglement or the formation of microcrystalline junction zones. The network appears as a static structure at timescales of minutes and shorter. because the fibers and junction zones are stabilized by multiple noncovalent interactions. and hence, the scission energy is much larger than kT. As a consequence, strong organogels behave as elastic solids up to a characteristic stress value (yield stress), with only little dependence on the timescale of the experiment. In an oscillatory rheology experiment, this behavior is reflected in the storage modulus G' being larger than the loss

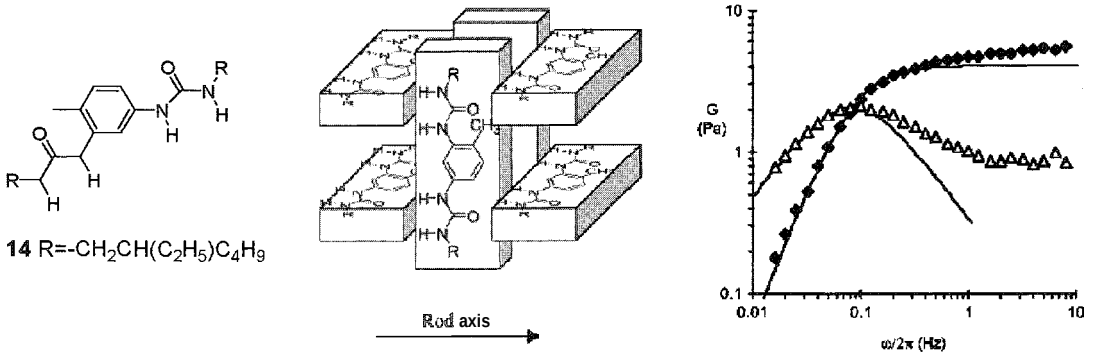

Fig. 8 A slight modification of the structure can lead to completely different properties, as is illustrated by methyl-substituted his-urea coinpound 14 that, in contrast to gelator 13. forms a typically weak gel. The oscillatory rheology experiment shows the weak gels characteristic frequency dependency of G' and G'' (right), and small-angle neutron scattering studies revealed that the molecular wires are only two molecules thick, as depicted in the tentative model in the middle. (Reproduced from Ref. [38].)

modulus G'' over a wide frequency range (Fig. 7), and if the applied stress (amplitude of the oscillation) exceeds the yield stress, the gel network breaks down to yield a viscous fluid. For most systems, the gel state can only be restored by a heating–cooling cycle through the gel–sol phase transition. but a few strong gels were reported to display thixotropy, i.e., a spontaneous restoration of the gel state occurs if the stress is taken away.[37]

Weak gels from LMWGs, on the other hand, are formed by the bis-urea compound 14 depicted in Fig. 8. which self-assembles into molecular wires in hydrocarbon solvents. and above a critical concentration, the wires entangle to form a network structure.[38] Because the molecular wires are only two molecules thick, there are only a few noncovalent interactions. resulting in small scission energies and short lifetimes of the wires. In such weak gels. the relaxation of stress is possible through mechanisms like reptation or scission and recombination of the chains. and their viscoelastic properties are governed by the relative timescales of these relaxation processes. This leads to a pronounced frequency dependency of G' and G'' in an oscillatory rheology experiment, and the lifetime of the wires is given by the frequency at which G' and G'' intersect (Fig. 8).

The strong correlation between viscoelastic properties of the gels and the fiber and network morphology stresses the importance of complementing the rheologicai studies with morphological studies. A first impression of the morphology of organogels can be obtained by microscopy techniques. Especially transmission electron inicroscopy (TEM) and more recently also atomic force microscopy (AFM),[39] are convenient methods to use to study fiber morphology. and high-resolution images can even reveal the fine structure of a fiber down to nanometer resolution. The 319 structure of the network can be studied by scanning electron microscopy on gel samples of which the liquid phase is removed by supercritical extraction. However-, with electron microscopy. one always has to deal with samples that are rather diverged from the native gel state with all risks of looking at artifacts. This limitation does not hold for x-ray or neutron scattering methods. which allow the characterization of the network morphology in the native state. but the downside is that analysis and interpretation of the data are more complicated, because the structural data are obtained in reciprocal space.[36] Especially high-flux x-ray sources as provided by synchrotrons are useful, because highly diluted gel systems (to circumvent multiple scattering) with low scattering intensities can be studied in real time, which allows one to follow the formation of a gel upon quenching from the solution state, or to study the deformation of the network upon application of stress. Moreover, the high-beam intensities makes it possible to collect data at very small angles, thereby probing structural features from one to several hundreds of nanometers, which allows characterization of the fiber shape and diameter. as well as mesh size of the network.

Together, microscopy, scattering methods, rheology, and thermotropic methods provide a detailed view of the gel network and its behavior. however, they do not provide information on the nature of the intermolecular interactions stabilizing the gel network and the supramolecular arrangement of the gelator molecules within the fibers. In supramolecular chemistry, such information is usually obtained from single x-ray crystal structures or 2D NMR spectroscopic studies: but unfortunately, these techniques are of limited value for organogels. The application of high-resolution solution-phase NMR techniques is limited to the pre-gel stage, because of the solid nature of the fibrous network.[40] and only in a few instances have LMWGs successfully been crystallized despite their tendency to gelate. Powder XRD is a powerful technique for native or dried gels, because it provides structural information on randomly oriented samples. Simple phases like lamellar or hexagonal phases can easily be recognized from the diffi-action patterns, and recent advances in this area made it possible to deduce even a crystal structure from high-resolution powder patterns. Such high-quality powder patterns were not yet reported for organogels, probably because the arrangement in the fibers is not as well defined as in crystals. Powder x-ray diffraction (XRD) patterns of gels were used to identify the gel-forming morph of hexatriacontane gels, by comparison with powder diffraction patterns of several crystalline forms of hexatriacontane,[41] but other examples showed that the arrangements in the gel and crystal states are not necessarily the same.[22,29] For insight into the supramolecular arrangement of the gelator molecules in these and most other gel systems, one has to rely on the nonconclusive information that emerges from changes in the electronic and vibrational spectra that occur by going from the solution to the gel state.

APPLICATIONS

The LMWGs are of great interest, because numerous applications for them are found in different areas, like cosmetics. drug delivery. separation technology, lubrication: and display technology. In particular. gels formed by salts of long-chain carboxylic acids or other organic acids. but also amide oligomers, have been known for a long time, and were used as lubricants or thickeners in commercial applications, but regrettably also as a

hardener of kerosene in Napalm. Dibenzylidene sorbitol is used on a large scale as a nucleating or clearing agent for polypropylene, and other LMWGs are used as rheology modifiers in personal care products like lipstick or antiperspirant sticks. It is foreseen that recent advances in the design and understanding of organogelators will lead to many more applications as rheology modifiers because of better possibilities for tuning the processing conditions or the molecular properties. And, the use of polymers to alter network morphology is a very promising development.[32]

The development of new LMWGs for water and nonclassical solvents is also of great interest. Low-molecular-weight hydrogelators based on carbohydrates or amino acids for water are potentially of interest for biomedical applications:[42–44] and recently, vancomycin was modified with pyrene, which turns it into a hydrogelator and enhances its antibacterial activity.[45] It was shown that the organogels can be used for the selective binding of guest molecules, which might be of interest for separation technology and drug delivery.[46] The gelation of supercritical CO_2 offers a new route to organic xerogels as new insulating material,[47] and gelled ionic liquids might find application as electrolytes in batteries or solar cells.[48] Functionalized organogels with, for instance, oligothiophene moieties: show enhanced electronic or ionic conductivity and are of potential interest in molecular electronics,[49] and the recent structuring of liquid-crystalline materials by organogelators led to liquid-crystalline materials with new electrooptical properties.[50]

Organogels were also used as templates for the construction of membranes and new hybrid materials. Polymeric membranes were prepared by the gel-template leaching method, in which membranes with defined channels were prepared by polymerization of a methacrylate ester liquid phase of an organogel, followed by extraction of the organogel gel matrix.[51–53] It is also possible to polymerize the gel phase of modified gelators containing a polymerizable group, resulting in a low-density xerogel.[54] The transcription of the organogel fibril structure into inorganic materials was pioneered by Shinkai et al. Toward this goal, the gelator molecules were extended with functional groups that strongly interact with the inorganic precursors, and as a consequence, the inorganic sol-gel process proceeds preferentially at the interface of the organogel network, to give an inorganic object of which the shape is reminiscent of the organic template (Fig. 9).[55]

The development of responsive organogels is a relatively unexplored area, but it might be of interest for, e.g., novel drug delivery systems or microfluidics. In contrast to chemical gels, the application of chemical or

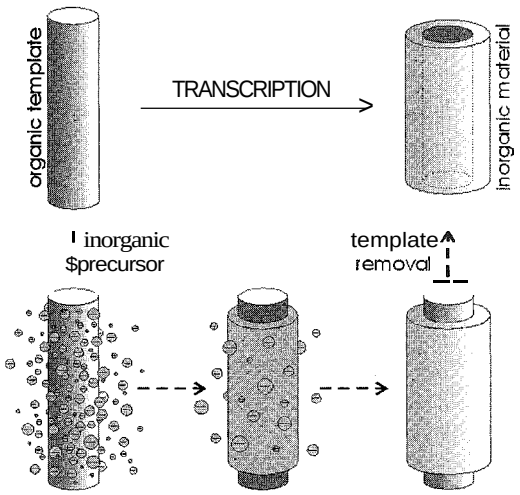

Fig. 9 Transcription of organic templates into an inorganic material. (Reproduced from Ref. [55].)

physical stimuli to organogels with encapsulated guest compounds can result in a reversible gel–sol phase transition (see also Fig. 1), thereby releasing its content. Shinkai and coworkers developed, for instance, an azobenzene-steroid gelator, of which only the trans azobenzene isomer and not the cis-isomer forms gels, and they found that the photochemically induced trans-cis isomerization is accompanied by a reversible gel–sol phase transition.[16] Unfortunately. the cis-isomer of employed azobenzenes is thermally unstable, resulting in a spontaneous (thermally induced) restoration of the gel state. The photo-bistable dithienylcyclopentenes do not suffer from this disadvantage, and recently it has been shown that also for these compounds the degree of aggregation can be controlled by light.[56] Other stimuli, like protonation in combination with light,[57] or ion-complexation[58] were also used to control the gel–sol phase transition. However, the response of organogels to stimuli is not limited to the gel–sol phase transition. Zinic and coworkers showed that a morphological transition from microspheres to a fibrous network can be induced by light,[59] and remarkably, a glycosylated amino-acid-based gelator for water displays a thermotropic volume-phase transition.[44]

CONCLUSION

The gelation of organic solvents by LMWGs is a phenomenon that has been known for a long time but, nevertheless, has been poorly understood. at least at the

molecular level. Only with the advance of supramolecular chemistry has it been realized that the formation of a fibrous network by small organic molecules is an example of self-assembly par excellence. From this perspective, the elucidation of several factors governing gelation and establishment of some of the design rules for new LMWGs were realized, and in recent years, this led to remarkable progress in the development of functional gelators with programmed properties. Applications of organogels in highly diverse areas ranging from cosmetics and drug delivery to material science and molecular electronics already are or will become reality within the near future.

It also became clear that the gelation of liquids by low-molecular-weight organic molecules is a complex process, of which the 1D assembly of gelator molecules is only a first step in a series of events that ultimately leads to the formation of a network structure. Understanding and controlling the different stages of the gelation process remain a huge scientific challenge, not only because the structural analysis of gels is still problematic. but also because of the prominent role of kinetics in the gelation process. Progress toward these goals, however, will be relevant not only for the possible applications of gels but also for related areas like crystallization and hierarchic structure assembly.

Glycoluril-Based Hosts

Johannes A. A. W. Elemans

University of Nijmegen, Nijmegen, The Netherlands

INTRODUCTION

In the early 1980s our group began a study on the possibilities of using the cyclic glycoluril hexamer cucurbituril **1** (Fig. 1a) as a host for small organic guests. Until recently."] however, modification of cucurbituril was inhibited due to the extreme insolubility of this macrocycle in most common solvents. In attempts to overcome this problem of solubility by attaching lipophilic phenyl groups to the glycoluril units: it was discovered that the reaction of diphenylglycolmil (DPG) 2 with formaldehyde in benzene gave a clip-shaped molecule, **3a**. This molecule appeared to have a rigid, U-shaped cavity, and it turned out to be an ideal host for dihydroxybenzene derivatives such as resorcinol and catechol.[2] Since then. an enormous variety of glycoluril-based hosts possessing numerous functionalities has been synthesized. Nowadays, these hosts find their applications in many different research areas. e.g., as mimics of biological systems. as amphiphiles, and as liquid crystals.[3] In this overview, only the most recent developments in glycoluril-based host chemistry will be discussed.

BINDING FEATURES

The crystal structure of host **3b** (Fig. 1b) clearly shows that this molecule possesses a well-defined and preorganized cleft. ^{1}H-NMR studies revealed that glycoluril-based hosts are excellent receptors for neutral guests, e.g., (di-)hydroxybenzene molecules.[4] The binding strength toward these types of guests can reach values of $K_a > 10^5 M^{-1}$, depending on the binding functions in the host molecule and the substitution pattern in the guest. The binding is a result of three cooperative effects. viz. hydrogen bonding. $\pi-\pi$ stacking. and a so-called "cavity effect," which can be simply described as the entropically favorable filling of an empty cavity by the guest. Recent work within our group enabled the separation and quantification of each of these effects."] Upon binding of a 1,3-dihydroxybenzene in a host of type 3 in chloroform, two hydrogen bonds are formed simultaneously between the hydroxy groups of the guest and the urea carbonyl groups of the receptor (Fig. 1c). The strength of these hydrogen bonds is directly correlated to the 5-substituent of the guest. which determines the acidity of the phenolic OH groups. It was found that for a series of 5-substituted 1,3-dihydroxybenzenes. the ΔG of binding to **3b** increases linearly as a function of the Hammett substituent constant σ_m(R).

The $\pi-\pi$ interactions between host and guest are readily influenced by subtle variations in the host side walls. Altering the 1,4-substituents on the side walls from methoxy to methyl to hydrogen significantly weakens the $\pi-\pi$ interactions and reduces the contribution of the cavity effect. Host 4 with two p-benzoquinone n-acceptor side walls somewhat surprisingly turned out to be a poor receptor for n-donor 1,3-dihydroxybenzene guests. Although favorable interactions were expected between the host and the guest, their orientation, imposed by the hydrogen bonds, is energetically less favorable than that found in the related complex with host 3b. Enlargement of the aromatic surface of the side walls to 1.4-dimethoxynaphtalene (Host ***5***) completely inhibited guest binding. due to a combination of unfavorable $\pi-\pi$ interactions and blocking of the cavity by the methoxy side wall substituents. Connection of the naphthalene walls at their 1.8-positions (Host 6) removes these constraints. Host 6, however, exists in three slowly exchanging conformers. of which only the *anti–anti* one possesses a cleft in which substrates can be bound (Fig. Id). The large aromatic n-surfaces of the side walls in 6 interact favorably with electron-deficient guests and silver ions. Binding occurs by an induced-fit mechanism: upon binding of the guest, the relative amount of *anti–anti* conformer was found to increase.[6,7]

All the binding processes described above were carried out using hosts based on the DPG skeleton. Recently. this central core was modified. and new host molecules were synthesized based on the propane-diurea skeleton.[8] The x-ray structure of **7** revealed that its cavity resembles the cavities of DPG-based hosts, the only difference being

that in the new host. the distance between the urea carbonyl groups is slightly shorter (5.2 A compared to 5.5 Å in the case of 3b). As a result of this closer distance. 1.3-dihydroxybenzene guests are bound by 7. approximately 10 times stronger. The exceptionally high binding constants measured for these guests (up to K_a = 2.4 *x* 10^6 M^{-1} for the complex between 7 and 5-cyanoresorcinol), highlight the fact that even a sub-Å

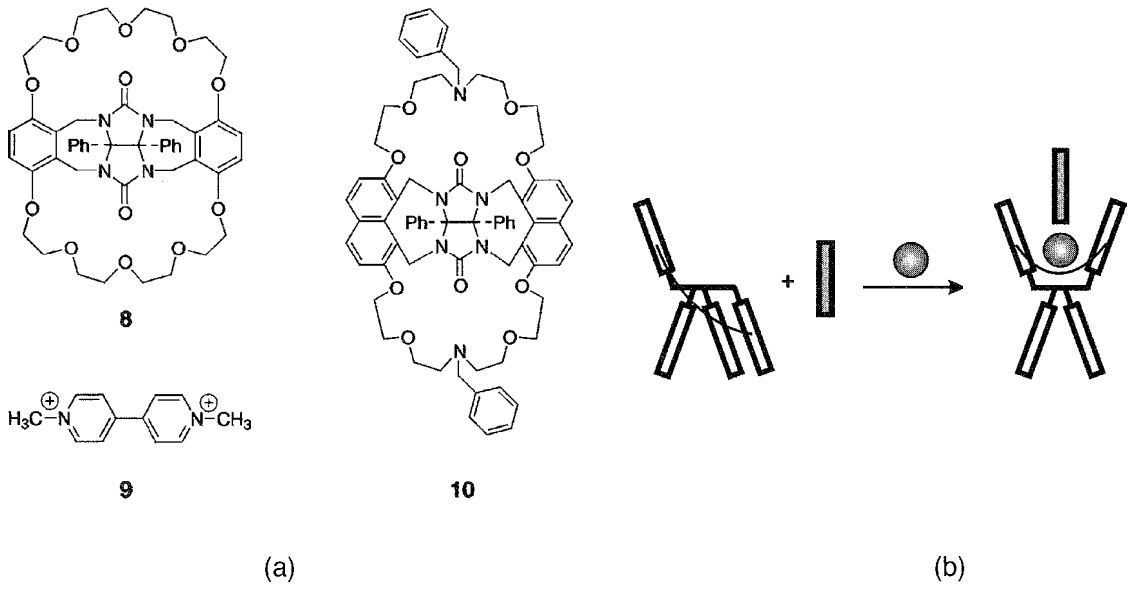

Fig. *2* (a) Basket-shaped host 8 and 10 dnd viologen guest 9 (b) The allosteric binding of a guest in Host 10. In the presence of Na^+ or K^+ (circle), electron-deficient aromatic substrates (rectangle) are bound more strongly

change in the host structure can have a dramatic effect on its binding properties.

Glycoluril-based hosts derivatized with crown ether moieties. such as 8, are known as molecular baskets because of their basket- or bowl-like shape (Fig. 2a). In addition to alkali metal ions and diammonium salts, these molecules are excellent receptors for charged aromatic compounds such as viologens (*N,N'*-disubstituted 4,4'-dipyridinium compounds) and polymeric derivatives thereof.[109] Host 8 binds 9 with a K_a of 5.7 x 10^4 M^{-1}, which is much stronger than the binding of 9 in the *bis*(paraphenylene)-[34]-crown-10 macrocycle studied by Stoddart and coworkers.[110] Upon complexation with **8,** the redox properties of 9 were modified, i.e., bound 9 is 100 mV more difficult to reduce than uncomplexed 9. Once reduced to its 1+ form, however, 9 is expelled from the cavity. In the case of polymeric derivatives of 9, the electrochemical properties of the polymer are altered by the addition of Host 8.

Another family of basket-shaped hosts was synthesized containing azacrown ethers that can act as linking points for functional groups. Naphthalene-walled basket 10 exists in three conformations and displays allosteric binding behavior.[111] Upon addition of alkali metal ions, the ***anti-anti*** conformation is induced, resulting in a host that is an ideal receptor for aromatic guests (Fig. 2b). As a result of this induced change, the binding of 1,3-dinitrobenzene is increased by a factor of 2 to 6, upon the addition of K^+ ions to a solution of 10, with two K^+ ions complexed between the crown ether rings in a cooperative manner. The second K^+ ion binds approximately 100 times stronger than the first.

MIMICS OF BIOLOGICAL SYSTEMS

Glycoluril-based host molecules were used as components of substrate-selective catalysts. Using nature as a guide, catalytically active metal centers were linked to the receptor cavities. These supramolecular systems were synthesized to mimic well-known processes in natural

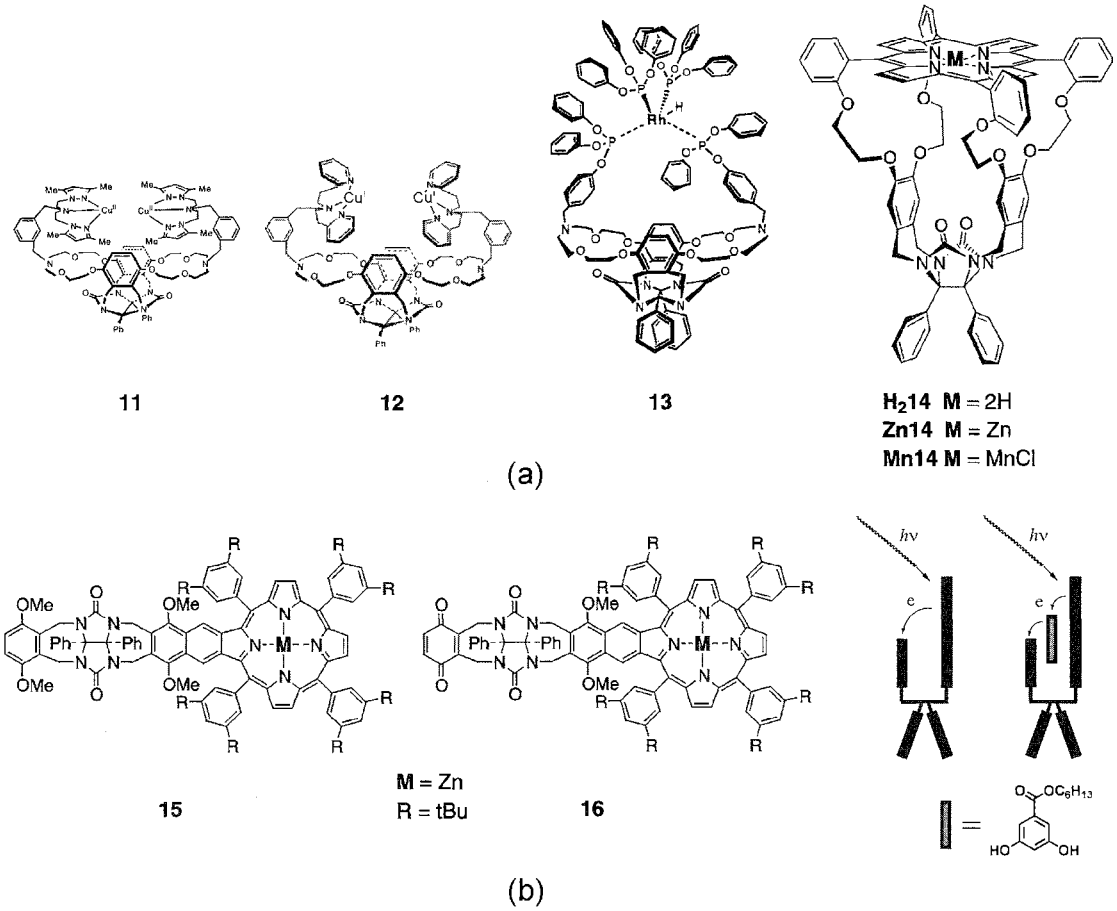

Fig. 3 (a) Examples of glycoluril-based supramolecular catalyst. (b) Porphyrin hosts **15** and **16** and the guest-mediated electron transfer occurring in these hosts.

enzymes, such as selective binding of a substrate, its catalytic conversion, and release of the product.

The first models were designed to carry out oxidation catalysis (Fig. 3a). Inspired by naturally occurring copper enzymes, pyrazole ligands were connected to a basket-shaped receptor. which, upon complexation of two Cu(II) metal centers, catalyzed the oxidation of alcohols to aldehydes (**11**).[12] The rate of oxidation of alcohols that were complexed in the receptor cavity, such as 3,5-dihydroxybenzyl alcohol: was accelerated more than 50,000 times compared to substrates that were not bound. The reaction, however, involved the irreversible reduction of Cu(II) to Cu(I) and, consequently. a stoichiometric amount of catalyst was required. The ideal oxidation catalyst would use molecular oxygen as the oxidant, e.g., as in the case of the tyrosinase enzyme. In order to mimic this property, the pyrazole ligands in **11** were replaced by pyridine ligands to give host molecule 12. This molecule, when complexed to two Cu(I) centers, was found to form metastable O_2 adducts in dichloromethane at $-85°C$, thus mimicking the naturally occurring hemocyanine oxygen carrier.[''''] Although 12 was still capable of complexing guests in its cavity. the host–guest geometry was not ideal. and oxidative splitting of the pyridine ligands of the host occurred in preference to oxidation of the guest. Molecular modeling confirmed that in the geometry formed upon O_2 complexation. the benzylic protons linking the pyridine functions to the basket are in direct proximity to the bound oxygen. Due to this close proximity. the host is oxidized in preference to the guest.

In addition to oxidative catalytic systems. glycoluril-based hydrogenation catalysts were developed. Following a synthetic methodology similar to that used for the preparation of **11** and 12. a tetrakis(triphenyl)phosphite Rh(I) hydride complex was linked to a molecular basket (13). The resulting supramolecular catalyst was capable of selectively catalyzing the hydrogenation of guests such as 5-allylresorcinol with a significant rate enhanceinent compared to nonbinding guests. e.g., 5-allyl-1,3-dimethoxybenzene.[14] The catalyst also exhibited many of the features encountered in enzymes. such as Michaelis–Menten kinetics. product inhibition, and rate enhanceinent by cooperative binding of a second substrate.

As a synthetic model of the enzyme cytochrome P450, a glycoluril-based host was equipped with a posphyrin roof.[15,16] Molecule H_2**14** possesses a rigid cavity in which a variety of guests. e.g., dihydroxybenzenes and viologen derivatives, can be bound. Because of cavity effects, **Zn14** displayed a high affinity for pyridine molecules ($K_a = 10^5\ M^{-1}$). As a result of a similar strong binding of pyridine in its cavity. host **Mn14** displayed an enhanced activity in the catalytic oxidation of alkenes.[17] Using **Mn14**, α-pinene was epoxidized at a 10 times higher rate than when manganese-tetrakis(*meso*-phenyl)porphyrin was used as the catalyst. When instead of pyridine the bulky ligand 4-t-butylpyridine was used, which does not fit in the cavity of **Mn14** and binds on the outside, no rate enhancement was observed. An advantage of this catalytic system was, however, that oxidative decomposition of the catalyst was inhibited, because the formation of μ-oxobridged manganese posphprin dimers no longer occurred.

Glycoluril-based hosts were also applied as mimics of the photosynthetic reaction center. One of the unresolved questions in the study of electron transfer processes in such a center is the role of intervening aromatic amino acid residues.[18] To study this role, a host was designed with one zinc-porphyrin side wall and one 1.4-dimethoxybenzene donor (15) or p-benzoquinone acceptor (16) side wall (Fig. 3b).[19,20] In a nonpolar solvent, such as cyclohexane or CCl_4, the fluorescence quantum yields of 15 and **16** were coinparable to that of zinc-tetrakis(*meso*-phenyl)porphyrin. In a more polar solvent, the quantum yield of **16** became much smaller due to solvent-mediated electron transfer from the porphyrin donor to the quinone side wall acceptor. A similar effect was observed when an excess of the guest hexyl 3.5-dihydroxybenzoate was added. Upon binding to Host 16 in CCl_4, this guest mediated the electron transfer, suggesting that in the natural system. the aromatic amino acid residues may play a similar role.

SELF-ASSEMBLY IN WATER

At the same time that Rebek's group began investigation of the hydrogen-bond self-assembly of glycoluril-based molecules into tennis-ball-like architectures,[21,22] we introduced water-soluble functionalities into glycoluril-based receptors with the objective to study the self-assembling behavior of the resulting molecules in water. The first approach was to attach long hydrocarbon tails to the nitrogen atoms of azacrown ether functionalized baskets. to give Compounds **17** and 18 (Fig. 4a). Upon dispersion of 17 in water, well-defined vesicles were formed with diameters between 500 and 4000 Å.[23,24] It was proposed that in these vesicles, the charged receptor cavities are directed toward the water layer, forming aggregates that possess a dimpled exterior. These supramolecular golf balls, as they became known. were still able to complex guests. such as magneson [4-(4-nitrophenylazo)resorcinol] in water. UV titrations indicated that below the critical aggregation constant (c.a.c.) of the compound, a 1:1 host–guest complex was formed ($K_a = 10^6\ M^{-1}$). Above the c.a.c., the titration data could only be fitted assuming a 2:1 host–guest complex ratio. This phenomenon was attributed to the fact that above the c.a.c., only the receptors on the outside of the

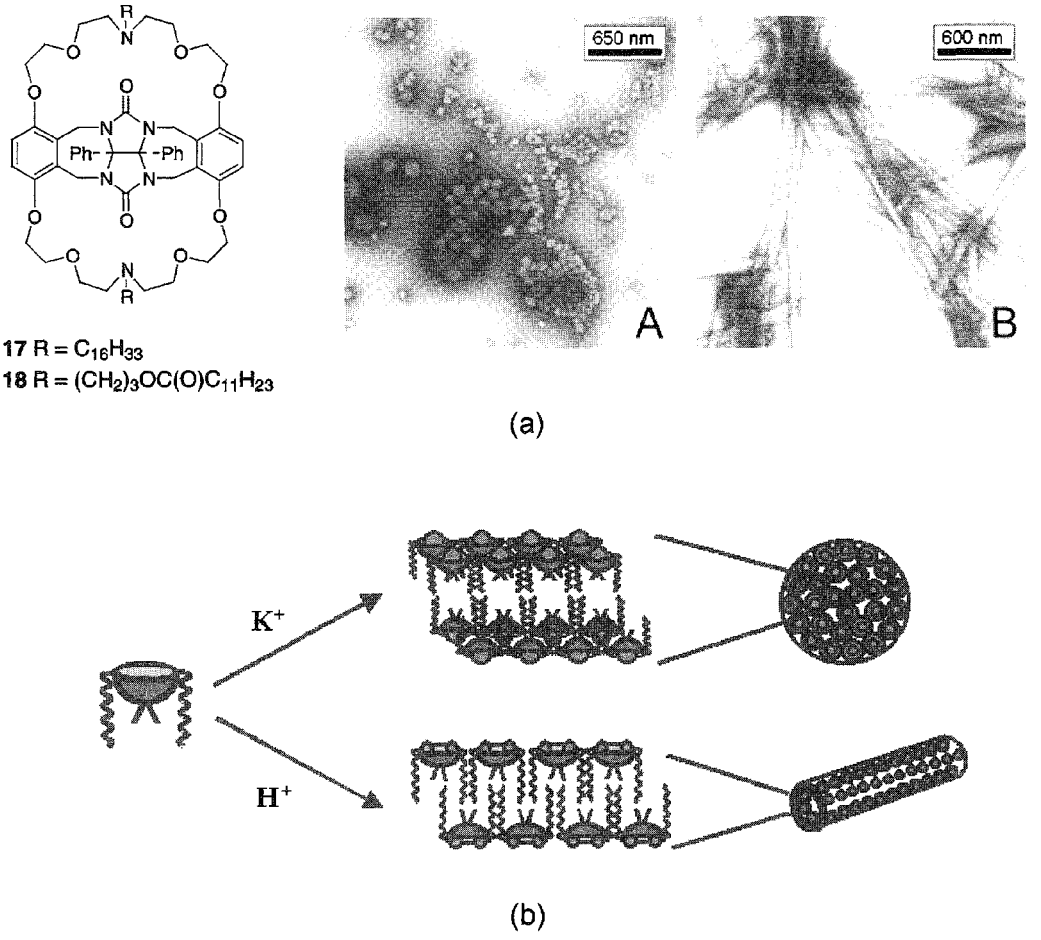

Fig. 4 (a) Transmission electron microscope images of aggregates formed by **17** in aqueous KCl solution (A) and in acidic water (B). (b) Proposed structures of the aggregates of 18 formed in the presence of K^+ and H^+ ions. (View *this art in color at www.dekker.com.*)

vesicle are able to bind magneson. and that the receptors on the inside of the vesicle are not accessible for the guests. Basket **18** was found to give tube-like assemblies with a diameter of 100 nm in aqueous HCl but vesicles in aqueous KCl or NaCl solution.[24,25] The morphologies of these superstructures could be manipulated by the addition of different alkali metal ions, such as Rb^+, which resulted in the formation of a mixture of tubes and vesicles. or Cs^+, which gave only nanotubes (Fig. 4a,b).

In the absence of guest molecules, Host 3b forms dimers in chloroforin as a result of cavity filling and favorable intermolecular π–π interactions (Fig. 1b). In chloroform. this dimerization was relatively weak (K_{dimer} = 16M^{-1}). It was reasoned, however. that this dimeriaation would be enhanced in water because of the hydrophobic effect. which acts as a driving force for self-assembly. Hosts **19**[26] and **20**[27,28] were designed and synthesized. both having a large hydrophobic cavity and on their convex side a water-soluble moiety, i.e., pyridinium in the case of **19** and a ruthenium–bipyridine coinplex in the case of 20 (Fig. 5a). Hosts **19** and 20 showed strong self-association in water (for both molecules K_{dimer} > 5000 M^{-1}). At concentrations above 1–2 mM, the solutions of **19** and **20** became turbid. and pearly dispersions were obtained. Samples of these dispersions were studied with the help of transmission electron microscopy (TEM) (Fig. 5b). A sample of **19** revealed the presence of well-defined razor-blade-like aggregates. which all had approximately the same shape and dimensions (1.2 x 8 μm) (Fig. 5b, A–C). Closer inspection of the aggregates showed that they were built up from a limited number of thin layers (approximately 50). Electron diffraction experiments revealed that the structures were not crystals but contained highly ordered arrays of molecules, displaying a repeating distance of 16.8 Å, which corresponds to approximately the length of one host molecule. Study of a sample of 20 showed the presence of rectangular aggregates that. similar to **19**, had well-defined

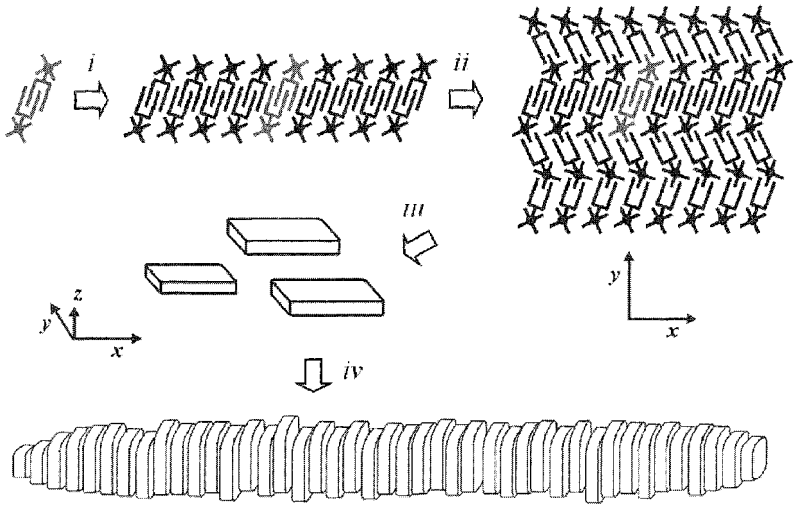
(b) Transmission electron micrographs of dispersions of Hosts **19** and 20 in water: A,B—razor-blade structures formed by 19 (A: bar = 900 nm, B: bar = 3500 nm); C—layered structure of a razor blade formed by **19,** bar = 120 nm; D—rectangular aggregates formed by 20. bar = 800 nm; E—cigar-like superstructure of the rectangular aggregates formed by 20, bar = 1500 nm; F—close-up of a "cigar" formed by 20, showing its constituting components. bar = 350 nm. (c) Proposed mechanism of hierarchical growth of the aggregates derived from **20**.

shapes and sizes (350 x 150 nm) (Fig. 5b, D). Interestingly, in some cases no rectangular aggregates were formed by 20, but larger "cigar-like" aggregates were formed (Fig. 5b, E). Close inspection of these "cigars" revealed that they were built up from smaller subunits that had the same dimensions as the rectangular aggregates. It was concluded, therefore, that the cigars are a higher-order aggregate of the rectangles.

Based on NMR, fluorescence; and powder diffraction experiments, for both **19** and **20**, a similar aggregate growth process was proposed. In Fig. 5c, a schematic representation of this growth process is depicted for compound 20. It starts with the formation of a head-to-head dimer, in which two molecules of **20** dimerize as a result of hydrophobic cavity filling. In a next step, dimers of 20 form an array, to which in a competing process molecules of 20 are attached in a head-to-tail binding geometry. Eventually. lamellar sheets of host molecules are formed that stack on top of each other, forming a rectangular structure.



(c)

Fig. 5 (*Continued*)

A unique aspect of the aggregates formed by 19 and 20 is that they are so well-defined in shape and size. The final shape of the aggregates apparently is encoded within the glycoluril building block. The fact that the aggregates have a finite shape is attributed to a fine balance between the enthalpy, i.e., the strength of the interactions between the molecules. and the entropy of the growth processes. At a certain moment. it is not favorable to attach new monomeric units to the relatively hydrophilic exte ior of the aggregates. It appeared that when the dispersion of 28 was prepared at higher temperatures (e.g., 70°C), the rectangular aggregates became smaller and more well-defined in size. At elevated temperatures, as a result of the increased contribution of kinetics. only the inost favorable modes of aggregation occur, and hence, a more defined aggregate structure is obtained. This unique phenomenon resembles self-repair processes that are ubiquitous in self-assembling systems occurring in nature.

SOLID-STATE MATERIALS

In order to introduce the aspect of liquid crystallinity in glycoluril-based hosts. Compound **21**, which has 12 hydrocarbon chains connected to its side walls. was designed and synthesized (Fig. 6a).[25,29] Molecules of 21 predominantly exist in the *syn–anti* conformation. but upon binding of a guest. the *anti–anti* conformation is induced. and the resulting complex exhibits liquid-crystalline (LC) properties. By changing the host–guest ratio, the nature and temperature range of the various LC phases could be tuned. The versatility of this concept of supramolecular induction of liquid crystallinity was demonstrated when multifunctional guests were used. The 4:1 host–guest complex of **21** with porphyrin 22 also displayed LC behavior. If a porphyrin that cannot bind was used, no mesophases were formed, which confirmed that the host–guest complex is the mesogenic species. Not only were the material properties of the porphyrin changed but also were its redox properties. Electrochemical studies revealed that the porphyrin core is encapsulated in the 48 hydrocarbon tails of the four hosts (Fig. 6b), causing the reduction potentials of the porphyrin to alter in a similar way to certain porphyrin-containing enzymes. such as cytochrome C. Through an identical process, liquid crystallinity could also be induced in polymers. The host–guest complex of **21**, with a copolymer of styrene and 3,5-dihydroxystyrene, gave a stable, discotic-like mesophase.

In another approach to introduce liquid crystallinity, aliphatic tails were connected to the convex side of a glycoluril-based host (23. Fig. 6a).[30,31] It was reasoned that in the solid state. this host would form dimers. in a similar way as the parent compound **3b**. As can be seen in Fig. 6c. such a dimer resembles the structure of a typical rod-like mesogen. Although the material formed by 23 exhibited the typical features of a liquid crystal, i.e., birefringent optical textures and a high degree of malleability, calorimetric and powder diffraction measurements showed that it was a plastic crystal composed of lamellae of dimers (Fig. 6c). Strong π–π interactions between the aromatic surfaces of adjacent molecules are the reason the material is not liquid crystalline. The

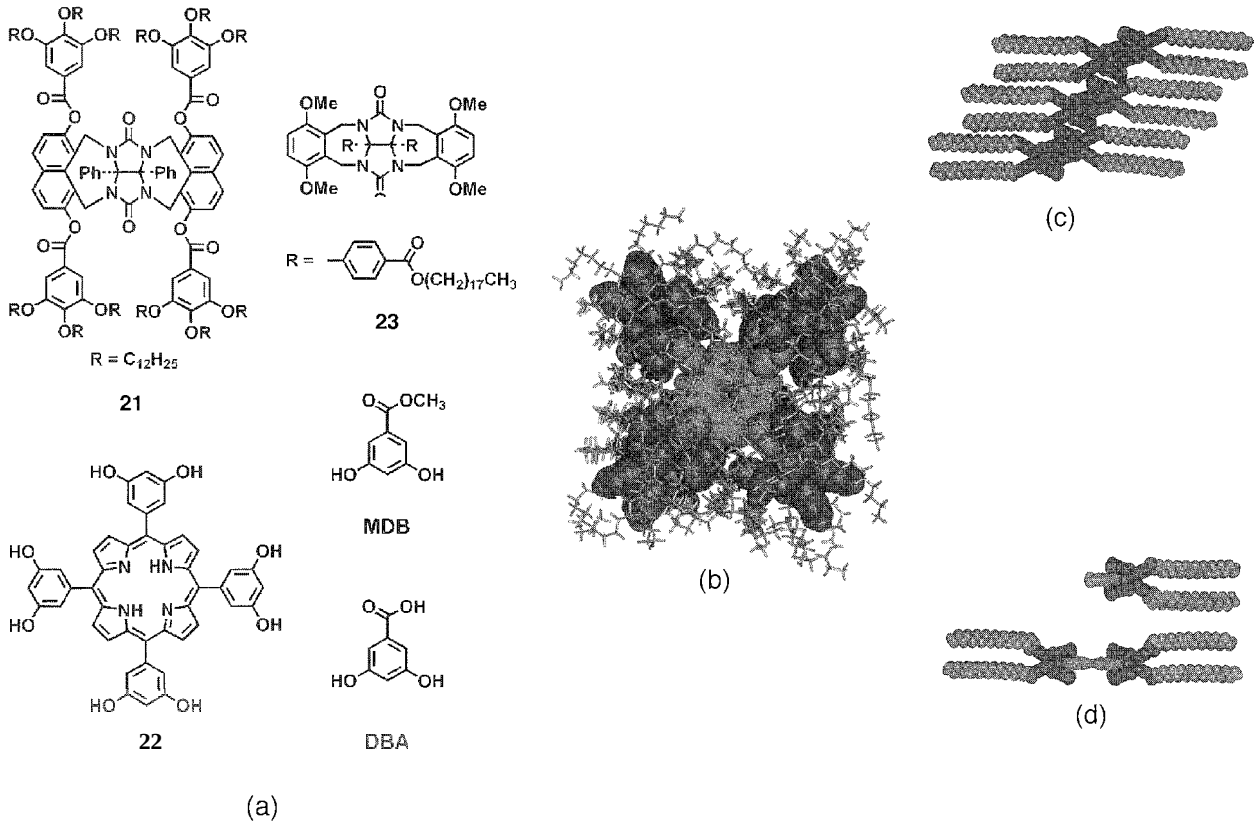


Fig. *6* (a) Host and guest molecules used in the glycoluril-based materials. (b) Computer–modeled representation of the liquid-crystalline host–guest complex between porphyrin %% and four molecules of Host 21. (c) Modeled structure of the arrangement of dimers in the lamellar plastic crystal formed by **23**. (d) Modeled structures of the 1:1 host–guest complexes between 23 and MDB (top) and between 23 and DBA (bottom). *(View this art in color at www.dekker.com.)*

materials properties of 23 could be tuned by the incorporation of guest molecules in the solid state (Fig. 6d). An equimolar complex of 23 and methyl 3,5-dihydroxybenzoate (**MDB**) lost its lamellar crystalline properties. due to the fact that the dimeric structure of the host was broken. A 1:1 complex of *23* and 3,5-dihydroxybenzoic acid (DBA). however, gave a material that showed a similar solid state behavior as free 23. Powder diffraction measurements revealed that the host–guest coinplex adopted a similar lamellar arrangement as the uncomplexed host, however, with an extended lamellar distance.

CONCLUSION

The preceding overview demonstrates that simple glycoluril building blocks can be used to create a wealth of host molecules capable of binding a variety of guests with very high binding constants. The host–guest systems proved their applications in functional mimics of biological systems. such as receptors, enzymes. and the photosynthetic reaction center. In recent years, the hosts were shown to be versatile building blocks in the self-assembly of well-defined nanosized materials, both in solution and in the solid state. It can be foreseen that in the near future, both features of glycoluril-based hosts, i.e., function and self-assembly, will be combined to generate highly ordered and functional supramolecular materials of which the properties can be precisely controlled.

Gossypol

Bakhtiyar T. Ibragimov
Samat A. Talipov
Institute of Bioorganic Chemistry of Uzbekistan Academy of Sciences, Tashkent, Uzbekistan

INTRODUCTION

Gossypol (Gp) is a natural polyphenolic compound[1] found in different organs of the cotton plant. This yellow pigment exists in plants as a protective agent against insects and diseases and is therefore sufficiently toxic even for human and animal organisms.[2] It is called Gossypol in order to indicate its plant origin (Gossypium) and chemical nature (phenol). Gp has been known from the end of the 19th century. Nevertheless, its unusual ability to demonstrate different types of biological activity and to form numerous supramolecular complexes has been discovered comparatively recently. In this entry. Gp's biological action. specific features of its chemical structure. stereochemistry. tautomerism. and optical activity will be briefly described. Special attention will be paid to its unique host properties, pseudopolymorphism (existing of the given host–guest complex in different crystal modifications) phenomenon. organic zeolite formation ability, and the reasons that make Gp a versatile host.

BIOLOGICAL ACTION AND STRUCTURE

Gp is not just harmful for humans and animals product. it may have a lot of useful applications. As it is one of the strongest antioxidants found in nature, investigators have tried to use it in the textile. rubber, and petroleum industries. but practical application of this natural compound is related mainly to its biological activity. Early investigations of Gp biological action revealed its antiviral and anticancer activities. Gp became the object of intensive biomedical studies after the discovery of its oral male contraceptive properties a quarter of century ago in China.[3] Later research showed that it has antifertility effects in males and females. A lot of other types of biological activity are characteristic for Gp, among which it is worth indicating its antimicrobial, antimalarial, antiparasitic, anti-HIV. immunosupressive, and interferon-inducing actions.'" To date, interest in the biological properties of Gp is still high, and dozens of papers devoted to it appear monthly.

The chemical structure of Gp was established by Adams[5] in the 1940s as a highly substituted symmetric binaphthalene (Scheme 1). The main factors defining stereochemistry of the molecule are the mutual arrangement of the naphthyl moieties (the dihedral angle) and disposition of the isopropyl groups relative to the appropriate halves. The dihedral angle between naphthyl moieties ranges from 70–106° in Gp crystals studied.[6] All polar substitutents are grouped on the one side of the naphthyl fragments, while hydrophobic parts are located on the opposite side. Such concentration of the polar groups makes possible the formation of an extensive system of intramolecular hydrogen bonds. The adjacent hydroxyl groups O3–H (O7–H) and O4–H (O8–H) are involved in H-bonding. giving rise to a five-membered conjugated ring system. whereas the H-bonded hydroxy O3–H (O7–H) and oxygen atom of the aldehyde group are part of a six-membered conjugated system. A coplanar arrangement of the naphthyl ring and aldehyde group forces the H-atom of the aldehyde group and hydroxy oxygen O1 (O5) to be displaced a short distance. This contact also can be considered as an intramolecular C–H...O hydrogen bond. The orientation of the hydroxy group O1–H (O5–H) enables an interaction of its H-atom with the π-electrons of the aromatic system in the other half of the molecule. In order to explain some features of Gp chemical behavior. Adams postulated the existence of the three tautomeric forms for Gp: aldehyde, quinoid. and hemiacetal.[5] The aldehyde form is the only tautomer found in numerous crystal modifications of Gp. The other two tautomers are fixed in Gp derivatives. The quinoid form is typical for solid-state Shiff's-base-type derivatives, while the hemiacetal tautomer is characteristic of crystalline Gp ethers.

Relatively bulky methyl and hydroxyl substitutents located in ortho-positions to the ordinary bond make a free rotation of the naphthyl moieties around the aryl–aryl bond impossible and give rise to the two distinguishable molecular conformations (atropoisomers) or two optically active forms (enantiomers). The racemization of chiral Gp takes place in raising the temperature up to 190°C. Only some kinds of cotton plants may synthesize enantiomeric Gp with a small excess (15–20%)—one of

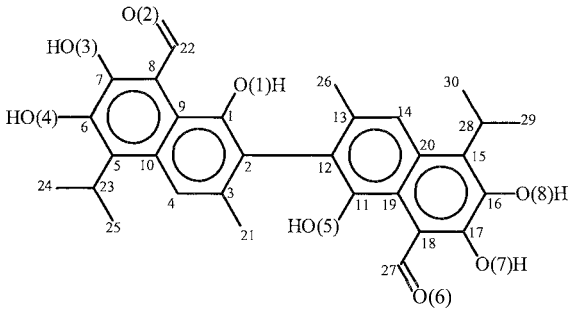
DOI: 10.1081/E-ESMC 120012747



Scheme 1 Gossypol molecule.

the antipodes. Therefore, optically active Gp for biomedical research has been obtained by chroinatographic separation of diastereoisomeric derivatives.[7] Results demonstrated that for main types of Gp bioactivity, a (−)-isomer is responsible (the absolute configuration of this antipode is determined as R by circular dichroism experiments).[8] This situation stimulated a search for relatively cheap and quick resolution methods for large-scale preparation of the R-form. The classic technique for resolution of racemates by preparation of diastereisomeric salts or enamine-type derivatives with subsequent fractional crystallization failed because of the surprisingly strong resistance of Gp to separation. The resolution of racemic Gp, however, by direct crystallization. has been achieved recently using polymorphism phenomena of the given host–guest complex.[9] It has been known for some time that crystallization of Gp from solutions in acetone results in formation of the stable 1:1 host–guest complex of racemic Gp with solvent molecules.[10] The lowering of crystallization temperature to −20°C leads to formation of the unstable 1:3 solvate of enantiomeric Gp with acetone.[11] i.e., unique host properties of Gp have been used for resolution of the racemic product.

GOSSYPOL—A UNIQUELY VERSATILE HOST COMPOUND

Investigations carried out by Adams and coworkers identified Gp complexes with pyridine and the first four members of the homologous *n*-monocarboxylic acids. Three crystal forms of Gp recrystallized from chloroform, ligroin, and a mixture of diethyl ether with petroleum ether have different melting points and have been considered as polymorphs.[12] These compounds. however. have not been characterized structurally. and therefore. their natures remain unknown. The recently established fin the 1980s) bioactivity of Gp required its large-scale production. Therefore, an Experimental Plant of the Institute of Bioorganic Chemistry of the Uzbekistan Academy of Sciences initiated production of this compound from by-products of the cottonseed industry. The production encountered instability problems of the physicochemical parameters of the final product precipitated from solutions in the binary solvent diethyl ether–hexane. In order to explain such behavior. we studied crystallization of Gp from that solution. Results showed that Gp could be crystallized from this binary solvent in four different crystal forms (two solvates and two polymorphs). This situation prompted us to conduct systematic investigations of Gp crystallization from a large number of organic solvents (polar, nonpolar, protic, aprotic, acids, alcohols, ketones, aldehydes, etc.) and led to the discovery of its unusual host property: Gp can form inclusion (host–guest) complexes (clathrates) with every solvent (120 examples). Therefore, the preparation of host–guest complexes with solid-state guests using common solvent for both components is a problem in the case of Gp, because the solid-state product is forced out from the complex formation by competing solvent molecules. Despite this problem, clathrates of Gp with solid-state species such as tropolone and naphthalene have been obtained.

To date, single crystals of over 80 Gp inclusion compounds have been prepared and characterized. The x-my structure determination was carried out for 45 clathrates. Results attested that depending on chemical nature (polarity), guest molecules may interact with the host component by using specific forces such as hydrogen bonds (coordinatoclathrates), or they may have no such interactions (true clathrates). Guest inolecules may be located in channels (tubulates), layers between host molecules (intercalates or layer-type clathrates), or totally enclosed cages (cryptates).[6] Gp can easily adjust its packing mode to form voids with shape. size. and chemical natures complementary to the guest molecules to be accommodated. This is achieved by producing a large variety of hydrogen-bonded assembles. Geometrical parameters of the intermolecular H-bonds formed by any of six potential proton-donor or eight proton-acceptor groups of Gp indicate that they are not very strong. This means that association of the host molecules is not driven by a single type of interaction. instead, Gp molecules form numerous, weak. even bent and multicenter intermolecular H-bonds. Therefore, alteration of the host molecules' association modes does not have to be related to large energetic changes in the system. which may explain the diversity of Gp crystal forms (see below).

Gp inolecules may be incorporated into finite bimolecular associates by centrosymmetric H-bonds (O5–H...O3, 05–H...O2, and O1–H...O2) and axially symmetric bonds (O1–H...O8 and O1–H...O6). These

*H:G = host:guest ratio.

associates or single Gp molecules are further incorporated by O8–H...O4 bonds (there are three kinds of this bond with different symmetrical relationships between proton-donor and proton-acceptor groups) or by O8–H...O2 and O1–H...O6 M-bonds to infinite higher-order networks. The networks found are one-dimensional (chain or column-like) or two-dimensional (layer-like) associates. A three-dimensional network has not been revealed among gossypol crystals.[113] The similarities of hydrogen bond patterns of the host (0, 1-, and 2-dimensional sets) or host–guest interactions (true clathrates or coordinato-clathrates) give a basis for classifying gossypol inclusion complexes into 14 structural types (Table 1). The same host associate of the definite structural type may be packed by different modes, leading to various crystal systems with different host:guest ratios (e.g., types III–V, X; Table 1) or affected by slight changes from the disappearance or formation of certain H-bonds (e.g., types I. II, and VII). Such situations subdivide some structural types into up to three subtypes or isostructural groups, leading to 24 groups in total. Some of these groups are represented by one clathrate only (e.g., groups II C, XI A. or XII A), but there are many groups having more than five representatives (e.g., group X A has 14 members). For the designation of isostructural clathrate groups (clathrate types). two-lettered symbols have been used

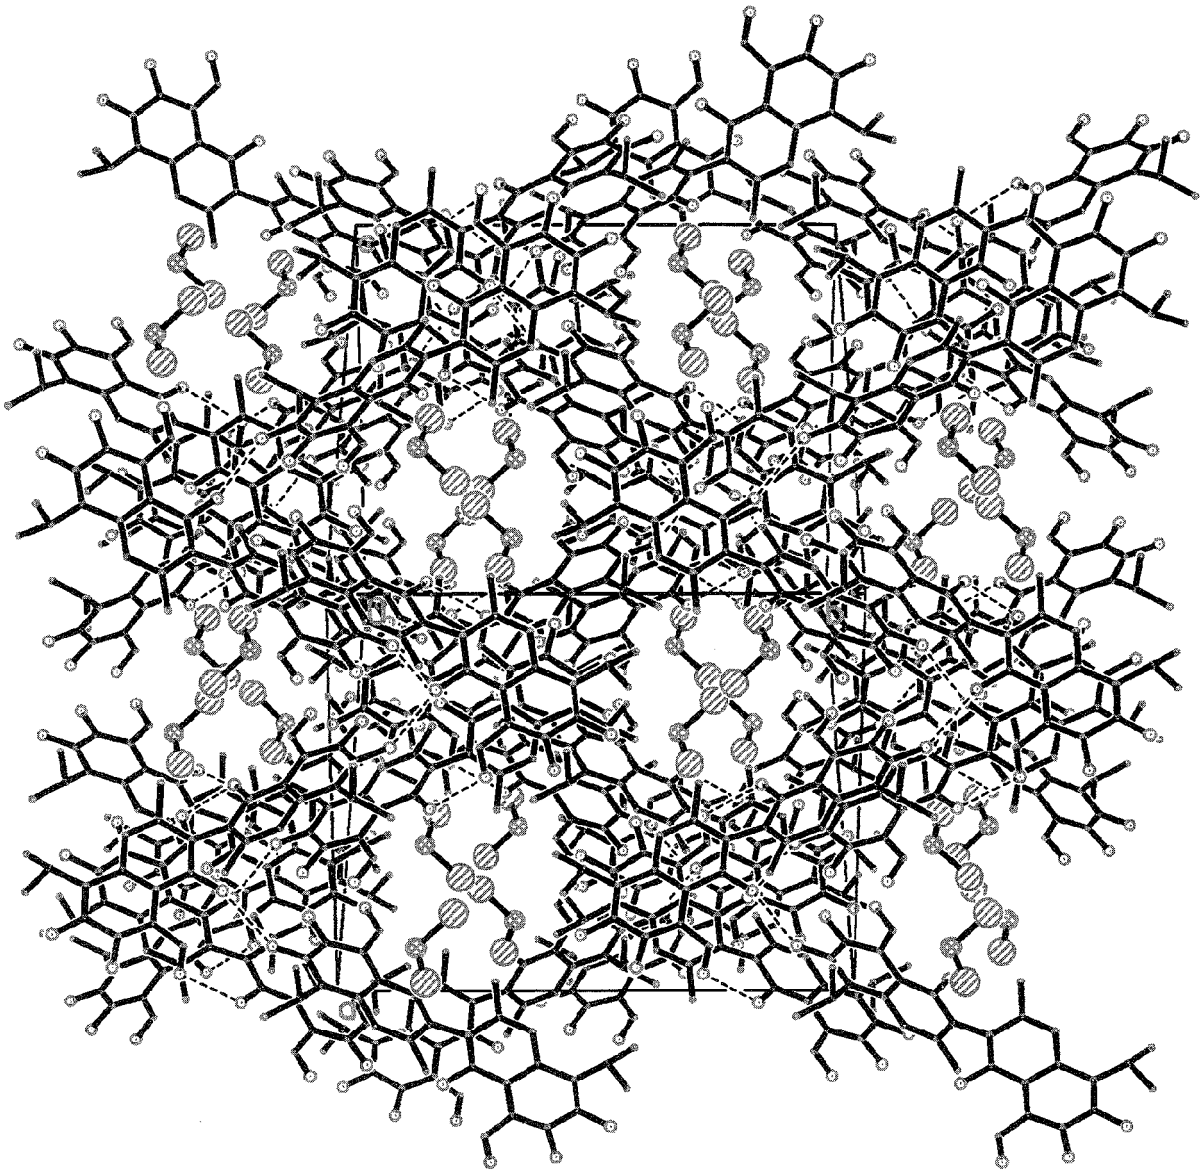

Fig. 1 *Clathrate* of gossypol with *dichloromethane.* (*View this art in color at www.dekker.com.*)

(Table 1). The first symbol indicates the host–guest interaction (M-coordinatoclathrates, V-true clathrates, or interaction with van-der-Waals forces), and the second specifies a topology of space occupied by guest molecules (T-tubulates, I-intercalates, and G-cryptates).

An inclusion compound of Gp may be sensitive to the shape and form of the guest molecule, e.g., each addition of a subsequent Cl atom to the CH_2Cl_2 molecule leads to formation of the new type of clathrate (rnorphotrophic transition): the host–guest complex of CH_2Cl_2 with Gp is an unstable tubulate (group VIII A; Fig. 1), the clathrate of $CHCl_3$ is a relatively stable intercalate (group V A; Fig. 2) and the solvate of CCl_4 is a very stable cryptate (group IV A; Fig. 3).[6] On the other hand, in some cases, inclusion complex formation by Gp may be not so sensitive to the geometry of the guest molecule, e.g., species relating to ketones, alcohols. acids, esters. dimethylformamide, acetonitrile, nitromethane. and tetrahydrofuran (16 entities) form isostructural inclusion compounds of group I A (Fig. 4).[14] In this example, different kinds of guest molecules form the same types of inclusion compound. The opposite situation is of great interest — formation of different types of Gp clathrates by the given guest molecule.

CAN GOSSYPOL FORM DIFFERENT INCLUSION COMPLEXES WITH THE SAME GUEST?

There were already two examples of such a possibility when we decided to investigate it in detail — diethyl ether and salisylaldehyde each form two different clathrates with Gp (Table I). The semisolvate of Gp with diethyl ether is obtained by desolvation of the monosolvate,[15] whereas clathrates of salisylaldehyde are formed from

solutions with different supersaturations.[6] As these findings were accidental. in order to establish the versatility of this phenomenon, systematic studies have been carried out.

Under ambient conditions, crystallization of Gp from solutions in dichloroinethane forms, as mentioned above, an unstable 1:I clathrate or a-phase complex (group VIII A; Fig. 1). Increasing the crystallization temperature to 30°C gives rise to the 1:1 host–guest complex (β-phase) relating to the group IV A (Fig. 3). Further increasing of the formation temperature to 36°C results in crystallization of a third, very stable 2:1 y-phase isostructural with clathrates of group V C.[16] The observed phenomenon has been called pseudopolymorphism of the given host–guest complex. It also took place in case of 1.4-dioxane. pyridine. and acetone. Raising the crystallization temperature to 40°C gives 1:1 modifications relating to the I A group instead of the conventional 1:3 clathrates of 1.4-dioxane (type XII) and pyridine (type XI).[17] Pseudodimorphism is also characteristic for clathrates of Gp with acetone. but here a new 1:3 modification has been obtained by lowering the crystallization temperature to −20°C (type XPV). The remarkable feature of the latter phenomena is in resolution of the racemic Gp in such a manner that each separate crystal of the solvate contains only one Gp enantiomer.[11]

INCLUSION COMPLEXES OF GOSSYPOL BASED ON ITS ORGANIC ZEOLITE

The clathrate of Gp with dichloromethane or dibromomethane obtained under ordinary conditions is very unstable. and removing the crystal from the mother liquid leads to spontaneous desolvation. Channels occupied by guest molecules do not collapse after desolvation, giving rise to a porous structure with relatively wide (diameter about 6 Å), empty channels. In case of the complex in the form of a single crystal. the latter is retained without destruction. It is surprising that the structure of this organic zeolite is supported by weak Van-der-Waals forces. Guest-free porous Gp obtained from its unstable clathrate may serve as an initial solid-state product for preparation of Gp's nonstoichiometric supramolecular complexes with some linear molecules. Indeed. it may easily absorb from the environment molecules of ammonia. alkylamines, alcohols, etc.[18] High selectivity of this zeolite analogue toward inclusion of linear amines such as methyl- and ethylamine may serve for creation of sensors for detecting these compounds in the environment. Moreover, the channel walls of the Gp zeolite have a specific structure with only one aldehyde group on it. while another group is hidden inside the crystal. This situation makes a solid-state reaction with linear amines possible in the organic zeolite matrix, producing unsymmetric Shiff's-base-type derivatives of Gp. The solid-state reaction takes place spontaneously under ordinary conditions.[18] The Gp zeolite analogue may be used for the separation and storage of linear molecules that do not react with Gp.

Thus, Gp is a unique host molecule including any solvent molecule via the liquid phase and certain linear molecules in the solid state. To establish the driving forces behind this unique host versatility is of great interest for supramolecular chemistry and of importance for the design of new versatile host molecules.

WHY CAN GOSSYPOL INCLUDE ANY SOLVENT MOLECULE?

This ability of Gp is related to its unique molecular structure. The factors responsible are the following (in order of decreasing importance):

1. Conformational mobility of the molecule—rotation around a single aryl–aryl bond.
2. Plurality of polar functional groups and their mutual arrangement.
3. Racemic nature of the compound.
4. Hydrophobic–hydrophilic separation in the molecule.

The conformational mobility of the molecule is of crucial importance in the host versatility of Gp. By appropriate rotation around an ordinary bond. Gp adjusts its form and size for optimal packing in crystals of inclusion complexes. Plurality of proton-donor and proton-acceptor groups and their mutual arrangement make possible an inclusion of guest molecules with different types of polar groups and construction of the numerous H-bonded host aggregates. A racemic mixture is important for crystallization of inclusion complexes in many different lattices, because enantiomeric Gp complexes would be crystallized only in chirai space groups. Indeed, the inclusion ability of pure (−)-Gp is limited. Hydrophobic–hydrophilic separation in the molecule (see above) leads to such separation in Gp clathrates: hydrophobic voids are prepared for inclusion of hydrophobic guests, while polar guests are included to hydrophilic space, meaning that clathrates of polar and unpolar guests are never isostructural. However. a possible way of violating the hydrophobic–hydrophilic separation is to introduce the hydrophobic substitutents into the hydrophilic part of the molecule. This transformation may be achieved easily by preparation of the Shiff's-base-type derivatives.

HOST PROPERTIES OF GOSSYPOL DERIVATIVES

The host properties of Gp derivatives with violated hydrophobic–hydrophilic separation have been studied in the example of dianilinegossypol (DaGp). The condensation reaction of Gp with aniline proceeds spontaneously and produces a product that is chemically more stable and less soluble in organic solvents. Therefore, the synthesis of the derivative and its consequent crystallization in the clathrate form can be performed in the same vial. DaGp forms inclusion complexes with a variety of small organic molecules. However, in contrast to Gp. the derivative does not include protic solvent molecules. Moreover, deterioration of the hydrophobic–hydrophilic separation compared to the Gp molecule dramatically influences the derivative's aggregation mode. The centrosymmetric dimer O5–H...O3 or single host molecules are combined by centrosymrnetric H-bond O8–H...O7 into two types of higher-order one-dimensional networks.[6] In both cases, the networks are built from *R* and *S* host molecules. i.e., chains are heterochiral."'' The heterochiral chains are also characteristic for diastereomeric condensation products of Gp with optically active amines such as 1-phenyl-ethylamine[20] or 1-methylphenylethylamine prepared for resolution of racernic Gp by subsequent fractional crystallization. Undoubtedly, the heterochirality of the host networks is at the root of the failure of diastereomeric separation by fractional crystallization. So the most optimal combination of all factors favorable for the host versatility is found in the Gp molecule, and elimination of any of them leads to a compound with worse inclusion ability.

CONCLUSION

Gp is the only known host giving 25 types of the different isostructural supramolecular complexes (clathrates). This natural compound demonstrates dozens of kinds of biological activity. Such behavior is explained by its special molecular structure — diversity of the polar functional (six proton-donor and two proton-acceptor) groups, conformational mobility. and racemicity. This finding may be used in the future in order to design or look for the new versatile host compounds.

Guanidinium-Based Anion Receptors

Eric V. Anslyn
Suzanne L. Tobey
University of Texas at Austin, Austin, Texas, U.S.A

INTRODUCTION

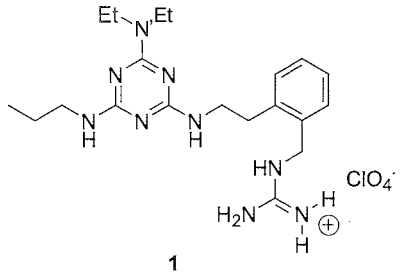
The guanidinium functional group is characterized by three amines joined to a central carbon atom (Fig. 1A). In nature, the guanidinium group is found as a side chain of the amino acid arginine and as part of the ring structure of guanine. In enzymes, arginine residues often function in catalytic reactions through charge pairing or hydrogen bonding to the activated complex, thereby imparting stabilization.[1–3,6]

In the development of effective anion receptors. many researchers in the field of molecular recognition incorporate the guanidinium group into receptor designs. The presence of one or more guanidinium groups markedly enhances the assembly of host and guest in bulk solution through electrostatic and hydrogen-bonding interactions. The guanidinium group is protonated and hence positively charged in aqueous media, with a pH up to approximately 13,[4,5] a range over which several important targets exist as anions in water. The high degree of stability of the guanidinium moiety is in part due to the delocalization of the positive charge across the three nitrogen atoms. Additionally, this delocalization renders all of the three nitrogen centers effective hydrogen-bond donors, permitting the formation of multiple hydogen bonds with multiple hydrogen bond acceptors. Another key feature of the guanidinium group is its geometry. which allows directional hydrogen bonds to be formed with an intended anionic target. Three different bonding motifs have been identified[6] (Fig. 1B), which exemplify the utility of the guanidinium group as a bidentate moiety as opposed to that of an ammonium group, for example. The delocalization. geometry, and pK_a range of the guanidinium functional group makes it very useful in anion recognition.

Anions vary in shapes and sizes, and exist in multiply charged states. They can be spherical as in the case of chloride, linear as in the case of azide. trigonal planar as in the case of nitrate. tetrahedral as in the case of phosphate, octahedral as in the case of hexacyanoferrate. and complex as in the case of dioctanol-L-α-phosphatidylcholine. Some targets for anion recognition have multiple pK_a values and can therefore have multiple charges. which depend on the pH of the solution. These features have to be taken into consideration when designing a synthetic receptor. It is the goal of this entry to exemplify the use of guanidinium groups in synthetic receptors that are designed to recognize and bind a variety of anionic targetr.

RECEPTORS DERIVED FROM A MELAMINE CORE

Yano et al. exploited the hydrogen-bonding capabilities of the guanidinium group through incorporation into a melamine derivative.[7] The synthesis of the receptor commenced with substitutions on cyanuric chloride. Various substitutions permitted the isolation of three receptors. ^{1}H NMR, UV-Vis, and fluorescence studies in chloroform yielded association constants for the binding of 6-azaflavin and 3-methyl-6-azaflavin to each of the receptors. A $K_a = 1.4 \times 10^5\ M^{-1}$ was reported for complex formation between receptor 1 and 6-azaflavin in chloroform, the magnitude of which is attributed to a complex formed via quintuple hydrogen bonds.



1

An extension of this receptor type led to complexation studies of 2 with the anionic semiquinone radical of 6-azaflavin.[8] The absorption spectrum of 6-azaflavin observed in the presence of 2 in chloroform indicated formation of the radical species. which was stabilized for a 48 h period. The anion radical was also observed by EPR spectroscopy. A binding constant of $7.7 \times 10^5\ M^{-1}$ was determined for the complexation of the anion radical, two orders of magnitude higher than complexation of 6-azaflavin with 2.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012718

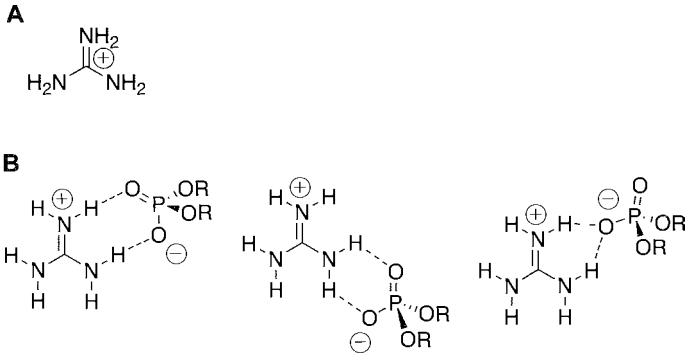


Fig. 1 A) A guanidinium group. B) The three types of bonding motifs to a guanidinium moiety.

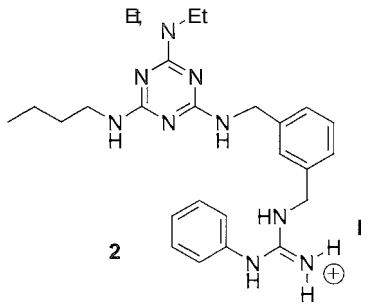
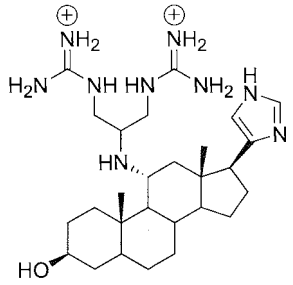


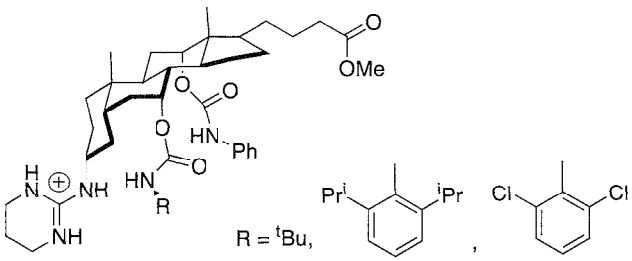
In later studies, several receptors were synthesized to incorporate the basic melamine core with different substitutions on the guanidiniurn moiety. These were used to explore the effectiveness of the hydrogen bonding of the guanidinium groups to various acceptor groups on the flavin rings.[9] Absorption studies were employed to determine pseudo first-order kinetics of the oxidation of N-benzyl-1.4-dihydronicotinamide and thiopheno! in the presence of 6-azaflavin and the receptors under anaerobic conditions. Complex formation of the flavin with the guanidiniurn moieties, through hydrogen bonding at N1 of the flavin, showed the largest rate accelerations for oxidation.

Making Use of the Steroid Scaffold

A scaffold that has been used for the design of abiotic receptors derives from steroids.[10] In research directed toward the use of abiotic receptors as mimics for RNase active sites, Malesse et al. developed a series of *bis*-(guanidinium) structures, including some derived from a steroid scaffold.[11] The compounds contain guanidiniurn and imidazole groups linked with spacers of different lengths. Hydrolysis experiments using 2-hydroxypropyl *p*-nitrophenylphosphate (HPPWP) as the substrate were monitored in acetonitrile and in water using UV-Vis spectroscopy. The observed rates were slower in acetonitrile (10^{-4} s^{-1}) when compared to water (10^{-7} s^{-1}), which the authors attributed to deactivation of the guanidinium moiety through intramolecular hydrogen bonding in acetonitrile. This was determined through ^{1}H-NMR studies on the steroid-based system. Steroid **3** had the largest rate constant for HPNPP cleavage in water (k = 14.3 x 10^{-7} s^{-1}), an increase by a factor of 10 over other (his)-guanidinium compounds studied. Receptor **3** also catalyzed transesterification behavior of the nucleotide Up(3′–5′)U with a pseudo first-order rate constant of 2.4 x 10^{-4} h^{-1}.



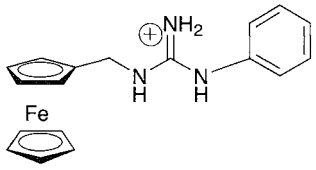
The steroid-based scaffold was also used by Davis and coworkers to effect the enantioselective extraction of *N*-acyl a-amino acids from aqueous media.[12,13] Synthetic manipulation of cholic acid delivers a family of steroid-type derivatives (4) with different binding units at C3, C7. and C12, which are predisposed to facilitate binding. A guanidinium group embedded in a six-membered ring was incorporated at C3 to enhance lipophilicity of the receptor. Variations in the asymmetry of the receptors using a variety of phenyl substituents permitted the researchers to tune the receptor for extraction of different amino acids.



4

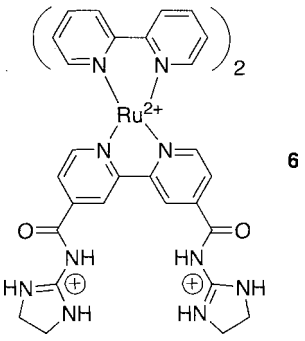
Metalloreceptors

A class of receptors that has gained increasing popularity is that of the metalloreceptors. The presence of a metallic center in a functionalized receptor ensemble can provide a binding site as well as an internal means of signaling the complexation of analytes. Beer et al. developed a ferrocenyl guanidinium binding unit for the recognition of inorganic and organic anions.[''' Receptor 5 was derived from ferrocenemethylamine and phenylmethylthiourea. Receptor ***5*** did not exhibit any binding affinities for phosphate, acetate, or benzoate based on ^{1}H-NMR studies in DMSO-d_6. However, pyrophosphate bound to **5** through hydrogen bonding with the guanidinium groupr in a 2:1 stoichiometry with K_a = 4.6 x 10^3 M^{-2}. The electrochemical behavior of the receptor in the presence of dihydrogenphosphate was monitored, and a reversible ferrocene redox wave was observed upon addition of pyrophosphate in H_2O/MeOH.



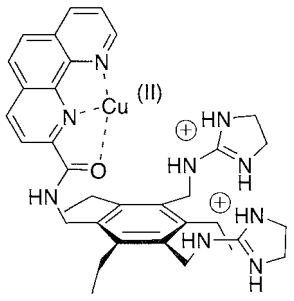
5

The work of Watanabe et al. provides another example of a receptor design inclusive of a metal center.[15] Receptor 6 makes use of an acylaminoimidazoline functionalized bipyridyl unit that simultaneously ligates a ruthenium center. The pK_a values of the acylaminoimidazoline groups were spectrophotometrically determined to be 2.0 and 3.9, significantly lower than alkyl or aryl analogues. This was thought to be a result of repulsive interactions between the metal center and the acylaminoimidazoline groups. Association of dibenzylhydrogenphosphate to 6 was monitored by ^{1}H-NMR in acetone to determine a binding stoichiometry of 1:1 and a K_a = 4.6 x 10^3 M^{-1}. Additionally, the changes in the absorption and luminescence spectra of 6, induced upon analyte addition. permitted the determination of binding constants for tetraethylammonium dipheny! phosphate and dibenzylhydrogen phosphate (3.3 x 10' M^{-1} and 4.8 x 10^3 M^{-1}, respectively) in acetone.



6

Anslyn and coworkers used a phenanthroline-bound copper moiety within a receptor design containing two aminoimidazoline functional groups.[16] The binding of citrate to 7 was monitored by fluorescence inodulation of the metallated phenanthroline unit. The complexation of 7 with citrate is thought to occur through charge pairing of two carboxylates with the guanidinium functional groups and coordination of one carboxylate to the copper center. Investigations on the photophysical properties of the system verify that the phenanthroline-bound copper and the pendant guanidinium groups work cooperatively in the binding of citrate. Application of this receptor to the analysis of commercially available beverages led to a successful quantification of citrate.



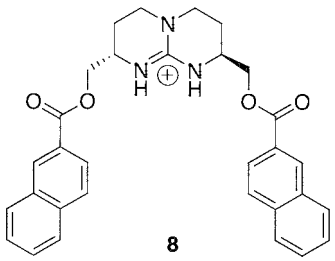
7

The Bicyclic Guanidinium Motif

A significant amount of work with guanidinium receptors revolves around a bicyclic motif exploited by Schmidtchen, de Mendoza. and Rebek. The design lends itself to a

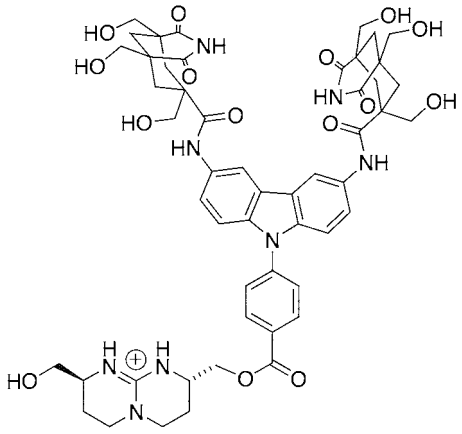
preorganized compound. while maintaining the binding abilities of the guanidinium functionality.[17] The synthetic methodologies involving guanidiniums are not typically applicable to bicyclic compounds. The syntheses of such bicyclic compounds from L-asparagine and D- asparagine were reported by de Mendoza.[18] Alternate synthetic access to the bicyclic core was reported by Schmidtchen.[19–21]

Derivitization of the bicyclic core with napthoyl groups afforded compound 8, which quantitatively extracted p-nitrobenzoate from an aqueous solution.[22] ^{1}H-NMR studies in $CDCl_3$ confirmed a 1:1 complex of 8 with triethylammonium p-nitrobenzoate and gave an association constant of 1609 M^{-1}. Binding resulted from charge pairing of the carboxylate with the guanidinium group and π-stacking of the napthoyl groups of 8 with the phenyl group of the analyte. Three additional compounds were designed with various *R* groups to access a family of lipophilic receptors.'''' The receptors were used in extraction experiments of monophosphate adenine nucleotides from water with varying selectivities. ^{1}H-NMR analysis was used to characterize the 1:1 complexes in $CDCl_3$, DMSO-d_6, and MeOD/D_2O. The complexes observed in DMSO-d_6 and MeOD/D_2O were weaker than those in $CDCl_3$, indicating the role of hydrogen-bonding in host–guest association.



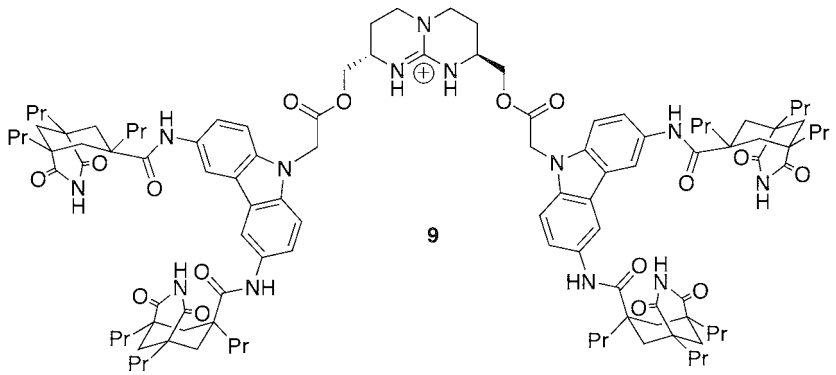
8

Incorporation of the bicyclic core into a larger macrocycle using a carbazole spacer and substituted Kemp's triacid yielded 9.[24,25] Based on extraction experiments from aqueous solutions, receptor 9 displayed a high affinity for 2'-deoxyadenyl(3'-5')-2'-deoxyadenosine. Additionally. NMR data of the complex suggested pairing the adenosine to the amide links of 9 and hydrogen bonding the phosphodiester link to the guanidinium moiety. Compound 10 was designed to incorporate the bicyclic guanidinium in a carbazole-based scaffold.[26,27] ^{1}H-NMR titrations in water were used to determine binding constants and the accompanying free energies of complexes formed between 10 and cyclic adenosine monophosphates. These data. when compared to those of a control host lacking the bicyclic guanidinium substituent. indicated that on average the guanidinium–phosphate interaction contributes 0.6 kcal/mol (ionic strength = 51 mM) and 0.3 kcal/mol (ionic strength = 501 mM) to the binding event (average ΔG of -3 kcal/mol).



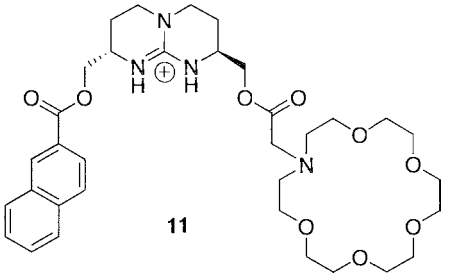
10

The design of 11 was aimed at the enantioselective recognition of zwitterionic aromatic amino acids[28] under neutral conditions.[29] The features of the receptor include a chiral structure. an aromatic substituent for n-stacking. and binding sites for a carboxylate group and an ammonium



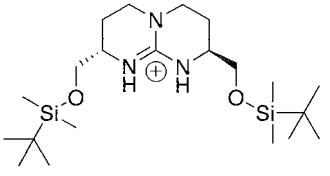
9

group. Liquid–liquid extractions were used to determine affinities of 19 seven amino acids. The largest response was found for L-tryptophan and L-phenylalanine, with extraction efficiencies of 40% as determined by ^{1}H-NMR integrations of the organic phase components. The D-enantiomers were not extracted when subjected to similar conditions. However, the (R,R)-11 receptor successfully extracted D-tryptophan and D-phenylalanine.



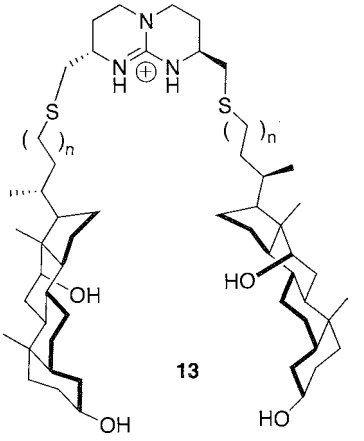
11

The introduction of silyl groups to the bicyclic core yielded **12**, which was shown to catalyze the Michael addition of pyrrolidine to unsaturated lactones.[30] Three receptor analogues were investigated. and the half-lives of the addition reactions were determined by ^{1}H-NMR. Compound **12** facilitated the largest decrease in half-life of 8.4-fold over the uncatalyzed reaction. The receptor is thought to stabilize the transition state through two-point hydrogen bonding to the guanidinium group. The catalysts did not show improvements in stereoselectivity over the uncatalyzed reaction.



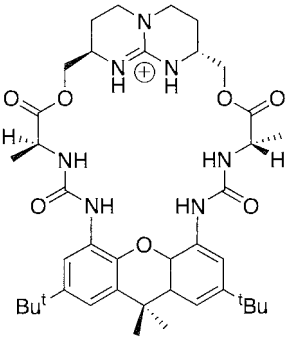
12

Modified deoxycholic side arms were placed on the bicyclic core (13) to provide a binding cavity for uronic acid salts.[31] The binding of the receptor to tetrabutylammonium D-gluconate and tetraethylammonium D-galacturonate was evaluated using ^{1}H-NMR studies in acetonitrile (K_a range = 7.0 x 10^3 M^{-1} to 3.2 x 10^3 M^{-1}). The binding constants were on the same order of magnitude when compared to a control compound, indicating that the steroid arms had little influence on the binding due to intramolecular hydrogen bonding.



13

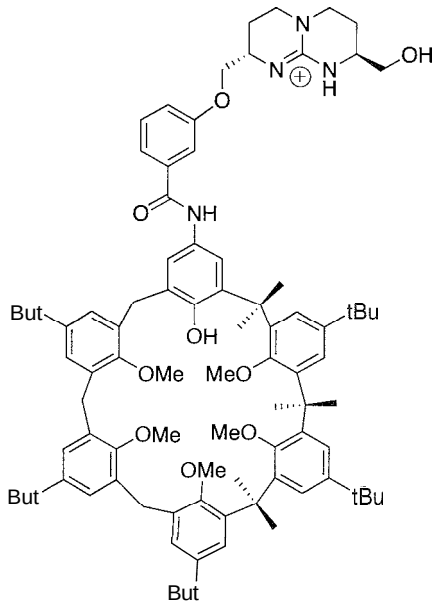
The bicyclic unit was incorporated into a macrocycle containing additional binding sites under the guise of urea groups.[32] The strength of the binding of diphenylphosphate to 14 was found to be greater than 10^5 M^{-1} in chloroform. The NMR data suggest that the analyte resides on the outside of the cavity.



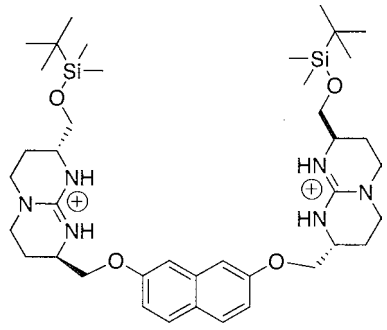
14

The combination of a calixarene subunit and the bicyclic guanidinium in macrocycle 15 demonstrates affinities for dicatonal-L-x-phosphatidylcholine (K_a = 7.3 × 10^4 M^{-1}) and acetylcholine (K_a = 7.3 x 10^2 M^{-1}) in chloroform.[33] These affinities are reduced in $CDCl_3$/CD_3OD (99:1). Kinetic studies were performed on the hydrolysis of p-nitrophenylcholine carbonate in the presence of 15, which showed a 149-fold rate enhancement over methanolysis. The guanidinium is thought to piay a role in the stabilization of the $B_{Ac}2$-type transition state. This provides an example of an artificial acetylcholinesterase.

Work by Schmidtchen involved the construction of a flexible receptor with two bicyclic guanidinium subunits appended to a 2,7,-dihydroxynapthalene core.[34] The complexation of this ditopic receptor (16) with a series of alkyl and aromatic dicarboxylates in methanol was



15

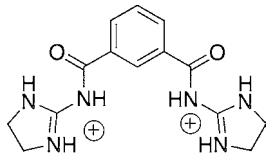


16

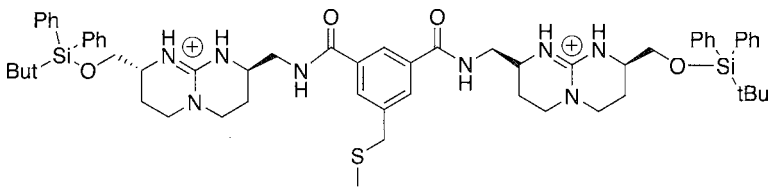
followed by ^{1}H-NMR techniques, resulting in binding constants ranging from 854–14,500 M^{-1}. Compound **16** also formed 1:1 complexes with phosphates in methanol and water when monitored by ^{1}H-NMR.[35] Alternate designs involved an alkyl spacer,[36] a peptide spacer,[37] a phenyl spacer,[38] and a phenyl spacer with an appended *closo*-borane cluster (**17**) to maintain the overall hydrophobicity of the receptor.[39] Association constants (on the order of 10^4 M^{-1}) were determined for **17** and different 0x0-anions in DMSO using ^{1}H-NMR techniques. Synthetic modifications of the receptor afforded a series of hosts that could bind sulfate in DMSO as determined by isothermal calorimetry.[40] The thermodynamic parameters indicate that complexation to 0x0-anions is entropically driven due to solvation effects.[41]

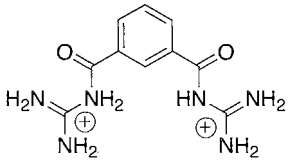
Phenyl-Based Receptors

bis(Acylguanidinium) receptors (**18**,**19**) were reported by Hamilton for the recognition of phosphodiesters.[42] The binding cavity of 19 is trigonal and complementary to dibenzyphosphate, resulting in a 1:1 complex with K_a = 4.6 x 10^4 M^{-1} in CD_3CN. Furthermore, this receptor exhibited rate enhancements of 700-fold in the hydrolysis of 2-hydroxypropyl p-nitrophenylphosphate in acetonitrile.[43] An analogue of the *bis*-guanidinium receptor was reported (20) and shown to have an affinity for glutarate of 4.8 x 10^2 M^{-1} in 12% D_2O/DMSO.[44] An extension of this receptor motif resulted in 21, with a bicyclooctane spacer that places the two guanidinium groups in proximity to interact with two carboxylates separated by 4–5 Å.[45] A 1:1 complex of **21** with aspartate pairs of peptide substrates was confirmed by NMR Job plots, and affinities ranged from 390–2200 M^{-1} in H_2O/MeOH. Binding studies of 24 with a series of peptides, using UV/Vis and CD techniques, supported the NMR studies.[46] The development of a tetraguanidinium receptor derived from the bicyclic guanidinium was reported by Hamilton and de Mendoza.[47] This receptor was used in the surface recognition of a tetraaspartate peptide based on shape and charge complimentarity in water and H_2O/MeOH mixtures. Reported are NMR, UV/Vis, and CD experiments and pH studies that confirm binding of **21** to the peptide surfaces.

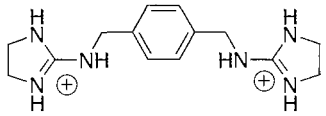


18

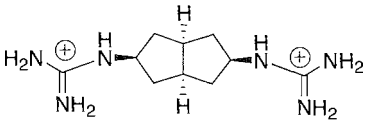




19



20

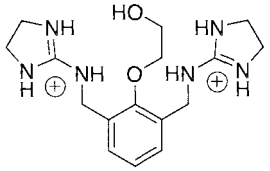


21

A variety of monoguanidinium scaffolds were used in isothermal calorimetry studies to determine the thermodynamic parameters involved in complexes with carboxylates.[48,49] The authors concluded that the guanidinium compounds form bidentate hydrogen bonds with acetate in DMSO with favorable enthalpy and entropy contributions (range K_a = 110–8700 M^{-1}). In one case. two acetates bind to one guanidinium group, which is characterized by endothermic heat patterns and positive entropy. This is suggestive of solvent reorganization.

Isothermal calorimetry and NMR titrations were used to characterize and quantify the binding of guanidinium receptors with nitronate anions in DMSO. The parameters of interest were the Gibb's free energy, enthalpy. and entropy.[50,51] The reported binding affinities indicate that nitronate anion complexation with a thiourea moiety is weaker than with a guanidinium moiety. The nitronate complex of 22 was used in investigations of nitronate alliylation reactions. A kinetic analysis of the reaction of nitronate with *p*-nitrophenylbromide in the presence of the receptor indicated that complex formation is responsible for the observed increase in the *C*-alkylation product over the *O*-alkylation product.

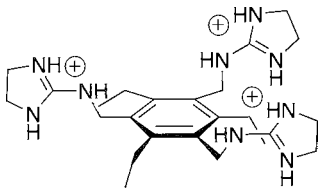
Göbel and coworkers reported the synthesis of *bis*(guanidinium) alcohols as mimics for the active site of staphylococcal nuclease.[52] The phosphorylation of these mimics with a cyclic phosphate was studied using ^{31}P-NMR methods.[53] The pseudo first-order rate constant for the phosphorylation of 23 was k_{obs} = 8.0 x 10^{-3} min ^{1} in DMF. Potentiometric titrations indicated that the acidities of the guanidinium groups are responsible for the differences observed in the k_{obs} values for various hosts.



23

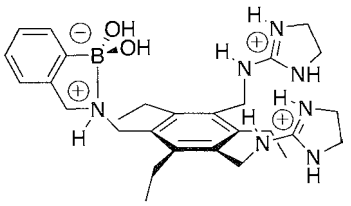
The HexaSubstituted Benzene Scaffold

Receptors are also derived from a 1,3,5-substituted-2,4,6-triethylbenzene compound. which provides a preorganized recognition scaffold with the binding moieties directed to one face of the ring. Substitutions at the 1,3,5 positions with aminoimidazoline groups resulted in **24**.[54] The complimentarity of the guanidiniums to carboxylates allowed for the determination of binding constants for several carboxylate-containing analytes. Compound 24 was found to be selective for citrate (K_a = 6.9 *x* 10^3 M^{-1} in D_2O). A crystal structure of 24 with tsicasballate bound to the cavity was reported, and it verified the orientation of the guanidinium groups to one face of the plane. Development of a competition assay in which a cavity-bound dye, 5-carboxyfluorescein, was displaced upon addition of citrate, was used to quantify the binding of citrate to the host. The assay was used to quantify the citrate content of eight commercial beverages containing competing analytes.



24

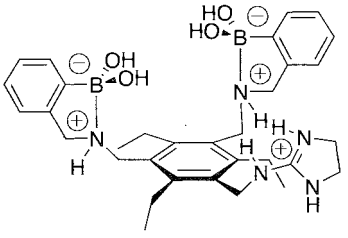
Another design involved receptor 25, in which one of the guanidinium-containing groups of 24 was replaced with a boronic acid.[55] The use of guanidinium groups for ion-pairing interactions and the boronic acid for complexing diols was intended to target the recognition of polyfunctionai analytes. The cavity of 25 was found to be effective in the recognition of tartrate (K_a = 5.5 x 10^4 M^{-1} in H_2O/MeOH 25:75) and malate (K_a = 4.8 *x*



25

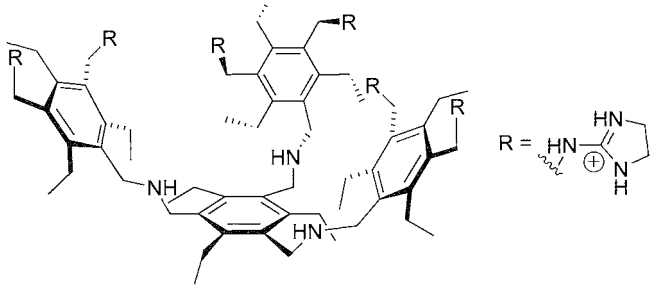
10^4 M^{-1}) based on a dye-displacement assay using alizarin complexone. The magnitude of the binding constants obtained suggests that the boronic acid and the guanidinium recognition units work cooperatively to effect binding of the analyte. Several wines were tested using this assay, and the tartaric and malate concentrations were accurately determined, as found by comparison to a control method in which ^{1}H-NMR studies were used.

Introduction of a second boronic acid functional group to the scaffold yielded compound 26, which was effective in binding phenolic acids.[56] A competition assay with pyrocatechol violet was used to determine the binding affinity for *26* for gallate (K_a = 1.0 x 10^4 M^{-1}). This sensing ensemble was used in the analysis of scotch whisky. The collective response of the host to the phenolic acid components of the whisky was correlated to the ages of the scotches.



26

An alternate approach yielded a bowl-shaped cavity with six recognition elements on the periphery (**27**).[57] The triethylbenzene scaffold aids in the orientation of the recognition units toward the interior of the cavity. Fluorescent

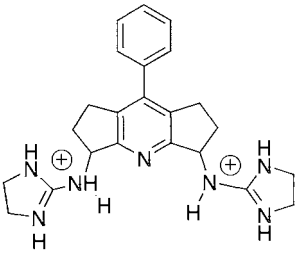


27

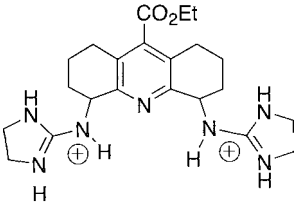
and UV/Vis methods were used to monitor the displacement of 5-carboxyflourescein from **27** upon addition of inositol-1,4,5-trisphosphate. This secondary messenger bound within the cavity with K_a = 4.7 $\times$ 10^5 M^{-1} in water.

Polyaza Clefts

Crescent-shaped polyaza clefts are commonly used in recognition ensembles.[58–62] Anslyn et al. reported the synthesis of several polyazaclefts characterized by a tricyclic core with appendant guanidiunium groups (28 and 29). ^{31}P-NMR titrations in DMSO/H_2O mixtures indicated that 29 bound dibenzyl phosphate with both 1:1 and 2:1 stoichiometries, with affinity constants on the order of 10^2 M^{-1}.[63] Receptor 29 bound dibenzylphosphate more strongly than a control host containing only one guanidinium group. An investigation on the extension of these binding motifs to phosphodiesters and phosphomonoesters yielded affinity constants on the order of 10^3 M^{-1} and 10' M^{-1} for 28 in DMSO.[64]



28

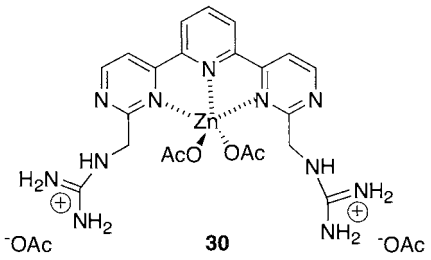


29

Modifications to the ring size of the spacer units and relative stereochemistry at C1 through synthetic means led to an array of clefts that were more or less rigid and more or less closed in architecture. These modifications resulted in manipulation of the guanidinium recognition units such that four-point hydrogen bonding with dibenzylphosphate as a surrogate was optimized. The complexes with dibenzylphosphate in DMSO/H_2O mixtures were enhanced by the presence of chloride and reduced by tetraphenylborate counterions.[65] The trends observed in the affinity constants were attributed to solvation effects of the complexes in the presence of these counterions. These observations were confirmed with a crystal structure analysis of meso-28-bound dibenzylphosphate. A participating chloride was found in the cocrystal

of *meso*-28 with bound dibenzyl phosphate. The physical studies indicated that 28 would be the most promising candidate for RNA hydrolysis studies. A kinetic assay was used to determine that 29 gave a 20.7-fold rate enhancement in the hydrolysis of mRNA when compared to imidazole alone.[66,67]

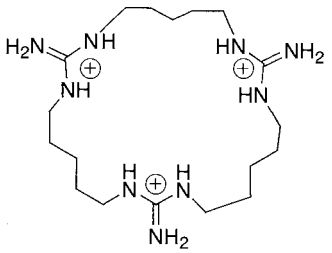
Recent work involves the use of a 2,2′:6,2″ terpyridine scaffold with a metal center and pendant guanidinium groups.[68] A dye displacement assay was employed in the determination of binding affinities for amino acids to the cavity of 30. The receptor was selective for aspartate with an affinity $1.5 \times 10^5\ M^{-1}$ in 1:1 water/methanol. Studies with the control host in which the guanidinium groups are absent indicate that the selectivity for aspartate is due to the interactions with the Zn(II) center and the guanidinium moieties.



30

Miscellaneous Designs

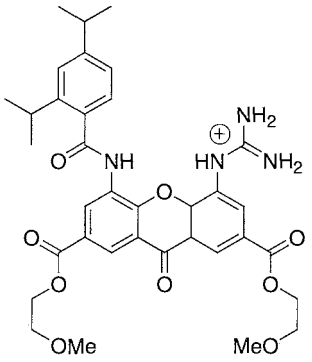
The synthesis of three polymacrocyclic compounds (31) reminiscent of crown ether designs with imbedded guanidinium groups has been reported.[69] The stability constants for binding of the phosphate anion are reported as determined from pH titrations in $MeOH/H_2O$ (9:1).



31

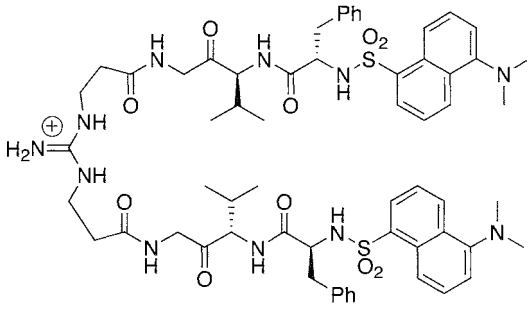
A xanthone-based receptor functionalized with a guanidinium group has been reported.[70] Complex formation with carboxylic acids is thought to occur through hydrogen bonding with the guanidinium. The association constants of several carboxylic acids with 32 in $CDCl_3$ were determined by ^{1}H-NMR studies. The reported values range from 10^9–$10^4\ M^{-1}$.

A tweezer-like receptor with arms derived from amino acids adjoined through a guanidinium group is



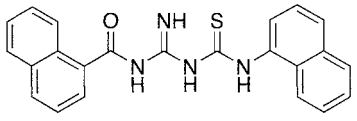
32

described.[71] Two such receptors were fluorescently labeled and used to screen a library of resin-bound peptides.[72] The receptor (33) is selective for peptides containing a carboxylic acid terminus in aqueous media. The mode of binding has not been verified but is deemed to be a result of carboxylate–guanidinium interactions.



33

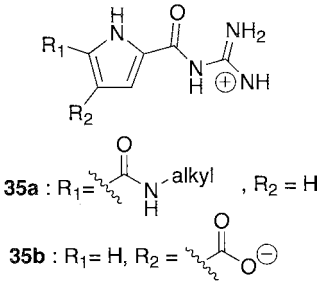
The development of a series of neutral anion receptors that undergo flourescent modulations upon complexation to anions has been reported.[73] The guanidine group in compound 34 is embedded in an iminolythiourea group. The emission intensity of the host was observed upon addition of various inorganic anions. Association of the guest to host is slow (72 h), but the increased rigidity of the host molecule upon anion complexation is thought to be responsible for the observed fluorescent enhancements. particularly in the presence of carbonate.



34

A pyrrole derivatized with a guanidinium moiety (**35a**) has been reported by Schmuck as an effective host for *N*-acetyl-α-amino acid carboxylates.[74] The binding constants as determined by ^{1}H-NMR titrations for a series of

analytes range from 10^6–10^2 in H_2O/DMSO mixtures. Further studies using a series of varied guanidiniocarbonyl pyrrole-type receptor molecules revealed that the guanidinium group and the amide NH on the pyrrole are necessary for the high K_a values reported.[75] A variation of this receptor in which a carboxylate group is appended at the 4 position (**35b**) has the propensity to oligomerize in DMSO.[76] ^{1}H-NMR titrations were used to determine dimerization constants at various temperatures for a van't Hoff plot. the results of which indicate that the oligomerization is entropy driven.

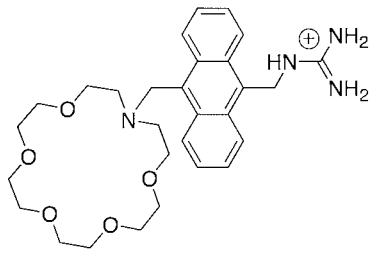


A recognition assembly (**36**) consisting of a cationic receptor (crown ether). fluorophore (anthracene), and an anion receptor (guanidinium) is used in the complexation of zwitterionic amino acids.[77] Complexation of amino acids to **36** at pH 9.5 led to an increase of the fluorescence intensity of the anthacene subunit in H_2O/MeOH. The binding constant for γ-aminobutyric acid was reported as 84 dm' mol^{-1}. while all other amino acids had lower affinities.

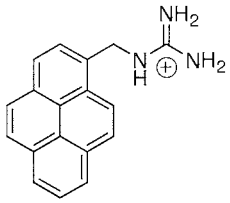
In tethering a designed core structure to solid phase with subsequent derivitization using peptide chemistry, a library of receptors as depicted in compound **37** was obtained.[78] The guanidinium group was incorporated for charge-pairing interactions, the peptide arms were intended to interact with the adenine moiety of ATP, and the fluorophore was necessary for detection protocols. Screening of the library with solutions of ATP permitted identification of derivatized beads selective for ATP. Further investigations indicated that an ATP-selective resin-bound receptor did not respond to AMP or GTP.

The incorporation of guanidinium groups in functionalized monolayers has been reported by Kunitake.[79–81] These functionalized monolayers were studied at an air–water interface and found to bind nucleotides. The reported binding affinities are on the order of 10^6 M^{-1} and were determined using XPS analyses. This was further manipulated to include mixed monolayers with guanidinium functional groups, as well as other recognition units.[82] The guanidinium and peptide amphiphiles bound peptides at the water–air surface with affinities of 10^3 M^{-1}.

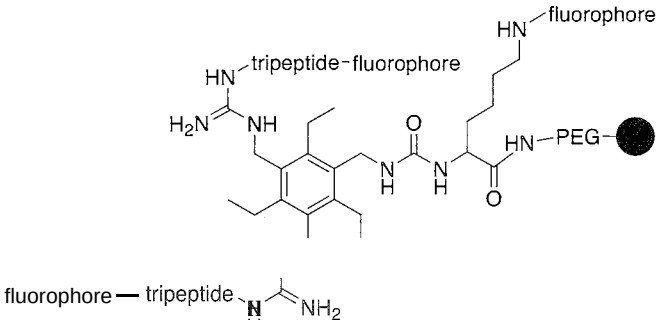
Teramae and coworkers reported an example of self-assembly for anion recognition.[83] A pyrene with an appended guanidinium group (**38**) forms complexes in 2:1 and 1:1 stoichiometries with pyrophosphate. The self-assembled complex was monitored by fluorescence and ^{1}H-NMR spectroscopy in MeOH. The binding affinity for the 2:1 complex is 9.8 x 10^7 M^{-2}, and that of the 1:1 complex is 1.3 x 10^4 M^{-1}.



36



38



CONCLUSION

The research reviewed above is representative of the utility of the guanidinium functional group in receptor designs. This functional group has gained popularity due to its inherent ability to effectively bind anions through ion pairing and hydrogen bonding. There still remains a great deal to be gleaned from using the guanidiniurn group as a binding site in receptors that are potentially more intricate in design.

Halogen Bonding

Pierangelo Metrangolo
Giuseppe Resnati
Polytechnic of Milan, Milan, Italy

INTRODUCTION

"Halogen bonding" is the term *introduced by Dumas et* al.[1] *for describing the attractive donor–acceptor interactions that involve halogen atoms functioning as* Lewis *acids. Within the framework of* Mulliken's theory,[2] *the* Lewis *bases owe their donor properties to the presence of atoms possessing one or more "lone pairs" of electrons* (i.e., N, O, S, *Se, I* , Br^-,...). *The stronger the* electron-withdrawing *environment around the halogen* atoms, *the higher their ability to be engaged in such noncovalent interactions. The resulting complexes were* considered *by* Prout and *Kamenar as belonging to the* $n \rightarrow \sigma^*$ type.[3]

The halogen bonding was first reported in 1863,[4] *and pale yellow crystals with the composition* $(CH_3)_3N \cdot Br_2$ *were obtained by directly adding trimethylamine to bromine* more *than* 100 *years* ago.[5] *While its implications impact all the fields where design and manipulation of* aggregation *phenomena play a key role, halogen bonding only recently has become an object of serious study as a well-defined, strong. specific. and directional interaction for* assembling complex *supramolecular architectures.*

Hassel *first deinonstrated that* halogen *bonding* is *a powerful tool in* driving the *self-assembly of endless chains of alternating donor and acceptor* modules.[6] *His solid-phase studies (using x-ray crystallography)* unequivocally *established the existence of a* D···X (*D=electron-pair donor, X=electron-pair halogen acceptor) interaction with a defined linear* geometry.[7] *These studies* suggested *an analogy with the hydrogen bonding. Theoretical and* experimental *data show that the two interactions have* comparable strengths.[8] *loth are also highly directional.* Similar *to the binding geometry in hydrogen bonding, halogens are directly linked to donor* atoms *with a bonding direction that roughly coincides* with *the axes of the lone-pair orbitals in the* non-complexed donor *molecule. Moreover, as expected for an* $n \rightarrow \sigma^*$ *interaction, the* N···X–C *angle in intermolecular halogen bonding spans over the range of* 160–180°, even *for weak interactions* (>3 Å *when iodine or bromine are* involved). Interaction *strength and* directionality *support* the *idea that the halogen bonding is of a "specific" type.*

HALOGEN BONDING

Halogen atoms that are involved in halogen-bonding formation can be bound to other halogens (elemental halogens and interhalogens) or to carbon or nitrogen atoms. The electron-pair donors can be neutral (N, O, S, *Se,...) or anionic* (*I* , *Br* , Cl^-, *F* ...) species.[9] *Interaction of these motifs results in a wide diversity of* supramolecular synthons *(Fig.* 1).

Calculations and experimental *data (in solid, liquid. and gas phases) show that the tendency of different halogens to give strong halogen bondings is* I>Br>Cl>F, *namely, opposite to the sequence of their* electronegativies. *Due to this, reports* on *short contacts having fluorine as the acceptor site are* rare,[10] *and they were never encountered in the solid state.*

The interaction energy spans the range 10–200 kJ mol^{-1}. *The lower value* is *calculated for the weak* N···Cl *halogen bonding, while the higher one is reported for the very strong* $I^- \cdots I_2$ *halogen bonding in the* I_3^- anion.[11]

Statistical studies carried out on the Cambridge Structural Database (CSD) confirmed *the existence of the halogen bonding. An accurate study by Lommerse et* al.[12] *on the* D···X–C (*D*=O,N *and X*=F, Cl, *Br. I) interactions demonstrates that the more electron withdrawing the carbon framework of the halocarbon is, the stronger* the *halogen bonding. Usually, the order of acceptor strength is* X–X>X–C(sp)>X–C(sp^2)>X–C(sp^3). *According to these studies, the attractive nature of the interaction is mainly due to electrostatic effects.However, polarization.* charge-*transfer, and dispersion contributions play important roles in the interpenetration of van der Waals* volumes *of halogen and donor atoms. Whether or not electrostatic or charge-transfer effects are the* main *cause of the complex formation still* remains *an open question. This also holds for hydrogen bonding. another entry thus being added to the analogies listed between the two interactions.*

The relative donor ability of different heteroatoms depends on the halogen partner, the analytical *technique used for the measurements. and the aggregation state of the complex. Toward iodo- and bromoperfluorocarbons and in solution. the* ^{19}F-NMR *technique gives the donor strength scale* N>S≥O, *when that all the donor atoms are in the same* sp^3 *hybridization state."" Fig. 1 Most frequently used halogen-bonding-based supramolecular synthons. Electron-pair donor sites were reported in black, while the acceptor sites are in grey. (*View this art in color at www.dekker.com.*)

state. the scale O>S was suggested, and recent theoretical calculations gave the scale P≥N>S [14] The donor strength scales N(sp^3)>N(sp^2)>N(sp) and O(sp^3)>O(sp^2) are fairly general, and increased electronegativity of substituents on the electron-donor atom decreases the strength of the halogen bond they form. Conversely, increased electron density on the electron donor results in stronger Interactions and it is thus not surprising that aromatic N-oxides or anions are good donors toward halocarbons.[15]

Some of the characteristics of halogen bonding depend on the nature of the interacting partners. for instance. the relative role of the specific forces acting between the atoms involved (e.g., electrostatic effects. polarization, charge-transfer, dispersion contributions). Some other characteristics remain constant in a wide variety of cases,

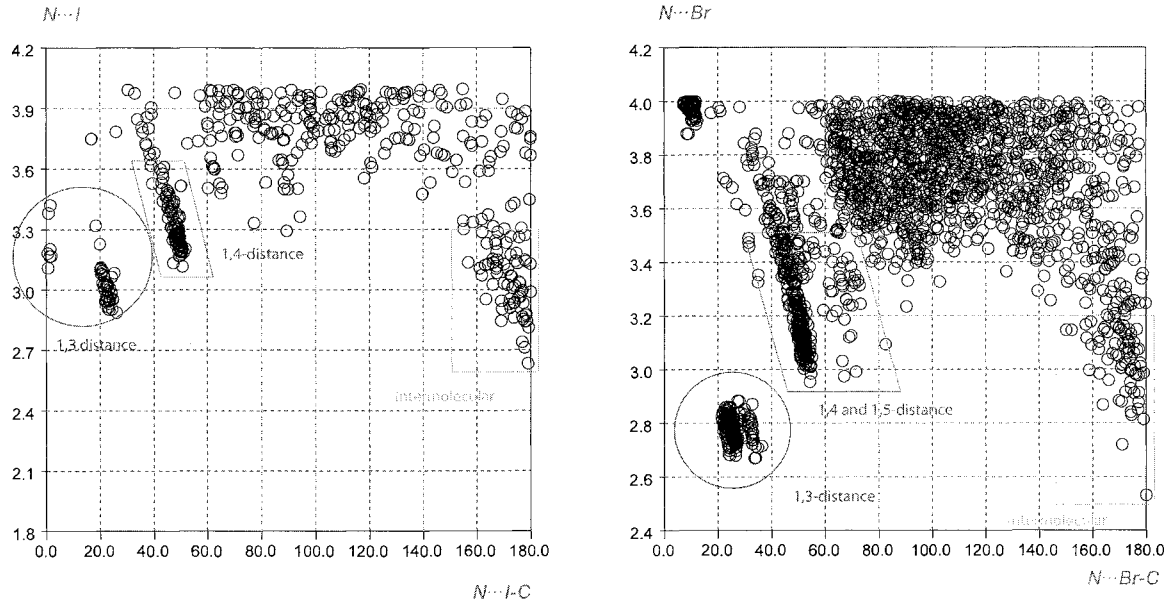

Fig. 2 The CSD scatterplots of N···X halogen-bonding distance versus N···X-C angle for X=I (left) and Br (right). Intra- (1,3-, 1,4-, 1,5-distances) and intermolecular contacts below 4 Å were reported. Error-free structures showing no disorder and with $R<0.06$ were considered. (*View this art in color at www.dekker.com.*)

for example, the angle D···X–C formed by the covalent and noncovalent bonds around the halogen atom (approximately 180°) and the value of the D···X distance for halogen bondings involving the same donor and acceptor atoms. The CSD scatterplots of N···X halogen-bonding distance versus N···X–C angle for X=I (left, 522 structures) and Br (right, 2107 structures) are reported in Fig. 2.

These plots show how the halogen bonding occurs both intra- and intermolecularly. Clearly, it may play a key role in understanding the conformational preferences of molecules and in designing the construction of supramolecular architectures.

Hundreds of supramolecular structures grounded on halogen bonding were reported since the seminal work of Hassel. The following part of this article will survey some

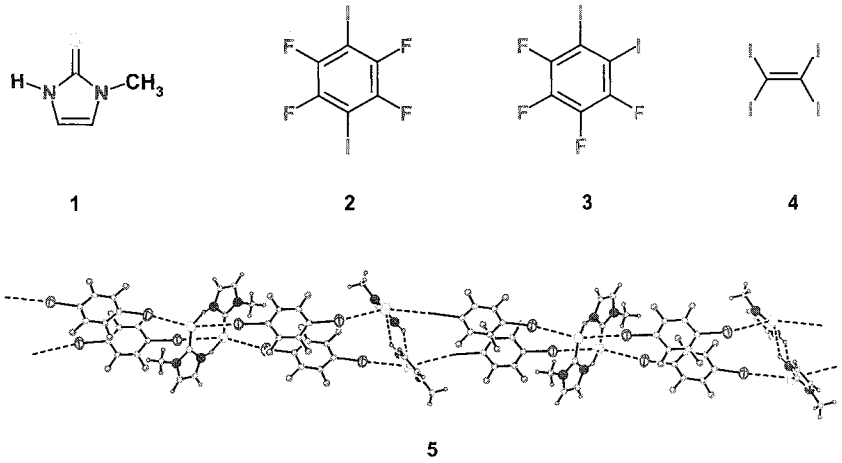

Fig. 3 Double-stranded chain structure in the halogen-bonded co-crystal **5** between 2-mercapto-1-methylimidazole (**1**) and 1,4-diiodotetrafluorobenzene (2). specimen examples proving the great potential of halogen bonding in the design of new and high-value functional materials, interpenetrated architectures,[16] etc.

2-Mercapto-1-methylimidazole (1) functions as an iodine sponge forming a stable halogen-bonded complex with the I_2.[17] Pennington et al. recently reported the preparation of new complexes of 1 with the organic iodides 1.4-diiodotetrafluorobenzene (2), 1,2-diiodotetrafluorobenzene (3). and (4) tetraiodoethylene.[18] All of these structures are characterized by the simultaneous presence of remarkably similar N–H···S hydrogen-bonding patterns and I···S halogen-bonding patterns. Endless one-dimensional (1D) chains of alternating donor 1 and acceptor 2 are present in cocrystal 5. which is formed through I···S···I interactions where sulfur works as a bidentate donor (Fig. 3).

These chains are then joined into supramolecular double strands through N–H···S interactions that link two molecules of 1 into a dimer. The other two complexes given by 1 show a similar supramolecular organization. This demonstrates the great potential of these components for crystal design. Moreover, hydrogen and halogen bondings can be seen as competing noncovalent interactions.[19] They can, however. also cooperate in the building of remarkably complex supramolecular structures.

The research for organic conductors in the last two decades revealed that if interesting electronic properties, such as superconductivity. are pursued, the design and control of the supramolecular arrangement in the crystal structure are as important as the design of an individual donor or acceptor molecule. For instance. the introduction on tetrathiofulvalene donor molecules (TTFs) of specific substituents able to be engaged in weak intermolecular interactions was extensively used in numerous molecular organic conductors with the aim of controlling the supramolecular arrangement of molecules in their crystal structures. The application of the hydrogen bond to TTFs was examined, but the intrinsic flexibility of the hydrogen bond was found to hinder reliable control of the organization of the crystal matrix. T. Imakubo et al. found that the N···I halogen bonding is suitable for this purpose, and they reported several unique crystal systems of supramolecular organic conductors based on the iodine-bonded TTFs.

Presented in Fig. 4 is the crystal structure of 8, which is the $Au(CN)_4^-$7 salt of diiodo(ethylenedithio)diselenadithiafulvalene (DIETS, 6),[20] with a 6/7 ratio of 2.

The two modules 6 and 7 stack separately into different layers that are joined by halogen bonding between each iodine atom of and the cyano groups of two different and adjacent $Au(CN)_4$ anions. The N···I halogen bonding distance is approximately 3 Å. These materials showed an onset temperature of the superconductivity under uniaxial strain parallel to the crystallographic c-axis.

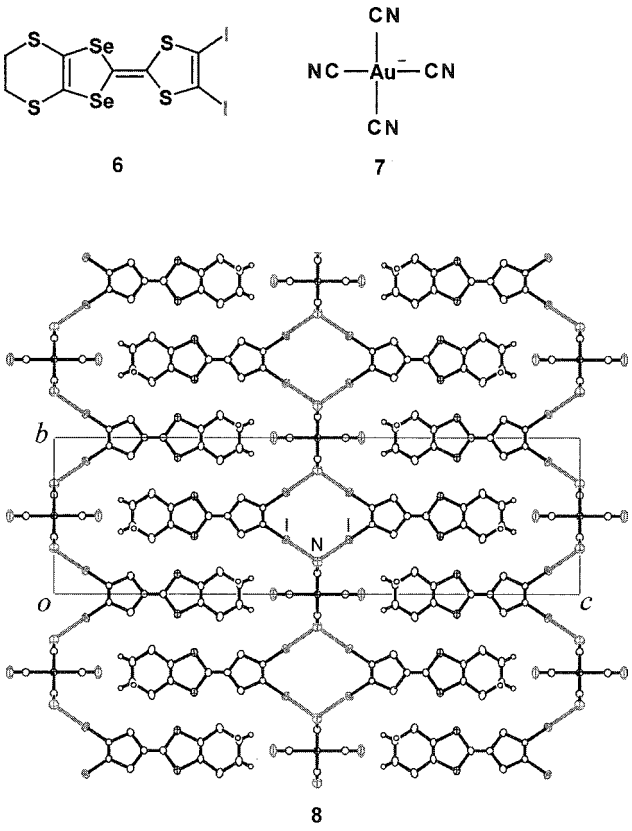

Fig. 4 Crystal structure of the salt 8 compounded by two molecules of diiodo(ethylenedithio)diselenadithiafulvalene (DIETS. 6) and one anion $Au(CN)_4^-$7 viewed along the a-axis. Halogen-bonding distance N···I=3.018(7) Å. Colors are as follows: black 70%—nitrogen: black 50%—iodine. Continuous gray lines represent halogen bonding?. (*View* this art *in* color *at www.dekker.com.*)

which is the highest among the known superconductors based on unsymmetrical organic π-donors. There seems to be no doubt that the strong halogen bonding between the layers of DIETSs and counteranions is stronger than the side-by-side chalcogen···chalcogen contacts in conductors based on TTFs. This affects the distortion manner under the uniaxial strain and. consequently, increases superconductivity.

Halogens, mainly I_2 and Br_2 but also Cl_2, interhalogens, such as ICl and IBr, and pseudohalogens, like ICN, have traditionally played a key role in the identification of the structural aspects of the halogen bonding. Nevertheless, these molecules may not be the ideal modules for defining the inherent characteristics of this intermolecular interaction. For instance, one or both of the iodine atoms of I_2 can work as electron acceptors, depending on the strength of the electron-donor species. Because of this, it is difficult to control the supramolecular architecture of the formed cocrystals. In other cases, I_2 can even work as

an amphoteric species, where one iodine atom functions as electron acceptor and the other as electron donor. More recently. particular attention was paid to triiodo- and tribromomethanes, as well as their tetrasubstituted analogues. and diiodobenzene derivatives.[21]

Resnati and Metrangolo et al. introduced dihaloperfluorocarbons, which are compounds of technological relevance. as new tectons for the construction of supramolecular systems, where halogen bonding could be studied free from interference of other interactions. Fluorine atoms and perfluorinated residues are strongly electronegative. As a consequence, the electron-accepting ability of halogen atoms in perfluorocarbon (PFC) halides is definitely higher than in the corresponding hydrocarbon (HC) halides. Different from C–H groups in HC halides, C–F groups in PFC derivatives have a weak tendency to give rise to any attractive interactions. As a consequence, the use of PFC halide5 minimizes possible interaction interferences in a pattern controlled by halogen bonding. Moreover, unlike the zigzag organization of the alkyl chains of their HC parents, PFC chains adopt an all-trans, rigid, rod-like twisted conformation that causes their typical alignment in parallel bars. Due to this behavior, telechelic dihaloperfluorocarbons can be considered ideal ditopic 180° tectons for halogen-bonding-based crystal engineering, with metrics that can be tuned by simply

choosing perfluoroalkyl chains of different lengths. The peculiar properties of perfluorocarbons along with the precise geometrical features of the halogen bonding allow a degree of architectural design that is unusual for supramolecular chemistry.[22]

The optical resolution of racemic molecules with a basic or an acidic functional group is frequently performed by resorting to hydrogen bonding to form diastereoisomeric salts with one of the numerous acid or basic resolving agents available in the literature. The use of halogen bonding as the driving force in the diastereoisomeric adduct formation for the resolution of chiral but racemic halocarbons was also reported.[23] Specifically, chiral haloperfluorocarbons are a virtually unknown class of compounds, and racernic 1,2-dibromohexafluoropropane (10) was resolved for the first time through cocrystallization with enantiopure (−)-sparteine hydrobromide (9). The driving force toward the cocrystallization is the $Br^{-}\cdots Br–C$ halogen bonding between bromide ions, which function as electron donors, and carbon-bound bromine atoms, which work as electron acceptors. Each bromide ion bridges the primary and secondary bromine of two distinct PFC units 9, each of which is bound to two adjacent bromide ions. Enantiopure infinite twofold helices develop parallel to the *b* axis (Fig. 5).

The resolution of 9 is the result of the highly specific inclusion of solely the (S) enantiomer in the chiral crystal 11 with a "halogen-bonded" helical arrangement. This arrangement maximizes the transfer of information from the HC to the PFC units.

From a supramolecular point of view, anionic species play a key role in many mineral or biological routes. Despite this, however, anion-centered self-assembly processes were little explored. Recently. anion coordination was addressed mainly through the design of *endo*-receptors; on the contrary, the electron-poor organic halides work effectively as *exo*-receptors of anions. The ability described here of the halide anions to act as electron donors to carbon-bound halogens may develop as a general protocol for halide-centered supramolecular chemistry.

Finally, the ability of the neutral halogen atoms to function as electron-pair donors toward other halogen atoms should be mentioned. Price et al. demonstrated the importance of the nonspherical atomic charge distribution on the halogens in directing the halogen–halogen interactions.[24] Desiraju convincingly argued that the halogen–halogen interaction, while weaker and less directional than other halogen bondings, is an attractive force that can be used for manipulating and organizing the supramolecular structure within a crystal.[25] In particular, triangular X_3 (X=Cl, Br, I) supramolecular synthons were extensively used in the design of hexagonal networks based on tritopic 120° tectons. such as 1,3,5-trihalobenzenes. Interesting examples of two-dimensional (2D) sheet-like structures[26] and hexagonal nanoporous architectures, also capable of hosting guest species with chiral discrimination,[27] were obtained.

CONCLUSION

"Does the concept of halogen bonding *contribute* to an *explanation* of *some* aspects *of* reactivity or *biological activity?*"

Reactions between dihalogen molecules XY and simple Lewis bases are of fundamental interest in organic and inorganic chemistry. Legon et al. demonstrated that the formation of prereactive halogen-bonded complexes D···XY characterizes the gas-phase chemistry of these reactions.[28] Thus, the halogen bonding may evolve into a covalent-bond-making reaction.

The use of halogell-substituted organic compounds as general anesthetics led to the investigation of the

mechanism of this activity. A nonspecific mechanism was proposed[1''' following the unitary theory of Overton. Halotane (1-bromo-1-chloro-2,2,2-trifluoroethane, 12) is a common volatile anesthetic used in therapy in the racemic form. The two enantiomers have different pharmacological activities: and the measured eudismic ratio was attributed to the specific binding with proteinaceous receptor sites. The enantioselective recognition of the drug in vivo may be mediated by the formation of halogen-bonded complexes with electron-pair donors present in the receptor pockets. This hypothesis is also supported by the evaluation of haiogen-bonding mediated intermolecular recognition in solution through the use of synthetic receptors.[30]

The x-ray crystal structures of complexes between halogen atoms containing drugs and their specific proteinaceous receptors have unequivocally proven the existence of halogen bondings that optimize the receptorial fitting. For example, short contacts were found between the iodine atoms of thyroid hormone thyroxin (T4) and the carbonyl oxygens of the aminoacidic residues in the pocket of transthyretin (TTR). which is the major transporter of T4 in the human body.[31] Short O···Cl and S···Cl contacts were detected in the crystal structure of the coinplex between the factor *Xa* of the human blood coagulation cascade and the inhibitor **13** (Fig. 6). which is used in the treatment of thrombotic diseases.[32]

The halogen bonding was also proposed to be involved in the toxicity mechanism of polyhaiogenated aromatic compounds, which are persistent environmental pollutants.[33]

''Does halogen bonding *open new perspectives in supramolecular chemistry?''*

The careful control of the overall architecture of crystalline organic solids is a topic of current intense interest, with the aim of obtaining desirable and useful properties. Metal coordination and hydrogen bonding are, by far, the most studied noncovalent interactions that drive the self-organization of inorganic and organic supramolecular structures, respectively. New interactions will have to he searched actively. because future crystal engineering projects will require full utilization of various methodologies. Halogen bonding represents an effective and reliable tool for crystal engineering. It can be considered a new item on the palette of noncovalent interactions at the disposal of the chemist to be used as the cement for assembling molecules into supramolecular structures.

New protocols based on halogen bonding were exploited to overcome the low affinity between perfluorocarbons and hydrocarbons. to design new molecular conductors, to prepare pseudopolyhalide salts,[34] to resolve racemic mixtures, to control polymorph interconversion,[35] and to tune the reactivity in the solid state.[36]

These results open new opportunities in the design and manipulation of molecular aggregation processes. The implications extend to diverse fields, such as organic chemistry, biopharmacology. and materials science.

Hemoglobins: O_2 Uptake and Transport

J. Timothy Sage
Northeastern University, Boston, Massachusetts, U.S.A.

INTRODUCTION

Enormous protein molecules containing many thousands of atoms execute the fundamental processes of life. In several remarkable cases. these molecular behemoths are designed to interact with the smallest molecules known, consisting of only two atoms. In particular, following the development of an oxygen atmosphere; many organisms evolved more efficient metabolisms based on reduction of O_2 to H_2O. In large organisms, specialized proteins enhance the transport of molecular oxygen.

These oxygen-binding proteins occupy an important place in the field of supramolecular chemistry. Because of the relative simplicity of diatomic ligand-binding reactions, these proteins provide outstanding laboratories for exploring the control of reactions by a highly organized local environment. The reaction takes place at a transition metal, and a number of highly selective spectroscopic probes can specifically monitor the electronic and vibrational properties of the active site. Molecular variants of naturally occurring proteins can test the influence of individual amino acids on the reactivity of the active site.

HEMOGLOBINS

The adult human body typically contains 3–4 g of Fe.[1] Approximately two-thirds of this Fe is bound to the oxygen transport protein hemoglobin,[2,3] located in red blood cells. Hemoglobins are also found in muscles and in the nervous system,[4] and in a wide range of species, including bacteria, plants. and animals.[5]

Hemoglobins share a common molecular architecture, composed of a polypeptide backbone and an iron porphyrin, as illustrated in Fig. 1. Molecular oxygen binds to the Fe at the center of the planar heme b (Fe protoporphyrin IX). The polypeptide adopts the globin fold constructed primarily from a-helices, customarily labeled with the letters A–H.[2] The heme group binds tightly to a hydrophobic pocket formed primarily from the E- and F-helices. and a bond between the heme Fe and the ε-nitrogen of a histidine in the F-helix (His F8) provides the only covalent link between the polypeptide and the heme.

The structure shown in Fig. 1. with a molar mass near 17.000 g, can form a building block for more complex molecules. The hemoglobin found in red blood cells is a tetramer formed from chemically distinct x- and β-subunits (two of each), which both adopt a globin fold. In common usage, hemoglobin (Hb) usually refers to the form of this tetrameric molecule found in adult humans. The monomeric hemoglobin from muscle tissue depicted in Fig. 1 is called myoglobin (Mb) to distinguish it from the Hb in blood.

The polypeptide matrix surrounding the heme active site plays an essential role, because iron porphyrins can participate in a wide variety of reactions other than simple binding, transport, and release of O_2. Burial of the active site in the protein interior restricts access to the immediate vicinity of the iron and protects the heme from possible reactions with larger ligands. including other hemes. The local environment of the oxygen-binding site must also enhance the selectivity of the heme for O_2 binding and release relative to undesirable side reactions. Possible heme reactions that must be guarded against include poisoning of the O_2-binding capability of the heme by other small ligands such as CO and activation of the bound O_2, which could lead to the irreversible oxidation of the heme or to the generation of reactive oxygen species such as peroxide and superoxide.

The reactivity of the active site is controlled not only by the chemical identity of amino acids in the active site but also by the positions of these groups. Moreover, these atomic positions are modulated by the dynamics of the global protein conformation. The characteristic dynamics of proteins allow their functional behaviors to respond to changing metabolic demands. Hb is a classic illustration, because the change in the arrangement of the four subunits on oxygen binding in the lungs permits the efficient cooperative release of oxygen from all four hemes in oxygen-poor tissues.'" The inaccessibility of the oxygen-binding site from solvent in the static structure of Fig. 1 also underlines the need for dynamical fluctuations to allow O_2 to penetrate and escape.

Summarized in Fig. 2 are some of the key geometrical factors and groups involved in controlling O_2 transport by hemoglobins. Protein influences on the active site of heme proteins are conventionally classified as proximal or distal. Proximal mechanisms for protein control of heme reactivity involve the covalent link with the protein through the histidine (His F8) ligand *trans* to the oxygen-binding site. Distal interactions involve direct interactions of

amino acid residues in the oxygen-binding pocket, such as the distal histidine (His E7), with the bound ligand.

Mb and Hb were the first proteins for which x-ray diffraction provided structural models with atomic detail.[6,7] As a result. they were investigated in great depth,[8] and textbooks often use these proteins to illustrate fundamental biochemical principles.[9] Many fundamental questions remain unanswered, but an understanding of some effects is beginning to emerge. For example, the physiologically crucial mechanism by which these proteins avoid being poisoned by endogenously produced CO was clarified in the 1990s, and new observations continue to refine the understanding of cooperative oxygen binding by Hb. Mb and Hb remain models for detailed investigations of protein dynamics,[8] and significant progress is now being made in understanding dynamical processes that allow for the penetration of small molecules to the buried active site.

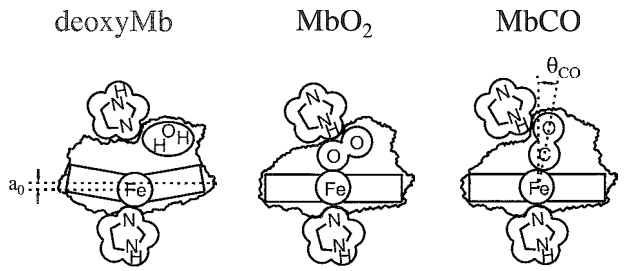

Fig. 2 Factors controlling diatomic ligand binding to hemoglobins. The Fe atom is displaced from the mean plane of the heme in deoxyMb (left) and moves into the heme plane on binding O_2 (center) or CO (right) Through the proximal histidine the protein may influence the Fe displacement a_0 and thus the energetic barrier to ligand binding. The shape and polarity of the proximal pocket stabilize O_2 binding through hydrogen bonding with the distal histidine (center) and destabilize CO binding by angular displacement θ_{CO} of the bound CO from its equilibrium geometry perpendicular to the heme plane (right).

DISTAL CONTROL OF REACTION SPECIFICITY

Interaction with residues in the heme pocket is the most direct means for the protein to influence the free energy of ligand binding. These interactions depend on the nature of the bound ligand and allow the protein environment to

selectively discriminate between the binding of O_2 and other small molecules. In particular, the binding affinity of CO is approximately 20,000 times the affinity of O_2 for free heme, but the CO/O_2 affinity ratio is reduced to about 25 for Mb.[10] This highly efficient discrimination between CO and O_2 is essential to prevent poisoning of the oxygen-binding site by endogenous CO, produced in the breakdown of heme.[11] Electronic and geometric differences in the nature of bound CO and O_2 allow distal residues to discriminate between these ligands.

Electrostatic Stabilization of Bound Oxygen

Binding of O_2, but not CO, is accompanied by substantial transfer of charge from the heme, giving rise to distinct charge distributions for the O_2 and CO complexes. Pauling [12] originally suggested that hydrogen bonding with the evolutionarily conserved distal histidine residue stabilized the bound O_2. This is now recognized as an essential factor. Crystallographic and spectroscopic evidence support the presence of a strong hydrogen bond between His E7 and O_2 in Mb and Hb,[13,14] and NMR data confirm hydrogen bonding to O_2 in both α- and β-chains of Hb.[15]

Extensive studies of mutant proteins establish a quantitative basis for stabilization of O_2 binding by the distal histidine. When His E7 is replaced with nonpolar residues, the oxygen affinity of Mb or the α-hemes in Hb drops by two orders of magnitude. largely because of an enhanced rate for O_2 dissociation.[10] Spectroscopic evidence also suggests hydrogen bonding of the distal histidine with CO in Mb.[16] Computational studies confirm these conclusions but estimate that the hydrogen bond to O_2 is 7–21 kJ/mol stronger than that to CO,[17,18] in reasonable agreement with the mutant studies.

Another distal factor is the presence of a water molecule bound to the distal histidine in deoxyMb, which is displaced upon ligand binding. The energetic cost of displacing the bound water. and thus its proposed influence on ligand binding,[10] is unclear. However, because CO or O_2 binding displaces the distal water, it has no influence on discrimination between these ligands.

Steric Discrimination Against CQ Binding

Significant differences in the energetically favored binding geometries of the bound ligands provide another possible criterion for discriminating between O_2 and CO binding. In the absence of the protein. bound CO is oriented perpendicular to the heme plane, while the O—O bond of bound O_2 lies approximately 60° from the heme normal. Thus, distal pocket residues could sterically discriminate against CO binding by displacing bound CO away from its energetically preferred structure.[11] In the 1990s, a semiquantitative reevaluation of the importance of steric destabilization of CO binding relative to electronic stabilization of O_2 binding was seen.

On one hand; more precise structural information from infrared crystallography[19,20] and ultrafast infrared photoselection measurements,[21] subsequently confirmed by high-resolution x-ray diffraction,[22] showed that the displacement θ_0 of the C—O bond from the perpendicular (Fig. 2) was smaller than previously believed. On the other hand, calculations revised downward the force constant κ for displacing CO from linearity.[23] Current estimates of the energetic cost $(1/2)\kappa\theta_0^2$ for the small displacement of bound CO from linearity observed in high-resolution x-ray structures of MbCO lie in the range 1–4 kJ/mol.[24] The additional energetic cost associated with displacement of distal pocket residues to accommodate the upright CO geometry[19] or with reorientation of the E- and F-helices[22] on ligand binding is more difficult to evaluate. Assuming that the latter contribution from protein distortion is equal to that of the heme-CO distortion yields an estimate[12] consistent with mutant studies,[10] indicating that the steric destabilization of CO binding is smaller than the enhancement of O_2 binding by the H-bond with the distal histidine. However, it is worth noting that approximately 1% of the Hb in the body of a nonsmoker is saturated with CO,[25] and a 2–8 kJ/mol enhancement of discrimination against CO binding may be a significant factor in maintaining this low level.

PROXIMAL INFLUENCE OM HEME REACTIVITY

In addition to interacting with the bound ligand, the protein can directly modulate heme reactivity by influencing atomic motion along the reaction coordinate connecting the ligated and deligated structures. Early structural data on porphyrin model compounds, as well as Hb, identified motion of the Fe into the plane of the heme, accompanied by adoption of a more planar porphyrin structure, as the most apparent structural change upon binding O_2 or other ligands.[26,27] The proximal histidine, which links the protein F-helix directly to the heme Fe. provides a natural conduit for influencing the "doming" of the heme. and thus for controlling ligand binding and dissociation *trans* to the histidine. In particular, changes in the positioning of the proximal histidine and the F-helix can control the affinity for O_2 and other exogenous ligands by influencing the energetic cost of changes in heme geometry that take place on ligation.

The largest effect attributed to this proximal influence is probably the control of ligand-binding affinity in Hb. Two distinct quaternary structures were identified for Hb (see next section). The R-state has a ligand-binding affinity between two and three orders of magnitude higher than that of T-state Hb, depending on solution conditions.[28] The rupture of the Fe–His bond of the r-hemes upon NO binding to deoxyHb or CN^- binding to metHb in the *T*-state strikingly illustrates the protein restraint on Fe motion into the heme plane.[29,30] The approximate $10\,cm^{-1}$ reduction of the Fe–His bond-stretching frequency in the T-state was also attributed to protein-induced strain in this bond.[31,32]

A particularly incisive method for evaluating the contribution of ihe covalent link with the protein is to sever the bond connecting the histidine imidazole ring and the protein backbone.[33] In these "proximally detached" hernoglobins, the electronic character of the heme–irnidazole complex is unchanged, but the protein can no longer control the heme conformation through the Fe–His link. In Hb. removal of the bond connecting the imidazole to the F-helix increases the T-state ligand-binding affinities, and quantitative comparison of CO binding and dissociation rates with R- and T-state native Hb confirins that the difference in affinity of the α-hemes is primarily controlled by the proximal linkage.[33]

In addition to restraining the motion of the imidazole toward the heme piane. the protein may also control the orientation and electronic character of the imidazole. In Hb and Mb, residues surrounding the proximal histidine restrain it in an eclipsed orientation relative to the pyrrole nitrogens. Because the imidazole ring follows the Fe into the heme plane on ligand binding. steric repulsion between the pyrrole nitrogens and the 6- and c-carbons of the irnidazole ring may influence the relative energy of the ligated and deligated hemes. Hydrogen bonding of the histidine N_δ with the backbone carbonyl at F4. as well as with the serine located at F7 (in Mb, but not in Hb) could also help stabilize this orientation or perturb the electronic character of the imidazole. In fact. mutations that remove the hydrogen bond to the imidazole or change its orientation lead to modest changes in ligand affinity.[34]

In summary, there is considerable evidence that the protein can influence the ligand-binding affinity through the proximal histidine. Mutant studies provide sorne information on the strength of such effects. However, further investigation is needed to bring the understanding of proximal effects to the same quantitative level that is beginning to be achieved for distal interactions. The hypothesis that the energetic cost $(1/2)ka_0^2$ of Fe displacement relative to the heme plane quantitatively determines variations in the free energy of ligand binding[35] is compelling, but quantitative tests will require experimental input on the effective force constant k for Fe displacement perpendicular to the heme. Emerging techniques may yield this information.[36,37]

COOPERATIVE OXYGEN BINDING IN HEMOGLOBIN

Hb is responsible for transporting molecular oxygen from the lungs to the tissues. The hemes of Hb are almost completely saturated with oxygen at typical alveolar oxygen pressures but are able to unload this oxygen over a narrower range of oxygen pressures than monomeric hemoglobins (Fig. 3). This facilitates efficient oxygen transport by minimizing the drop in oxygen pressure from the lungs to the tissues. This characteristic oxygen-binding curve reflects the fact that oxygen binds cooperatively, that is, binding of oxygen at one site enhances the affinity of the remaining sites. Perutz proposed a detailed stereochemical model for cooperative oxygen binding by hemoglobin,[27,38] and many predictions of this model were confirmed quantitatively.[38,39] Textbooks often use Hb to illustrate interactions among spatially separated active sites in rnultimeric proteins.[2,9,40]

The mechanism outlined by Perutz[27,38,39] builds on the allosteric model proposed by Monod. Wyman, and Changeux[41] (see Fig. 3). The fundamental assumption is that there are distinct high-affinity and low-affinity conformations, called R and *T*, respectively. Oxygen binding to any of the hemes does not directly influence the affinity of the other hemes but thermodynamically stabilizes the high-affinity R-state relative to the T-state. The resulting gradual shift from the *T*-state to the R-state as the protein becomes oxygenated is paralleled by an increase in the average affinity of the unbound sites. This two-state model describes the oxygen-binding curve of Hb in terins of three parameters: the oxygen affinities K_R and K_T of the R- and T-states and the equilibrium constant $L_0 = [T_0]/[R_0]$ between the unligated *R*- and T-states.

Perutz identified the *R*- and T-states of the MWC model with structural models for HbO_2 and deoxyHb, respectively, and proposed a plausible mechanism by which oxygen binding would destabilize the T-state relative to the R-state. Rigid-body rotation of one heterodimer ($\alpha_1\beta_1$) relative to the other ($\alpha_2\beta_2$) provides an approximate description of the structural differences between the *R* and T structures. which are stabilized by a distinct set of salt bridges at the $\alpha_1\beta_2$ and $\alpha_2\beta_1$ interfaces in these two limiting structures. Binding of oxygen to the T conformation leads not only to local structural changes at the heme but also to a shift of the F-helix that weakens salt bridges at the subunit interfaces, thus destabilizing the T-state relative to the R-state. Perutz also provided a plausible account of the mechanism of heterotropic effectors. including protons. CO, chloride ions; and diphosphoglycerate. which stabilize the *T*-state and thus reduce oxygen affinity.[27,38,39]

Increasingly detailed quantitative tests continue to refine the original MWC model but have not altered the fundamental scientific picture. The simple MWC model neglects differences in the binding affinity of the two hemes and assumes no direct interaction among the hemes in *R*- or T-states. In fact, differences in the binding affinity of α- and β-hemes are detected in elegant oxygen-binding measurements on T-state hemoglobin crystals,[42] and measurements of tetramer/dimer dissociation for all ligation microstates suggest that the binding of one ligand slightly enhances the affinity of the other site within the same dimer.[43] However. these effects partially cancel each other and are both less than an order of magnitude, in contrast to the several hundred-fold difference in affinity of the *R*- and *T*-states.[44]

Many questions remain unanswered. A simple thermodynamic consequence of the MWC model is that binding of each subsequent oxygen decreases the *R*/*T* equilibrium constant L_0 by the ratio $c = K_T/K_R$ of the oxygen affinities of the two conformations. Qualitatively. the reduced affinity of the *T*-state can be attributed to proximal restraint on the α-hemes,[33] while distal interactions may play a larger role in the low affinity of the β-hemes.[38,45] However, although some aspects of the energetics of the R–T transition can be explored theoretically,[46] it remains a challenge to account quantitatively for the large magnitude of the free energy of cooperativity:

$$\Delta\Delta G = -k_B T \ln c = 15 \text{ kJ/mol}$$

A related question is what exactly are the structures of the R- and the *T*-states? Perutz originally identified these states with structural models derived from x-ray diffraction measurements on ligated and deligated Hb crystals grown from concentrated salt solutions. However, the report of a fully ligated Hb with an *R*-like quaternary structure distinct from the R-state conformation identified in earlier structures suggests that crystallization selects only a subset of the conformations that comprise the R-state of the MWC model.[47] In the absence of a quantitative understanding of the large difference in oxygen affinity for the R- and T-states, the possibility exists that the oxygen-affinity varies significantly among R and among T substates. If so, then mechanistic understanding of RIT differences in oxygen affinity may require knowledge of the relative populations and oxygen affinities of different *R* substates present in solution.

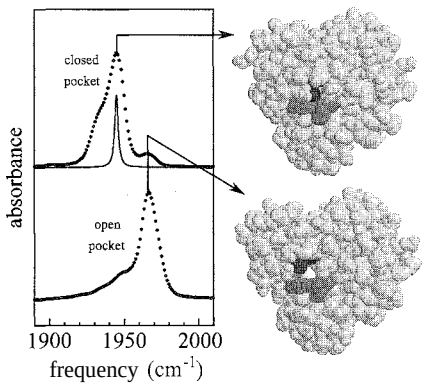

Fig. 4 Structure (right) and spectra (left) of open and closed conformations of myoglobin. Both x-ray diffraction and infrared absorption data were recorded on single crystals of MbCO at pH 6 (top) and pH 4 (bottom). Displacement of the distal histidine (blue) from the heme pocket in the open structure leads to a shift of the C-O stretch frequency from 1945 cm^{-1} to 1966 cm^{-1}, and may facilitate entry and exit of small molecules. The solid curve represents the contribution of an individual protein conformer to the IR band, based on the 2.7 cm^{-1} homogeneous linewidth expected from IR photon echo measurements.[55] The heme is rendered in red. the bound CO in white. the distal histidine in blue. and the remainder of the protein in green. Atomic coordinates for structural models of MbCO at pH 6 and pH 4 were obtained from the Protein Data Bank files 1vxf and 1spe, respectively.[52] (*View this art in* color *at www.dekker.com.*)

DYNAMICAL CONTROL OF GLOBIN REACTIONS

Proteins are necessarily dynamic objects. The relatively weak noncovalent interactions stabilizing the highly organized three-dimensional structure are constantly disrupted by thermal fluctuations. In fact, operation of these molecular machines relies on this dynamical behavior. Myoglobin is a "poster child" for the functional importance of protein dynamics, because the inaccessibility of the oxygen-binding site from solvent in the static structure derived from x-ray crystallography (Figs. 1 and 4) highlights the need for structural fluctuations that allow O_2 migration to and from the binding site. The dynamical behavior of proteins and its relation to physiological function was probably investigated in greater depth for Mb than for any other protein.[8,48]

Conformational Heterogeneity

Numerous observations show that in thermal equilibrium, an ensemble of chemically identical proteins samples a wide distribution of conformations. Early measurements found that recombination of photolyzed CO to Mb at cryogenic temperatures was highly nonexponential, because the conformational substates have rebinding rates distributed over many orders of magnitude.[49] These substates correspond to a large number of local minima on the complex energy surface of the protein, which are sampled during molecular dynamics simulations.[50] These conformational distributions also inhomogeneously broaden spectral lines of protein-associated chromophores.[51]

In some cases. such as the *R* and Tstructures of Hb. it is possible to characterize distinct conformations. As discussed above. the O_2 affinities of these structures differ by more than two orders of magnitude: and form the starting point for modeling the allosteric behavior of Hb.[39] Another example is the open and closed pocket conformations of MbCO with peak C–O stretch frequencies near 1960 and 1945 cm^{-1}, respectively (Fig. 4).[19,52,53] In the open conformation, the distal histidine is displaced from the heme pocket, and the O_2 dissociation rate increases by approximately three orders of magnitude,[54] similar to the effect of His E7 mutations.[10] However, the population of the open state is only 3–5% in vitro at neutral pH, and a physiological role for this conformation remains to be established.

In general. structural models based on x-ray diffraction from protein crystals represent an average over many conformational substates. Because the homogeneous line width of the C–0 stretch is only 2.7 cm ' at room temperature,[55] the broad C–O stretch bands observed in the crystalline state (Fig. 4) for open and closed states reflect contributions from a distribution of conformational substates with differing C–O frequencies. Furthermore, these substates are kinetically as well as spectroscopically distinct.[56] These observations suggest a fundamental challenge: conformational changes too small to distinguish with available structural techniques nevertheless result in reaction rates that vary by more than an order of magnitude.

Conformational Dynamics

At low temperatures, each protein is trapped in a particular conformational substate, and dynamics are nearly harmonic. Qualitatively different dynamical behavior appears above a dynamical transition near 180 K, where the mean square displacement of the Fe atom in myoglobin, as determined using Mossbauer spectroscopy, strongly deviates from a harmonic extrapolation of low-temperature behavior[48,57] (Fig. 5). Hydrogen fluctuations

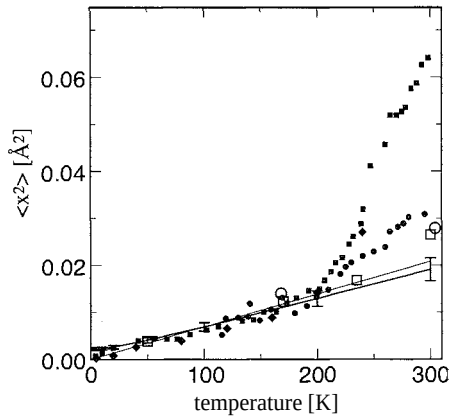

Fig. 5 Mean square displacement (MSD) of Fe in Mb as a function of temperature. illustrating the dynamical transition near 200 K. All values are determined from measurements of the 14.4 keV nuclear resonance of ^{57}Fe. Filled symbols. derived from measurements of recoilless absorption using Mossbauer spectroscopy, indicate the total Fe mean square displacement (MSD) averaged over the 140 ns nuclear-excited state lifetime. Above the dynamical transition, the 140 ns MSD of Mb solutions (filled squares) clearly deviates from a linear extrapolation of low-temperature measurements (thin solid line) or from the MSD calculated from the density of vibrational states (thick solid line). In contrast; the dynamical transition is not apparent in Fe MSD measurements averaged over a 5 ps time scale (open squares). determined from vibrational transitions near the nuclear resonance with 0.85 meV energy resolution. In constrast. 5 ps and 140 ns MSD values (filled and open circles, respectively) measured for dry oxidized Mb agree; suggesting that dehydration suppresses the dynamical transition. The dynamical transition signals the activation of protein conformational dynamics on time scales longer than a few picoseconds. (Reprinted with permission from Ref. [57]. Copyright 2001, American Physical Society.)

observed using inelastic neutron scattering reveal the same dynamical transition.[58] This characteristic change in atomic dynamics is believed to signal the onset of interconversion among conformational substates. Suppression of this dynamical behavior in the lyophilized protein[58] (Fig. 5) illustrates the essential role of solvent in activating protein dynamics.

Reaction kinetics also change above the dynamical transition, because the time scale of conformational interconversion becomes comparable to or faster than ligand binding. In contrast to the broad distribution of rebinding rates at low temperatures,[49] only two kinetically distinct conformational states contribute to CO rebinding to Mb at high temperatures."'" The rate of interconversion depends strongly on solvent viscosity and has a value of $\sim 10^6$ s^{-1} in aqueous solvent at 273 K. Analysis of double-pulse kinetic measurements,[59] in agreement with direct IR measurements in glycerol/water solutions."'" shows that the populations of these states correspond to the spectroscopically distinguishable open and closed pocket states shown in Fig. 4.

The rate of geminate CO rebinding to open or closed states represents an average over many substates, which interconvert more rapidly than 100 ns at physiological temperatures.[59] Thus, the kinetic properties of the structurally distinguishable open and closed states represent an average over many structurally indistinguishable substates. On the other hand, these substates are spectroscopically distinguishable on the 4 ps dephasing time of the C–O oscillator at room temperature[55] (Fig. 4). Measurements of the ^{57}Fe nuclear resonance are consistent with these bounds on conformational interconversion, because the Fe fluctuations activated above the dynamical transition (Fig. 5) take place faster than the 141 ns lifetime of the excited ^{57}Fe nucleus but slower than the 5 ps time scale of vibrational measurements[57]

Ligand Entry, Migration, and Escape

As noted above. it is apparent from x-ray structures that conformational fluctuations must take place to allow diatomic ligands to migrate between the active site and solvent. The pathways that the ligand follows, and the dynamical processes required to permit ligand migration. remain the focus of active investigation. An early suggestion that displacement of the distal histidine from the heme pocket would open a channel between the active site and solvent,[61,62] similar to the open-pocket structure shown in Fig. 4, found some theoretical support.[63] However. later calculations found that a CO molecule released at the heme migrated to various internal cavities before escaping from the protein.[64]

Time-resolved x-ray structures find electron density associated with a photolyzed CO approximately parallel to the heme group following photolysis with a 7.5 ns laser pulse.[65] Interestingly, electron density attributed to the photolyzed CO gradually develops in a cavity on the proximal side of the heme, bounded in part by the heme and the proximal histidine, with a maximum occupancy at 100 ns that decays to half the peak value in several microseconds.[65] The possible relevance of this proximal cavity to ligand migration under physiological conditions is uncertain because of the possibility that the crystal lattice perturbs the protein dynamics.

Spectroscopic probes provide a more precise determination of the time constant for CO escape from the heme pocket, approximately 200 ns at 20°C.[66] Temperature-dependent measurements of the rate for entry of water following NO photolysis from metMb find a 42 kJ/mol Arrhenius barrier, identical to the barrier for CO escape from photolyzed Mb, suggesting a common mechanism for ligand exit and entry.[67] Approximate equality of the rates for CO escape and interconversion of the open and closed conformations (Fig. 4) at 273 K is consistent with escape via the pathway created by displacement of the histidine in the open conformation.["] Detailed kinetic analysis of various mutant Mbs led to the conclusion that photolyzed ligands escape along classical pathway.[68] A reported transient volume change, interpreted as the entry of photolyzed CO into solvent, with a rate three to four times slower than the rate for CO escape,[69] indicates that some ligands may remain in the protein interior after leaving the heme pocket. However, observation of the same 42 kJ/mol barrier for the transient volume change[69] implicates the same fundamental process in escape of the ligand from the heme pocket and from the protein.

Hofmann-Type Clathrates

Toschitake Iwamoto
Iwaki Meisei University, Iwaki, Fukushima, Japan

H

INTRODUCTION

A group of the clathrate compounds formed between the metal complex host diamminemetal(II) tetracyanometallate(II) and aromatic guest molecules (G), $[M(NH_3)_2M'(CN)_4]\cdot 2G$, is named a Hofmann-type clathrate.''' after German chemist K. A. Hofmann (1870–1940), who discovered the prototype $Ni(CN)_2\cdot NH_3\cdot C_6H_6$, by chance, in 1897.[2] The formula was revised as $[Ni(NH_3)_2Ni(CN)_4]\cdot 2C_6H_6$ based on the crystal structure determined by Powell in 1949–1952.[3,4] The host metal complex involves two kinds of nickel(II) atoms different in coordination geometry, octahedral and square planar, linked successively by ambidentate cyano ligands to form a two-dimensional (2D) network. The octahedral nickel(II) is coordinated with a pair of the ammine ligands at *trans* positions. Thus, the host network can be divided into the two building blocks. square planar $[Ni(CN)]_4^{2-}$ and *trans*-$[Ni(NH_3)_2]^{2+}$, respectively. The guest benzene molecule is entrapped between the metal complex networks in cavities formed by the protrusion of the ammine ligands. A wide variety of Hofmann-type host structures were subsequently derived by means of crystal engineering. i.e., replacement of the nickel(II) in either one or both metal sites, by the appropriate metal species and that of the ammines by other unidentate or ambidentate ligands.

HISTORICAL BACKGROUND

A remarkable amount of progress in chemistry. particularly in inclusion and coordination chemistry, was made by fortuitous discovery of something new. as in the case of chlorine clathrate hydrate, quinol-host clathrates, Prussian blue, ferrocene, etc. The formation of complex compounds between metal salts and organic molecules can be traced to the year 1827 and the discovery of Zeise's salt $KCl\cdot PtCl_2\cdot C_2H_4\cdot H_2O$ (=$K[PtCl_3(C_2H_4)]\cdot H_2O$), as an incidental product of a redox reaction between platinum(IV) chloride and ethanol. The discovery stimulated chemists in the nineteenth century to seek novel inorganic–organic molecular complexes. Hofmann and Küspert tried to pass coal gas through an amrnoniacal solution of nickel hydroxide. The product they reported in 1897 showed the coinposition $Ni(CN)_2\cdot NH_3\cdot C_6H_6$; the cyanide and benzene were afforded from the coal gas used for lighting at the time.''' The apparently anomalous behavior of the $Ni(CN)_2\cdot NH_3$ salt was reported in 1903: namely, that the salt yielded the molecular complex $Ni(CN)_2\cdot NH_3\cdot G$ with an aromatic G. neutral C_6H_6, basic $C_6H_5NH_2$, and acidic C_6H_5OH, respectively.[5] Further examination revealed that the aromatic G was limited to that with a molecular volume not larger than that of aniline, i.e., pyrrole, furan, thiophene, benzene, phenol, or aniline. From these observations, Hofmann concluded that the aromatic molecule G was not combined by any covalent or coordination bond through certain atoms but as a whole with the inorganic moiety to fill up a space upon the formation of the complex compound.[6] His view should be evaluated in the context of the earlier and excellent insight into the formation of inclusion compound. which requires a fitness of size and shape between the host and the guest. His view is a bit different in concept from Fischer's ''Key-and-Lock'' theory. Fischer persisted in the interaction between functional molecules fitting each other in shape and size, but Hofmann pointed out that the geometrical fitness is dominant regardless of the functional group on the guest. as exemplified by the isostructural clathrates of benzene. aniline. and phenol. Furthermore. Hofmann's host is not an Avogadro molecule but an infinite lattice of coordination polymer. Avogadro molecule here denotes a discrete chemical species built of a definite number of atoms belonging to certain elements. i.e., an ordinary molecule or molecular ion, the simplest examples being BH_4^-, CH_4, and NH_4^+, discriminated from those polymeric ones giving no definite molecular weight but only a formula weight, as in solid NaCl, SiO_2, etc.

A half century after the discovery of Hofmann's benzene compound. Powell verified Hofmann's view by determining the crystal structure of the complex,[3,4] a modernized sketch of which is shown in Fig. 1. The host has a layer structure involving stacking of 2D networks linked by cyano ligands, in which a network of square planar $[Ni(CN)_4]^{2-}$ anions play the role of an N-connected cross-shaped linker to four octahedral Ni(II) cations at the respective N ends; a pair of the ammine ligands protrude up and down from the octahedral Ni(II) cation in the

Encyclopedia of Supramolecular Chemistry

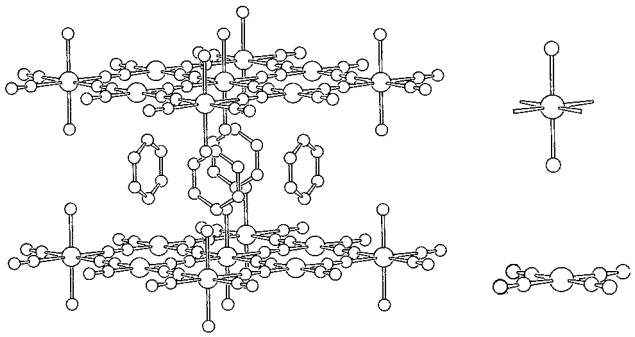

Fig. 1 A view of Hofmann-type benzene clathrate $[M(NH_3)_2M'(CN)_4]\cdot 2C_6H_6$: diamminemetalM(II) (right upper) and tetracyanometallateM′(II) (right lower) as building blocks of the host.

network. The *stacking of the flat network with the* ammine *protrusion* makes *an interlayer cavity for a guest benzene* molecule, *which is surrounded by four* ammine *ligands. The* limited *size of the square-mesh of the network, about 5.3* Å *edge length, allows the aromatic guest to have a* substituent *no* more *voluminous than an* amino *group.*

A primitive attempt at crystal engineering was tried by Baur *and* Schwarzenbach:[7] *an apparently* systematic *series was obtained by replacing the octahedral* Ni(II) *by* Cd(II), Cu(II), *and* Zn(II), *respectively. as* $[Cd(NH_3)_2Ni(CN)_4]\cdot 1.5C_6H_6$, $[Cu(NH_3)_2Ni(CN)_4]\cdot C_6H_6$, *and* $[ZnNi(CN)_4]\cdot 0.5C_6H_6$, *for the last of which the* ammine *ligands was lost. The apparently systematic but* nonstoichiometric *compositions were caused* from *the inappropriate drying of the products over concentrated sulfuric acid under reduced pressure. An extensive investigation by* Iwamoto *et al. since* 1966[8–15] *clarified that the series could be formulated as substantially stoichiometric* $[M(NH_3)_2M'(CN)_4]\cdot 2G$ *for octahedral* M=Mn, *Fe. Co.* Ni, Cu, Zn, *or Cd; square planar* M'=Ni, *Pd. or Pt: and aromatic* G=C_4H_4S, C_4H_4NH, C_6H_6, C_6H_5OH, or $C_6H_5NH_2$. *Iwamoto proposed naming the series Hofmann-type* clathrates[1] *in recognition of* K. *A. Hofmann's remarkable foresight into molecular inclusion phenomena.*

So-called Werner clathrates are another prominent series of clathrate compounds formed between a metal complex host and an aromatic *guest molecule. The name Werner originates* from *A. Werner. who established the coordination theory of metal complex compounds. The host of the series has* a *general formula* $[M(NCS)_2(4\text{-}Mepy)_4]$, *and in fact, the series is obtained conceptually by replacement of C N and* NH_3 *in the* Hofmann-type *host by SCN and 4-Mepy* (4-methylpyridine), *respectively. This was done in order to increase the* inclusion *capability* for *bulkier substituted aromatic molecules, in particular. those related to the petroleum industry. However. the host does not* have a *polymeric structure like that of the Hofmann-type but comprises a discrete metal-complex molecule. The name Werner was used to differentiate the host as a coordination complex from other kinds of complexes,* e.g., *organic–organic or organic–inorganic molecular complex, charge–transfercomplex, etc. Hence, the name of Werner* is *independent of molecular inclusion phenomena.*

STRUCTURAL FEATURES

The metal complex layer in the Hofmann-type hosts is not only a typical GN-linked 2I9 network but also a singular example of a regular structure with a flat and orthogonal (crystallographically tetragonal) square mesh. as well as the Prussian blue framework that is orthogonal, cubic, and three-dimensional (3D). *The Hoffman-type clathrates represent an* isomorphous *series of octahedral transition metal* M(II) *cations in a high-spin state* Mn(d^5), Fe(d^6), Co(d^7), Ni(d^8), Cu(d^9), *and* Zn(d^{10}) *or* Cd(d^{10}), *while the square planar* d^8 M′(II) *ions. Ni.* Pd, *and* Pt, *are in a low-spin state and are always diamagnetic. likely to* Tutton's *salts* $M(I)_2[M(II)(H_2O)_6](SO_4)_2$ *and alums* $M(I)[M(III)(H_2O)_6](SO_4)_2\cdot 6H_2O$.

As for the crystal engineering of the Hofmann-type hosts, the two building blocks, the trans-$[M(II)(NH_3)_2]^{2+}$ *rod with four equatorial extensions fi-om the* M(II) *center and the* $[M'(II)(CN)_4]^{2-}$ *cross are important; their alternating array gives a network. The topological features of the network are conserved in the Hofmann-type derivatives, in which the* NH_3 *is replaced by other unidentate ligands. such as* H_2O, NH_2CH_3 *(mmaj.* $NH(CH_3)_2$ *(dma),* $N(CH_3)_3$ (tma), *or unidentate coordinated* $NH_2(CH_2)_2OH$ *(mea).* $NH(CH_2CH_2)_2NH$ *(piperazine: den). The substituted network possesses a more lipophilic or hydrophilic surface than the original Hofmann-type compounds. Moreover, the flat network* becomes *corrugated and shifts to a certain* extent in *stacking so that the size of the cavity* and *the number of cavities per formula unit of the host complex change one by one. Examples are* $[Cd(H_2O)_2Ni(CN)_4]\cdot 4H_2O$, $[Fe(H_2O)_2Ni(CN)_4]\cdot 2C_4H_8O_2$, $[Cd(mma)_2Ni(CN)_4]\cdot 1.5(o\text{-}CH_3C_6H_4NH_2)$, $[Cd(dma)_2Ni(CN)_4]\cdot 0.5C_6H_6$, $[Cd(tma)_2Ni(CN)_4]$ *(no cavity).* $[Cd(mea)_2Ni(CN)_4]\cdot C_4H_4NH$, *and* $[Cd(den)_2Ni(CN)_4]\cdot 2C_6H_5OH$.

The stacking of the 2D network in *the Hofrnann-type hosts is extended to a* 3D *lattice work by linking the octahedral* M(II) *sites in adjacent networks with an* ambidentate *ligand such as an* α,ω-diaminoalkane $NH_2(CH_2)_nNH_2$ *(diam:* $n=2$–9*). mea,* $NH_2CH(CH_3)CH_2NH_2$ *(pn), den. etc. In the case of* α,ω-diaminoalkanes $NH_2(CH_2)_nNH_2$, *en* ($n=2$; *Hofmann-en-type). as well as mea and* pn, the *original Hofmann-type structure is retained,*

but adjacent networks are spanned by the ambidentate en, mea, or pn in place of the contacting pair of NH_3 ligands protruding into the interlayer space. In the case of pn, the methyl groups occupy a cavity so as to give the stoichiometry of $[Cd(pn)Ni(CN)_4]\cdot 1.5C_4H_4NH$. The bridging diam with the longer methylene chain ($n \geq 3$) keeps the host topology the same as that of the Hofmann-en-type—$[Cd(en)Ni(CN)_4].2C_6H_6$—but the size and shape of the cavities, and accordingly, the number of guest molecules in the chemical formula, change one by one. as well. Examples include the following: $[Cd(tn)Ni(CN)_4]\cdot 0.5(o\text{-}CH_3C_6H_4NH_2)$ (n=3), $[Cd(dabtn)Ni(CN)_4]\cdot C_6H_5N(CH_3)_2$ (n=4), $[Cd(daptn)Ni(CN)_4].1.5(p\text{-}C\cdot H_3C_6H_4NH_2)$ (n=5), $[Cd(dahxn)Ni(CN)_4]\cdot m\text{-}CH_3C_6H_4NH_2$ (n=6), $[Cd(dahpn)Ni(CN)_4]\cdot 1.5$(2-methylquinoline) ($n$=7), $[Cd(daotn)Ni(CN)_4].C_6H_{13}OH$ (n=8), and $[Cd(danon)Ni(CN)_4]\cdot 0.5(o\text{-}C_6H_4(CH_3)_2$ (n=9). In general, longer aliphatic chains increase the flexibility of the host lattice structure and the lipophilic character of the inclusion cavity.

STRUCTURAL DEVELOPMENTS

Replacement of the square planar $[M'(II)(CN)_4]^{2-}$ in the Hofmann-type host by a tetrahedral tetracyanometalate(II), e.g., $[Cd(CN)_4]^{2-}$ or $[Hg(CN)_4]^{2-}$, gives another series of clathrates with apparently the same chemical composition. i.e., the Hofmann-Td-type—$[Cd(NH_3)_2Cd(CN)_4]\cdot 2C_6H_6$. The structure of the host involving the tetrahedral moiety is closely related to that of the original Hofmann-type, given the change of point group from D_{4h} of the square planar moiety to T_d of the tetrahedral one, as shown in Fig. 2. As an idealized representation. the square planar moiety is twisted at the central atom by 90° upon replacement by the tetrahedral one. Half of the number of the tetragonal cavities in the Hofmann-type host are twisted along the body-diagonal plane by 90° with respect to one another. but the volume of the cavity remains unchanged. Actually, the unit cell of the Hofmann-Td-type becomes twice the size of the Hofmann-type: generally $Z = 1$ for the Hofmann-type but $Z = 2$ for the Hofmann-Td-type.

A number of compounds with chemical compositions that are similar to that of the original Hofinann-type ciathrates were reported. However. as usual for other inclusion compounds. similarity in composition does not necessarily co relate with similarity of structure. For example, in the $[Cd(pn)Ni(CN)_4]\cdot G$ series with aliphatic guests, the host structure is entirely different from the Hofmann-pn-type pyrrole clathrate $[Cd(pn)Ni(CN)_4].(3/2)C_4H_5N$. Two subseries of structures were observed for the channel cavities. one being a snake-like extension similar to chat observed for the urea–host inclusion compounds and the other a nodal extension similar to that observed for the thiourea-clathrates. Many cyanometal-complex-host clathrates and cyanometal complexes were observed with similar compositions and entirely different structures.

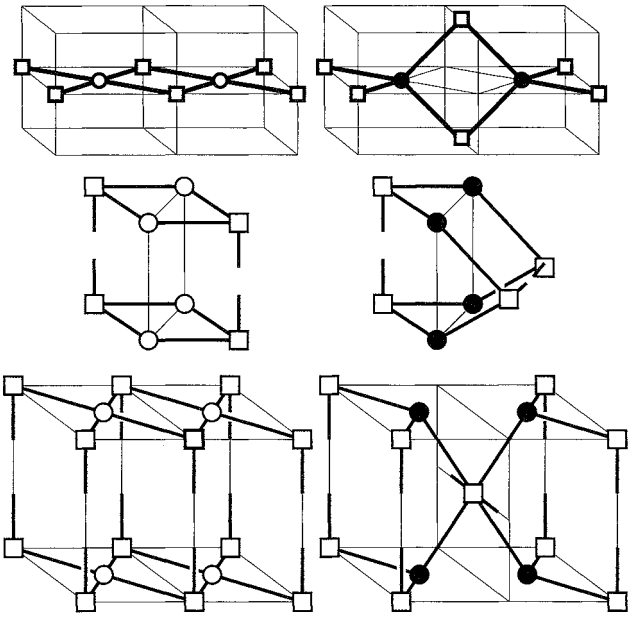

Fig. 2 The replacement of a square planar center (open circle) by a tetrahedral (solid circle) one; the open square denotes an octahedral center. (Left top) Flat network in the Hofmann-type. (Right top) Twisted network in the Hofmann-Td-type. (Left middle) A rectangular box cavity in the Hofmann-type. (Right middle) A twisted biprismatic cavity in the Hofmann-Td-type. (Bottom) A couple of Hofmann-type unit cells (left) makes a unit cell (right) of the Hofmann-Td-type.

CONCLUSION

During the earlier stages of research on Hofmann-type clathrates, Hofmann's benzene clathrate was applied to purify benzene produced probably by the coal chemical industry; at the time, the elimination of trace amounts of thiophene was a problem. Syntheses of polythiophenes, polypyrroles, etc., examined in a few cases, appear to have been unsuccessful. However. if the Hofmann-type structure is seen as a system composed of robust metal complex host and guest molecules entrapped discretely in the cavity, it may act as a reservoir of unstable species as the guest. An example is the long-lived cyclohexadienyl radicals generated in $[Cd(en)Hg(CN)_4]\cdot 2C_6H_6$ by γ-ray irradiation; the thermally stable $C_6H_7\bullet$ radicals survive up to 423 K in a vacuum-sealed tube.[16,17]

Almost all important contributions to the chemistry of Hofmann-type and related inclusion compounds and host cyanometal complexes were revicwcd in the literature.[12–15]

Homocalixarenes

Peter J. Cragg
University of Brighton, Brighton, United Kingdom

INTRODUCTION

Of all the macrocycles encountered in supramolecular chemistry, two are predominant: calixarenes and crown ethers. Conventionally, calixarenes are 2,6-metacyclophanes derived from phenols, with a single CH_2 group separating each phenolic moiety (see *Calixarenes: Synthesis and Historical Perspectives*). It is possible to introduce variation into the calixarene framework by extending the bridge between phenols to create a range of "homocalixarenes." This bridge majj consist solely of alkyl groups or may have heteroatoms. such as nitrogen or oxygen, incorporated in the chain. Introduction of heteroatoms has the additional interesting effect of combining crown ether (or azacrown ether) features with those of calixarenes. The potential of homocalixarenes and their derivatives to form a wide range of supramolecular complexes is therefore vast and as yet largely untapped.

NOMENCLATURE

The term "homocalixarene" was coined by Brodesser and Vogtle in 1994 to describe calixarene analogues containing two or more CH_2 groups between the aromatic moieties.[1] Homocalixarenes in which all the bridges were expanded to the same degree are termed all-homocalixarenes; those in which bridges of differing lengths occur are usually given names based on cyclophane nomenclature (see *Cyclophanes: Definition and* Scope).

An additional subgroup of these compounds contains combinations of CH_2 groups and heteroatoms such as oxygen ("hornooxacalixarenes") or nitrogen ("homoazacalixarenes"). The presence of heteroatoms is reflected in the nomenclature, thus a calix[4]arene in which one CH_2 was replaced by CH_2OCH_2 is described as a dihomooxacalix[4]arene.[2] The "dihomo" element of the name implies two additional atoms in the cyclic framework; "oxa" implies that one of these is oxygen: and "calix[4]arene" is the class of the parent compound. Other structural features that contribute to nomenclature include the "lower-rim" substituents (if any) attached to the phenolic oxygens, the "upper-rim" substituents found in the 4-position of the phenols. and, in the case of homoazacalixarenes. the substituents on the nitrogens.

HOMOCALIX[*N*]ARENES

The simplest member of this group is calix[2]arene, 8,16-dihydroxy[2.2]metacyclophane, comprised of two *p-t*-butylphenols linked through ethylene bridges.[3] Larger *all*-homocalixarenes containing three phenols with all ethyl[4] and all propyl[5–7] linkers have been prepared. Trimers with combinations of methyl and ethyl[8] and methyl and propyl[9] bridges, tetramers linked by two methyl and two propyl bridges,[10,11] and *all*-homocalix[4]arenes[12] are also known.

Synthesis

Two main procedures were used to prepare homocalixarenes. The first uses the sulfone extrusion route (Fig. 1) initially developed by Vogtle to prepare [2.2.2.2]biphenylophane and extended by Tashiro and Yamato to synthesize dihomocalix[3]arenes, dihomocalix[4]arenes, and homocalixarenes with differing lengths of bridges.[12,13] Typically. this method combines 2,6-(chloromethyl)-4-*t*-butylanisole with *bis*(3-thiomethyl-5-*t*-butylanisole)methane to prepare the sulfur-containing intermediate. This is transformed into the dihomocalix[3]-arene through pyrolysis under reduced pressure followed by hydrolysis. The second synthetic route owes much to the work of Yamato,[14] who pioneered an approach that employs base-catalyzed (Fig. 1) condensation of linked phenols with formaldehyde to prepare the asymmetric homocalixarenes. A typical example involves the preparation of 1,3-*bis*(5-*t*-butyl-2-hydroxyphenyl)propane from 4-t-butylanisole. and its subsequent reaction with paraformaldehyde under basic conditions to form the tetrahomocalix[4]arene. Variations on this method are used to synthesize 4-*t*-butylhexahomocalix[3]arene through cyclization of 2,6-(bromomethyl)-4-*t*-butylanisole.[13] An indication of the success of these synthetic methods may be given by the observation that bishomocalix[3]-, [4]-, [5]-, [6]-, [7]-, and [8]arenes are all available.

Derivatives

Alkylation of the lower rims of these compounds was largely restricted to methyl substituents. with the notable

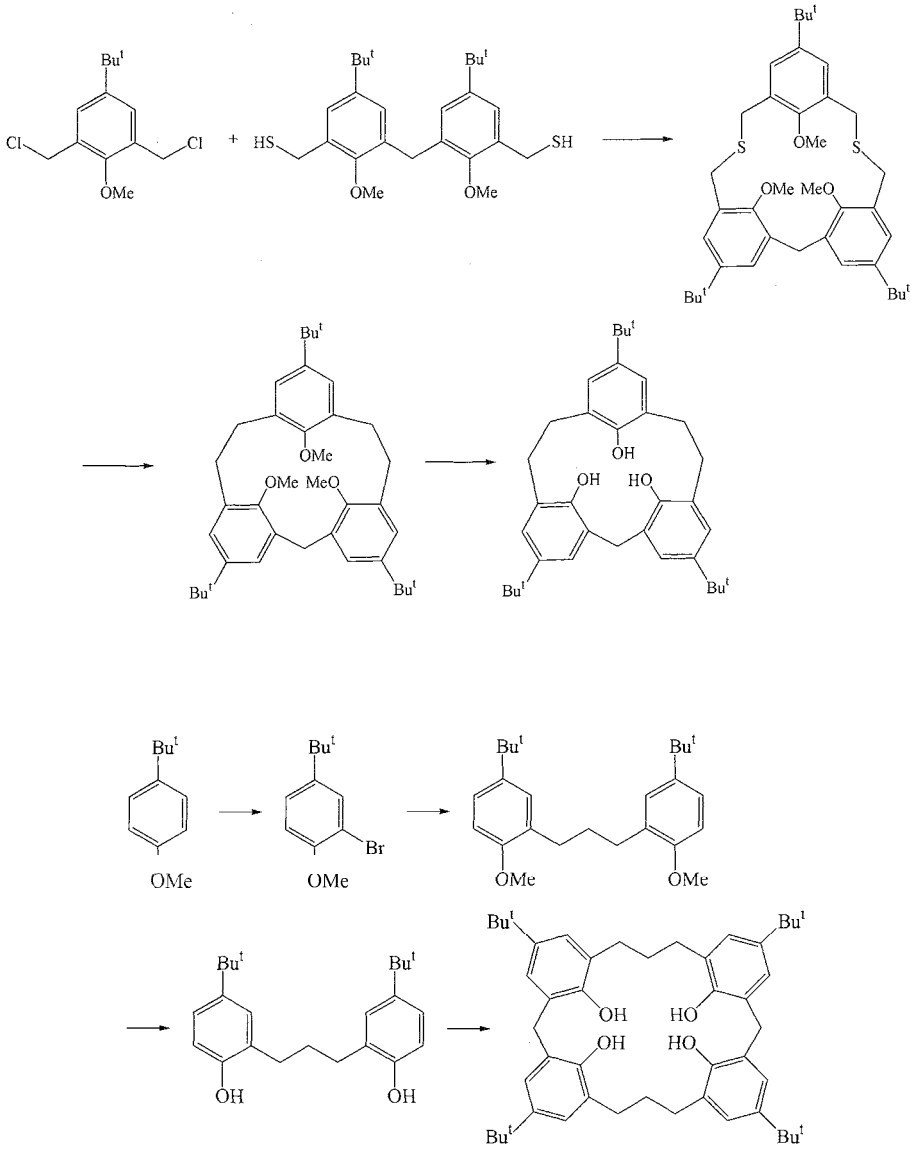

Fig. 1 Homocalixarene synthesis: sulfone extrusion (top) and base-catalyzed (bottom) methods.

exception of hexahomocalix[3]arenes and tetrahomocalix[4]arenes. Methyl-, benzyl-, and diethylacetamide and ethylacetate derivatives of both were prepared.[5,15] In addition, the tripyridyl derivative of the hexahomocalix[3]arene was prepared.[5] Unlike the calix[*n*]arene family. where many conformers may be formed, the homocalix[3]arenes can only adopt cone conformers and the less sterically demanding partial cone conformers. Unfortunately. the partial cone conformers of these derivatives tend to collapse on the macrocyclic cavity, thus reducing the potential for host–guest interactions. Statistically, only 25% of *O*-alkylated products should form in the generally more useful cone conformer, however, this may be improved by correctly choosing reagents. For example, the choice of base can influence the ratio between cone and partial cone conformers of the products formed from *O*-alkylation of hexahomocalix[3]-arene. The ester and amide derivatives may be synthesized as the cone conformer or partial cone with 95% or 67% specificity, respectively. More striking is the reaction of 4-*t*-butylhexahomocalix[3]arene with 2-(chloromethyl)pyridine. Use of sodium hydride as the base, in tetrahydrofuran, gives the cone conformer exclusively; however, if cesium carbonate is substituted as the base, only the partial cone conformer is formed. Free rotation of the aromatic groups through the annulus allows the cone conforiner to form readily when the lower-rim substituents are relatively small: however, as these groups become

larger. the macrocycles can no longer interconvert between conformers through rotation alone.

Complexes

The importance of the cone conformer for guest binding may be illustrated through the extensive investigation of binding carried out on the pyridyl derivative of hexahomocalix[3]arene, which is selective for Ag^+ over alkali metals and the butylaminonium cation. This is true in either the cone or. surprisingly, partial cone conformer; nevertheless, the strongest binding occurs with the cone conformer.[6] Unsubstituted homocalixarenes display metal extraction profiles that unusually reflect their flexibility and number of phenolic binding sites rather than the size of the cavity they form: *bis*homocalix[5]arene binds Ca^{2+}, Sr^{2+}, and Ba^{2+} to an equal extent. whereas the larger *bis*homocalix[8]arene is specific for Ba^{2+} over all other alkaline earths. Incorporation of lower-rim amido groups further enhances the discrimination of the latter for Ba^{2+}. There are other consequences of metal–homocalixarene interactions: cation–π interactions between alkali metals and the aromatic rings of *bis*homocalix[2]arene were cited as reasons for difficulties in its selective demethylation.[15]

HOMOOXACALIX[*N*]ARENES

Homooxacalix[*n*]arenes (oxacalixarenes) are members of the calixarene family of macrocycles that incorporate one or more ethereal bridges (CH_2OCH_2) in place of CH_2 groups, which link phenol moieties through the 2- and 6-positions. The first members of the family to be reported were hexahomotrioxacalix[3]arenes,[16–19] however. many others are now known. The synthesis of the entire series of expanded calix[4]arenes (dihomooxa-, both isomers of tetrahomodioxa-. hexahornotrioxa-, and octahomotetraoxacalix[4]arenes) as the corresponding methyl ethers was described in detail by Masci.[20] Oxacalix[4]arenes, notably dihomodioxacalix[4]arene, enjoyed some success as chelators for lanthanides and actinides; nevertheless, the oxacalix[3]arenes remain the focus of attention.[''']

HEXAHOMOTRIOXACALIX[3]ARENES

Synthesis

Hexahomotrioxacalix[3]arenes (oxacalix[3]arenes) were first reported in 1962,[16] but it took another two decades until a reliable synthetic method appeared.[17] Additional routes and refinements continue to make these coinpounds more accessible.[18,19] The most straightforward synthesis involves the acid-catalyzed condensation of 2,6-*bis*(hydroxymethyl)-4-*t*-butylphenol in refluxing o-xylene. Mixtures of hexahomotrioxacalix[3]arenes and octahomotetraoxacalix[4]arenes are usually formed, however, if *p*-toluenesulfonic acid is used as the catalyst, the hexahomotrioxacalix[3]arene is the sole product[''' ((Fig. 2).

Derivatives

The attractive threefold symmetry of the oxacalix[3]arenes and potential for modification at upper and lower rims led to their application as models for ion channel filters,[22] chiral recognition agents,[23] sensors for neurotransmitters, rotaxanes, and molecular capsules.[24] Derivatization generally takes place at the lower rim through reaction of phenolic oxygens with a variety of species. including alkyl iodides, *N*, N-diethylchloroacetamide, ethylbromoacetate, and 2-(chloromethyl)pyridine. As with hexahomocalix[3]arenes in general. the main drawback of lower-rim substitution is that statistically only 25% of the product forms in the cone conformation. Likewise. careful control of alkylating conditions can direct the product conformer: reaction of 4-*t*-butylhexahomotrioxacalix[3]arene with *N*, N-diethylchloroacetamide using sodium hydride in tetrahydrofuran gives the cone product. whereas cesium carbonate in acetone gives the partial cone product. Once *O*-alkylation occurred. the macrocycle is frozen into the conformation it adopted. unless the substituent is a propyl group or smaller. Interestingly, the hexahomotrioxacalix[3]arene derivatives are more conformationally mobile than their hexahomocalix[3]arene analogues. The propyl ether derivative of the latter cannot rotate through the macrocyclic annulus, and the ethyl ether derivative inverts at 90°C compared to 50°C for the oxygen-containing homologue.

Complexes

The parent oxacalix[3]arenes show little ability to bind alkali metals,[18] however, a range of quaternary ammonium cations are attracted to the symmetric cavity. Deprotonation of the phenol moieties allows them to bind to transition metals (scandium, titanium, vanadium. rhodium. molybdenum. gold. etc.), lanthanides (lutetium. yttrium, and lanthanum), and actinides (uranium: as uranyl). Oxacalix[3]arenes derivatized on the lower rim can complex gallium, mercury. and alkali metals, including sodium, in a manner reminiscent of natural transmembrane cation filters. One major use was to purify crude samples of fullerenes. The pseudo-C_3 symmetry of the macrocyclic cavity is complementary to threefold symmetry elements of C_{60}, which binds preferentially in

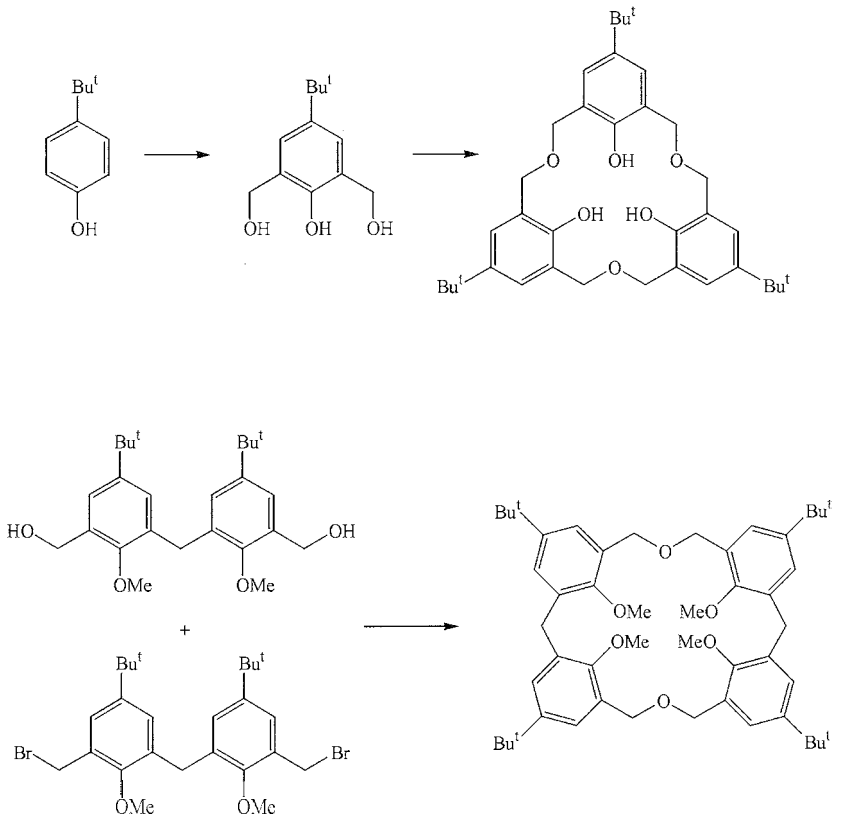

Fig. 2 Homooxacalixarene syntheses: hexahomotrioxacalix[3]arene (top) and tetrahomodioxacalix[4]arene (bottom)

aromatic solventr. The oxacalixarene-C_{60} coinplex can be isolated and the pure fullerene liberated through dissolution in dichloromethane.[25]

DIHOMOOXACALIX[4]ARENES, TETRAHOMODIOXACALIX[4]ARENES, AND OTHER DERIVATIVES

Synthesis

Initially, the expanded oxacalix[4]arenes were obtained as trace products from the preparation of calix[4]arenes:[26,27] however, high-yielding routes have since been reported in which the expanded calix[4]arenes are the major products.[20] For example. optimized synthetic methods are now available to prepare cone and partial cone conformers of tetrahomodioxacalix[4]arene (as their methyl ethers) through the reaction of a *bis*(hydroxymethyl)phenol methyl ether dimer or trimer with a *bis*(bromomethyl)phenol methyl ether dimer or monomer, respectively, via Williamson ether syntheses.

Derivatives

The majority of examples of expanded calix[4]arenes in the literature are 4-*t*-butyl derivatives of dihomooxa- or tetrahomodioxacalix[4]arenes, as parent compounds or as phenyl ethers and esters,[28,29] although *p*-methyl- and p-phenyl-containing compounds were reported.[30,31]

Complexes

X-ray crystallographic determinations illustrate a range of complexes exhibiting inclusion of m-xylene, dimethylformamide, tetrahydrofuran. triethylamine, dimethylsulfoxide. or acetone. iThe expansion of the calix[4]arene framework is particula ly suited. however. to europium and uranyl complexation by phenolic oxygens.[21]

HOMOAZACALIX[*N*]ARENES

Analogous to the homooxacalixarenes. the homoazacalixarenes contain nitrogen bridge heads with an array of

substituents. Homoazacalix[4]arenes may be prepared through cyclization of methylene-bridged 4-substituted phenol dimers or tetramers in the presence of amines. Homoazacalix[3]arenes are synthesized through acid-catalyzed cyclization of 2,6-*bis*(hydroxymethyl)phenols with arnines followed by thermal dehydration or base-catalyzed cyclization of 2,6-di(chloromethyl)phenols with amines (Fig. 3).

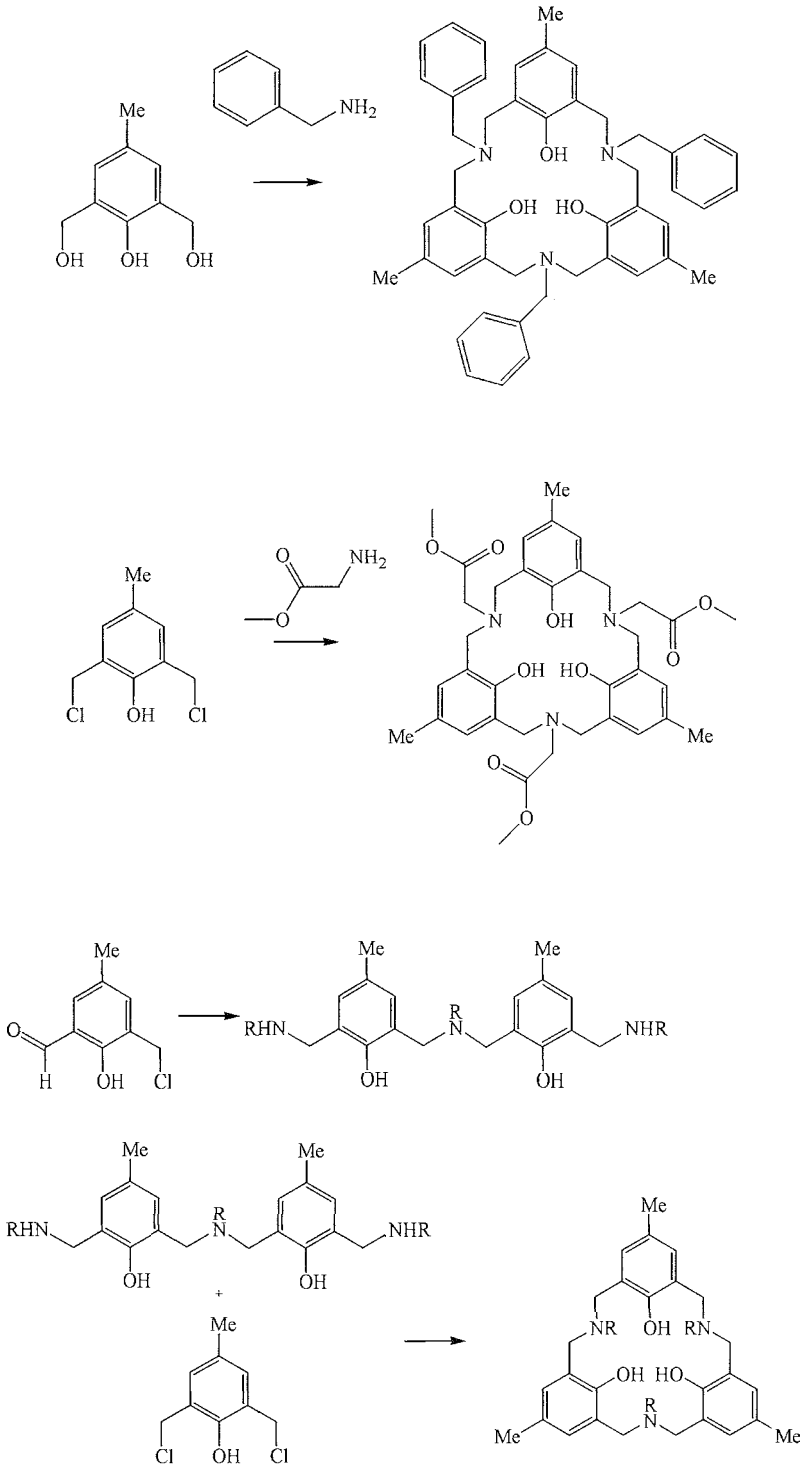

Fig. 3 Homoazacalixarene syntheses high-temperature (top), base-catalyzed (center). and convergent (bottom) methods

Synthesis

The first hornoazacalixarene was reported by Hultsch,[16] who prepared hexahomotriazacalix[3]arene through direct reaction of 4-t-butylphenol with hexamethylenetetramine, however, his method has yet to be verified. The first practical synthesis was that of tri(4-methyl-*N*-benzyl)hexahomotriazacalix[3]arene by Takemura.[32] In the two-step process, 2.6-bis(hydroxymethy1)-4-methylphenol was first refluxed in toluene with benzylamine, solvent was removed. and the residue was thermally dehydrated at 135°C to give the azacalix[3]arene in 38% yield. A convergent synthesis was developed by Hampton based on the reaction of 2-(chloromethyl)-5-methylbenzaldehyde with benzylamine (to form a dimer), followed by the addition of *bis*(chloromethyl)-4-methylphenol to give the compound in 95% yield.[33] Characterization of the product prepared by Hampton's method indicates that Takemura's procedure generates a mixture of oligomers, predominantly the azacalix[3]arene and its azacalix[4]arene homologue.

An alternative to this method. and one by which a variety of *N*-substituents may be introduced, is through the base-catalyzed reaction of a suitable amine, such as an amino acid ester with 2,6-*bis*(chloromethyl)phenols.[34] The advantage of this method is that the *N*-substituents

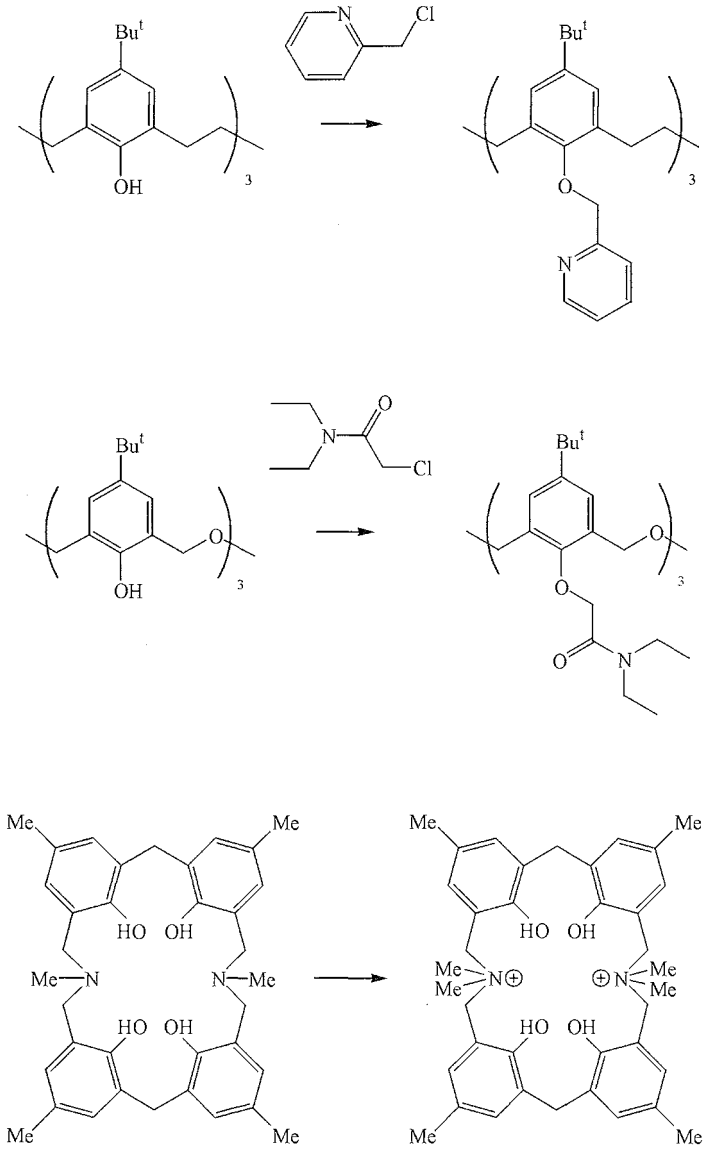

Fig. 4 Derivatives of the parent macrocycles: *O*-alkylation of hexahomocalix[3]arenes (top) and hexahomotrioxacalix[3]arenes (center): formation of tetrahomodiazacalix[4]arene betaine (bottom).

may be derived from volatile amines that would not be stable in refluxing o-xylene. Other azacalixarenes are made through condensation of benzylamine with *bis*(hydroxymethyl)phenol dimers or tetramers to yield tetrahomodiazacalix[4]arenes and dihomoazacalix[4]arenes.[35] Reaction of the *bis*(hydroxymethyl)phenol dimers with methylamine produces a dibishomoazacalix[4]arene that can be quaternarized to form the cationic azacalix[4]arene betaine.[36]

Derivatives

Unlike homocalixarenes and homooxacalixarenes, little was done to derivatize the lower, phenolic rim of the homoazacalixarenes. Upper-rim substituents, thus far, are limited to chloro, methyl. and t-butyl groups. The greatest scope for variation came in the groups appended to the bridging nitrogen. Early examples include benzyl and glycine methyl ester derivatives. but this range has since extended to include pyridyl, acetyl, i-butyl, allyl, and the N-unsubstituted derivative first reported by Hultsch (Fig. 4).

Complexes

Crystal structures of dihomoazacalix[3]arene containing *N*-glycyl methyl ester substituents and its trimethylsiloxy derivative show that the former adopts the cone and the latter the partial cone conformer, though neither includes solvent in the solid state. Structures of tri(4-chloro-*N*-benzyl)hexahomotriazacalix[3]arene complexed to ytterbium nitrate and neodymium nitrate show that the metal is centrally coordinated to ail three phenolic oxygens. This provides an interesting contrast with the dimeric structures determined for hexahomooxacalix[3]arenes. Di(4-methyl-*N*-benzyl)tetrahomodiazacalix[4]arene complexes the uranyl cation in two distinct modes that may involve all four phenolic groups or just two (Figs. 5,6).

(*View this art in* color *at www.dekker.com.*)

CONCLUSION

Expansion of the calix[*n*]arene framework, thus increasing the interphenolic separation by homo- or heteroatomic moieties: yields homocalixarenes with increased flexibility over the parent macrocycles. This. in turn, gives rise to novel inclusion complexes, particularly where oxqgen or nitrogen heteroatoms are incorporated in the macrocycle. The expanded macrocyclic cavities present in homocalixarenes give the compounds the potential to complex large guests. as evidenced by the oxa- and azacalixarene complexes of lanthanides and actinides. Modification of the upper and, more importantly, lower rims of the phenolic groups allows for even greater functionality to be

added to the compounds. Unlike the parent calix[*n*]arenes, the derivatized homocalixarenes are less constrained in the range of conformers that they can adopt and readily interconvert, as long as the lower-rim substituents are not too bulky.

Much of the early research into homocalixarenes focused on simply extending the intesphenolic bridges. however, the current trend is to exploit the binding properties of heteroatoms incorporated in the macrocyclic framework. To this end, research into the synthesis and inclusion chemistry of oxa- and azacalixarenes has now become the main area of interest for those working on homocalixarenes.

Hydrogen Bonding

Gautam R. Desiraju
University of Hyderabad, Hyderabad, Andhra Pradesh, India

INTRODUCTION

The hydrogen bond, which in its simplest form may be abbreviated as X–H···A (*X*, donor; A, acceptor) is an intermolecular interaction of fundamental importance.[1] It is of great significance in molecular association. because it is common. strong enough, and sufficiently directional. No other interaction has ail three of these attributes, and supramolecular assemblies constructed with hydrogen bonds are structurally robust and orientationally specific. An additional feature of hydrogen bonding is that it is also weak enough to be dissociated in solution. In effect, the hydrogen bond with its intermediate energy (0.540 kcal/mol) can be formed easily. and it can also be broken easily. It is, therefore, of importance in supramolecular processes in solution, where kinetics and reversibiiity are critical issues. The hydrogen bond is a complex interaction and also a composite interaction.[2] It is complex, because it involves at least three atorns. one of which is the all-important bridging H-atom. It is composite in character, because it may be dissected into four main components — electrostatic. covalency. dispersion–repulsion. and polarization — that have widely differing attributes and consequences. Hydrogen bonding has been studied for about a century, and the literature on the subject is vast. The phenomenon constantly lends itself to new research and reinterpretation.[3] In this article, the subject of hydrogen bonding is sketched with respect to supramolecular chemistry. and with an emphasis on how present-day ideas in structural chemistry have evolved. The treatment given here is necessarily abbreviated and subjective.

WHAT IS A HYDROGEN BOND?

Surprisingly, this is stiil debated. A geometrical definition is easier than a chemical one. The hydrogen bond X–H $\cdot\cdot A$ is constituted with a donor X–H and an acceptor A. Readers will note that this convention is exactly the opposite as that used in the rest of the chemical literature, wherein donors are electron-rich species, and acceptors are electron deficient. The hydrogen bond may be described in terms of the d, D, θ, and r as shown in Fig. 1. and certain limits and ranges are well accepted for these geometrical parameters. With the ever-increasing quality of modern diffraction data, H-atoms can be identified accurately, and the distance d and the angle θ are most commonly used. If the hydrogen bond is extended on the acceptor side as X–$H\cdot\cdot A$–Y, an acceptor angle ϕ, $H\cdot\cdot A$–Y may also be defined. Often, a donor group will present itself to two or more distinct acceptors (say, A_1 and A_2), or an acceptor will likewise interact with several donors (X_1–H and X_2–H). These multifurcated interactions are common, especially if both strong and weak donors and acceptors are considered. Multi-atom acceptors like double and triple bonds and aromatic rings were also identified and are of general significance.

A hydrogen bond, X–$H\cdot\cdot A$, is an interaction wherein a hydrogen atom is attracted to two atoms. X and A. rather than just one, and so acts like a bridge between them. What is the nature of this attraction? Chemists are in agreement that all hydrogen bonds are electrostatic interactions. and that the attraction always increases with the increasing electronegativity of X and A. Disagreements arise as to the extent of electrostatic character required to term an interaction X–$H\cdot\cdot A$ as a hydrogen bond. By "eiectrostatic" is meant an interaction with an r^{-1} to r^{-3} energy–distance dependence, so that dipole–dipole interactions are included, and a distinction is drawn between electrostatic and van der Waals interactions, which are interactions between dipoles or induced dipoles with an r^{-6} dependence. During the first 50 years of this phenomenon. the term '-hydrogen bond" was restricted to interactions like N–H···O, O–H···O, and F–H···F, in which the donors and acceptors are activated.[4] Today, the concept of the hydrogen bond extends to weaker interactions like C–H···O and O–H···π, which have hardly any covalent character and are only marginally electrostatic."[5] The domain of the hydrogen-bond phenomenon expanded even more with the inclusion of interactions like C–H···π, which is more of the dispersion–repulsion type (van der Waals) with oniy residual electrostatic character.[6] This conceptualization and extension was largely the handiwork of suprarnolecular chemists who found it convenient to define a hydrogen bond as an interaction capable of maintaining a certain regular suprarnolecular organization.[7] The operational definition of a hydrogen bond for a supramolecular chemist is then functional; rather than geometrical.

Encyclopedia of Supramolecular Chemistry

energetic, or spectroscopic. although all of these definitions have large common intersections. The functional criterion of a hydrogen bond still has its basis in electrostatics—the more long-range an interaction, the more specific will be its orienting effect during crystallization and self-assembly. So, it was proposed that any interaction X–H· ·A with an r^{-4} or shallower energy–distance dependence should be termed a hydrogen bond.[5] According to such a definition, all O–H· ·π interactions are hydrogen bonds, as is the C–H· ·π interaction in acetylene. but the C–H· ·π interaction in benzene is not. However, any criterion to define a hydrogen bond will be, in the end, simplistic, because hydrogen bonding is a complex phenomenon and does not lend itself easily to a simple and accurate definition. Considering the chemical connotations of the word bond, it was suggested that the term "hydrogen bridge" may be more suitable for the phenomenon than "hydrogen bond."[2]

TYPES OF HYDROGEN BONDS

Hydrogen bonds may be classified as very strong, strong. and weak based on their ability to determine and control supramolecular structure.[1,5] Listed in Table 1 are pertinent geometrical, energetic, thermodynamic. and functional attributes. The table provides a rough guide and is not intended to divide hydrogen bonds into watertight compartments. The reader will easily recognize the differences among the three categories. To assign a hydrogen bond in the borderline regions, chemical considerations are more advisable than numerical criteria and cutoff definitions.

Very strong hydrogen bonds occur in an energy range of 1540 kcal/mol and are formed by unusually activated donors and acceptors. Frequently, they are formed between an acid and its conjugate base, X–H· ·X^-, or

Table 1 Some properties of very strong, strong, and weak hydrogen bonds. *X–H· ·A*

	Very strong	Strong	Weak
Bond energy (−kcal/mol)	15–40	4–15	<4
Examples	$[F\cdots H\cdot\cdot F]^-$	O–H· ·O=C	C–H· ·O
	$[N\cdot\cdot H\cdot\cdot N]^+$	N–H· ·O=C	O–H· ·π
	P–OH· ·O=P	O–H· ·O–H	Os–H· ·O
IR ν_s relative shift	>25%	5–25%	<5%
Bond lengths	H–A ≈ X–H	H· ·A>X–H	H· ·A≫X–H
Lengthening of X–H	0.05–0.2 A	0.01–0.05 A	≤0.01 A
X· ·A (D) range	2.2–2.5 Å	2.5–3.2 Å	3.0–4.0 Å
H· ·A (d) range	1.2–1.5 Å	1.5–2.2 Å	2.0–3.0 Å
Bonds shorter van der Waals cutoff	100%	Almost 100%	30–80%
Angle (θ) range	175–180°	130–180°	90–180"
kT (room temperature)	>25	7–25	<7
Effect on crystal packing	Dominant	Distinctive	Variable
Utility in crystal engineering	Unknown	Useful	Partly useful
Relevance in biological structures	Unknown	Important	Ubiquitous
Covalency	Pronounced	Weak	Vanishing
Electrostatics	Significant	Dominant	Moderate

Source: Adapted From Ref. [5]

between a base and its conjugate acid, X^+–H···X. They are often intramolecular and assisted by resonance. A distinctive characteristic of very strong hydrogen bonds is their substantial covalent character so that the X–H and H···A distances are comparable. Very strong hydrogen bonds are of great importance in the context of chemical reactivity and biological mechanisms.

Strong hydrogen bonds (4–15 kcal/mol) are largely electrostatic. They are certainly the most familiar (ice. DNA, proteins) and well studied of hydrogen bonds. To many structural chemists and biologists, the properties associated with this category exemplify hydrogen bonding as a whole.[8] Molecules that contain functional groups capable of forming strong hydrogen bonds always do so, unless there are adverse steric factors. Their ability to control and modulate supramolecular structure means that they are reliable agents of intermolecular architecture. The strong hydrogen bond is the master-key of molecular recognition, and full control of this interaction will lead to mastery of supramolecular chemistry in general.

Weak hydrogen bonds (<4 kcal/mol), although numerous, were not identified in a general sense until recently.[5] These bonds are electrostatic, but this characteristic is modified by variable dispersive and covalency (charge-transfer) components that depend substantially on the nature of the donor and the acceptor group. The strongest of these, say bonds such as O–H···Ph and C≡C–H···O, are electrostatic and comparable to a bond like O–H···O–H. They lie in the energy range of 2–4 kcal/mol. The weakest of these are formed by unactivated methyl groups and are barely stronger than van der Waals interactions (about 0.5 kcal/mol). Bonds formed by weak donors with strong acceptors have been studied the longest. This set includes C–H···O/N and more recently M–H···O, where *M*=Tr.[9] The second set is constituted with strong donors like O–H and N–H and weak acceptors like C≡C, Ph, and M. Bonds formed with weak donors and weak acceptors (C–H···π, S–H···π. C–H···M, C–H···F–C) are at the end of the hydrogen-bonding regime.

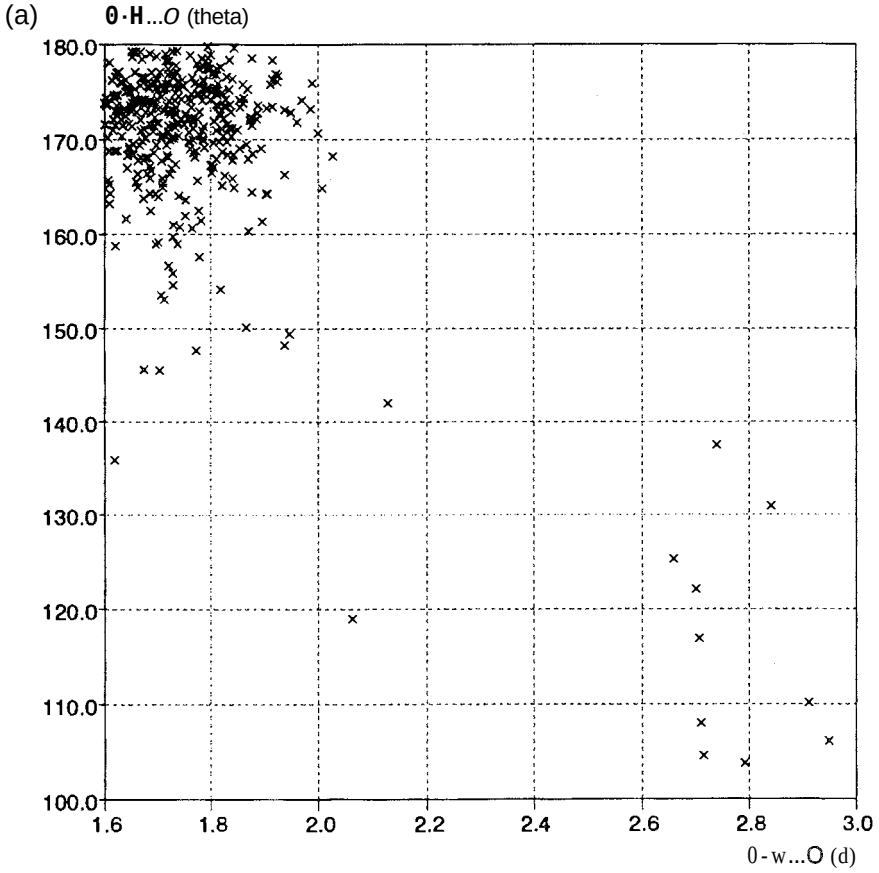

Fig. *2* Difference between strong and weak hydrogen bonds. θ–d scatterplots for (a) O–H···O and (b) C–H···O hydrogen bonds in representative crystal structures (CSD data). The weak hydrogen bonds span a much wider range of angles and distances than the tightly grouped sample of the strong hydrogen bonds. Note. however, the roughly inverse θ–d correlation that is characteristic of all hydrogen bonds for the C–H···O data. (From Ref. [5].)

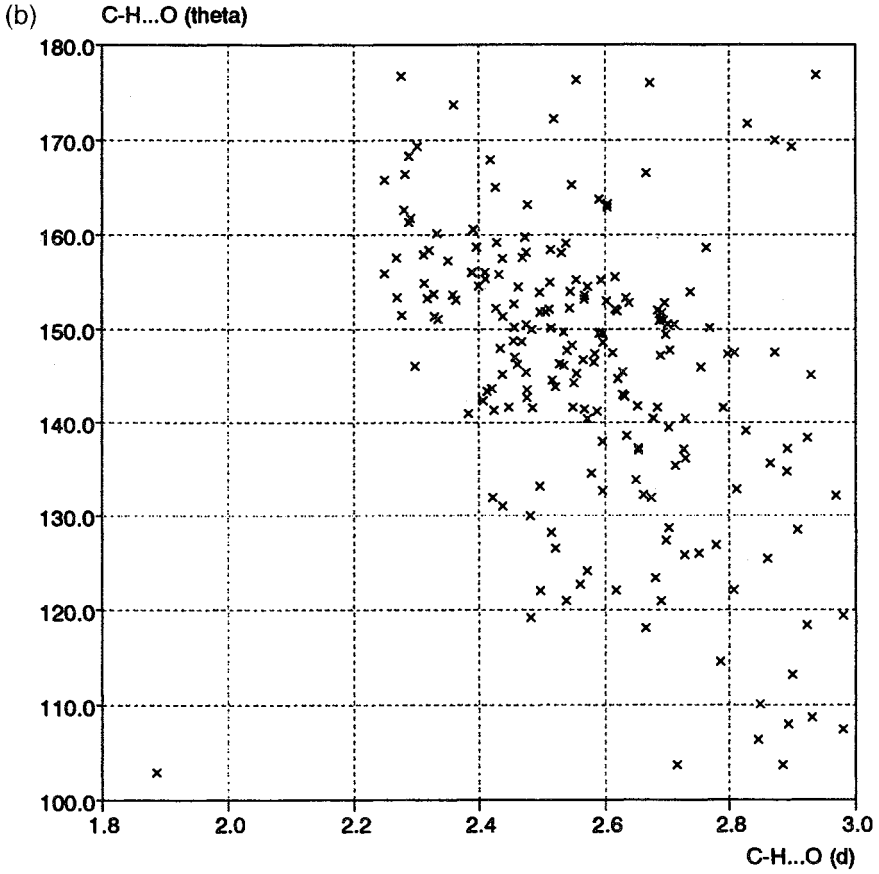

Fig. 2 (*Continued*).

DETECTION OF HYDROGEN BONDS

A number of methods and techniques are available. and the most appropriate needs to be chosen for the system in hand. Diffraction methods are especially important, because they are easy, fast, and accurate, and they may be applied to the weakest of hydrogen bonds. Advances in crystallographic hardware and software and automated methods of crystal growth of biological crystals means that we may reasonably expect a very large number of accurate crystal structure determinations in the near future. The number of organic and organornetallic crystal structures has grown to around 300,000 during the last 75 or so years. It is expected that this number will touch nearly 500,000 in less than a decade from now. A great majority of these structures will contain some type of hydrogen bond. Neutron diffraction is closely associated with the field of hydrogen bonding, because only with this technique is the crystallographer able to accurately establish the position of the most crucial atom in the interaction. namely, hydrogen.

An important consequence of the ever-growing number of small-molecule crystal structure determinations has been the development of methods for the storage and retrieval of crystallographic data. This has. in turn, led to the widespread use of crystallographic databases, and this was a development of great significance in the study of hydrogen bonding.[10] The Cambridge Structural Database (CSD) and the Protein Data Bank (PDB) are especially relevant. As a representative example, the reader's attention is directed to Fig. 2, which presents d–8 scatterplots for strong (O–H· . ·O) and weak (C–H· · ·O) hydrogen bonds obtained from around 500 and 150 accurately determined and representative crystal structures. The geometrical parameters of the strong O–H· . ·O bonds cluster within a narrow d–θ region, but this is certainly not the case for the weak C–H· . ·O bonds. However, as shown in Fig. 2, despite their scatter, these interactions have the inverse length–angle correlation that is characteristic of an electrostatic interaction like hydrogen bonding. So, the C–H . ·O interaction is a hydrogen bond. but it is "soft." Crystallographic databases also permit the analysis of more extended supramolecular patterns and networks in crystals. This was realized early in the development of databases, and this is of much utility in subjects such as crystal engineering[11] and structural genomics.[12]

Vibrational spectroscopy is the classical method for the study of hydrogen bonding in condensed phases."] Its applicability ranges from the strongest to the weakest hydrogen-bond types, and in both solution and in the solid state. The probe here is the vibrational frequencies of the atomic groups involved in hydrogen bonding, and because these frequencies can be measured accurately, subtle effects can be detected. Correlations of structural and vibrational parameters were established for various strong hydrogen-bond types. Despite the many benefits, the spectroscopic method is not free from drawbacks. Even for relatively simple systems, spectral complexity can prevent proper interpretation; this is the case: in particular, for systems exhibiting vibrational coupling. Furthermore, it is not always easy to distinguish between intra- and intermolecular effects based on vibrational spectra. Recent improvements in instrument technology and. parallel growth of interest in weak hydrogen bonds led to a renaissance of IR techniques in the hydrogen-bonding field, in particular: for solid samples.

Quantum chemistry complements crystallography and spectroscopy in the study of weak intermolecular interaction~.''~Theoretical methods can provide benchmark values for the energies of intermolecular interactions without the complicating effects of the solid-state or solution environment. Crystallography and spectroscopy provide information on equilibrium geometries, as many experimental techniques do. Computational methods, on the other hand, can be used to study domains of the potential energy surface, which are far from the equilibrium structure. Because of the widespread availability of powerful and yet low-cost computers, theoretical methods are now accessible to a large number of structural chemists, including experimentalists. Theory coupled with database research emerged as an effective way to study weak intermolecular interactions. Theory enables one to compartmentalize the various contributions to hydrogen-bond energy and also to dissect and study the important phenomenon of cooperativity. Of more recent interest is the computational treatment of small molecular clusters, or supramolecular synthons, and to examine their roles in crystal growth and stabilization. In the biological area, molecular dynamics (MD) may be useful, because it enables study of the dynamics of the breaking and making of weak hydrogen bonds. In this way, not only the energetics but also the lifetimes of weak hydrogen bonds may be studied.

THE HYDROGEN **BOND** IN SUPRAMOLECULAR CHEMISTRY

Strength and directionality render the hydrogen bond of critical importance in establishing and maintaining supramolecular structure. Hydrogen bonds are simpler to detect and their manifestations easier to demonstrate in the solid state than in solution. Most definitive studies are, therefore, based on crystal structure determinations. Robertson was the first to enunciate the principle of maximum hydrogen bonding.[14] In his words:

> *all the available hydrogen atoms attached to* electronegative *groups. are generally employed* in *hydrogen bond formation. Some of the bonds* formed *may be weaker than others. but the molecular packing is generally capable of adjustment in such a way as to permit the fulfillment of this condition.*

This principle appears to be of universal application. Donohue, in suggesting to Crick and Watson that the DNA bases are hydrogen bonded and in pointing out the appropriate tautomeric structures, paved the way for the double helix structure, and incidentally provided a blueprint for multipoint recognition in biological molecules." Powell described the structures of the clathrate compounds of β-hydroquinone (Fig. 3a) and introduced the network depiction for hydrogen-bonded arrays.[15] Many years later. Herbstein[16] described the crystal structure of benzene-1,3,5-tricarboxylic acid (trimesic acid) in terms of a 2D network (Fig. 3b). The main impetus to visualization of a crystal structure as a network came later from the important paper of Ermer[17] on the crystal structure of adamantane-1,3,5,7-tetracarboxylic acid (Fig. 3c). In this paper, a 3D hydrogen-bonded network was described, and a specific discussion of network interpenetration, which is multiple catenation, was included. Although interpenetration was not new (it occurs in the β-quinol clathrates of Powell and in trimesic acid), Ermer's vivid description of this structure was one of the key events that led to the establishment of crystal engineering as a distinct subject.

It was always well recognized that hydrogen bonding plays an important role in crystal engineering. the design and synthesis of solid-state supramolecular structures.''"] Schmidt and Eeiserowitz realized early the need to develop guidelines by examining the packing systematics of organic molecules, and they carried out a survey of amide crystal structures.[18] Leiserowitz subsequently provided a detailed analysis of the crystal packing of carboxylic acids.[19] Desiraju showed that weak hydrogen bonds could be brought into the scope of crystal engineering.[7] A comparison of the strong hydrogen bonds in the Whitesides rosette structure of melamine-cyanuric

"Surprisingly. the special supplement of *Nature* commemorating the 50th anniversary of the DNA structure, 23rd January. 2003 (reprinted from vol. 421. no. 6921) makes no mention of Donohue.

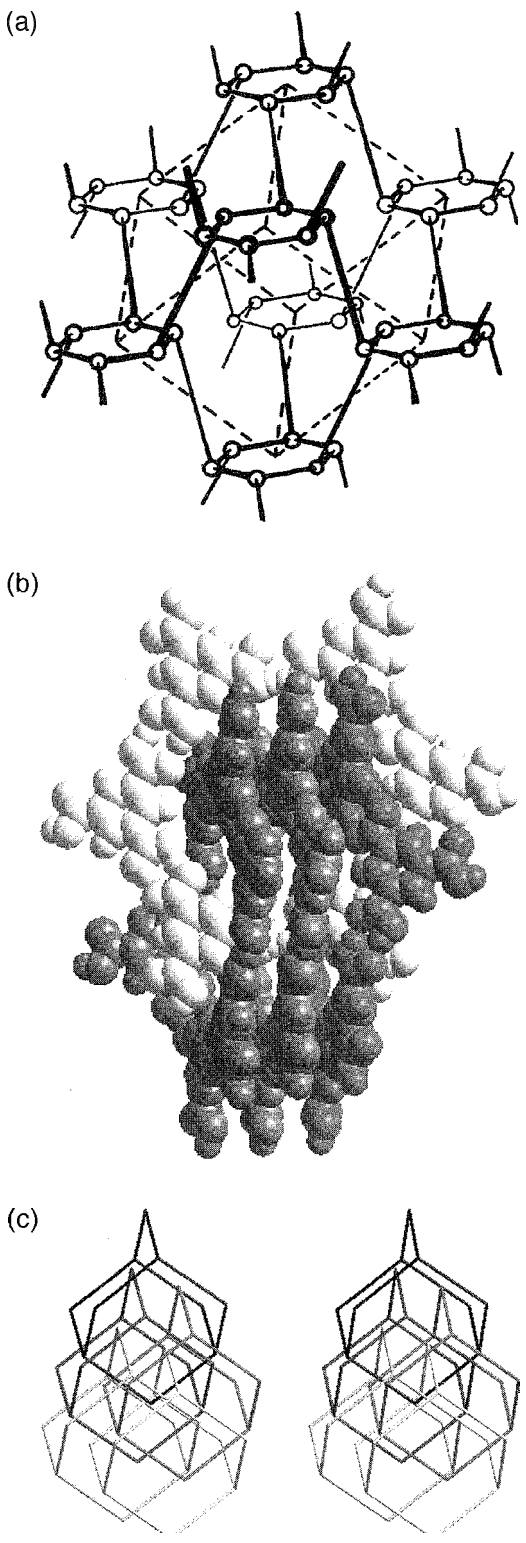

Fig. *3* (a) Network structure in the β-quinol structure (after Powell). The solid lines represent hydrogen bonds. (b) Interpenetrated two-dimensional networks in trimesic acid. acid[20] and the weak hydrogen bonds in the molecular complex of 2,5-dibenzylideneacetone and *sym*-trinitrobenzene[''] is illustrative (Fig. 4). Etter reformulated the principles set forth by Roberston and Donohue with an added stipulation that the best hydrogen-bond donors and acceptors form intermolecular hydrogen bonds with each other.[22] A number of rules for specific classes of functional groups were also provided. In retrospect, much of this is more by way of guidelines rather than rules. Exceptions are common, and today's exceptions become tomorrow's rules as the number and variety of crystal structure determinations increase. As the subject of crystal engineering has grown in breadth and scope, a very large number of crystal structures that were designed using the principles of hydrogen bonding have been reported. As stated previously, hydrogen bonding is the interaction of choice in crystal design strategies, and the reader is directed to the general and specialist literature on this topic. It would be impossible to provide even partial coverage here.

Hydrogen bonding is also extremely important in the construction of supramolecular aggregates in solution. Because issues of kinetics and reversibility need to be considered. it is important that the assembling interactions be as strong and as numerous as possible.[23] Typically, O–H···O, O–H···N, N–H···O, and N–H···N interactions are employed, and many systems, derived from the melamine–cyanuric acid recognition; were investigated. This system, which is based on three-point hydrogen-bonded recognition (Fig. 4), is archetypical. The need for multiple binding sites follows from the fact that the individual interactions are not robust enough to maintain supramolecular organization in solution. Reinhoudt described the formation of large aggregates that display suprarnolecular chirality.[''] Stoddart used hydrogen bonding in supramolecular-assisted molecular synthesis, in which the noncovalent interaction has a templating

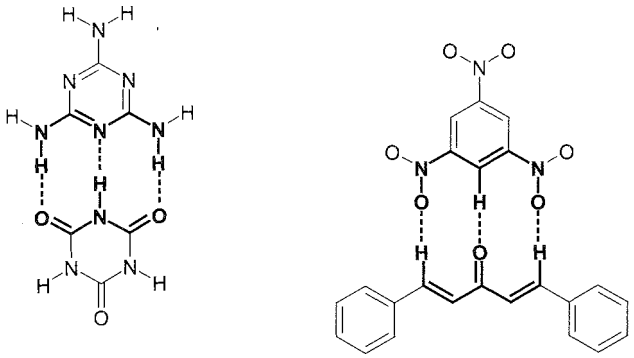

Fig. 4 Three-point recognition motifs consisting of strong and weak and hydrogen bonds.

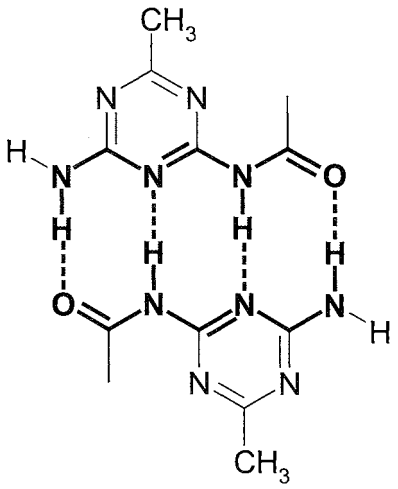

Fig. 5 Four-point recognition in a supramolecular polymer (after Meijer).

function and brings together molecular components for a covalent bond-forming process.[25] Meijer used four-point recognition in the synthesis of supramolecular polymers (Fig. 5). Hydrogen bonding is strong enough to maintain the polymer structure and weak enough to confer flexibility. thereby bringing a new element of variety to polymer chemistry.[26] By attaching hydrophobic residues to hydrogen-bonding functionalities, Fenniri et al. showed how entropic assistance from hydrophobic groups may favor the formation of supramolecular hydrogen-bonded aggregates.[27] Supramolecular reactions in solution are subject to thermodynamic control, and while this may confer benefits in subsequent dynamic applications, it is clear that molecules need to be designed with a clear perception of their supramolecular characteristics, the chief among which is their propensity for hydrogen bonding.

CONCLUSION

The great versatility of hydrogen bonding in supramolecular design and construction will ensure that this interaction will be used in many interesting and diverse chemical systems. An anonymous referee report on the paper by Taylor and Kennard[10] was included by the authors as the conclusion of their paper. It is worthwhile to ponder, with pleasure and anticipation, 20 years down the line, the statement made: ''*there have been some heroic attempts and a few minor advances but rationalization of crystal structure—hydrogen bonding patterns is still at the foot of the rainbow.*''

Hydrogen Bonds to Metals and Metal Hydrides

Robert H. Crabtree
Yale University, New Haven, Connecticut, U.S.A.

INTRODUCTION

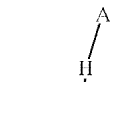
Classical hydrogen bonds[1] of general type A–H...B (**1**) have a weak acid A–H as hydrogen bond donor and lone pairs of electronegative atoms like F, O, and N as the hydrogen bond acceptor or weak base component, B (see "Hydrogen Bonding"). Since 1990. two new classes of hydrogen bonds have emerged, 2 and 3, that both retain the usual A–H donor component but differ in the nature of the acceptor. In the first class,[2] an electron pair in a nonbonding orbital on transition metal atoin of a metal complex plays the role of B (2). In the second,[3,4] the proton acceptor is the σ bonding electron pair of an M–H bond (3). The first type differs from classical hydrogen bonding only in that the nonbonding electron pair of B is located on an unusual element. In the second case. no nonbonding electron pair is involved, so in that sense. the situation is fundamentally different from that in classical hydrogen bonds.

A—H- - - -B

1

A—H- - - -M

2



3

From another point of view, the situation in 2 or **3** is not so different from the classical case, **1.** If we regard a hydrogen bond as an interrupted proton transfer, any base capable of being protonated by a strong acid should form a hydrogen bond with a suitable weak acid. Metals in neutral complexes can often be protonated with strong acids to give cationic hydrides. Also, M–H bonds in neutral complexes $[L_nMH]$ can protonate to give dihydrogen complexes, $[L_nM(H_2)]^+$, where the molecular hydrogen ligand is bound side-on. In this view, hydrogen bonding between M or M–H and weak acids A–H is an incomplete proton transfer just as is the case for **1.** Any proton transfer implies the existence of such an intermediate form. even if only as a transient. Other basic element hydride bonds such as B–H can also give Type 3 hydrogen bonds. so a transition metal is not required, just an element E that is sufficiently electropositive to give a hydridic E–H group.

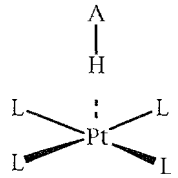
Other H-bridged metal complexes that seem at first sight to be hydrogen bonded are, in fact. very different. Complexes and compounds with 2-coordinate H bridging between two metals are coinmon in inorganic chemistry, but the great majority are not hydrogen bonded. Typical examples are $[(OC)_5Cr–H–Cr(CO)_5]^-$ and $H_2B(H)_2$-BH_2. Unlike the near-linear situation in the A–H...B fragment of a hydrogen bond, in these bridging hydrides, the E–H–E bonds are strongly bent (E = element). They are classified as σ-complexes[5] and can be considered as consisting of an H^- ion simultaneously donating two valence electrons to each of two sixteen-valence electron metal fragments by bridging to form three center two-electron bonds. In a σ-complex, the bridging H often shows a high-field NMR shift on bridging in contrast with the low-field shift normally seen for **1–3**.

A–H...M HYDROGEN BONDING

This area developed from the x-ray and neutron diffraction work of Brammer,[2,6,7] who first drew attention to the N–H...Pt interactions in a complicated square planar Pt(II) amine structure in 1991. In this work, also cited were prior structures proposed as examples of the same type of interaction. Starting from a square planar Pt(II) complex, an N–H bond is typically located in the otherwise vacant fifth coordination position of a square pyramid (4) with d(H...Pt) near 2.25 Å. The H...O distance in a classical hydrogen bond is often around 1.8 Å, or 0.4 Å longer than the van der Waals radii of O. If

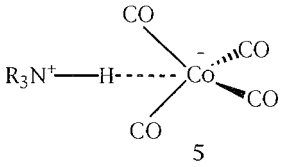
Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012758

the van der Waals radius of a metal like Pt is ca. 2 Å, 2.4 A would be reasonable for an H...Pt hydrogen bonding distance.



4

In a more straightforward example. Brammer[6,7] recognized that an ammonium counterion of type R_3NH^+ could form N–H...M hydrogen bonds with $[Co(CO)_4]^-$ anions (5). Having 18 valence electrons, $[Co(CO)_4]^-$ ion is unable to form three center two-electron bonds, which would require <18 e. Taken together with the linearity of the NHCo system, the hydrogen bonded character of the system was clearly demonstrated. As expected, a more basic metal, achieved by replacing one CO by PPh_3[7] gave a stronger interaction, N...Co decreasing from 3.437 to 3.294 Å. In this case. the tetrahedral $[Co(CO)_4]^-$ ion was minimally distorted by the interaction, the N–H approaching along a C_3 axis of the tetrahedron. The N–H bond is slightly elongated, and the NH stretching frequency in the IR spectrum is shifted to a low-energy shift on adduct formation, as is also the case for classical N–H...B hydrogen bonds.



5

Like the classical A–H...B interaction, a predominantly electrostatic origin was proposed. In line with this idea, the presence of the following features[2] was suggested for identification of an A–H...M hydrogen bond: 1) protonic AH; 2) basic M; 3) a downfield proton NMR shift on bridging (the opposite situation from σ-complexes); and 4) linear A–H...M. The metal could be electronically saturated (e.g., $[Co(CO)_4]^-$) or not [e.g., square planar Pt(II)].

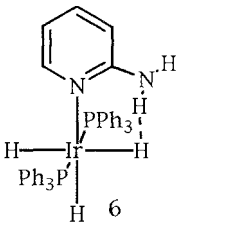
Whenever proton transfer takes place in an A–H...M system, an $A^-...H–M^+$ hydrogen bonded group must be considered as a stable form or transient intermediate. Because A^- is a base, this is equivalent to a classical A–H...B hydrogen bond with an acidic M–H replacing the usual A–H. Spectroscopic evidence shows that cationic metal hydrides interact in this way with bases such as O = PPh_3.[8] Such a situation is probably best considered a classical hydrogen bond of Type **1.**

A-H...H–M HYDROGEN BONDING

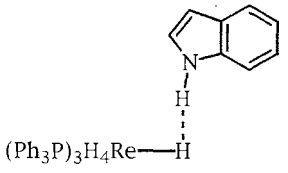
In spite of its relatively recent development. hundreds of A–H...H–M hydrogen-bonded species of Type **3** are now known. These are said to contain a dihydrogen bond, often shortened to DHB to avoid confusion with the IUPAC term. dihydrogen (H_2). DHBs have proven to be attractive to the computational chemistry community because they prominently involve hydrogen atoms. The field has implications for inorganic and organic chemistry, and perhaps also biochemistry, because some enzymes involve metal hydrides. In addition, a variety of physical and spectroscopic techniques were successfully applied to the problem. Reviews of the field are available.[3,4]

The first suggestion of an A–H/H–M attractive interaction was in a 1990 proposal that invoked them to explain the close contact (H...H, 2.4 Å) between the IrOH proton and the Ir–H hydrogen found in the neutron diffraction structure of *cis*-$[Ir(OH)H(PMe_3)_4]$.[9] The H...H distance is long and about equal to the sum of the van der Waals radii for two H atoins (2 × 1.2 Å), and so the interaction may be relatively weak and better considered a dipole–dipole interaction. A short d(H...H) of 1.86 Å was found by neutron diffraction[10] in mer-$[Fe(H)_2(H_2)(PEt_2Ph)_3]$, a study originally carried out to test the author's earlier spectroscopic assignment[11] of this species as an H_2 complex. The orientation of the H_2 ligand that brings it close to a terminal FeH hydride was explained by Eisenstein on theoretical grounds[10] as involving a proton–hydride attraction termed the "*cis*-effect." Now, it can be considered as a dihydrogen bond, because of the very short H...H distance (1.86 Å). Here the role of A–H is taken by a proton of a molecular hydrogen complex, known to act as a weak acid in most cases.

Structures that are more representative of typical DHBs (e.g., 6–7) came from the author's and Morris' groups in the form of an extensive series of metal hydrides in which a DHB is formed with OH or NH protons (= A–H) as the weak acid partners, both intramolecularly and intermolecularly. The characteristics of the DHB proved to be a short H...H distance (ca. 1.8 Å versus the sum of the van der Waals radii of 2.4 Å) found from x-ray and neutron diffraction work in the solid state and by NMR relaxation time studies in solution. Theoretical and experimental studies led to a typical A–H...H–M interaction strength of ca. 4–8 kcal/mol.



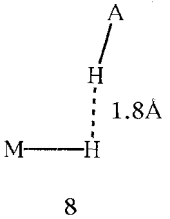
6



7

Unlike classical hydrogen bonds,[1] A–H...B, where A and B are electronegative atoms or groups, in A–H...H–M, M and H are much less electronegative than the N, O, or F atoms common in the classical type. Morris[4] used an alternative descriptive term: proton–hydride interaction.

Rather than the linear arrangement of the classical hydrogen bond, dihydrogen bonds show a different conformational preference, such that the N–H or O–H bond approaches the M–H bond in a side-on direction (8 but as also seen in 6–7), although linear examples were also found in cases where conformational or steric effects disfavor a bent geometry. Eisenstein found in DFT calculations that the potential energy surface is flat, so distortions from the ideal geometry are not very costly.[12] The A–H...H is roughly linear, however, A–H points to the M–H bond rather than directly toward M or H.



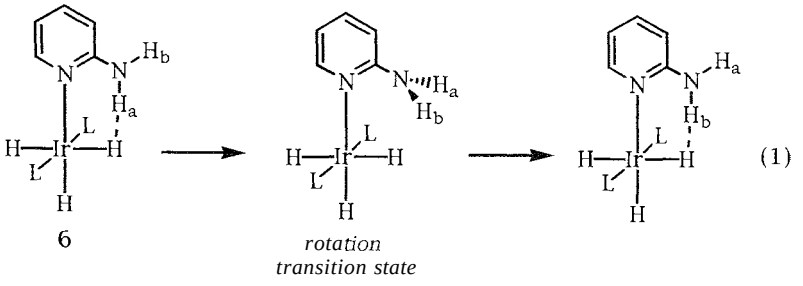
8

The A–H group shows the same spectroscopic trends compared to the free A–H group in all of the hydrogen bonds 1–3: a reduced ν(A–H) stretching frequency in the IR spectrum and a deshielding of the AH proton leading to a low-field shift of the resonance. The effect of hydrogen bonding of Type 2 on the spectroscopic properties of the metal fragment is still insufficiently understood. although H...M coupling was seen in certain cases. Two proton NMR effects were recognized for **3:** an H...H coupling of 2–9 Hz is sometimes seen, together with a significant increase in the T_1 relaxion rate of the two hydrogens as a result of their close proximity.[3,4]

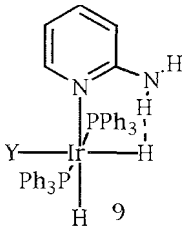
INTRAMOLECULAR INTERACTIONS

Complex 6, an intramolecular case of DHB. was chosen to get some idea of the energetics of the interaction. By a VT NMR method, one can estimate the H...H bond energy from the C–NH_2 rotation barrier in 6. In the transition state for **6**→**6′**, (Eq. 1), the H...H bond is broken. and the resonance energy of the NH_2 group with the pyridine ring is lost. The intrinsic C–N rotation barrier in the absence of dihydrogen bonding can be estimated at ca. 6 kcal/mol using a combination of experimental data and Hartree–Fock calculations by Eisenstein and Clot. By measuring the barrier for **6**/**6′** and subtracting 6 kcal/mol, we arrive at an apparently reasonable estimate of the H...H bond energy: 5.0 kcal/mol for **6**.[13]

When one hydride in 6 is replaced by any of a variety of anions, Y, to give 9, the strength of the DHB varies strongly. When Y is a weak *trans* effect ligand like F, the DHB is very weak, but it becomes strongest when Y is a high *trans* effect ligand. Because H ligands *trans* to high *trans* effect ligands tend to be particularly hydridic,[14] this implies that a basic hydride is best for dihydrogen bonding, in accord with the electrostatic bonding model mentioned above. The high *trans* effect nitrosyl ligand causes particularly strong dihydrogen bonding to H *trans* to NO.[15]



6 *rotation transition state* (1)



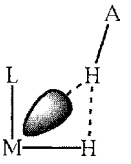
9

When Y = F^-, often considered the best hydrogen bond acceptor. a classical NH...F hydrogen bond is formed in 8. Using the NMR method of Eq. 1, the bond strength was found to be just a little more (5.2 kcallmol) than that for the N–M...H–Ir bond in the Y = H^- analogue (5.0 kcallmol). This illustrates the unexpectedly high DHB interaction strength, at least for Y = H.

This finding was paradoxical. because hydrogen bonding energies'" decrease on moving from the classical lone pair H-bond, N–H...(lone pair) (4–8 kcallmol). to the N–H...(π bond) case, in which the proton acceptor is usually an arene π system. ($\leq$ 2 kcallmol). so one might expect that any N–H...(σ bond) type, where the acceptor is an σ bond, would have a negligible bond energy (<1 kcal/mol). In contrast, N–H...H–E interaction energies can be up to 4–8 kcallmol, which are almost as large as for the N–H...(lone pair) case. This requires E to be an electropositive element such as boron or a transition metal, so that the hydride has significant hydridic character. and even then we usually need to have a high *trans* effect ligand *trans* to the H in question. It is still not clear why the dihydrogen bonding energies in species such as 6 are so large. The H...H distance of 1.8 Å is essentially the same as the H...B distance in the classical hydrogen bond. so an unusually close approach of donor and acceptor atoms is not the critical factor. Possibly, the ready polarization of the soft L_nM–H system by the AH dipole may be a factor.

THE MATURE OF A–H...H–E HYDROGEN BONDING

In the first A–H...H–M hydrogen bonds.'" AH was NH or OH. and M was a d^6 metal (as in 6–7). This raised a possible ambiguity; because a d^6 metal's d_π nonbonding electrons could; in principle. interact with the A–PI proton. considering this orbital points between the ligands and therefore directly toward an NH_2 proton as seen in diagram 10. A typical H...M distance in such a case was found to be 2.8 A. Admittedly, the AH proton is always close to the MH hydride, but this may have nothing to do with a proton–hydride interaction. Instead, the AH might interact with the d, electrons adjacent to the M–H bond simply because PI is the sterically smallest ligand present that allows the NH to approach the metal d_π orbital closely. In that case. the A–H...H–E system becomes just another example of the A–H...M hydrogen bond of Type 2, and the H...H interaction would be repulsive.



10

Because neither B nor N have nonbonding electrons, the case of BH_3NH_3 was useful to resolve this A–H...M/H...H ambiguity. BH_3NH_3, a solid, has a m.pt. of + 104°C or almost 300 degrees higher than that of its isoelectronic analogue ethane (m.pt., –183°C). This elevation might have been due to polar effects, but the polar molecule CH_3F, having a dipole moment about 0.4 of that for BH_3NH_3, has a m.pt. of –140°C, suggesting that polar effects alone should lead to a m.pt. for BH_3NH_3 of about –100°C. The 200" additional m.pt. elevation seemed likely to be associated with hydrogen bonding.

Cambridge Structural Database (CSD) data on intermolecular N–H...H–B hydrogen bonds[116] showed that the structures were essentially identical in the transition metal and boron examples. Therefore, the nature of the interaction was taken to be similar. If that is true, the d, nonbonding electrons play no more than a supporting role. The range of H...H distances is similar in both cases [1.7–2.2 Å versus 2.4 Å.[16] the sum of the van der Waals (vdW) radii for two hydrogens]. In BH_3NH_3, only true dihydrogen bonding was possible, resolving the ambiguity mentioned above. Therefore, dihydrogen bonding is real.

According to the reported x-ray crystallographic coordinates, BH_3NH_3 had an entirely different configuration from that shown in **3.**

The B–H...H–N configuration found was the reverse of the one in 3: B–H...HN appeared to be almost linear, and N–H...HB appeared strongly bent. A subsequent neutron diffraction structure of BH_3NH_3, carried out to resolve this problem. showed that the B and N were previously misassigned; the true assignments produced a normal BHHN configuration as expected.

A DFT caiculation on $[BH_3NH_3]_2$[116] shows a BH...HN conformation similar to that in **3** and an H...H bond energy of 4.6 kcal/mol per bond, comparable to the transition metal analogues. The calculation also suggested

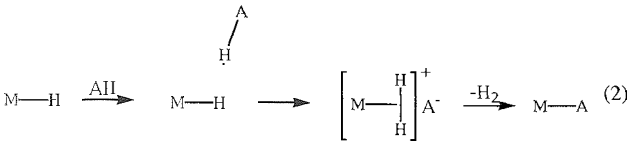
that the BPI bonds polarize on forming the H...H interaction. which may help explain the relatively high interaction energy, and that the boron is more negatively charged than the hydride. The entire B–H bond should probably be considered as being the true proton acceptor. The $^1J(H^-...H^+)$ coupling in the range 2–7 Hz is seen in the ^1H NMR spectrum of cornpounds such as **5–6**, so the H...H bonding is not entirely electrostatic. Small $^1J(H,B)$ couplings were recently seen for classical A–FI...B hydrogen bonds.[17]

In other theoretical work,[18] Calhorda et al.[19] found a large number of complexes in the CSD database with short MH...H(O,N) distances. Their DFT study on $[(H_3P)_4IrH(OH)]PF_6$ showed that the counterion needed to be included to obtain agreement with experimental results.

INTERMOLECULAR INTERACTIONS

The metric parameters and interaction energies in **6** and **9** might be artefacts if the NH bond is held too rigidly. Intermolecular systems were used to resolve this problem. In such cases. an acid AH cocrystallizes with a metal hydride (L_nMH). Normally, however, AH and L_nMH crystallize separately. To favor cocrystallization, one needs an acid such as indole, which as a liquid cannot crystallize, and a base, $ReH_5(PPh_3)_3$, which forms poor quality powders on attempted crystallization (see Crystal Engineering with Hydrogen Bonds). An x-ray structure of the 1:1 cocrystal **(7)** gave a short (<2 Å) H...H distance. High-quality crystals allowed a high-quality neutron diffraction structure to be obtained.[18] The same conformation (4) was seen as previously, so the constraints of chelation were not dominant. The H...H distance of 1.73 Å for (7), the smallest reliably determined, is much smaller than the sum of the van der Waals radii for two hydrogens (2.4 Å).

Approximate energetics for adducts of $ReH_5(PPh_3)_3$ with indole (3.6 kcallmol) and with a hindered phenol, ArOH (5.6–5.8 kcallmol), were estimated[18] by IR spectroscopy with a modified Iogansen[20] equation, relating the Δν(NH) or Δν(OH) to the interaction energy.



(2)

(3)

Full equilibrium studies[18] by UV/Vis give a ΔG of 5 kcallmol for $ReH_5(PPh_3)_2(C_5H_5N)$ and indole. Adducts[14] between acidic alcohols such as $(CF_3)_2CHOH$ and the hydridic hydride, $[WH(CO)_2(NO)(PMe_3)_2]$ give association energies of ca. 5.5 kcallmol by the Iogansen method: full equilibrium studies gave an interaction energy of 4.9 kcallmol.

REACTIVITY

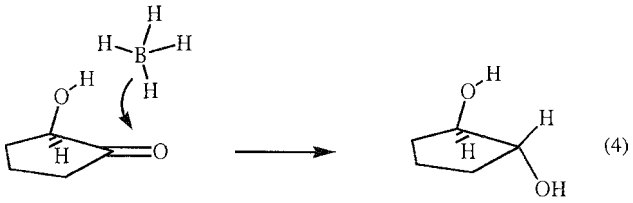
Protonation of metal hydrides may often go via the pathway of Eq. 2. which also shows the side-on binding of the H_2 ligand resulting from proton transfer.

In one case,[22] an equilbrium was seen between $RuH_2(dpm)_2$ (dpm = $Ph_2PCH_2PPh_2$), and a dihydrogen complex formed as a result of proton transfer from an alcohol such as $(CF_3)_2CHOH$ (Eq. 3). Other related cases are known.[21–23]

OTHER CONSEQUENCES OF H...H BOND FORMATION

Many metal hydrides protonate to give H_2 complexes,[24] but kinetic protonation can take place on M–H to give an M–(H_2) complex, even when protonation is thermodynamically favored at the metal. Protonation of CpFeH(dppe) gave the dihydrogen complex at −80°, followed by rearrangement to the dihydride at 25°.[25] Kinetic protonation by A–H at M–H is consistent with the presence of a dihydrogen bonded A–H...H–M precursor adduct as intermediate. Proton transfer in the adduct gives the H_2 complex, and conversion to the *trans* dihydride is slower, because motion[26] of the heavy atoms is needed.

Gatling and Jackson[27] showed how dihydrogen bonding to an –OH group of a hydroxyketone can direct the attack of borohydride to one face of the molecule; indeed, the product is 99.7% *trans* (Eq. 4). The effect was suppressed by addition of F^-, an additive that interrupts the hydrogen bonding. Under the conditions used, formation of an intermediate borate ester could be excluded.



(4)

The role of dihydrogen bonding in stabilizing the transition states for solid state reactions involving loss of H_2, such as in the thermal decomposition of triethanolamine/$LiBH_4$ or of BH_3NH_3 was emphasized recently in experimental[29] and theoretical[29] work.

CONCLUSION

A combination of computational and experimental approaches gives an understanding of the proton–hydride interaction in the DHB.[30] This new type of hydrogen bond influences the physical properties and reactivities of a number of main group and transition metal compounds and seems to be important in cases of protonation of hydrides by acids AH.

Hydrophobic Effects

Hans-Jörg Schneider
Universität des Saarlandes, Saarbrücken, Germany

INTRODUCTION

Hydrophobic interactions are considered to be essential in many systems, be it micelles, vesicles. colloids. membranes and transport; self-organization, polymer interactions, protein folding and ligand binding, nucleic acids, drug action. water-mediated organic reactions,[1–4] and in the last decades. also synthetic host–guest complexes. Hydrophobic effects belong to the most often cited intermolecular forces: chemical abstracts already cite 2735 reviews on the topic, and there is a large number of books[5–7] and reviews[3,4,8–14] on the topic. In this article. only a short introduction can be given, which is eased by the increasing evidence that hydrophobic binding, at least in the sense of entropic contributions, plays a small role in most synthetic host–guest complexes.

FUNDAMENTALS

Hydrophobic binding cannot be understood without understanding the special properties and structure of water. Liquid water can best be viewed as a fluctuating mixture of loose "open" iceberg structures, favored by Coulombic hydrogen bonds, and more dense ice-type structures. favored by dispersive interactions of the oxygen atoms. Solid-state structures of ice ("ice II") show each water molecule surrounded in a tetrahedral arrangement by four other molecules, each of which is linked with each other by hydrogen bonds. For liquid water. x-ray and neutron diffraction studies give radial distribution functions. with about 90% of all molecules having, on the average, the oxygen atoms in relatively close contact. and allowing for many hydrogen bonds. Water structure and energetics change dramatically with the state. Solvation of cations and anions leads to special structures around the charged species that were recently elucidated, also with neutron inelastic scattering methods.[15,16] Salts like sodium chloride have little effect on the water structure, whereas. e.g., guanidinium halide or urea slightly increase the excess self-association of water; the effect of a solvent like trifluorethanol depends on concentration—at low values, there is a strong increase in the self-association of water.[17]

The hydrophobic effect is thought to arise from the exceptionally high energy needed to form a cavity in a solvent, which in a very small space has more interactions between the solvent molecules than any others, and which is characterized by low expandability. Water has an exceptionally high internal cohesion energy density, resulting in a large vaporization enthalpy and a high surface tension. The classical Frank–Evans hypothesis[18] explains the hydrophobic effect mainly by the loss of freedom of water molecules involved in solvation of nonpolar solutes. In this description, solvation requires specific orientation of water molecules toward the solute surface as a "clathrate" (sometimes called "iceberg" structure). in order to maintain a large number of hydrogen bonds between the water molecules. The number of water inolecules suffering from entropic disadvantage is higher, if two cavities must be formed for the accommodation of two separate solute molecules *A* and *B*, than the number obtained by forming one larger cavity that accominodates both A and *B* (Fig. 1A).

The Frank–Evans model has come under debate recently, mainly as the transfer free energy of unpolar solutes to water can be quantitatively described by the so-called scaled particle theory (SPT) on the basis of molecular size, density, and pressure of water alone. without the need to introduce hydrogen-bond functions to account for special water structures.[19] The low solubility of hydrocarbons in water can be due to the small volume of water molecules: with the consequence that a large number of solvent molecules are involved in the creation of a cavity of sufficient volume.[4] Also, neutron diffraction shows no evidence of enhancement of water–water interactions in the presence of unpolar solutes over that in pure water,[20] which speaks like recent computational results[21–23] against the clathrate hypothesis of a particular structure-making effect by solute solvation. A recent description of the hydrophobic effect is based on the high activity coefficient of the aggregating solute in water. while that of the bulk water is close to one.[24] As an alternative to the Frank–Evans model, one can consider the formation of two cavities in water, which reduces translational motions of the solvent molecules, with a subsequent entropy disadvantage (again, the disadvantage is smaller for one larger cavity than for two smaller cavities). The solvation of the solute can then

DOI: 10.1081/E-ESMC 120012669

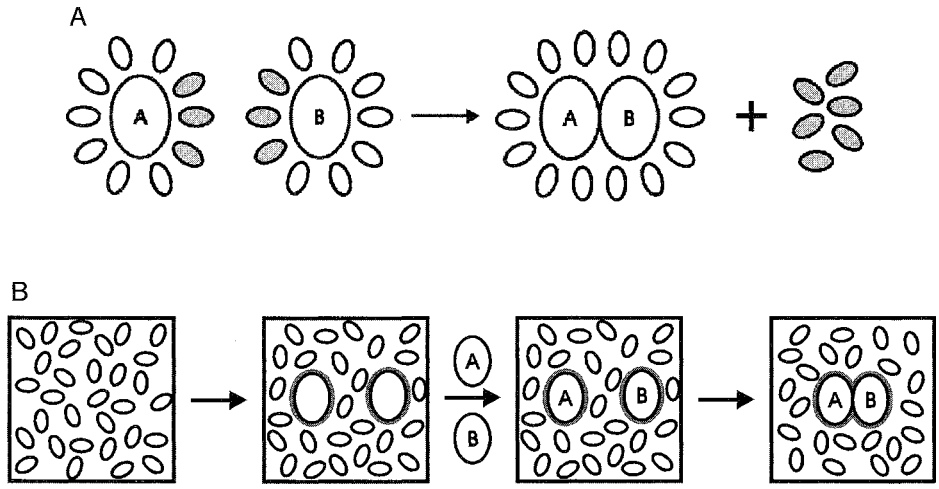

Fig. 1 (A) Liberation of solvent molecules by association of two solute molecules A and B. (B) Creation of cavities in solvent and association of two solute molecules A and B. (*View* this *art in color at www.dekker.com.*)

be accompanied by favorable enthalpic contributions (Fig. 1B). One often observes entropy–enthalpy compensation in hydrophobic binding. At higher temperatures, solute clustering becomes less entropy driven than enthalpy driven. The energy needed to form cavities in a cohesive solvent like water explains the low solubility of lipophilic solutes in water. and their preference for lipophilic media. In addition, a distinction was introduced between ''bulk'' and "pairwise" hydrophobic interactions.[4,25] Bulk interactions stand for the association of a large nuinber of nonpolar molecules, as occurs in micelle formation or protein folding. Each nonpolar molecule in such a process changes its aqueous surroundings to a completely (or nearly completely) nonaqueous environment, in the same way as with the transfer of nonpolar solutes from water to organic solvent.

A so-called nonclassical hydrophobic effect,[26] which can have an enthalpic origin. is based on the consideration of disruption of cohesive forces in the solvent by forming cavities. again with an advantage of one larger rather than two smaller cavities.'"' Another driving force due to the special tendency of water molecules to form many hydrogen bonds can result if the few water molecules inside a host cavity are unable to form as many hydrogen bonds as the outside bulk water. Such "unhappy" water molecules were experimentally located in crystal structures of cyclodextrins[28] and of peptides.[29] Replacement of such water molecules by a guest molecule will lead to a gain of additional hydrogen bonds of the expelled water and would show as enthalpic advantage.

With all models. hydrophobic interactions will increase with the size of those surface parts that are no longer exposed to water but are buried in a nonpolar environment. Quantification of the hydrophobic interaction free energy ΔG_{hp} is, therefore, usually based on calculations of this excluded surface ΔA by an equation with a factor γ describing the cohesive force by the surface tension of the solvent, or by the inicroscopic free energy related to the interfacial tension between a lipophilic solute and water:

$$\Delta G_{hp} = \text{const } \gamma \Delta A$$

For the hydrophobic contribution, measurements of solvent transfer give ΔG values of 80–140 J/(mol Å^2).[11] Studies with engineered proteins indicate similar numbers, but in some cases. values as high as 500 J/(mol Å^2) are given. Experimental data from associations of about 50 different aromatic compounds, which are noticeably independent of heteroatoms and charges within the π-systems, lead to a value of 430 J/(mol Å^2).[30] The size exclusion ΔA can be conveniently assessed by computer-aided evaluation of the surface difference for the host and guest molecules before and after association.

The most direct way to factorize interaction energies of unpolar solutes with water is based on thermodynamic measurements of the solute transfer from gas or from a hydrocarbon medium to water. Such measurements with the transfer of linear alkanes from hexane to water yield. as increments for a CH_2 group, $\Delta\Delta G = 3.85$, $\Delta\Delta H = 2.75$ kJ/mol. respectively; the enthalpic contribution dominates for the CH_2 group; in contrast to the CH_3 group, for which one observes AAC = 8.4, AAH = −5.4 and $T\Delta\Delta S = -13.8$ kJ/mol, respectively.[31] Another often-used way to evaluate hydrophobic contributions of solutes is based on measurements of distribution coefficients between water and a lipophilic solvent, for which one traditionally

used *n*-octanol.[32] The method is of prime importance in medicinal chemistry for determining the lipophilicity of potential drugs. and therefore. it was applied to thousands of compounds. Based on these partition constants (P), one can derive corresponding substituent values $\pi_X = \log(P_{R-X}/P_{R-H})$ that also allow the hydrophobicity of many compounds to be estimated.

CYCLODEXTRIN COMPLEXES

The best-studied examples for hydrophobic interactions in host–guest chemistry are cyclodextrin complexes, although it is often not clear to what degree they are really dominated by a solvophobic force. Obvious examples of solvophobic effects are found if the substrates have a high polarizibility and if the cavity allows a tight fit, in which case calorimetric data speak for a dispersive binding mechanism (see the entry on van der Waals interactions in this *Encyclopedia*). For cyclodextrin complexes with hydrocarbons, one observes a similarity of thermodynamic parameters to those of transfer of the same hydrocarbons from water to a hydrocarbon medium (Table 1). The a-cyclodextrin complexes are more exothermic, with unfavorable AS values, which speaks for van der Waals and not hydrophobic interactions in these tightly fitting systems. Generally. one observes large negative heat capacity changes ΔC_P that. however, were found to be strongly temperature dependent.[33] This is typical for the transfer heat capacity,[13,34] e.g., binding of *n*-heptane to β-cyclodextrin is endothermic at 273 K (AN = 6.3kJ/mol) but is exothermic at 323 K (AN= −8.8 kJ/mol).[35] This illustrates that arguments based on the relative values of AH and TAS are questionable. Also, AS can give either favorable or unfavorable contributions to AG, depending on the chosen standard state. because AC and AS, in contrast to AN, are concentration-dependent units (cf. Table I).

Complexes of aliphatic alcohols with α-cyclodextrin show a linear correlation between lg K and the number of carbon atoms, n_C in normal alcohols, yielding binding increments for the methylene group of AAG = −3.0 kJ/mol, $\Delta\Delta H = -3.83$ kJ/mol, and $T\Delta\Delta S = -0.83$ kJ/mol.[36] These numbers are close to the increments obtained from the transfer of methylene group from hexane to water, discussed above. In contrast, the complexation of a whole molecule, e.g., I-hexanol, is totally "enthalpy driven" in sharp contrast to the more entropy-driven transfer thermodynamics of *n*-hexane.[13] Similar thermodynamics were found for the complexation of alicyclic carboxylic acids, such as admantanecarboxylic acid, bicyclo[2.2.2]-octanecarboxylic acid, etc., and β-cyclodextrin,[37–39] with AG = −3.3 kJ/mol for neutral acids and −2.5 kJ/mol for their anions per methylene group. Again, complexation is enthalpy driven and is characterized by large negative ΔC_P values [−440 and −397 J/(mol K) for adamantanecarboxylate binding to a- and β-cyclodextrins, respectively]. There are many calorimetric data on cyclodextrin complexes in water,[36] and they are all enthalpy driven, in contrast to expectations on the grounds of the Frank–Evans principle.

There is, however. indication that complexation in cavities too wide for a tight fit. and with substrates of smaller polarizibility, is accompanied by some less-entropic

Table 1 Thermodynamic parameters for the complexation by cyclodextrins and transfer from water to hydrocarbon media of heptane cyclohexane, and benzene at 298 K

	ΔG			ΔS		
Solute	**M**	**m.f.**	**ΔH**	**M**	**m.f.**	**ΔC_P**
Complexation with a-cyclodextrin						
cyclo-Hexane	−15.1	−25.1	−19.2	−13.8	19.8	−303
n-Heptane	−21.6	−31.6	−21.3	1.0	34.6	−492
Benzene	−8.6	−18.6	−13.1	−15.1	18.5	−272
Complexation with β-cyclodextrin						
n-Heptane	−19.7	−29.7	−0.6	64	97.6	−305
cyclo-Hexane	−21.4	−31.4	−5.4	53.6	87.2	−316
Benzene-12.8	−22.8	−1.9	36.6	70.2	−498	142
Transfer from water to hydrocarbon						
n-Heptane		−28.6	−0.7		94	
cyclo-Hexane		−28.2	0.1		95	−360
Benzene		−19.4	−2.1		58	−225

Units: kJ/mol for AG and AN and J/(mol K) for AS and ΔC_P. Values of AG and AS are given for two standard states: 1 M solution (Column M) and unit mole fraction solution (Column m.f.).
(From Refs. [31, 33].)

disadvantage than those with tight fits and with substrates of higher polarizibilities, such as nitrophenolate, which is dominated by van der Waals interactions. With, e.g., nitrophenole or adamantane carboxplic acid and β-cyclodextrin, there is a favorable entropic contribution, which. however, is still small compared to the enthalpic driving force (e.g., AN=−21.6 kJ/mol. $T\Delta S$=+2.9 kJ/mol for adamantane carboxyiic acid).[37–39] With less-polarizable substrates, there is a noticeable preference for loose binding that would lead to smaller entropic restrictions. This is evident from NMR studies of complexes with substrates offering alternative smaller phenyl rings or larger naphthyl moieties for complexation. Although the cavity of β-cyclodextrin is geometrically well disposed to take up naphthalene rings, one observes its intracavity inclusion only with the wider γ-CD cavity.[40] A similar preference for loose binding in an aqueous medium is observed with cycloveratrylene complexes.[41]

CYCLOPHANE COMPLEXES

Calorimetric measurements with Cyclophane 1 (Scheme I) and several benzene derivatives show a rough correlation with the lipophilicity parameters lgP of the substrates, but always with dominating AH values against large $T\Delta S$ disadvantages (Table 2).[42] Noticeably, studies with similar complexes in many different solvents exhibit the same enthalpic origin of complexation, with no special entropic advantage in water or. e.g., in methanol. Complexes of lipophilic compounds with the Cyclophane 2 (Scheme 1) show like those with **1,** an affinity decrease with an increasing amount of organic solvents in aqueous solutions.[43] The observed lgK values are a linear function of the solvent polarity parameters, even more so of a solvent hydrophobicity parameter. The sensitivity against solvent change is as expected. larger for complexes with more hydrophobic cavities, such as cyclodextrins.[43] These changes seem to be characteristic of a hydrophobic binding mechanism but would also agree with dispersive interactions. because the higher polarizibility of organic solvent molecules would lead to a similar affinity change.

Table 2 Selected thermodynamic parameters (kJ/mol) for the complex formation between cyclophane **I** and 1,4-disubstituted benzene guests (1,4-X-C_6H_4-X) in water at 293 K

X	ΔG	AH	TΔS	A	logP[b]
COOMe	−28.5	−49.4	−20.9	−251	2.6
MeO	−22.5	−41.8	−19.3	−84	2.2
Me	−22.3	−30.1	−7.8	−84	3.15
CN	−21.9	−43.1	−21.2	−126	1.0

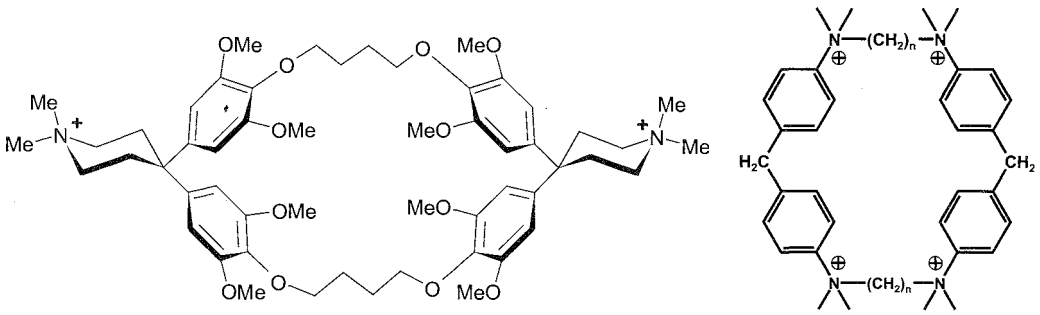
OH	−15.4	−43.1	−27.7	−251	0.6

[a]J/(mol K).
[b]Logarithms of partition constants of guest molecules between octanol and uater.
(From Ref. [42].)

As mentioned above, a possible explanation of the always-dominating enthalpic force in the complexation with synthetic hosts may be the unusual water configuration in the corresponding cavities. Molecular modeling shows that, e.g., inside Cyclophane 2, only five water molecules can be accommodated. which on the average can only materialize two hydrogen bondr.

CONCLUSION

In summary, the evidence for classical hydrophobic effects in supramolecular complexes is often missing. Careful investigations with model compounds. where one can measure the balance of conformations. show that stacking interactions, e.g., with more hydrophilic heterocyclic aromatic moieties, are stronger than with more hydrophobic arenes.[44] This (as well as the small effects of alkyl in comparison to aryl ligands in associations with. for instance, porphyrins) evidence supports the finding



Scheme 1. Cyclophanes 1 and 2.

that many interactions believed to be solvophobic are, in fact, dispersive (see entry on van der Waals interactions in this *Encyclopedia).* The stability decrease of stacked aggregations in model compounds[45] or in nucleic acid components[46] upon addition of organic solvents does not necessarily imply that solvophobic forces dominate. as the high polarizibility of organic molecules leads at the same time to decreased van der Waals attractions between host and guest. It should be noted that other interactions in supramolecular complexes, like ion pairing in water, are entirely entropy driven but are not usually considered to be of hydrophobic nature.

Hydroquinone

Thomas C. W. Mak
Chi-Keung Lam
The Chinese University of Hong Kong, Hong Kong SAR, People's Republic of China

INTRODUCTION

Hydroquinone, p-$C_6H_4(OH)_2$, also known as quinol in the older literature) exists in three polymorphic forms (or crystalline modifications). a-Hydroquinone is the stable form at room temperature, whereas the metastable monoclinic γ-form can be prepared by sublimation or rapid evaporation of a solution in ether. Crystallization of hydroquinone from a common solvent such as methanol generally yields a clathrate with guest solvent inolecules trapped inside cavities of the β-hydroquinone host lattice.''.''The existence of the β polymorph of hydroquinone (empty β-hydroquinone clathrate), which can be obtained by crystallization from n-octane, was reported in 1981.[3] Described in this article are the structural features of these compounds. and some recent developments are also covered.

CRYSTAL STRUCTURE OF β-HYDROQUINONE AND TOPOLOGICAL EQUIVALENCE

The salient symmetry aspects of the crystal structure of β-hydroquinone, or equivalently the β-hydroquinone host lattice, are best understood with reference to the structural archetype of polonium.[4] In its low-temperature α-form, polonium is the only element known to have a simple cubic crystal structure (a = 335.9 pm) in which each atom has six near neighbors. At ∼ 36°C, the α form transforms to a rhombohedral β modification (Fig. 1a. a_1 = 336.8 pm, α = 98.24"; also isostructural with ReO_3). Now consider an assembly of six hydroquinone molecules with their terminal OH groups H-bonded into an $[OH]_6$ ring in accordance with 3 symmetry. Replacement of each atom in the β-polonium structure by an $[OH]_6$ ring, such that each edge of the rhombohedral unit cell is matched by a p-phenylene moiety (i.e., the C_6H_4 aromatic ring plus its two para C – 0 bonds) linking a pair of $[OH]_6$ rings. gives rise to the idealized *single* P-hydroquinone host network shown in Fig. 1b. The topological equivalence of this open-meshed three-dimensional network with the host-water framework of hexamethylenetetramine hexahydrate, with an O—H· ·O hydrogen bond replacing each p-phenylene moiety. was noted several decades ago,[5,6] and Ermer described the structure of β-hydroquinone as superpoloniuin and its building blocks as supercubes (or, more precisely. superrhombohedra).[7,8]

The hypothetical single β-hydroquinone structure is inherently unstable, as it has a large unoccupied cavity at the center of the unit cell. In fact a second. translation-equivalent network (displaced by one-half of the vertical body diagonal of the supercube) can be introduced such that the spacious voids of each network are filled by [OH], rings of the other. This system of two mutually interpenetrating, but unconnected, networks constitutes the basis of the β-hydroquinone host lattice, which can accommodate small guest species such as Xe,[9] H_2S,[10,11] SO_2,[12] or MeOH[13] in cavities that are each sandwiched between a pair of $[OH]_6$ rings belonging to different networks (Fig. 2). Entrapment of a guest molecule in a β-hydroquinone clathrate is represented schematically in Fig. 1c, which shows a pair of interlocking supercubes with vertices and edges that represent the $[OH]_6$ rings and the p-phenylene groups, respectively.

β-HYDROQUINONE CLATHRATES

The classical studies of Powell and coworkers established that all three cystallographically distinguishable types of β-hydroquinone clathrates (designated I. II, and 111) have the same general formula 3 $C_6H_4(OH)_2$·x G, where G represents an encaged guest species, and x is a site occupancy factor that depends on the conditions of adduct formation (e.g., Xe, x = 0.866; H_2S, x = 0.874).[14–18] In Table 1, the first entry is empty β-hydroquinone, with unit-cell dimensions that are the smallest in the series.'']

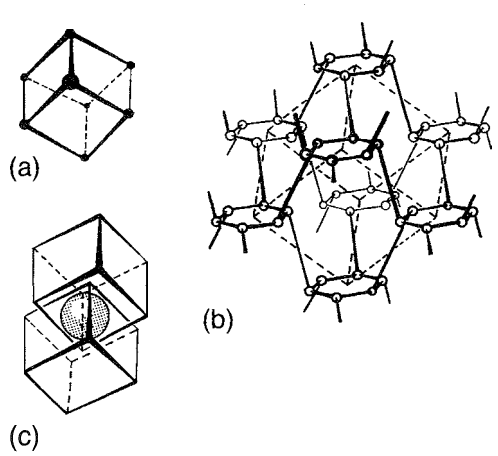

Fig. 1 (a) Perspective view of a rhombohedral unit cell of P-polonium with its principal symmetry axis drawn vertically. (b) Single β-hydroquinone network constructed from the linkage of $C_6H_4(OH)_2$ molecules by O—H···O hydrogen bonds. Each corner of the rhombohedra1 unit cell is occupied by a nearly planar $[OH]_6$ ring, and the *p*-phenylene groups are represented by slant lines. (c) Enclosure in the β-hydroquinone host lattice. The enclosed molecule is represented by a sphere imprisoned between two interlocking supercubes. Each vertex of a supercube represents an $[OH]_6$ ring and each edge a *p*-phenylene group. The crystal structure consists of an infinitely extended three-dimensional array of this cagework.

Structure of Type I Clathrates

In Type I clathrates. cavities with *3* site symmetry are present. In Fig. 2a, a stereoview of such a centrosyinmetric cage of the unsolvated form is shown. The top and bottom of the void are formed by nearly planar hexagons of H-bonded oxygen atoms; an ordered arrangement of hydrogen atoms is apparent in the $[OH]_6$ rings, and the host molecules point alternately above and below the mean plane of the oxygen atoms. The hexameric units forming the ceiling and floor of a given cage belong to two identical, but displaced, three-dimensional interlocking networks (Fig. 2b).

In the Type I xenon[9] and hydrogen sulfide[10,11] clathrates, the encaged guest species occupies an approximately spherical cavity of mean free diameter ~480 pm. The H_2S guest molecule undergoes pronounced thermal motion, particularly in the direction of the centers of the $[OH]_6$ rings. The results are consistent with rotational disorder of the guest molecule.

Recent *ah initio* calculations showed that when small guest molecules (either nonpolar Ne or polar HF) are accommodated in the β-hydroquinone cage structure, the unit cell parameters of the empty host lattice remain largely unaffected. Moreover, the magnitudes of the host–guest interaction energies were estimated as ~ −2 kcallmol with Ne and −7 to −9 kcallmol with HF as the guest species.[19]

Structure of Type II Clathrates

In Type II clathrates, the space group symmetry is lowered from *R 3* (in Type *I)* to R3, and guest accommodation is provided in cages that are still trigonal, although no longer centrosymmetric. For the linear guest molecule methyl isocyanide, the cage length, corresponding to the c-spacing. is markedly increased compared with that of a Type I system. Illustrated in Fig. 3a is the alignment of MeNC molecule along the c-axis in its Type II clathrate.[20] In the methanol clathrate,[13] the encaged MeOH molecule exhibits three preferred orientations related by C_3 rotation about the c-axis; in each orientation, the C — 0 bond is tilted by 35° from the c-axis to facilitate interaction of its hydroxy group with each of three phenolic oxygen atoms of the adjacent $[OH]_6$ ring (Fig. 3b). Host–guest interaction is reflected by unequal O—H···O hydrogen bonds in the $[OH]_6$ ring, a feature also found in the Type II hydrogen chloride clathrate studied by x-ray and neutron diffraction methods.[21]

Structure of Type III Clathrate

In the acetonitrile clathrate of hydroquinone, the only authenticated Type III system, a further reduction in space group symmetry from R3 (in Type II) to P3 occurs. There are now three distinct clathration cavities in the shape of prolate spheroids. The three symmetry-independent MeCN molecules fit snugly inside these cavities, one guest molecule being aligned in the opposite sense to the other two.[19]

CRYSTAL STRUCTURES OF α-HYDROQUINONE

α-Hydroquinone belongs to space group $R\bar{3}$, with a_h = 3846(2) pm. c = 565.0(3) pin, and 54 $C_6H_4(OH)_2$ molecules in the triple primitive hexagonal unit cell.[22,23] As shown in Fig. 4a, two crystallographically independent hydroquinone molecules in the asymmetric unit are involved in forming two interpenetrating. open. H-bonded networks similar to those in β-hydroquinone and capable of enclathrating small molecules, such as carbon dioxide.[" sulfur dioxide,[24] and argon,[17] whereas the third forms double helices consisting of H-bonded chains of $C_6H_4(OH)_2$ molecules about a threefold screw axis.

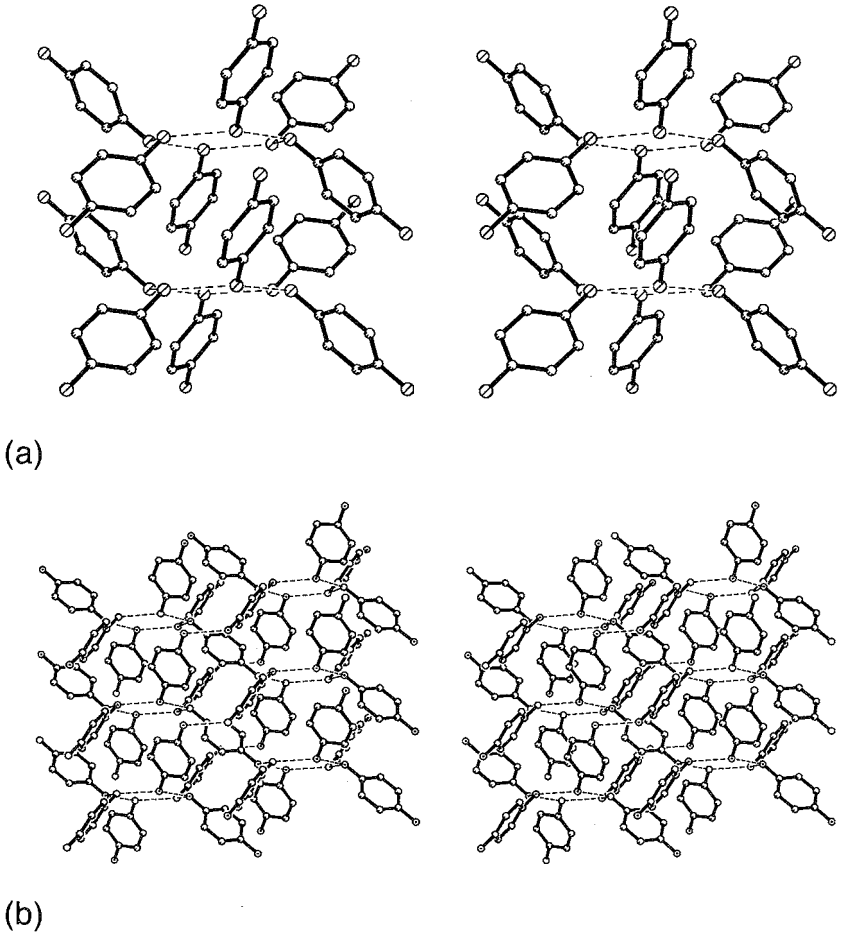

Fig. 4 Stereoviews illustrating (a) the construction of a clathration cage in unsolvated β-hydroquinone, and (b) more extended portions of two identical, but displaced, three-dimensional networks that constitute the β-hydroquinone host structure.

The networks and helices are Fa-bonded together in such a way that the interpenetrating networks are directly linked to each other (in contrast to the unconnected, complementary networks of β-hydroquinone), as are two strands of the double helix. With the presence of three cages (similar in size to those of the β form) per unit cell, the maximum host:guest molar ratio expected for an α-hydroquinone clathrate is 18:1.

Table 1 Crystal data for β-hydroquinone clathrates*

Type	Space group	a	c	Guest species	Interatomic O···O distance(pm) in $[OH]_6$ ring
I	*R*3 (No 148)	1661 3 (3)	547.46 (5)	None	267.8 (3)
		1661 0 (3)	552.4 (1)	Xe	270.5 (2)
		1661 6 (3)	548.9 (1)	H_2S	269.6 (1)

*Lattice parameters (pm) are given for a hexagonal unit cell

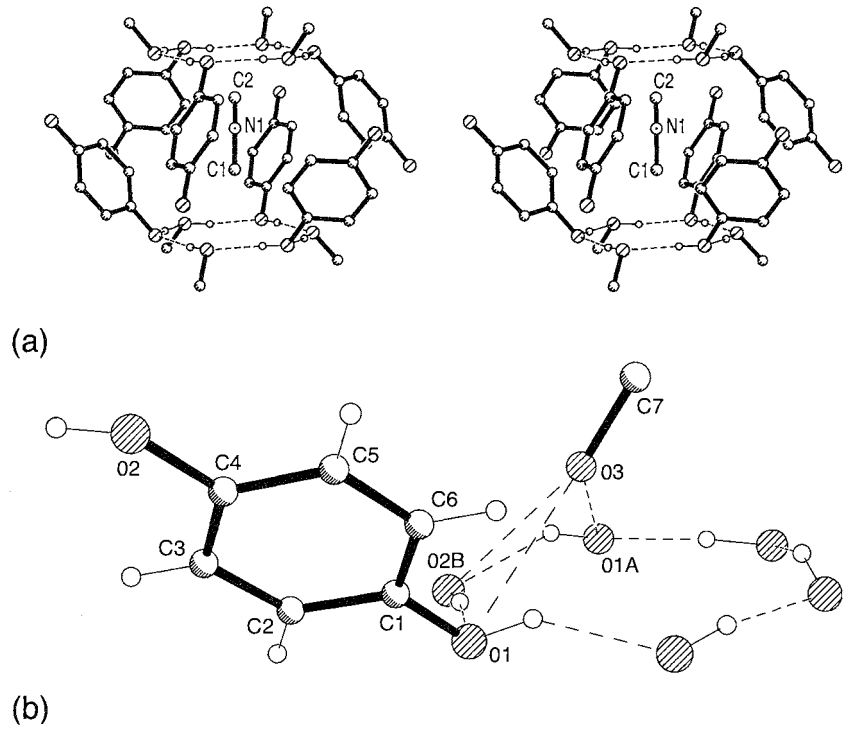

Fig. **3** (a) Stereoview showing a MeNC guest molecule trapped inside a cage in the structure of a Type II β-hydroquinone clathrate. For clarity. all hydrogen atoms were omitted; (b) host–guest interactions in the Type II methanol clathrate of β-hydroquinone; the disordered MeOH guest molecule is inclined at an angle of 35° to the c-axis.

CRYSTAL STRUCTURES OF γ-HYDROQUINONE

Crystals of the γ-form of hydroquinone are monoclinic, space group $P2_1/c$, with a = 807. b = 520, c = 1320 pm, β = 107°. and Z = 4.[25] The structure is built from sheets of H-bonded hydroquinone molecules (Fig. 4b). There are no H-bonded hexameric units, and the inclusion properties are still not well-linown. In accord with the instability and pronounced cleavage of the γ-form, these sheets are apparently held together only by van der Waals forces.

HYDROQUINONE HOST LATTICES WITH ENCLATHRATED FULLERENES

Ermer noted that the edge length of a supercube (−1000 pm) in the single β-hydroquinone (HQ) host framework closely matches the diameter of buckminsterfullerene, C_{60}, and predicted that the resulting supramolecular host–guest complex would have the stoichiometric formula $3C_6H_4(OH)_2{\cdot}C_{60}$, with enclathration being favored by the π-donating properties of HQ and the unusually strong electron-acceptor character of C_{60}. Guided by these considerations. the 3:1 complex was successfully prepared as black dendritic crystals by dissolving stoichiometric amounts of the two components in hot benzene and conducting subsequent crystallization.[7] A similar preparation using a 6:1 molar mixture of HQ and high-purity C_{70} yielded black shiny hexagonal plates of the complex $9C_6H_4(OH)_2{\cdot}2C_{70}{\cdot}2C_6H_6$, which appeared brownish-red in transmitted light.[8] The crystal structures of complexes have been determined using MoK_α data collected at room temperature.

Crystal Structure of $3C_6H_4(OH)_2{\cdot}C_{60}$

The 3:1 adduct of HQ with C_{60} crystallizes in space group $R\bar{3}$ m (No. 166) with Z = 3 in a hexagonal unit cell of dimensions a_h = 1621.5(2) pm and c = 1384.6(2) pm.[7] The corresponding rhombohedra1 unit cell has a, = 1043.8(3) pm and $\alpha = 2\sin^{-1}(a_h/2a_r) = 101.92(2)°$. The HQ molecule occupies a site of symmetry $2/m$. whereas the C_{60} molecule is highly disordered, with relatively shallow electron-density maxima smeared out tangentially over a sphere of radius 351 pm.

The architecture of the single β-hydroquinone host lattice of $3C_6H_4(OH)_2{\cdot}C_{60}$ may be compared with that of empty β-hydroquinone, with hexagonal unit cell edges

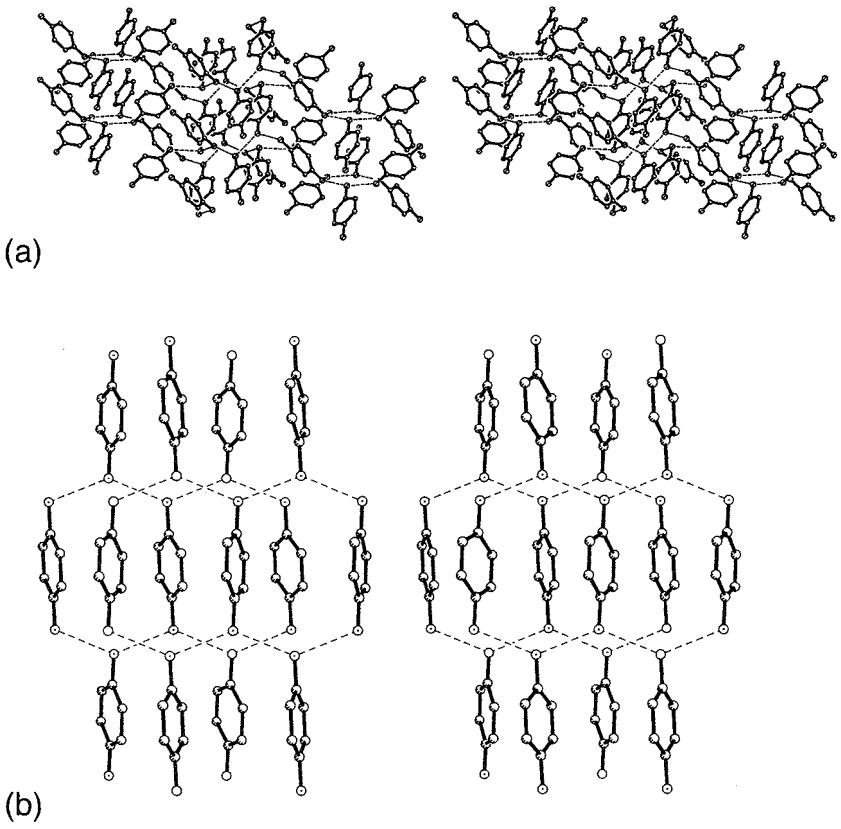

Fig. 4 Stereoviews: (a) the structure of α-hydroquinone, in which two crystallographically distinct $C_6H_4(OH)_2$ molecules are used to construct the unoccupied cages. while a third independent molecule forms double helices around a threefold screw axis in the middle; (b) the crystal structure of γ-hydroquinone built from sheets of H-bonded molecules.

that are a_h = 1661.3 pm and c = 1094.9 pm (the c-axis is doubled to allow for twofold interpenetration). The considerable trigonal elongation (with concomitant contraction of its "waist" as measured by a_h) of the HQ supercube in $3C_6H_4(OH)_2 \cdot C_{60}$, compared to β-hydroquinone, is a consequence of the highly puckered $[OH]_6$ ring, which takes a cyclohexane-like chair conformation with O···O = 279.9 pm, O···O···O = 112.9°, and dihedral angle O··O··O··O = 50.5°. Accordingly. the C_{60} molecules fit tightly inside the cavities of the rather strained single HQ host network. Furthermore, the distance between the centers of a C_{60} cluster and a polar face-to-face orientated HQ molecules is 657.4 pm (Fig. 5a), leading to a distance of 310 pm between the C_{60} surface and the HQ plane, which matches the interplanar stacking distance in the 1:1 charge transfer (CT) complex of HQ with quinone (quinhydrone).[26,27] The implied host–guest charge transfer interaction in $3C_6H_4(OH)_2 \cdot C_{60}$ is consistent with the high electronegativity of C_{60} and the π-donor properties of HQ, as well as the deep color and metallic luster of the crystals.

The orientational disorder of the enclathrated C_{60} in the single β-hydroquinone host network was studied using MoK_α data at four different temperatures, 100, 200, 293, and 373 K. The results showed that the two independent bond lengths of the buckminsterfullerene. d_{56} common to a pentagon and a hexagon and d_{66} common to two hexagons, changed smoothly by −0.03 Å as functions of temperature between 100 and 373 K: the higher the temperature, the longer was d_{56} and the shorter was d_{66}, while the molecular diameter remained almost constant between 7.072 and 7.075 Å.[28]

Crystal Structure of $9C_6H_4(OH)_2 \cdot 2C_{70} \cdot 2C_6H_6$

This inclusion complex $9C_6H_4(OH)_2 \cdot 2C_{70} \cdot 2C_6H_6$ crystallizes in space group P $\bar{3}$ m1 (No. 164). with a_h = 1710.2(5) pm, c_h = 2390.4(9) pm. and Z = 2.[8] There are three types of independent HQ molecules of site symmetry *m*: Types 1 and 2 each with a crystallographic mirror plane containing the C — 0 bonds and orthogonal to the molecular plane, and Type 3, with the mirror plane normal to the C — 0 bonds. The C_{70} molecules occupy two nonequivalent 3*m* sites (Types A and B) and exhibit orientational disorder such that their principal molecular C_5 axes are normal to the c-axis. The

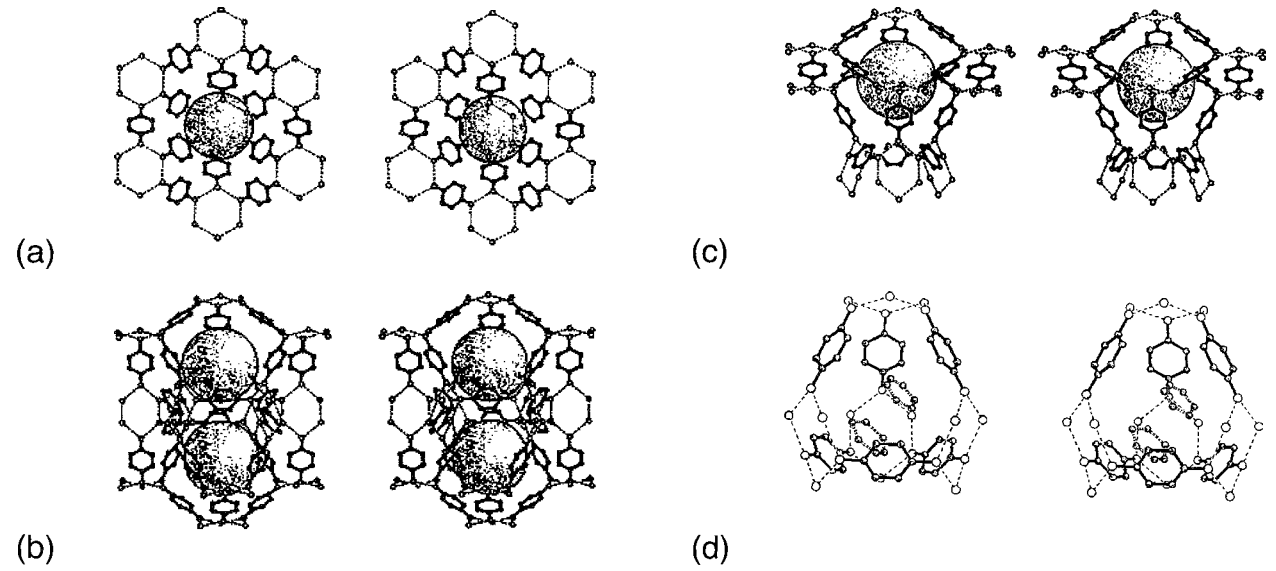

Fig. 5 (a) Stereoview of the crystal structure of $3C_6H_4(OH)_2{\cdot}C_{60}$ viewed parallel to the c-axis. Stereoviews of the disordered C_{60} molecule is depicted as a large sphere, and the O—H···O hydrogen bonds are represented by broken lines. The b-axis is horizontal and orthogonal to a vertical mirror plane containing the c-axis. The crystal structure of $9C_6H_4(OH)_2{\cdot}2C_{70}{\cdot}2C_6H_6$; (b) the peanut-shaped twin cage viewed in the [210] direction. The h-axis is horizontal, and the c-axis is vertical. The two disordered Type A C_{70} guest molecules in the cage are represented as large spheres, and the O—H···O hydrogen bonds are shown as broken lines; (c) the medium-size cage containing a Type B C_{70} guest niolecule viewed along [210]; and (d) the small tetrahedral cage viewed in the [210] direction. the encaged pair of face-to-face benzene molecules being shown in one of the six possible orientations.

enclathrated benzene molecules are grouped in pairs around a $3m$ site and are less well characterized in the x-ray analysis.

The HQ host architecture of the $9C_6H_4(OH)_2{\cdot}2C_{70}{\cdot}2C_6H_6$ complex contains three nonequivalent chair-like $[OH]_6$ rings located in sites of symmetry $3\,m$, $3m$, and $2/m$, respectively. The three-dimensional HQ host network contains three kinds of cavities: 1) large cage of site symmetry m accommodating a pair of C_{70} clusters of Type A (see Fig. 5b); 2) medium-size cage of symmetry $3m$ containing a C_{70} cluster of Type B (see Fig. 5c); and 3) small cage of symmetry $3m$ enclosing a pair of benzene molecules (see Fig. 5d).

In the first type of cage, the large cage is bounded by 14 $[OH]_6$ rings and 24 p-phenylene units. It has the shape of a peanut shell, with each equivalent half-filled by one Type A C_{70} molecule, such that the principal symmetry axis of C_{70} lies perpendicular to the 3 axis of the cage. The two enclosed C_{70} molecules are 1010 pm apart center-to-center, and each is additionally involved in six face-to-face and nine edge-to-face contacts with the enclathrating HQ molecules: three face-to-face with HQ (Type 1) at 697 pm near a polar cap, six edge-to-face with FIQ (Type 2) at 963 pm, and three face-to-face plus six edge-to-face at 706 pm and 863 pm, respectively, with HQ (Type 3) that constitute the equatorial waist of the cage. Conceptually, this large cage may be generated from the single HQ host cage of 3 $C_6H_4(OH)_2{\cdot}C_{60}$ by elongation along the trigonal axis and equatorial insertion of a macro-ring of six H-bonded HQ (Type 3) molecules.

The second type of cage, the medium-size cage: is surrounded by 10 $[OH]_6$ rings and 15 p-phenylene connectors. Starting with the simple HQ supercube of $3C_6H_4(OH)_2{\cdot}C_{60}$, the medium-size cage may be obtained by replacing a vertex on the trigonal axis by an equilateral arrangement of three linked vertices.

The third cage, the small cage, takes the shape of a trigonal pyramid assembled from four $[OH]_6$ rings and six p-phenylene linkers. Electron-density distributions from difference Fourier maps suggest that this approximately tetrahedral cage encloses a pair of face-to-face benzene molecules. which are necessarily subject to orientational disorder around the C_3 axis of the cage. However. the quality of the x-ray intensity data is insufficient to establish this staggered benzene sandwich model as unequivocal.

CONCLUSION

A comparative study of the crystal structures of tetrafluoro-, tetrachloro-, and tetrabro~nohydroquinone showed that they are built of an almost invariant network of O—H···O hydrogen bonds that is analogous to that of γ-hydroquinone, indicating the robustness of this kind of hydrogen-bonding pattern. Both Cl and Br atom, tend to

form a polarization-induced X···X contact to interconnect adjacent layers. but the F atom does not manifest this type of interaction.[29]

The crystal structure of 2.5-di-tert-butylhydroquinone is topologically equivalent to the α-form of arsenic.[30] Introduction of the bulky *tert*-butyl substituents next to the phenolic groups of the hydroquinone leads to the polar stacking of nonpolar, puckered hydrogen-bonded sheets with trigonal symmetry. Similar to the case of β-hydroquinone, the novel layer structure constructed by 2,5-di-tert-butylhydroquinone may be developed from *r*-. As through replacement of the As atoms by H-bonded three-meinbered rings of oxygen atoms, and the As–As bonds by covalent 2.5-di-tert-butyl-p-phenylene links. The formation of the three-membered rings of H-bonded oxygen atoms are rare but are rendered favorable by the presence of a bulky alkyl group close to the hydroxyl group (e.g., tertiary alcohols).

In the presence of bridging water molecules. calix[4]-hydroquinone can self-assemble to form a linear tubular polymeric structure, having an infinitely extended one-dimensional hydrogen-bonded array that can be suspended in aqueous solution and also be grown to very thin tubes as well as a bundle of well-ordered three-dimensional chessboard-like rectangular arrays. These arrays possess useful electrochemical/photochemical properties and can function as an organic nanotube template for designing molecular electronics components.[31] For example, ultrathin silver wires with 0.4 nanometer width can be grown up to micrometer-scale length inside the pores of these self-assembied calix[4]hydroquinone nanotubes by electro/photochemical redox reaction in an ambient aqueous phase.[32]

Imaging and Targeting

Stephen Faulkner
Rebecca J. Aarons
University of Manrhester, Manchester, United Kingdom

INTRODUCTION

The twin fields of imaging and targeting developed rapidly over the last quarter of a century. Both exploit the interactions between discrete species. albeit in very different ways. This brief overview examines the two concepts separately, covering the broad range of techniques being used at the beginning of the twenty-first century. with particular emphasis on the exploitation of molecular recognition and metal binding.

IMAGING

Noninvasive imaging of biological systems has the potential to provide information relating to the structure and function of tissue without resort to surgery. Traditionally, this relied on the use of x-rays for hard-tissue imaging. However. a range of soft-tissue imaging techniques were developed in the last quarter of a century that extends the range of options for clinical diagnosis and opens the possibility of specific and functional imaging. In the three key areas. advances in detection and data–processing techniques were applied and combined with exploitation of biological and chemical supramolecular processes.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the dominant form of soft-tissue imaging. MRI uses the principles of gradient field NMR spectroscopy to build contrast between tissue types. It relies on the relaxation properties of water protons in a magnetic field." These vary naturally from one tissue type to another. depending on the freedom of movement of water protons. Protons tumbling rapidly relax more quickly than those tumbling slowly. so the signal obtained from fluid media is different than that obtained from viscous media (e.g., water protons associated with protein molecules will relax more slowly than bulk water). These differences in relaxation rates are used to create a tissue map.

Paramagnetic species are of increasing importance in MRI. because they enhance the relaxation rates of water protons in the medium surrounding them. giving rise to improved contrast.[2,3] Such species are known as contrast agents. A variety of classes of paramagnetic contrast agent exist, and one of the most important is that consisting of paramagnetic ions. particularly gadolinium ions. Gadolinium(III) is an ideal species for use as a contrast agent. It possesses seven unpaired electrons combined with a long electron spin relaxation time. while bound water niolecules are in rapid exchange with bulk solvent. The free ion is toxic, making it unsuitable for use as a contrast agent. Instead, gadolinium complexes are used. The ideal gadolinium complex should have high kinetic stability to minimize toxicity. while still allow close approach of water molecules and facile exchange of inner- and outer-sphere solvent molecules with the bulk solvent. These two aims must be balanced, because they are. in part, contradictory: kinetic stability is best achieved in rigid complexes that exclude solvent from the inner coordination sphere, while rapid exchange of solvent molecules is best achieved with significant numbers of coordinated water molecules.

Shown in Fig. 1 are some typical contrast agents. These all have hard donor atoms and, with one exception, are eight coordinate ligands. The exception. a texaphyrin,[4] a five-coordinate ligand, trades some kinetic stability in favor of increased inner-sphere coordination of water molecules. Of the other molecules, two (DTPA and BOPTA)[2] are acyclic and derived from diethylenetriamine. This makes them relatively simple to prepare but results in lower kinetic stability of the gadolinium complexes relative to ligands based on a rigid inacrocyclic backbone (DOTA, DO3AHP. and GADOBENZ).[2,5] The increased stability of the macrocyclic complexes arises as a result of preorganization of the ligands combined with restricted rotational freedom in the ligand backbone. $[Gd.DTPA]^{2}$, $[Gd.BOPTA]^{2}$, $[Gd.DOTA]^{-}$, and [Gd.DO3AHP] allow the close approach of one water molecule to the metal center. Contrast arises from the inner and the outer coordination spheres of solvent molecules. By contrast, GADOBENZ has bulky (and hydrophobic) benzyl groups appended to the phosphinate donor groups. These prevent the close approach of water, and the contrast

DOI: 10.1081/E-ESMC 120012799

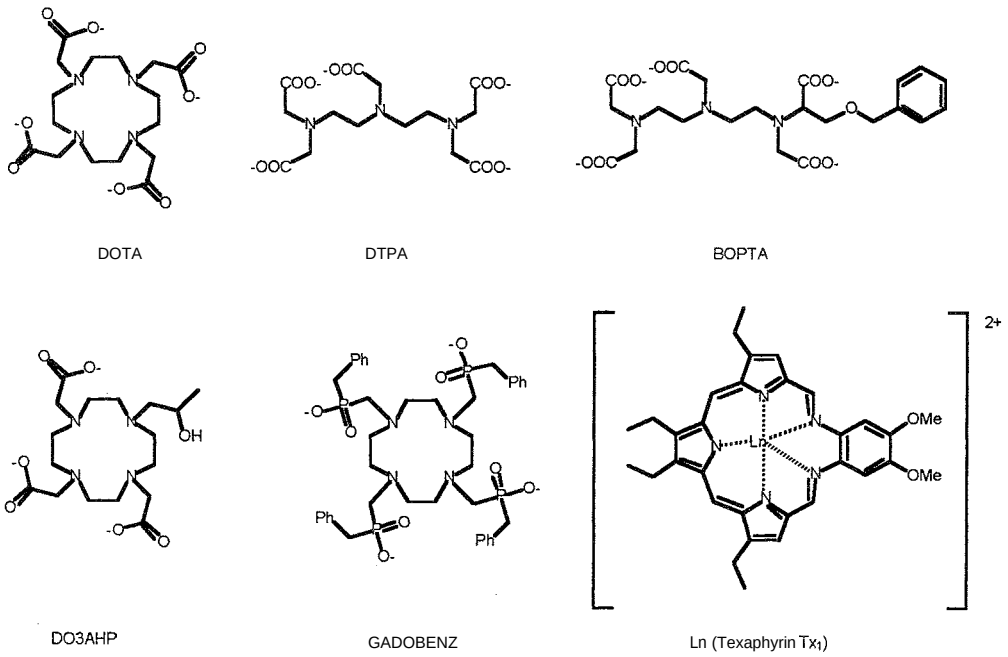

Fig. I Ligands and complexes used as MRI contrast agents

properties of this species arise solely as a result of exchange of outer-sphere solvent.[5] The nature of the inner- and outer-sphere solvation for a particular complex can be determined by field cycling relaxometry[3] or by luminescence measurements on analogous lanthanide complexes.[6]

Current interest centers on the possibility of developing smart contrast agents. targeted to particular cell lines and to cell surface receptors. There is some debate as to whether the use of targeting vectors (vide infra) to specify cell surface receptors will prove an effective means of generating contrast, because agents such as those described above give rise to reasonable contrast at concentrations well above those of typical cell surface receptors.[7]

Accordingly. it becomes necessary to improve the effectiveness of the contrast agent. One approach to this problem is to increase the number of gadolinium ions present. for instance, by preparing dendrimers bearing many gadolinium ions.[8] The effectiveness of a contrast agent is measured by its relaxivity, the paramagnetic relaxation rate enhancement caused by a 1 mM solution of the complex. This may be regarded as the sum of the inner- and outer-sphere relaxivities, with the inner-sphere contribution dominating for systems where there are bound water molecules. The chief determinant of the inner-sphere relaxivity is the rotational correlation time of the complex. This can be exploited for inononuclear complexes by placing the complex at the hub of a much larger molecule or by utilizing the binding of the contrast agent by albumin proteins and the consequent reduction in rotational freedom.''' Dendritic systems achieve higher relaxivities by increasing the effective gadolinium concentration. The inner- and outer-sphere contributions for individual ions in surface-functionalized dendrimers are comparable to those for mononuclear complexes.

Positron Emission Tomography and Single-Photon Emission Tomography

While smart imaging with MRI contrast agents still represents a challenge. other imaging techniques have achieved the goals of smart. or functional, imaging. Tomographic imaging with radioisotopes represents a useful alternative, particularly where the goal involves imaging species at low concentrations. Because background radiation in vivo is generally very low, radioisotopes can be detected at very low concentrations. At such low concentrations. the risk to health is minimal.

There are two main techniques. each of which utilizes different types of radioisotopes to obtain an image:

1. Single-photon emission tomography (SPET),[9] also known as single-photon emission computer tomography (SPECT). depends on the emission of gamma rays by appropriate isotopes. These gamma rays can be detected by a gamma camera; and images are then obtained using conventional mapping techniques.
2. Positron emission tomography (PET)[10] uses positron (β^+)-emitting isotopes as signaling moieties. Positrons are antimatter and annihilate when they encounter an electron, giving rise to two photons,

each of 511 keV. This annihilation occurs almost instantly when the positron is produced, i.e., before it can travel through tissue. The production of such photon pairs can be detected using a technique called coincidence detection, which registers a signal every time two photons of appropriate energy arrive simultaneously at an array of detectors. These signals can then be deconvoluted to give rise to images showing the localization of the isotope.

Both SPET and PET use isotopes with short half-lives to optimize image contrast while minimizing dose.

Considered to be among the best choices for SPET are ^{99m}Tc (half-life 6 h) and ^{123}I (half-life 13 h), as they have monoenergetic emissions (141 kev and 159 keV, respectively) that make them easy to detect, and they provide a lower radiation dose to the patient.

We can pass over iodine in a few words. The iodide ion is not an option, as it tends to localize in the thyroid, so covalently linked species are the best. These tend to be prepared at the hospital by iodination of a suitable organic molecule (usually one containing a double bond). Such reactions need to be fast. given the short half-life of the nuclide.

Suitable isotopes of metal ions are more readily used in complexes. Among others, gallium (^{67}Ga), technetium (^{99m}Tc), and indium (^{111}In) complexes have been used.

Positron-emitting isotopes are more numerous and more varied. They also tend to have a wide range of half-lives, although all have the same photon energy owing to the way in which the photons are produced. Among the isotopes commonly used for PET are ^{11}C (half-life 0.3 h), ^{18}F (half-life 2 h), ^{55}Co (half-life 18 h), ^{64}Cu (half-life 13 h), ^{66}Ga (half-life 9.5 h), ^{83}Sr (half-life 33 h), ^{94g}Tc (half-life 5 h), and ^{120}I (half-life 1.4 h).

It is important to consider how quickly the radionuclide can be delivered to the patient from the source (including the time taken for any complex or compound preparation). Unless the hospital has a cyclotron and the chemistry is simple, half-lives of the order of minutes are too short. There is an alternative, in that nuclides that are not positron emitters may produce them by radioactivative decay. Such nuclides, called generators, can have longer half-lives and, thus, provide a ready source of short-lived positron emitters. It is also important that the parent and daughter nuclides be easily separated, so that the parent can produce more daughter nuclides while the first batch is being used. Examples of such systems include the use of ^{134}Ce (half-life 3 days) to produce ^{134}La (half-life 7 min). and the use of ^{68}Ge (half-life 271 days) to produce ^{68}Ga (half-life 68 min).

The choice of radionuclide depends on the type of imaging envisaged. For simple imaging, isotopes with short half-lives are suitable. For targeted imaging, the localization process may take up to 72 h, meaning that short-lived isotopes will decay before they can be used.

As a result of the short half-lives of the nuclides described above, the complexes chosen for their delivery are, of necessity, simple. In Fig. 2, complexes A through C are designed for use with technetium ions.[11–13] Pertechnetate is readily available but must be reduced in situ to Tc(V) or Tc(I) before complexation is possible. Ligands D and E are suitable for the complexation of ^{64}Cu for positron emission tomography.[14,15] In all cases, it is

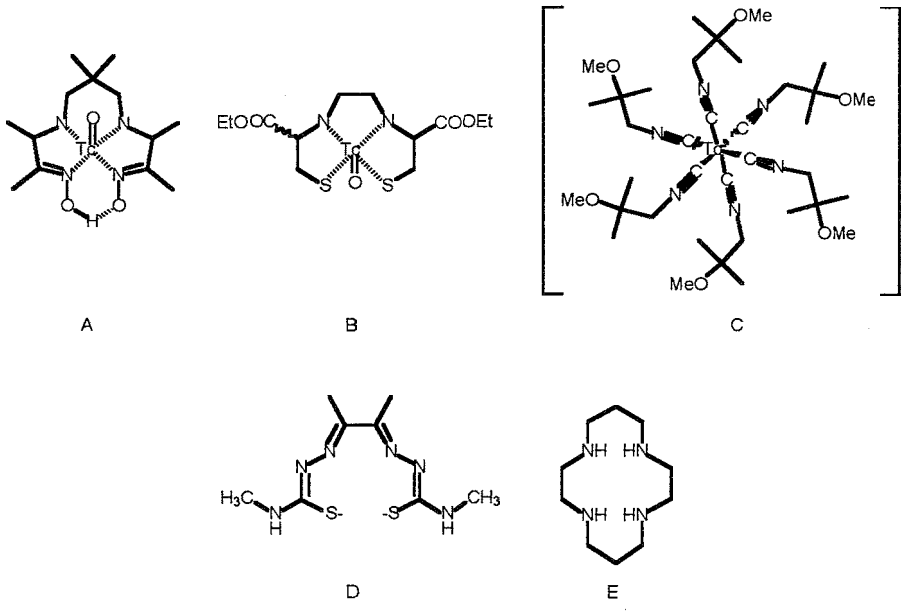

Fig. 2 Ligands and complexes used in radioisotope-based imaging techniques

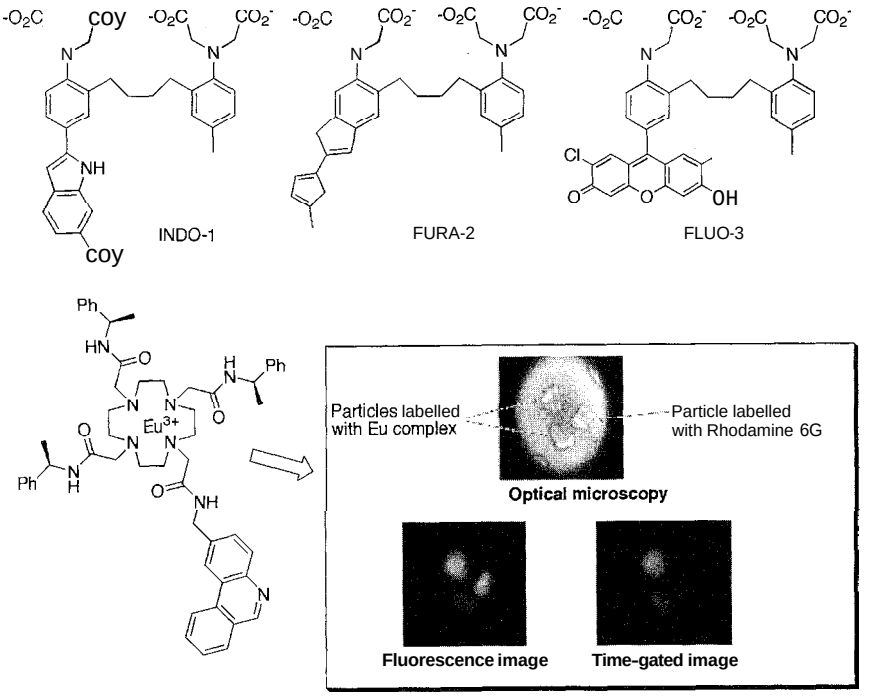

Fig. 3 Ligands and complexes used in luminescent imaging

essential that the manipulation and purification of the complex can be achieved with minimal effort in as short a time as possible, because such manipulations are generally performed at the hospital by nonchemists.

Luminescence-Based Imaging Techniques

MRI and radiochemical imaging techniques are both highly effective for whole-body imaging but tend to offer limited spatial resolution when applied to systems where a degree of magnification is necessary. Both techniques are capable of resolution to the millimeter level but offering higher resolution is difficult. For many physiological applications. for example, the study of subcellular processes, higher resolution is essential. Optical microscopy offers the desired resolution but suffers some disadvantages—chief among these is the nature of the technique. Contrast in optical microscopy arises from differing degrees of light absorption by the sample. and as such, the potential of the technique for specific imaging is limited by the absorbance of the tissue.

Fluorescence offers one route around this problem. The emission of light by an electronically excited molecule can occur in any direction and need not necessarily be colinear with the absorbed photon. The sample can thus be observed perpendicular to the probe beam. This results in an enormous improvement in sensitivity, because any signal represents an increase on a zero background. By contrsst. absorption must be detected as a small decrease in a large signal—a much less sensitive approach. Biological samples are fluorescent in their own right (a phenomenon known as autofluorescence), as a result of the presence of naturally occurring chromophores. However, most biological absorption occurs in the UV, and most autofluorescence occurs in the blue region of the spectrum. Thus. autofluorescence can be avoided by using fluorescent compounds (or fluorophores) that absorb light at longer wavelengths than biological absorption.[b]

Smart fluorescent indicators are widely used in fluorescent imaging microscopy. INDO-1,'''' FURA-2,[17] and FLUO-3[18] (Fig. 3) belong to the same family of calcium indicators. All share a binding site derived from BAPTA, comprising two amine and four carboxylate moieties (at the top of the molecule). which is selective for calcium ions over other endogenous metal ions. The acyclic binding site has considerable rotational freedom, allowing rapid binding and release of metal ions and minimizing the degree to which low concentrations of ligand will buffer metal ion concentrations. In each case. the left-hand side of the molecule also constitutes an extended conjugated system in which one of the amine groups in the binding site acts as an electron donor. Because this amine performs a dual function, the availability of the nitrogen lone pair to the conjugated system will vary depending on whether or not a metal ion is bound. This, in turn, will affect the photophysical

[b]For a detailed treatment of fluorescence microscopy. see Ref. [16]

properties of the system. In the case of INDO-1 (for the free ligand λ_{ex} = 349 nm. λ_{em} = 485 nm; for the calcium complex λ_{ex} = 331 nm, λ_{em} = 410 nm),[17] little change is observed in the absorption spectrum, but the emission spectrum is shifted considerably. The reverse is true for FURA-2 (for the free ligand λ_{ex} = 362 nm, λ_{em} = 512 nm; for the calcium complex λ_{ex} = 335 nm, λ_{em} = 505 nm).[17] Because the free and bound systems can thus be distinguished without difficulty, the calcium concentration may be quantified easily. Both INDO-1 and FURA-2 absorb light at relatively short wavelengths. similar to those associated with biological absorption. This gives rise to a significant fluorescent bacliground. FLUO-3 attempts to overcome this problem by shifting the excitation band to lower energy and longer wavelength. However. the increase in conjugation and the presence of another donor unit in the fluorescein-like chromophore conspire to ensure that, while the intensity of fluorescence changes on binding calcium, the shift in excitation and emission wavelength between the free and the bound species is so small as to be negligible (for the free ligand λ_{ex} = 556 nm. λ_{em} = 576 nm; for the calcium complex λ_{ex} = 553 nm. λ_{em} = 576 nm).[18] Quantification of the calcium ion concentration therefore becomes more complicated, requiring the use of ratio experiments.

An alternative approach can be used to remove background fluorescence, allowing accurate imaging even when autofluorescence occurs. Because fluorescent compounds have short luminescence lifetimes. typically of the order of 0.1–10 ns, it is easy to envisage using a probe molecule that has a much longer luminescence lifetime (of the order of 500 ns–1 s). The fluorescent emission will have decayed almost completely 100 ns after an excitation pulse, while any longer-lived luminescence will still be present. It is easy to envisage a system in which a period of time is allowed to elapse after the excitation pulse, ensuring that only the desired luminescence is collected, while fluorescence is rejected. This approach is called time-gated imaging. Organic phosphors tend to be unsuitable for this approach to imaging, because their luminescence is quenched by dissolved oxygen in solution. Lanthanide complexes. such as the europium complex shown in Fig. 3. are ideal—particularly when an organic chromophore is used to harvest light and transfer energy to the metal center.[19] Lanthanides have low extinction coefficients and absorb light weakly, but they have long luminescence lifetimes (0.1–5 ms for europium and terbium complexes[20] and 0.1–10 μs for ytterbium[21] and neodymium complexes[22]). They are also well established as acceptors of energy from aromatic donor chromophores, which can be used to solve the problem of extinction coefficient.

The europium complex in Fig. 3 bears a phenanthridine chromophore on the ligand. which absorbs light effectively. The images show three particles. The two on the left were labeled with the europium complex, while that on the right was labeled with rhodamine 6G, a fluorescent dye that absorbs and emits light at the same wavelengths as the europium complex (λ_{ex} = 355 nm, λ_{em} = 615 nm).[19] It is clearly seen that it is impossible to differentiate the particles by conventional optical microscopy or fluorescence imaging. However, time-gated imaging completely rejects the rhodamine fluorescence. illustrating how the technique can dramatically improve signal-to-noise ratios in systems where background fluorescence is problematic.

TARGETING

Selective therapy or chemotherapy of disease states has long been a challenge for medical science. Chemotherapy for cancer and genetic disorders represents the greatest challenge. because both disease states arise within the patient and are thus difficult to differentiate from normal tissue. The development of such techniques concentrates on the delivery of drugs or genetic material to specific sites. Targeting of this kind is achieved by incorporating a targeting vector specific to sites on or within the cells being targeted, into the assembly being used for therapy. Such assemblies may be covalently linked,[23] may rely on coordination of a metal ion,[24] or may be noncovalent assemblies held together by supramolecular interaction~.''Supramolecular chemistry interactions remain important regardless of the nature of the assembly; all rely on noncovalent interactions between the targeting vector and the targeted site.

Antibodies

It is possible to raise antibodies to specific cell types (e.g., cancer cells.)" The strategy is simple in its early stages and involves implanting a foreign tumor into an animal. The immune system then fights this tumor, raising antibodies to it. that recognize any unusual proteins on the surface of the cells. These antibodies can then be expressed in cultures. However, the process is not finished. because the animal's body system. with the original tumor. will recognize the antibodies as foreign. This means that the antibodies then have to be humanized, by modifying their structures to retain selectivity but suppressing the immune response.

In general. while vectors derived from antibodies offer high specificity. they have drawbacks. They are difficult to make and tend to have much larger molecular weights

"Details of monoclonal antibody-based technique? can be found in Ref. [26].

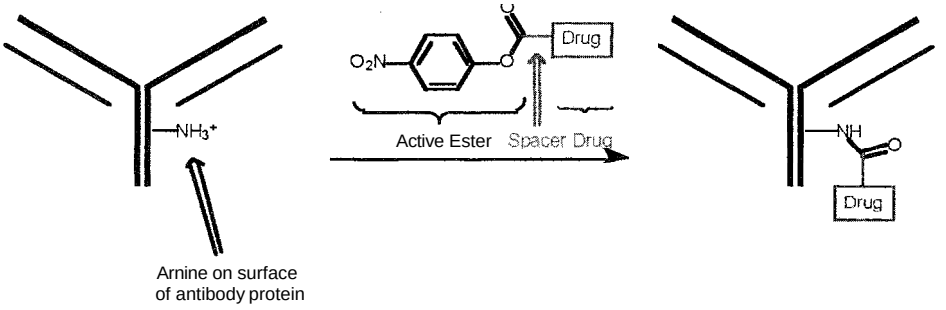

Fig. 4 Formation of an antibody conjugate.

than the rest of the BFCA. meaning that the amount of drug delivered is small relative to the molecular mass of the antibody conjugate.

Shown in Fig. 4 is a cartoon representation of the preparation of an antibody conjugate from a monoclonal antibody. The antibody surface is covered with hydrophilic residues. Some of these. particularly side chains containing amines and thiols. are nucleophilic. The cartoon illustrates the use of an active ester to form an amide. covalently linking the antibody to the drug, though other

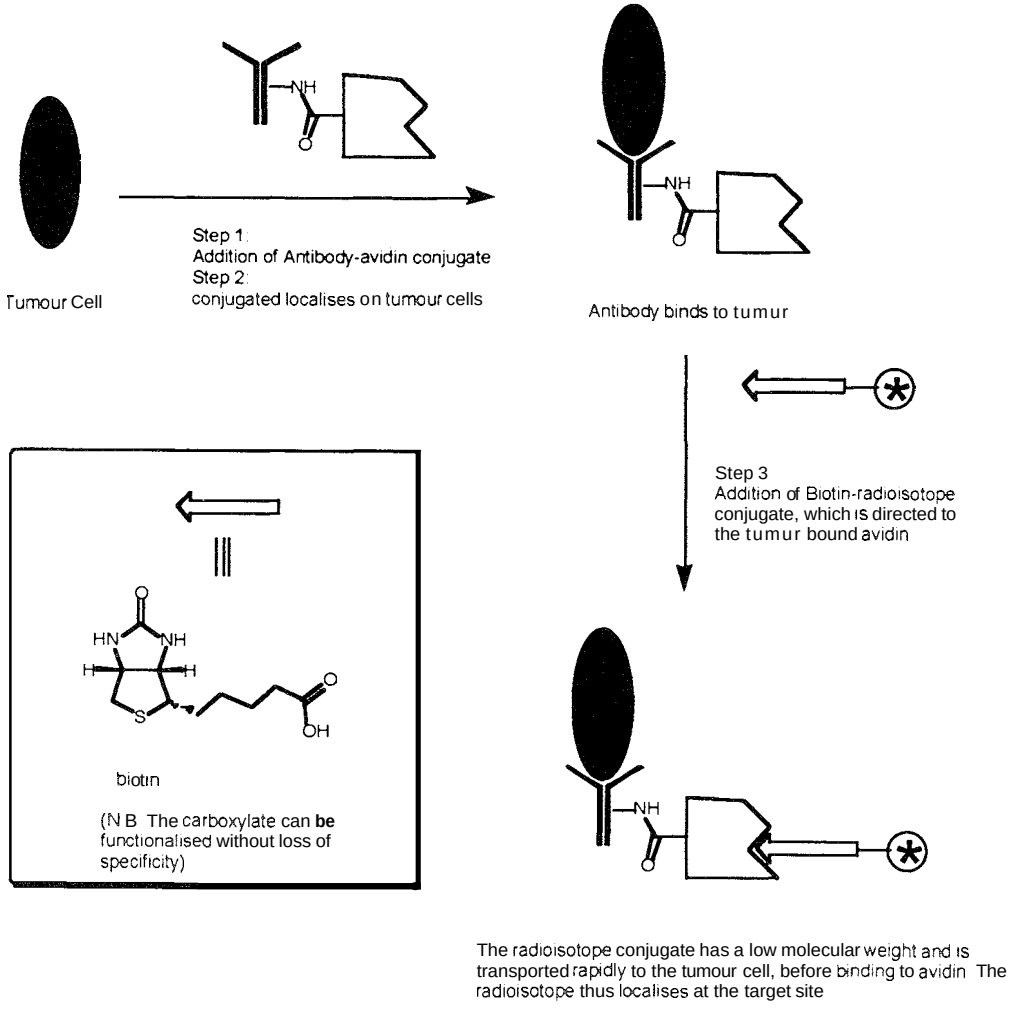

Fig. 5 A tumor pretargeting with an antibody–avidin conjugate

approaches using isothiocyanates or thiol reactive maleimides are equally valid. All of these reactive groups must be used in aqueous solution at ambient temperatures to avoid denaturing the antibody.

bow-Molecular-Weight Targeting Vectors

Low-molecular-weight targeting vectors are much simpler to prepare than antibodies. Such targeting vectors are derived from bioactive peptides (e.g., in the chelating agent octreotide)[27] and small molecules such as biotin, which bind strongly to biological receptors or proteins. While they are easier to prepare, there are two potential problems with using low-molecular-weight vectors. First, the vector and the therapeutic agent are likely to be of similar size; the presence of the drug inay thus alter the specificity of the targeting vector, particularly where a metal complex is being delivered. Second. small targeting vectors, particularly peptides. inay be metabolized in vivo: this problem is often overcome by using cyclic peptides as delivery vectors. In such systems. the lack of terminal residues reduces the susceptibility of the peptide to hydrolysis.

Small conjugates also have one great advantage over antibody conjugates in that they localize rapidly. whereas antibody conjugates, being large, are transported slowly through the body. This is particularly important when delivering radioisotope conjugates, where the slow localization of an antibody conjugate can represent several half-lives of the isotope being delivered. To avoid minimizing the dose in this way, the two approaches can be combined using a technique known as tumor pretargeting.[28] In this approach, a monoclonal antibody is used to deliver a nonendogenous protein to the tumor cell. This can then be targeted using a low-molecular-weight conjugate. Illustrated in Fig. 5 is this approach. The antibody is used to deliver avidin to the tumor cell. Because both components are unstable, the long localization time is relatively unimportant. The avidin is then used as the substrate for a low-molecular-weight conjugate between biotin and a metal complex. This approach allows the unstable component to localize quickly and combines the best aspects of antibody-based techniques with those of techniques using low-molecular-weight vectors.

Gene Targeting

From the supramolecular chemist's viewpoint, gene therapy is an exercise in drug delivery. In this case, the drug in question is DNA, which must be directed to appropriate cells. then be internalized by the cell and subsequently by the nucleus—a process commonly called

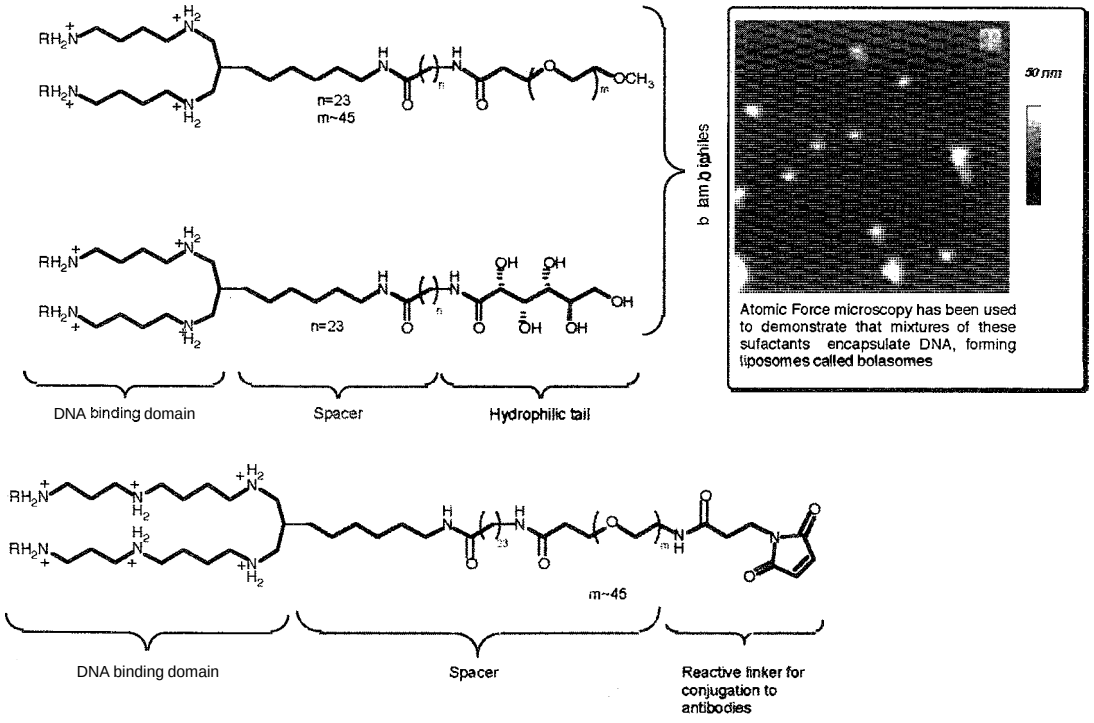

Fig. 6 The use of bolaamphiphiles as DNA-encapsulating agents

transfection. To do this, the drug DNA must be stabilized throughout its passage through the body.

The vast majority of approaches to DNA delivery use DNA enveloped in the coat proteins of adenoviruses or retroviruses.[29] This approach uses a biological delivery system without modification. An alternative approach is rapidly gaining in popularity and offers a solution based on chemistry and self-assembly using surfactants to form micelles or liposomes that encapsulate the DNA.[25,30]

An example of this approach is illustrated in Fig. 6. The surfactants shown consist of polyamine groups linked via a spacer group to hydrophilic sugar moieties.[25] In aqueous solution at physiological pH. the amine groups are protonated and can bind to DNA through electrostatic interaction with the minor groove. Mixtures of these surfactants can be self-assembled around the DNA, forming a liposome, sometimes referred to as a bolasome, that can transport the DNA into cells without difficulty. Furthermore, self-assernbled structures like these can be directed to specific cell lines using monoclonal antibodies. The maleimide-bearing surfactant molecule can be linked to an antibody once the bolasome is formed, providing a large targeting vector conjugate. In this way, targeting methodologies are being applied to a new and burgeoning area.

Inclusion Compounds: Selectivity, Thermal Stability, and Kinetics

Luigi R. Nassimbeni
University of Cape Town, Rondebosch, Western Cape Province, South Africa

INTRODUCTION

The history of inclusion compounds dates back to the early nineteenth century, with Humphrey Davy's discovery of chlorine hydrate. but the field of inclusion phenomena, or host–guest chemistry, a subfield of supramolecular chemistry, is growing dramatically, particularly in the last 10 years. This can be seen at a glance in Fig. 1, which shows the number of abstracts appearing in *Chemical Abstracts* under the term "clathrate" and "inclusion compound" (Fig. 1a) and "supramolecular chemistry" (Fig. 1b).

It is instructive to list some of the main discoveries in this field, and listed below are 10 significant events:[1]

• 1811	Sir Humphrey Davy prepares chlorine hydrate.
• 1823	Michael Faraday confirms Davy's observation and determines the composition of chlorine hydrate.
• 1849	F. Wohler prepares a β-quinol•H_2S molecular complex.
• 1894	E. Fischer introduces the "lock and key" principle.
• 1947	D. E. Palin and H. M. Powell publish the crystal structures of β-quinol•H_2S compound.
• 1948	H. M. Powell coins the word "clathrate."
• 1967	C. J. Pedersen prepares crown ethers.
• 1969	J.-M. Lehn and coworkers synthesize cryptands.
• 1974	D. J. Cram and J. M. Cram introduce the terms "host." "guest." and "host–guest complexation."
• 1978	J. -M. Lehn introduces the concept and term "Supramolecular Chemistry."
• 1987	The Nobel prize for Chemistry was awarded to D. J. Cram. J. -M. Lehn. and C. J. Pedersen for their nork in the field of supramolecular chemistry.

CLASSIFICATION

Host inolecules may be broadly classified into two main types: those that form molecular complexes by fitting convex guests into the concave cavity of the host (examples include cyclodextrins, cyclophanes. calixarenes, cycloveratrylenes, and various carcerands[2]); and those that form lattice inclusion compounds by packing in such a manner as to leave cavities, channels. or layers in the crystal structure so as to accommodate various guest molecules.[3] Many of the compounds that act as hosts in the inclusion compounds were discovered by chance, but in the last 20 years, considerable effort has gone into the synthesis of host molecules with specific properties, and Weber reviewed the principles of directed host design.[4] He showed that a successful molecule should be bulky and rigid in order to provide suitable space so as to accommodate a guest. In addition, it is helpful for the host to have a high-affinity functional group that can engage in specific host–guest interactions, such as hydrogen bonding.

The templating effect of the guest in the formation of a given crystalline lattice inclusion compound is a subject currently under debate. What. for example, is the role of a "noncompetitive" solvent in the crystallization of a given compound? The fact that it can give rise to a different polymorph of the compound in question. suggests that there is a molecular recognition step involving the solvent during crystallization.[5] The guest may template the reaction, forming an inclusion compound that retains its structure even when the guest is removed, as occurs in the case of gossypol with dichloromethane.[6] This occurs infrequently with organic host molecules. and in most cases; the host compound reverts to its nonporous, α-phase, upon desorption.[7] The synthesis of an inclusion compound is carried out by dissolving the host in a liquid guest and allowing concentration of the solution. In the case of a solid guest, a noncompetitive solvent may be employed. The powdered host compound may also be exposed to vapors of the guest, and single crystals of diffraction quality may sometimes be prepared in this way.[8] Host–guest compounds may also be synthesized by direct grinding of two solids, although the mechanism of such reactions is not clearly understood and may involve partial melting.[9]

The general formation of the inclusion compound may be as follows:

$$H_{(s\,\alpha)} + nG_{(l)\text{ or }(g)} \rightarrow H \bullet Gn_{(s\,\beta)}$$

where a represents the nonporous phase of the pure host; H is the apohost, and β is the phase of the host–guest compound with guest :host ratio n, and l = liquid. g = gas, and s = solid.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012852

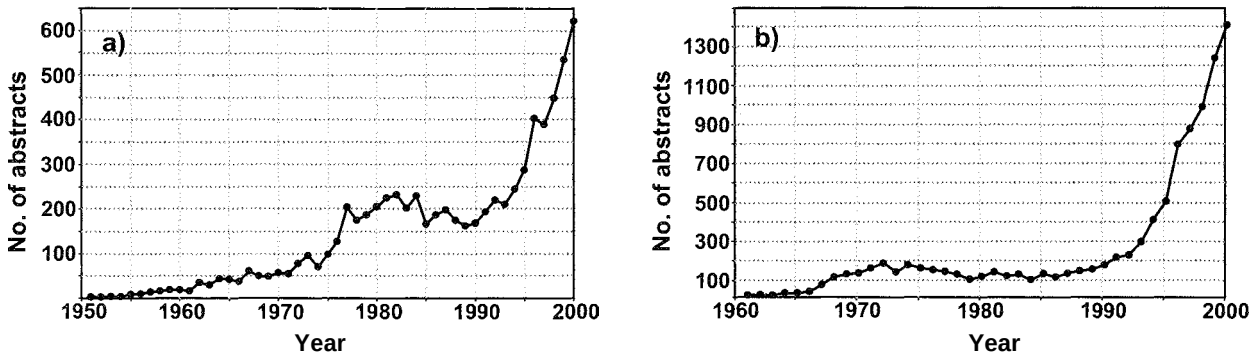

Fig. 1 (a) Number of abstracts found for the terms ''clathrate'' and ''inclusion compound,'' for the years 1950–2000 (b) Number of abstracts found for the term ''supramolecular,'' for the years 1950–2000

When the β-phase decomposes upon heating, it may do so in multiple steps:

$$H \bullet Gn_{(s,\beta)} \rightarrow H \bullet G(n - m)_{(s,\gamma)} + mG_{(g)} \uparrow$$

$$H \bullet G(n - m)_{(s,\gamma)} \rightarrow H_{(s,\alpha)} + (n - m)G_{(g)} \uparrow$$

The intermediate γ-phase, $H \bullet G(n-m)_{(s,\gamma)}$, may be stable over a wide teinperature range, but single crystals of $H \bullet Gn_{(s,\beta)}$ generally break up to form fine powders of the intermediate γ-phase, making it impossible to subject the latter to single-crystal structure analysis. However. demonstrated in recent work was the possibility of controlling the guest : host ratio of an inclusion coinpound by changing the crystallization temperature.[10] In this regard. Ibragimov formulated a rule that predicts the topology of inclusion compounds.[11] In essence, this states that at low crystallization temperatures. one may expect high guest : host ratios with layer or tubulate structures, and that by raising the temperature, the guest: host ratio decreases, giving rise to cryptates (true clathi-ates). When the temperature is sufficiently high and close to the boiling point of the guest. its thermal mobility is too great to allow entrapment. and the host crystallizes in its nonporous a-phase. This technique was employed to control the selectivity of xylene isomers by a dicarboxylic host.[12] A proper thermodynamic analysis, linking the guest–host ratio with the crystallization temperature has yet to be made.

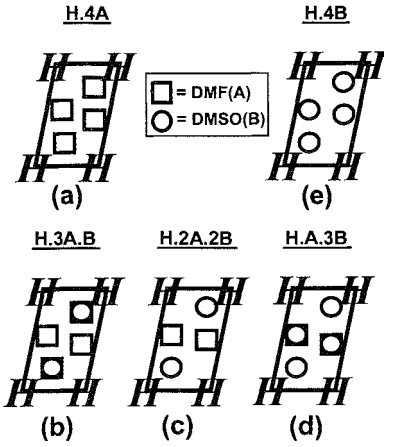

Fig. 4 The location of Guests A and B in the system H • 4A • (4 − n)B. (Reproduced by permission of the Royal Society of Chemistry.)

Recently, a clathrate system was announced in which the host entraps mixed guests. and the stoichiometry is controlled by the relative concentrations of the guests in the starting mixture. The host, *trans*-9,10-dihydroxy-9,10-*bis*(*p*-*tert*-butylphenyl)-9,10-dihydroanthracene (N) forms inclusion compounds with dimethylformanide (A) and dimethylsulfoxide (B) of the type H • nA • (4 – n)B, such that n varies from 0 to 4.[13] The results of competition experiments are given in Fig. 2, which shows that the stoichiometry of the inclusion compounds varies in discrete steps, giving rise to five distinct compounds: H • 4A, H • 3A • B, H • 2A • 2B, H • A • 3B, and H • 4B.

The compounds are isostructural with respect to the locations of the host atoms, shown in Fig. 3. The changes that occur in the positions of the guests are summarized in Fig. 4a–e.

This system, which allows control of the ratio of mixed guests, has implications in crystal engineering.[14] Thus, the physical and chemical properties of such compounds can be governed, which is significant for fields such as chemical sensors. optical and electronic properties of organic crystals, as well as their thermal stabilities and kinetics of decomposition.

SELECTIVITY

Selectivity Coefficient, Competition Experiments

The complementarity of molecular shape defines the process of molecular recognition. and the strength and directionality of the various intermolecular interactions are responsible for the stability of a given host–guest compound. In their account of the nature of supramolecular interactions, Steed and Atwood[15] discussed the full range of forces that impinge on a molecular assembly. They vary from strong ion–ion interactions ($\sim$250 kJmol^{-1}) to weak van der Waals forces (<5 kJmol^{-1}). Of these, the hydrogen bond is particularly important, and its properties were extensively reviewed.[16,17]

A quantitative measure of the selectivity of a given host compound for a given guest in a mixture is obtained by competition experiments. For a pair of competing guests, these involve the setting up of a series of vials in which the concentrations of the guest mixtures are varied systematically, and the dissolved host is allowed to crystallize under controlled conditions. The relative quantities of the enclathrated guests and of the mother liquors are analyzed with a suitable analytical technique, such as gas chromatography. thermal gravimetry, or NMR spectroscopy. In general, three kinds of selectivity curves arise. as shown in Fig. 5. The term X_A is the mole fraction of Guest A in the liquid mixture, and Z_A is that of Guest A entrapped in the crystal. The diagonal line represents zero selectivity; Curves b_1 and b_2 occur when Guest A is strongly selected over B for the whole concentration range.

Following Ward,[18] we may define a selectivity coefficient:

$$K_{A:B} = (K_{B:A})^{-1} = Z_A/Z_B{*}X_B/X_A \quad (x_A + x_B = 1)$$

Thus, $K_{A:B} = 1$ yields Curve a; $K_{A:B} = 2$ and 5 yield Curves b_1 and b_2, respectively; while Curve c results

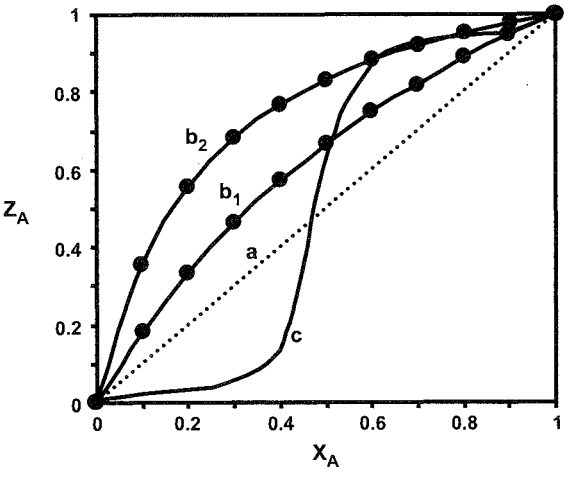

Fig. 5 Selectivity curves obtained from competition experiments. X_A = mole fraction of Guest A in the liquid; Z_A = mole fraction of Guest A in the crystal: Curve a represents zero selectivity. $K_{A:B} = 1$; Curves b_1, and b_2 represent selectivities with $K_{A:B} = 2$ and 5. respectively: and Curve c represents concentration-dependent selectivity.

when the selectivity is concentration dependent. These experiments can be extended to analyze simultaneous competition by three guests. The results are displayed on an equilateral triangle in which each apex represents a pure guest. Consider three guests A. B. and *C*, that compete in pairs for enclathration by a host *H*, such that $K_{A:B} = 5$, $K_{A:C} = 2$. and $K_{C:B} = 1$. A complete selectivity profile is shown in Fig. 6.

Three-component samples taken from the area represented by the circle centered at $X_A = X_B = X_C = 1/3$ will move toward the upper apex, showing an enrichment of Guest A by enclathration. When one of the pair-wise competition experiments gives rise to a concentration-dependent selectivity, the three coinponent experiments are more difficult to predict, because the synergistic effects of the third guest are difficult to estimate. They require a judicious sampling of the three component mixtures and generally result in a split of the enrichment process.[''] interestingly, it was demonstrated that competition experiments can also be carried out with solid guests by grinding appropriate mixtures with the solid host. This was shown in the inclusion by the host 1,1,6,6-tetraphenyl-hexa-2.4-diyne- 1.6-diol of the isomers aminobenzonitrile (ABN). Competition experiments showed that this host selected the guests in the preference of 2ABN > 3ABN > 4ABN, and the result of the solid–solid reactions yielded results that were remarkably similar to those carried out in solution using 1-butanol as a noncoinpetitive solvent.[8]

Competition experiments by enclathration can be employed to separate isomers with similar boiling points, and if we consider the selectivity diagram of the two-component systeins A–B with $K_{A:B} = 5$, discussed earlier, we can employ a McCabe–Thiele-type plot[18] to show that by starting with an initial mixture of $X_A = 0.1$, we can achieve an enrichment $X_A = 0.93$ in three successive crystallization steps (Fig. 7).

This technique has industrial implications. Guanidium organosulfonates were employed to separate isomeric mixtures of xylenes and dimethylnaphthalenes[18] as well as mixtures of xylenols.[19]

THERMAL STABILITY

Thermal Gravimetry (TG), Differential Scanning Calorimetry (DSC), Lattice Energies

Thermal gravimetry (TG) and differential scanning calorimetry (DSC) are the most accessible tools for the

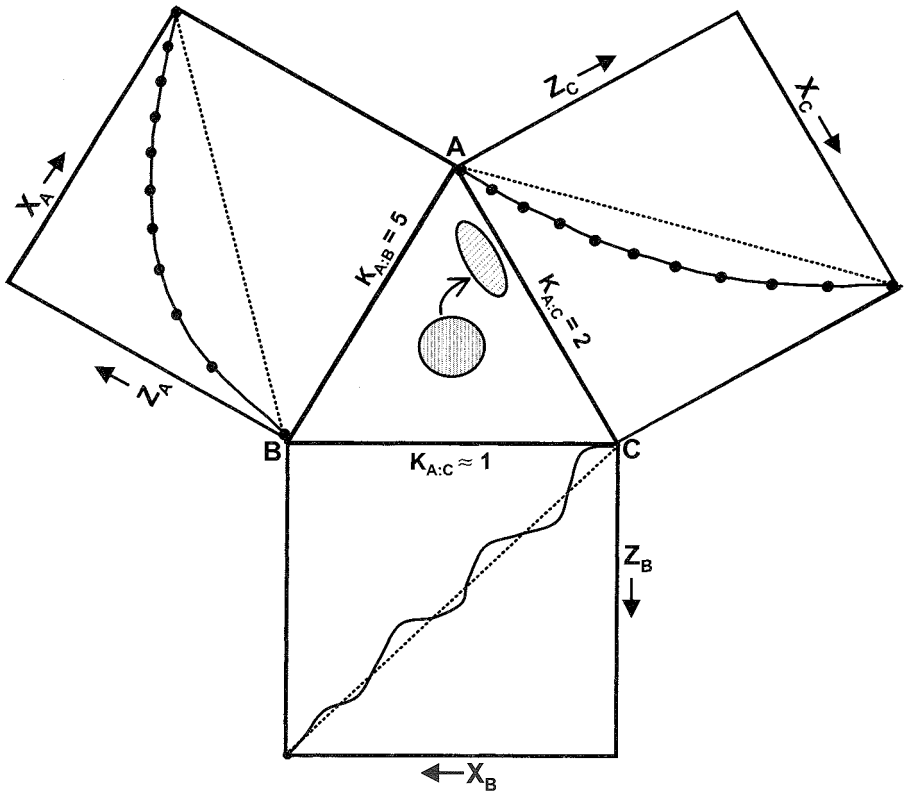

Fig. **6** Selectivity curves for a three-guest system A. B. C, such that $K_{A:B} = 5$. $K_{A:C} = 2$. and $K_{A:C}$

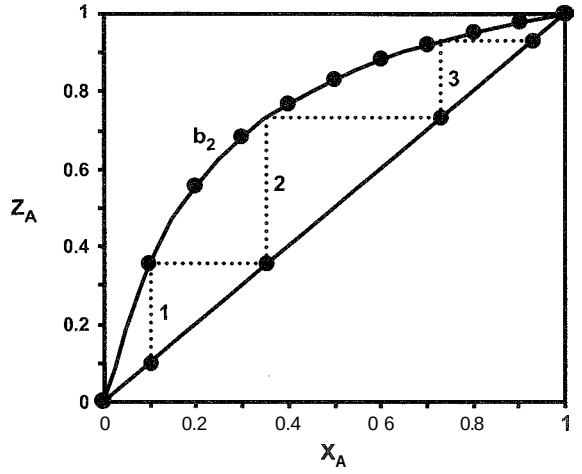

Fig. 7 McCabe–Thiele-type plot foı a txo-component system with $K_{AB}=5$ showing that Guest 4 ıs enriched from $X_A=0\,1$ to $X_A=0\,93$ ın three successıve crystallization steps

quantitative study of the thermal stability of inclusion compounds. When the guest is relatively volatile. TG is a suitable method for obtaining accurate host–guest ratios of inclusion compounds, and mass losses with an accuracy of 1–2% can be routinely obtained with modern commercial thermal balances. It should be emphasized that this is important, because inclusion compounds are often non-stoichiometric, and crystal structure analysis is not a suitable analytica! tool in this instance. This is because. in the refinement process, the site occupancies and temperature factors of the guest atoms are correlated. The DSC measurements yield the onset temperatures of the guest release reaction. T_{on}, and their associated enthalpy change *AN*. Such a measurement should be treated with caution. and accurate values can only be achieved if care is taken with regard to instrument calibrations, flow rate of the purging gas. heating rate. and the particle size distribution of the sample. The latter is crucial and is sometimes difficult to achieve, because the inclusion compound may be labile and not lend itself to crushing or sieving. A recommended technique is to prepare a sample of the host–guest system under conditions of fast stirring, which yields powders with small particles with a narrow size distribution. It should be noted however, that crystals grown under different conditions may yield inclusion compounds with different host : guest ratios; with differing structures, or different polymorphs of the same compound. It is thus important to monitor each preparation by x-ray powder diffraction to ensure consistency. Shown in Fig. 8 are the idealized curves of an inclusion compound $H\bullet G_n$ with a volatile guest that decomposes in a single step. The DSC shows two distinct endotherms: the first corresponding to guest loss followed by the second, due to melting of the host.

The multistep thermal decompositition of a host–guest system can be followed in this way. An illustrated example is given in Fig. 9, which shows the decomposition of the clathrate formed between the inorganic host tetrakis(4-aminopyridine)diisothiocyanatonickel(II) and dimethylsulfoxide. The TG shows four distinct steps: A. corresponding to the loss of two DMSO guests per host molecule: followed by B, corresponding to the loss of two 4-aminopyridine ligands; and C and D, due to the loss of single 4-aminopyridines. The DSC yields endotherms corresponding to B and C, but the trace for D is complex due to ligand decomposition.[20]

In order to obtain accurate. reproducible results for the desorption step, an apparatus was devised that measures the vapor pressure of a volatile guest over a large temperature range. The device comprises a transducer, which converts pressure to a voltage signal, which is amplified and fed to a computer. The inclusion compound is placed in a small flask, open to the transducer, both of which are immersed in a water bath. The temperatures of the compound and the water bath are monitored by thermocouples; and the heating rate is controlled. The method is fully automated and yields curves of P versus T under equilibrium conditions. The semilogarithmic plot of ln P versus $1/T$ has a slope of $-\Delta H/R$ and yields values of the enthalpy change of desorption to a precision of approximately 2%. This was employed in the study of the thermodynamics of decomposition of *bis*-(9,9′-dihydroxy-9.9'-difluorene)$\bullet$0.5 ethanol over the temperature range 30–80°C. yielding a AH=17.9 kJmol^{-1}.[21] When an inclusion compound decomposes, the guest release reaction is made up of two components: the desorption of the guest. and the rearrangement of the "empty cage" or β_0

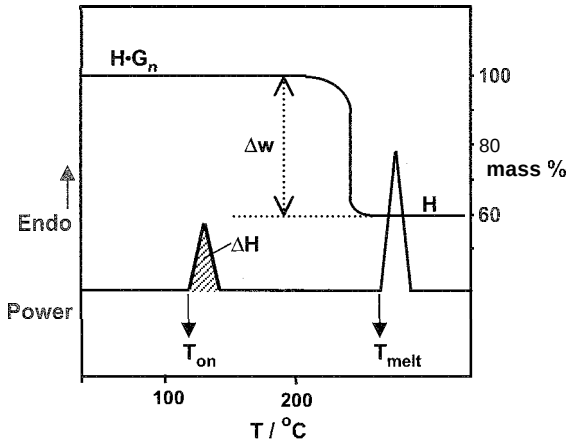

Fig. 8 The TG and DSC curves for the decomposition of an inclusion compound $H\bullet Gn_{,,\beta)} \rightarrow H_{,,\alpha)} + nG_{(g)}\uparrow$

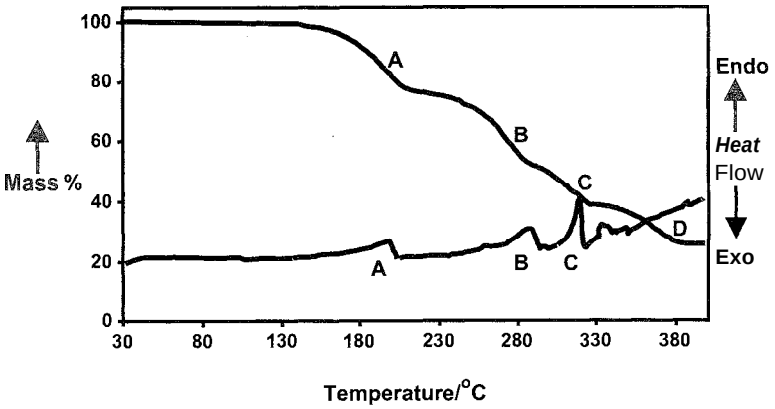

Fig. **9** Multistep decomposition of the inorganic clathrate tetrakis(4-aminopyridine)diisothiocyanatonickel (II) • 2 DMSO. (Reproduced by permission of the Royal Society of Chemistry.)

structure of the host to its nonporous α-phase.[22] The DSC endotherm measures the sum of these, generally with a precision of about 10%. The onset temperature T_{on} and the AH of the guest release reaction are measures of the thermal stability of the host–guest compound. To compare the stabilities of a series of compounds with different guests. one may calculate T_{on}/T_b, where T_b is the normal boiling point of the guest. High values of T_{on}/T_b and of AH are indicative of high thermal stability and of strong host–guest interactions. A quantitative measure of thermal stability is the lattice energy of the compound in question. This may be evaluated by the method of atom–atom potentials using the refined positions of accurate crystal structure determinations.

One may employ force fields of the following type:

$$V(r) = a\exp(-br) - c/r^6$$

where r is the interaction distance. and the coefficients a. b, and c are those given by Gavezzotti.[23] Care must be taken to incorporate a suitable hydrogen-bonding potential, such as that of Vedani and Dunitz,[24] which is formulated as $V\ (H\text{-bond}) = (A/R^{12} - C/R^{10})\ \cos'\ \theta$, where R is the distance between the donor hydrogen and acceptor atom.

θ is the Donor–H .... Acceptor angle, and the $\cos^2\theta$ term is the energy penalty paid by the bond in order to take nonlinearity into account. Such lattice energy calculations often correlate well with enthalpies of the guest release reaction and with onset temperatures.[8]

In cases where the guest is a high-temperature boiling liquid, the DSC may yield a single endotherm corresponding to the dissolution of the host in the escaping guest. In such cases. the AH and the dissolution temperatures may be correlated to the lattice energies of the compounds.

KINETICS

Kinetics of Desorption

The kinetics of desorption of a host–guest compound with a volatile guest may be monitored by measuring the mass as a function of time. The fraction decomposed. α, is evaluated from the mass loss:

$$\alpha = (m_o - m_t)/(m_o - m_f)$$

where m_o is the initial mass, m_t is the mass at time t, and m_f is the final mass. A generalized α-time curve is shown in Fig. 10. It comprises an initial step A, often attributed to the decomposition of impurities or superficial materials. followed by B, an induction period during which nucleation takes place. This is followed, in turn. by an acceleration period C, a deceleration period D, and finally completion, Step E.

Various models can be fitted to the α-time curves that correspond to particular mechanisms of the desolvation reaction.[25] The most common are as follows:

$$-\ln(1 - \alpha) = kt \quad \text{(First order—F1)}$$

$$1 - (1 - \alpha)^{1/2} = kt \quad \text{(Contracting area—R2)}$$

$$1 - (1 - \alpha)^{1/3} = kt \quad \text{(Contracting volume—R3)}$$

The best way to obtain the activation energy for the desorption reaction is to carry out a reries of isothermal runs at selected temperatures, finding the appropriate rate law and deriving the corresponding rate constants that can be employed in the Arrhenius equation:

$$k = \exp(-Ea/RT)$$

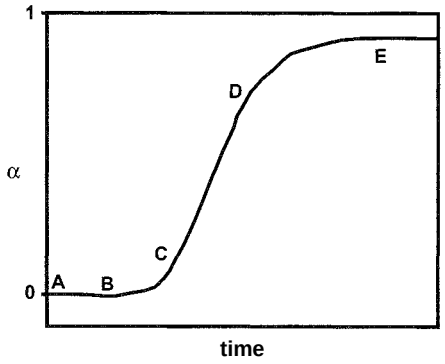

Fig. 10 Generalized α-time curve for a decomposition reaction.

The application of this equation to heterogeneous reactions is controversial, but Galway and Brown discuss this topic and give theoretical justification for its use.[26,27]

Kinetics of Enclathration

The kinetics of enclathration between a solid host and guest vapor received relatively little attention. This is because measurements are experimentally difficult, and the inclusion compounds formed are often unstable under ambient conditions. A suitable suspension balance, which allows measurement of mass change with time under controlled conditions of guest vapor and temperature, was constructed for this purpose.[28] An interesting aspect of these reactions is that they give rise to anti-Arrhenius behavior, in that for a given vapor pressure of the guest, the rate of the reaction decreases with increasing temperature. This arises from the fact that a threshold pressure, P_o, is required to initiate the reaction of the gaseous guest uptake by the host. This was noted for the enclathration of acetone vapor by the host *trans*-9,10-dihydroxy-9,10-diphenyl-9,10-dihydroanthracene,[29] when a plot of k_{obs} versus p at two different temperatures gives rise to two straight lines, as shown in Fig. 11.

Thus, when we consider the rate constant at a fixed pressure of (say) 100 mmHg, we obtain a value of 0.57 s^{-1} at *284* K. which decreases to 0.10 s^{-1} at 303 K.

Guest Exchange

The question of guest exchange in inclusion compounds received little attention, despite that fact that such processes are important for sensing and catalysis based on inclusion. However, a number of host–guest systems with organic and metal-containing hosts that entrap volatile guests were recently studied.[20,30] The host 1,1,6,6-tetraphenyl-2,4-diyne-1.6-diol (*H*) forms inclusion compounds with tetrahydrofuran (THF), and thiophene (THIO), and we analyzed the dynamics of the reaction:

$$H \bullet THF_{(s)} + 2\ THIO_{(g)} \rightarrow H \bullet 2\ THIO_{(s)} + 2\ THF_{(g)}$$

This was performed by exposing a powdered sample of $H \bullet 2\ THF_{(s)}$ to thiophene vapor in a closed vessel at 25°C. The resultant product was analyzed periodically by *DSC*, and the results are given schematically in Fig. 12.

In such reactions, there are two possible mechanisms for the exchange between guests G1 and 62:

1. The host–guest system retains its structure throughout the exchange and so behaves like a zeolite, with the

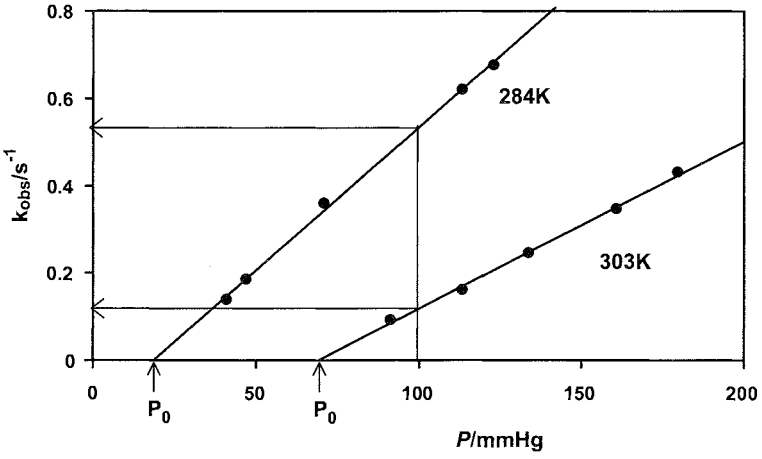

Fig. 11 Plot of k_{obs} versus guest pressure for the enclathration of acetone vapor by *trans*-9,10-dihydroxy-9,10-diphenyl-9,10-dihydroanthracene. Note the existence of threshold pressures P_o at both temperatures.

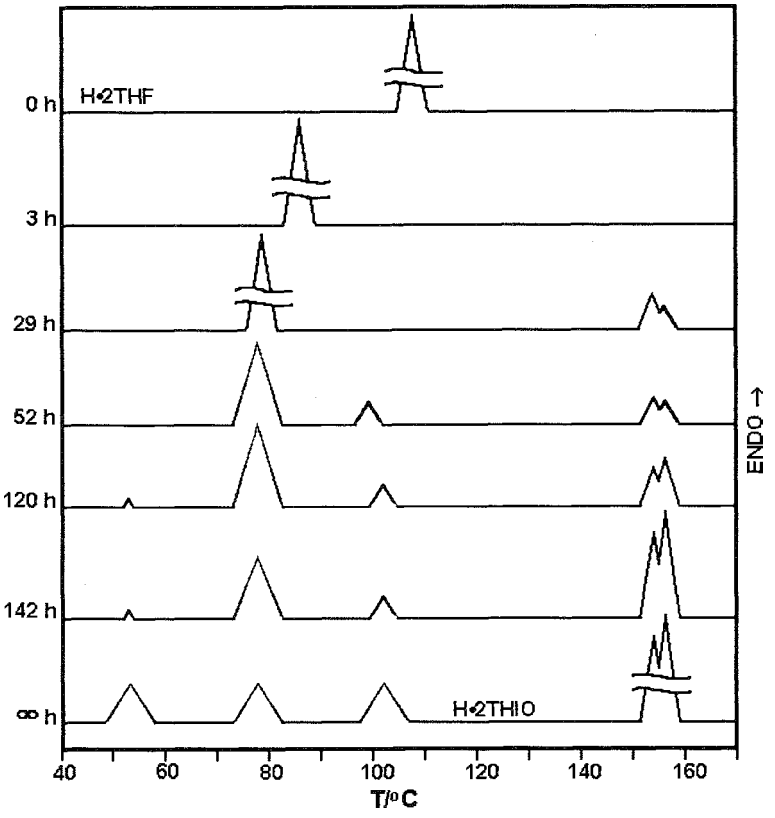

Fig. 12 The DSC curves for the guest exchange in the reaction Ha2 $THF_{(s)}$ + 2 $THIO_{(g)} \rightarrow H \bullet 2$ $THIO_{(s)}$ + 2 $THF_{(g)}$, with *H*=1.1.6. 6-tetraphenyl-2.4-diyne-1,6-diol (Reproduced by permission of the Royal Society of Chemistry)

channels remaining open to incoining and outgoing guest molecules:

$$H \bullet nG_{1(s)} + nG_{2(g)} \rightarrow H \bullet nG_{2(s)} + nG_{1(g)}$$

2. The host–guest system desorbs to yield the apohost (a-phase), which in turn, absorbs the incoming guest and forms the new structure:

$$H \bullet nG_{1(s,\beta)} \rightarrow H_{(s,\alpha)} + nG_1 \uparrow$$

$$H_{(s,\alpha)} + nG_{2(g)} \rightarrow H \bullet nG_{2(s,\beta)}$$

In the second mechanism, there would be a small but detectable amount of the apohost present throughout the time of guest exchange. We showed this to be the case in the study of the diol host *H* and its inclusion compounds, with G_1, G_2=furan, tetrahydrofuran, and thiophene.[30] It was noted that the kinetics of these exchange reactions depend on such factors as the particle size distribution of the $H \bullet nG_1$ solid, the vapor pressure of the incoming guest, and the strength of the host–guest interactions of both the reactant and the product.

In conclusion, the structures and topologies of inclusion compounds form the basis of their reactivities and their physico-chemico properties. An understanding of the molecular recognition process occurring in these compounds forms the basis of predicting their behavior.

Inclusion Reactions and Polymerization

Mikiji Miyata
Osaka University, Osaka, Japan

INTRODUCTION

A variety of monomers can be trapped in the inclusion spaces at the inolecular level and polymerized under suitable conditions. Such a reaction is called inclusion polymerization.[1–10] The study of inclusion polymerization started soon after the discovery of a honeycomb structure of urea inclusion compounds. The early study aimed to obtain highly stereoregular and asymmetric polymers in the spaces. Further studies brought about a profound understanding of the space effects from various viewpoints. Now. inclusion polymerization is classified between bulk or solution polymerization and solid state polymerization. In other words. it may be situated as low-dimensional and space-dependent polymerizations. Such a polymerization closely relates to supramolecular chemistry from a viewpoint of molecular information and expression.

GENERAL FEATURES

Cyclic Process

In Fig. 1, a cyclic process for inclusion polymerization is shown. The process consists of four steps: 1) hybridization of a host assembly with a solvent; 2) complexation of the host with a guest monomer; 3) polymerization of the monomer; and 4) separation of the resulting polymer from the host. This cycle is based on spontaneous and noncovalent phenomena, such as intermolecular association and dissociation among host–host, host–guest, and guest–guest components.

The host components (Fig. 1a) are first recrystallized from usual solvents for isolation and purification. This operation produces host assemblies with or without the solvents (Fig. Ib). There are two methods for obtaining inclusion compounds with the monomers (Fig. 1c): by the addition of monomers into the solvents and by replacement of the guests with retention of the host assemblies, called intercalation.

The polymerization should consist of four elementary reactions: an initiation. a propagation, a termination. and a chain transfer. γ-Ray and UV irradiation are preferably employed for the initiation, although conventional free-radical initiators are also available. The propagation reaction can be accelerated at elevated temperatures. because molecular motions of the included monomers are constrained in the inclusion spaces. The termination reaction is inhibited due to isolation of the active species in the spaces. Any transfer reaction might take place between the host and guest components.

Inclusion polymerization usually results in host–polymer composites (Fig. 1d). The addition of suitable solvents induces separation of the resulting polymers from the hosts. The separated polymers sometimes involve the host component even after thorough solvent treatment. This may be explained by the fact that the initiating radicals come from the hosts in some cases. The separated host components assemble together by recrystallization to give original inclusion compounds with solvents (Fig, 1a).

Effects of the Inclusion Spaces

Inclusion polymerization may be reasonably distinguished from other polymerizations by various effects of the inclusion spaces. as mentioned below. Shown in Fig. 2 is a general relation in size between the inclusion spaces and guest molecules. A macroscopic flask (Fig. 2a) in a chemical laboratory practically has an infinite space as compared with a monomeric molecule. enabling us to neglect any effects of the space. Monomer molecules freely move in the space at moderate temperatures. In contrast. a molecular flask at a nanometer level (Fig. 2b. c) has spaces nearly equal to guest molecules in size. Because electromagnetic forces work among the host and guest molecules. monomer molecules are constrained in the spaces, even at relatively high temperatures, leading to the observation of various space effects. On the other hand; assemblies composed of the monomers only (Fig. 2d) have no inclusion spaces in the solid state, meaning that the space effects may be ignored. In this case. the monomer molecules can move slightly below their melting temperatures.

A comparison among the polymerizations in the different states is summarized in Table 1. The monomer molecules form low-dimensional and anisotropic assemblies in the inclusion and solid states; although they form three-dimensional and isotropic assemblies in the solution

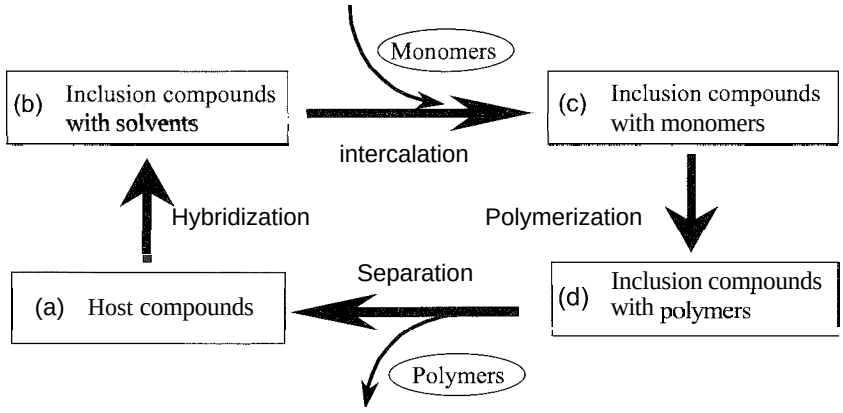

Fig. 1 A cyclic process for the study of inclusion polymerization. Parts (a) through (d) show products of the inclusion process.

or bulk state. One- or two-dimensional assemblies are formed in a channel (canal) or an interlayer, where corresponding one- or two-dimensional inclusion polymerization may take place. respectively. The inclusion spaces vary in size, shape, polarity, and chirality. The use of a set of the different spaces enables us to observe different inclusion polymerizations, leading to interpretation of the space effects.

ONE-DIMENSIONAL INCLUSION POLYMERIZATION

Hosts and Monomers

Inclusion polymerization is now recognized as a general polymerization that is useful for over 100 different monomers. Shown in Figs. 3 and 4 are some hosts and monomers employed so far for one-dimensional inclusion polymerization, respectively. First, a pair of hosts, urea (Fig. 3a) and thiourea (Fig. 3b), were used for the polymerization of 1,3-butadiene and 2,3-dimethyl-1,3-butadiene, respectively. Perhydrotriphenylene (Fig. 3c) was applied to many methyl-substituted butadiene derivatives, yielding the corresponding polymers with 1,4-*trans* units. Pioneering work was accomplished for optical resolution of the racemic host. leading to the first asymmetric inclusion polymerization of 1,3-pentadiene.

A chiral host could readily be available from a naturally occurring compound. The use of steroidal acid, deoxycholic acid (Fig. 3d), yielded coinprehensive polymers, particularly, optically active polymers from prochiral monomers. Many derivatives of deoxycholic acid have the corresponding characteristic inclusion abilities. For example, use of apocholic acid (Fig. 3e), cholic acid (Fig. 3f), and chenodeoxycholic acid (Fig. 3g) enabled us to perform one-dimensional inclusion polymerization of various diene and vinyl monomers.

Other effective hosts are cyclophosphazenes, such as *tris*(*o*-phenylenedioxy)cyclotriphosphazene (Fig. 3h) and

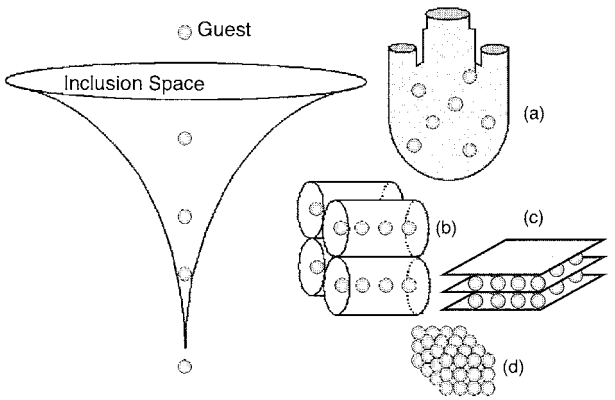

Fig. 2 A relative relationship between spaces and guest molecules: (a) a container with a macroscopic space: containers with molecular-level spaces called (b) channels and (c) interlayers: and (d) a molecular assembly without containers. (View *this art in* color *at www.dekker.com.*)

Table 1 Space effects among the polymerizations in different states

Polymerization	Solution or bulk	Inclusion	Solid stale
Space size	Macroscopic	Molecular-level	None
Assembly	Isotropic	Anisotropic	Anisotropic
Space effect	Negligible	Not negligible	Negligible
Dimensionality	Three-dimensional	Low-dimensional	Low-dimensional

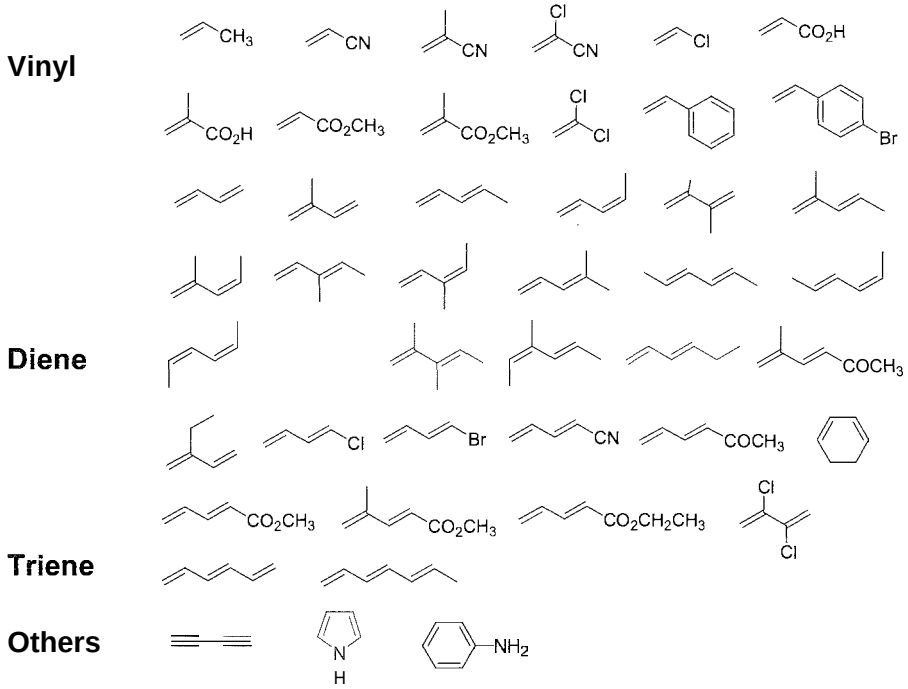

Fig. 4 Various monomers used for one-dimensional inclusion polymerization

tris(2,3-naphthalenedioxy)-cyclotriphosphazene (Fig. 3i). They were utilized for inclusion polymerization of many diene and vinyl monomers. Cyclodextrins were used for addition polymerization as well as polycondensation. Some kinds of inorganic polymers were used for one-dimensional polymerization. For example, a novel zeolite ZSM-5 was employed for the polymerization of vinyl monomers, such as propylene and 1-hexene.

It can be seen from Fig. 4 that many diene monomers were polymerized using various hosts. It might be possible to polymerize multiconjugated monomers, such as trienes and tetraenes, in one-dimensional spaces. Diacetylene spontaneously polymerized in channels of three hosts: perhydrotriphenylene, deoxycholic acid, and apocholic acid. On the other hand, there are not so many studies of the polymerization of vinyl monomers, because highly stereoregular polymers are not obtained.

Reaction Mechanism

Direct evidence for polymerization in the channels is given by crystal structure analysis. We can compare crystal structures before the polymerization and after the polymerization. Computed tomography works well in simulating whether or not inclusion polymerization will take place. Comparison of cross sections of channels with those of polymers enables us to consider whether or not the resulting polymers can be accommodated in the channels.

Radical species during inclusion polymerization can readily be detected by ESR spectroscopy, indicating that the radicals are thermally stable in the channels. The reason is that the radicals in the channels do not meet with each other due to the host walls. y-Irradiation produces radicals of the host component as well as the monomers. Monomeric and propagating radicals were observed in the case of urea. while only the propagating radicals were observed in the case of perhydrotriphenylene, deoxycholic acid, and apocholic acid. Simulation of the spectra clarified that the propagating radicals do not rotate freely, indicating that mobilities of the radicals are constrained in the channels.

Molecular motions are much smaller in channels than in solution at the same temperature. This indicates that the polymerization may proceed slowly. But the neighboring monomers are located very near, suggesting that the reaction may proceed rapidly. This is how the reversed effects work during the propagation reaction. It is known that inclusion polymerization smoothly occurs at low temperatures in the channels of urea, thiourea, and perhydrotriphenylene. However, in the case of steroidal hosts, we observed a decrease in polymerization rates. For example. in one case, the polymerization reached a saturated state after 1 month.

Table 2 Parameters for the inclusion and solution polymerizations

Parameter	Inclusion	Solution
*k*p	10^{-3} kg mol^{-1} s^{-1}	10^{0}–10^{3} L mol^{-1} s^{-1}
kt	10^{-9} kg mol^{-1} s^{-1}	10^{7}–10^{10} L mol^{-1} s^{-1}
[M]	10^{-3} mol kg^{-1}	10^{-7}–10^{-8} mol L^{-1}
Lifetime of M	$>10^{6}$ s	0.1–1 s

Shown in Table 2 are the rate constants for the polymerization of *trans*-1-chloro-1,3-butadiene in the channels of deoxycholic acid. The rate constant of the propagation (kp) was about 10^{-3} kg mol^{-1} sec^{-1}, less than 10^{-3} of that for the solution. The termination rate constant is extremely small: about less than 10^{-10} of that for solution. Another important finding is that the concentration of radicals in the channels amounted to about 10^{-3} mol per 1 kg of the host by means of ESR spectroscopy. This concentration exceeds that for usual solution polymerizations by a factor of 10'. These results indicate that decrease of the propagation rate may be compensated for by a decrease of termination reaction and by an increase of radical concentration.

Steric Control

There are many possible schemes for addition reactions of diene monomers from electronical and steric viewpoints. Because the monomer molecules arrange along the direction of the channels, α,ω-addition may selectively take place in one-dimensional inclusion polymerization. Therefore, conjugated polyenes, such as dienes and trienes, may selectively polymerize by 1,4- and 1,6-addition, respectively. 1,3-Butadiene polymerized via 1,4-addition exclusively in the channels of urea and perhydrotriphenylene. while the same monomer polymerized via both 1,2- and 1,4-additions in the channels of deoxycholic acid and apocholic acid. Moreover, we have to evaluate head-to-tail or head-to-head (tail-to-tail) additions in the case of dissymmetric conjugated diene monomers such as isoprene and 1.3-pentadiene.

Tacticities of the polymers were estimated. For example, poly(l.3-pentadiene) was highly isotactic in the channels of perhydrotriphenylene, while it was preferentially isotactic (meso:racemic = 2:1) in the channels of deoxycholic acid. A completely isotactic polymer was utilized to prepare a unique polymer. hemitactic polypropylene, by hydrogenation of a completely 1,4-*trans* isotactic poly(2-methyl-1,3-pentadiene).

Chiral hosts provide chiral molecular-level spaces, where asymmetric inclusion polymerization may occur. A

requirement is that the polymerization proceed via head-to-tail and isotactic addition along a one-dimensional array in a chiral channel. So far, many optically active polymers were prepared from prochiral diene monomers by using chiral hosts. For example, optically resolved perhydrotriphenylene gave asymmetric polymers from *trans*-1,3-pentadiene. while deoxycholic acid gave those from *cis*-1,3-pentadiene. These polymers were ozonolyzed to give optical yields over 10% e.e. and about 20%, respectively.

Space-Size Effects

It is considered that the motion of guest molecules depends on the space sizes even at the same temperature. That is, the molecules can move more freely in a larger space than in a smaller space. Such a difference would affect polymerization behaviors. Such space effects can be observed on the basis of subtle changes of polymerization behaviors by using a suitable set of hosts. Use of a set of the hosts, deoxycholic acid, apocholic acid, cholic acid, and chenodeoxycholic acid, enables us to observe the effects of one-dimensional polymerization in detail. On the other hand, a pair composed of urea and thiourea is not suitable for such an aim, because the pair does not include identical monomers at the same temperatures.

The following three points were ascertained: 1) polymerizabilities of the monomers; 2) motion of polymer chains around the ends of the propagating radicals; and 3) microstructures of the resultant polymers. These space-size effects are summarized in Table 3.

Only a definite scope of monomers can be polymerized in a given host. This indicates that inclusion polymerization displays a sterically different boundary condition from other polymerizations. That is, an increase of one methylene unit of one monomer can induce an inhibition of the polymerization in a given channel (Fig. 5a,b). Moreover, the relative sizes of the channels change the polymerizabilities of the identical monomers. Even though a monomer does not polymerize in a small channel, the same monomer polymerizes in a larger channel, (Fig. 5b,c). For example, 4-methyl-1,3-pentadiene polymerized in the smaller channels of deoxycholic acid,

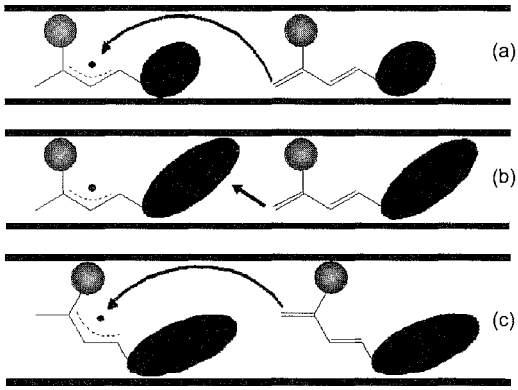

Fig. **5** Polymerizabilities of the monomers in the channels: (a) smaller monomers in a smaller channel can be polymerized; (b) larger monomers in a smaller channel are not polymerized: and (c) larger monomers in a larger channel can be polymerized.

while 2,4-dimethyl-1,3-pentadiene did not. However, the latter polymerized in the larger channels of apocholic acid.

The radicals can move depending on space sizes and shapes. So, it is considered that the propagating radicals are tightly included in the smaller channels and loosely in the larger channels. This means that an identical monomer exhibits different ESR spectra in various channels. A set of steroidal hosts enabled us to detect a large amount of such slightly different ESR spectra of the propagating radicals from various vinyl and diene monomers having alkyl and polar substituents. Simulation studies showed that such spectra may be explained by different conformations of the polymer chain ends.

Stereoregularities of the resulting polymers depend on the sizes of the host channels. Moreover, the space effect in chirality was observed in asymmetric inclusion polymerization of *trans*- or cis-2-methyl-l,3-pentadiene by using a pair of hosts, deoxycholic acid and apocholic acid. We obtained optically active polymers with predominant absolute configurations (R). Optical yields varied with the polymerization conditions and the hosts. A maximum optical yield of the *trans* monomer was *36%* in the channel of apocholic acid.

Table **3** Space-size effects on one-dimensional inclusion polymerization

Inclusion *space*	Polymerizability	*Propagating radicals*	*Selectivity* of *reaction*
Large space	Large scope	Large motion	Low selectivity
↓	↓	↓	↓
Small space	Small scope	Small motion	High selectivity

The chiral and sequential carbon chains express their information through their architectures (A), host–guest compounds (B), and reactions of the guests (C). *(View this art in color at www.dekker.com.)*

TWO-DIMENSIONAL INCLUSION *POLYMERIZATION*

Some two-dimensional inclusion polymerizations are known. For example. montmorillonite and graphite were used for the polymerization of vinyl monomers such as methyl methacrplate and styrene, respectively. Polymerization of salts of 6-amino-2,4-*trans*,*trans*-hexadienoic acid was performed using perovskite-type layered compounds on UV or γ-ray irradiation, resulting in stereoregular polymers with a high head-to-tail, 1,4-*trans* structure. Many organic long-chain compounds form bilayered membranes to form a matrix for the two-dimensional polymerization. For example, photopolymerization was carried out using cast films composed of double-chain ammonium amphiphile involving a cross-linked acrylate polymer. Extraction of the amphiphile with methanol left a multilayered film.

Recently, it was found that crystalline organic salts of unsaturated carboxylic acids with aromatic amines were polymerized by UV irradiation to yield highly stereoregular polymers.[11,12] The bilayered polymeric aggregates were ascertained to replace amine components through intercalation. So. the polymerization is considered to correspond to one of the two-dimensional inclusion polymerizations. In this assembly, the aromatic part of the amines corresponds to the host component, while the alkyl part of the acids corresponds to the guest component. The amines employed are benzylamine, 1-naphthylmethylamine, long-alkylamines and their derivatives, and so on.

The polymerization of sorbic acid was found to proceed highly selectively to give a 1,4-*trans*, *erythro*-diisotactic structure, because ^{13}C-NMR spectrum of the polymer exhibits simple and sharp absorptions. Although the resulting polymers showed no optical rotation. crystal structural analysis tells us the following interesting feature of the polymerization. The molecules in one array polymerize to give a chiral polymer with (*R*,*R*) absolute configuration. while that in the neighboring array do so with (*S*,*S*). This means that we obtained a racemate of chiral polymers.

INCLUSION *POLYMERIZATION BASED ON MOLECULAR INFORMATION*

The study on inclusion polymerization by using steroidal hosts led us to the concept of molecular information and expression. as follows. It is theoretically considered that molecular information at a nanometer level may originate from sequential and chiral carbon chains, like proteins and steroidal molecules. As shown in Fig. 6a, the proteins express their molecular information through noncovalent bonds by the following processes: molecular architecture (Fig. 6A). host–guest compounds (Fig. 6B), and reactions of the included guest components (Fig. 6C). Similarly. the steroidal molecules express their information through the noncovalent processes (Fig. 6b). Therefore, inclusion polymerization corresponds to one step of the expression process of molecular information that the sequential and chiral carbon-chains store.

CONCLUSION

Starting from the synthesis of stereoregular and optically active polymers, we reached the idea that inclusion polymerization constitutes one of supramolecular chemistry from a viewpoint of the space effects. Now such a study might be connected to nanotechnology. because the polymerization can produce molecular composite materials, such as molecular wires; layers, and so on. The bottom-up technology would be constructed through various

noncovalent processes that are based on the principle of molecular information and expression.

Incommensurate and Commensurate Structures

Kenneth D. M. Harris
Cardiff University, Cardiff, Wales

INTRODUCTION

It is convenient to regard a crystalline solid inclusion compound to be composed of two chemically distinguishable substructures: the host and guest substructures. In many cases. the guest molecules are disordered within the crystalline host structure, but in those cases for which the guest molecules are ordered (at least sufficiently well ordered that an average lattice periodicity may be defined),an important concept is the degree of structural registry between the two periodic (host and guest) substructures. Here. we focus only on the simplest case of one-dimensional (1D) tunnel host structures in which both host and guest substructures have well-defined periodicities along the tunnel (Fig. 1). The periodic repeat distance of the guest molecules along the tunnel (c-axis) is denoted c_g, and the periodic repeat distance of the host substructure along the tunnel is denoted c_h. The degree of structural registry between the two periodic substructures is assessed by considering the relationship between c, and c_h.

Conventionally, the ratio c_g/c_h is used as a basis for dividing these systems into two categories—commensurate and incommensurate. The ciassical definition assigns the inclusion compound as commensurate if c_g/c_h is a rational number and as incommensurate if c_g/c_h is an irrational number. However. because experimental measurements of c_g and c_h can never be made with absolute precision, it is more practical to define an inclusion compound as commensurate if (and only if) c_g/c_h is sufficiently close to a rational number with low denominator. This is equivalent to stating that, for a commensurate system, small integers p and q can be found that satisfy the relationship $pc_h = qc_g$. If no sufficiently small integers p and q can be found, the inclusion compound is incommensurate.

An important consequence of an incommensurate relationship between the host and guest substructures is that, in principle, each guest molecule within a given tunnel samples a slightly different environment with respect to the host structure. For a commensurate material, on the other hand, the guest molecules in the tunnel sample only one or a small number of different local environments within the host structure. Clearly, several chemical and spectroscopic properties of the guest molecules may reflect these differencesin the distribution of local environments for commensurate and incommensurate structures.

X-ray diffraction studies of the inclusion compound can be used to measure the values of c_g and c_h. For example, as shown in Fig. 2, a single-crystal x-ray diffraction oscillation photograph recorded for the crystal oscillating about the tunnel axis shows distinguishable sets of layer lines for the host and guest substructures in an incommensurate system, and the values of c_g and c_h may be determined from the spacing of the layer lines within each set. In the case of a commensurate inclusion compound, separate layer lines due to the host and guest substructures cannot be distinguished, and all layer lines are described by a single periodicity along the c-axis.

We now consider in more detail the consequences of the incommensurate/commensurate nature of a tunnel inclusion compound in terms of diffractionand structural properties, and then energetic aspects and vibrational properties are discussed.

DIFFRACTION PROPERTIES AND STRUCTURAL ASPECTS

In terms of diffraction properties and structural properties, a commensurate inclusion compound behaves as a conventional crystal. The periodicities of the host and guest molecules within the inclusion compound are described by a common three-dimensional (3D) periodic lattice, and the symmetry of the structure is described by a conventional 3D space group. Correspondingly, all diffractionmaxima in the diffraction pattern are described by a single 3D periodic reciprocal lattice. As discussed in more detail below. the inability to rationalize all diffraction maxima in the diffraction pattern of an inclusion compound by a single 3D periodic reciprocal lattice often provides the first indication that the structure rnay be incommensurate.

For a tunnel inclusion compound in which the host and guest substructures have an incommensurate relationship along the tunnel (c-axis). the host and guest substructures are generally commensurate in other directions by virtue of the fact that the guest molecules are constrained to occupy the tunnels within the host

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012729

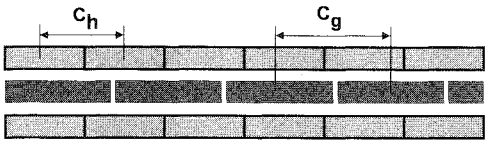

Fig. 1 Two-dimensional representation of a tunnel inclusion compound viewed perpendicular to the tunnel axis. The definitions of c_g and c_h are shown. (View this art in color at *www.dekker.com.*)

substructure. This implies that when the structure is projected onto a plane perpendicular to the tunnel axis, there is a commensurate relationship between the host and guest substructures, and corresponds to the host and guest substructures having a common a^*b^* reciprocal lattice plane.

Each substructure in the inclusion compound can be considered in terms of an incommensurately modulated "basic" structure. The basic structure has 3D lattice periodicity and crystallographic symmetry described by a 3D space group. The incommensurate modulation to a given basic structure represents the structural perturbations that arise from its interaction with the other substructure. Thus, the basic structure is an hypothetical entity and represents the structure to which the real substructure would relax if there were no interaction with the other substructure (i.e., in the absence of host–guest interaction). Clearly, the incommensurate modulation in one subsystem has the same periodicity as the basic structure of the other subsystem. In summary, the incommensurate inclusion compound can be considered as an intergrowth of two incommensurately modulated substructures.

The lattice describing the periodicity of the basic host structure is (a_h, b_h, c_h), and the corresponding reciprocal lattice is (a_h^*, b_h^*, c_h^*). The lattice describing the periodicity of the basic guest structure is (a_g, b_g, c_g), and the corresponding reciprocal lattice is (a_g^*, b_g^*, c_g^*). The vectors c_h and c_g are parallel to each other and are directed along the tunnel axis. As a consequence of the incommensurate relationship between c_h and c_g, the complete diffraction pattern from the inclusion compound cannot be rationalized on the basis of a single 3D periodic reciprocal lattice. Thus, it is not possible to express the positions (S^*) of all diffraction maxima within the diffraction pattern in terms of a linear combination

$$S^* = H\,a_1^* + K\,a_2^* + L\,a_3^*$$

of three reciprocal lattice vectors (a_1^*, a_2^*, a_3^*) with integer coefficients H, K, and L. For an incommensurate tunnel inclusion compound of the type described above, one additional reciprocal lattice vector (a_4^*) is required in order

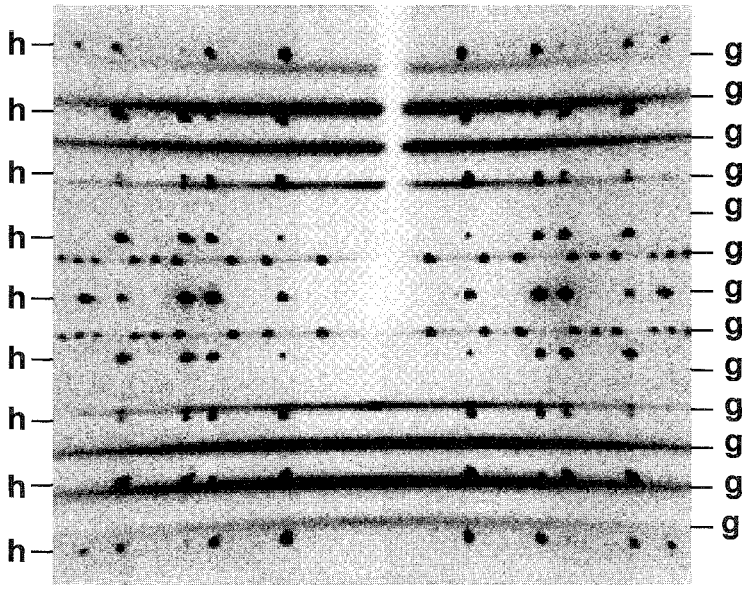

Fig. 2 Single-crystal x-ray diffraction oscillation photograph for an incommensurate tunnel inclusion compound (the 1,9-diiodononane/urea inclusion compound), recorded for a single crystal oscillating about its tunnel axis. The layer lines (horizontal) from the host component are indicated (h) on the left-hand side. The layer lines from the guest component are indicated (g) on the right-hand side. In this case, the guest layer lines contain discrete scattering (sharp spots) and diffuse scattering. The fact that separate sets of layer lines are observed for the host and guest components is a consequence of the incommensurate relationship between c_h and c_g.

to have integer indexing of all diffraction maxima in the diffraction pattern. Thus,

$$S^* = H\,a_1^* + K\,a_2^* + L\,a_3^* + M\,a_4^*$$

with integer coefficients H, K, L, and M.

In practice, one possible choice for the set (a_1^*, a_2^*, a_3^*, a_4^*) is (a_h^*, b_h^*, c_h^*, c_g^*) (note that; as discussed above, the host and guest substructures have a common a^*b^* reciprocal lattice plane, and hence: $a_h^* = a_g^*$ and $b_h^* = b_g^*$). The diffraction maxima (H, K, L, M) can be subdivided as follows:

1. $M = 0$: "Main reflections" from the host substructure, which primarily contain information on the basic host structure and also contain information on the incommensurate modulations within the guest substructure.
2. $L = 0$: "Main reflections" from the guest substructure, which primarily contain information on the basic guest structure and also contain information on the incommensurate modulations within the host substructure.
3. $L \neq 0$ and $M \neq 0$: "Satellite reflections" due to the intermodulations of the two substructures.

Clearly, the (H. K, 0, 0) reflections are a superposition of main reflections from both substructures, representing the common a^*b^* reciprocal lattice plane discussed above. A more detailed discussion of these concepts relating to the diffraction properties of incommensurate 1D inclusion compounds has been given elsewhere.[1–4]

Corresponding to the requirement for four reciprocal lattice vectors to describe the positions of all diffraction maxima. the structural periodicity of the incommensurate inclusion compound in direct space requires four lattice vectors, and the symmetry of the composite inclusion compound requires a four-dimensional (4D) superspace group.[5] Methods have been developed[6–11] and applied for deriving the superspace group symmetry of incommensurate intergrowth materials. Examples include a general discussion of superspace concepts for urea inclusion compounds,[2] as well as the development of superspace descriptions for the specific cases of the *n*-heptadecane/urea,[12] octane/urea,[13] octanedioic acid/urea,[14] and suberic acid/urea[15] inclusion compounds.

It is important to emphasize the benefits of understanding the symmetry properties (and structural properties) of the composite inclusion compound in a superspace group, rather than restricting the structural description of such materials at the level of the separate basic structures. Knowledge of the structural properties of the separate basic structures contains no information on the modulations that each subsystem experiences in the real inclusion compound. The modulations may have an important bearing on properties of the inclusion compound. even though they may, in some cases, represent rather small structural perturbations.

ENERGETIC **ASPECTS**

To understand the commensurate versus incommensurate nature of 1D inclusion compounds at a more fundamental level, a commensurate/incommensurate classification that reflects a division in the energetic "behavior" of the inclusion compounds within each category has been developed.[16] This theoretical approach considers the magnitude of fluctuations in the average host–guest interaction energy per guest molecule as the guest substructure is moved along the tunnel keeping the guest periodicity c_g fixed. If these fluctuations are sufficiently small (i.e., within $\pm\varepsilon$. where ε is some physically meaningful energy term), the inclusion compound is said to exhibit incommensurate behavior, whereas if these fluctuations are sufficiently large (i.e., larger than $\pm\varepsilon$), the inclusion coinpound is said to exhibit commensurate behavior. In the commensurate case. a significant energetic "lock-in" between the host and guest substructures will occur for a specific position of the guest substructure relative to the host substructure. whereas for the incommensurate case, the energy of the inclusion compound is essentially independent of the position of the guest substructure relative to the host substructure.

Methodology has been developed[17] for applying these concepts to predict structural properties of 1D inclusion compounds from knowledge of potential energy functions for the inclusion compound (with known host structure and fixed c_h). Fundamental to this approach is the definition of an appropriate energy expression—the "characteristic energy" of the inclusion compound—that directly indicates the relative energetic favorability of inclusion compounds with different guest periodicities. The optimum guest structure for the inclusion compound corresponds to minimum characteristic energy, and the methodology allows the following structural properties to be established from computed potential energy functions (describing host–guest interaction, guest–guest interaction. and intramolecular potential energy of the guest molecules) for the inclusion compound of interest: the optimum guest periodicity *(c,).* whether this value of c_g corresponds to commensurate or incommensurate behavior, and the optimum conformation of the guest molecules within the host structure. The method has been applied successfully to predict structural properties of alkane/urea inclusion compounds[18] in agreement with experimental results.

VIBRATIONAL PROPERTIES

We now consider the question of obtaining direct experimental evidence of incommensurateness in solid inclusion compounds. recalling that from consideration of values of c_g and c_h measured experiinentally from diffraction data, it may be ambiguous whether the st ucture is genuinely incominensurate or whether it represents a commensurate superstructure. The vibrational properties of a crystal depend directly on its energetic properties, and as now discussed, the energetic reasons that underlie incommensurate behavior in a solid inclusion compound have a direct manifestation in terms of the acoustic vibrational modes of the material. First. we recall that conventional crystals (including commensurate inclusion compounds) have three translation invariances (i.e., a translation of the crystal with no change of energy), corresponding to translation along the x, y, and z axes in 3D space. An incommensurate 1D inclusion compound. on the other hand, has four translation invariances. The extra translation invariance is an internal translation invariance and corresponds to the shift of the guest substructure relative to the host substructure along the incommensurate direction (as discussed above, the energy of an incommensurate inclusion compound is, in principle, independent of the shift of the guest substructure relative to the host substructure along this direction). There is an acoustic phonon corresponding to each translation invariance in a crystal, and therefore, an incommensurate 1D inclusion compound should have four acoustic phonons and a commensurate inclusion compound should have three acoustic phonons. The additional acoustic mode in the incommensurate system is called the "sliding mode,'' and observation of the sliding mode can be taken as direct experimental evidence for incominensurate behavior of the inclusion compound (unfortunately. the converse is not true. as there are experimental reasons that the sliding mode may be difficult to detect, even if the material is incommensurate). Brillouin scattering investigations may be used to assess the existence of the sliding mode, and there have been several reports of the quest to observe the sliding mode in solid inclusion compounds.[19–23]

CONCLUSION

The opportunity for certain classes of solid inclusion compounds, such as the 1D tunnel structures discussed in this article. to form structures that may be commensurate or incommensurate represents an intriguing aspect of these materials. both with regard to understanding the fundamental energetic reasons underlying commensurate versus incommensurate behavior and with regard to establishing a detailed characterization of the properties of the incommensurate systems. The diffraction properties of incommensurate materials and the corresponding structural descriptions in direct space present challenges that extend beyond the normal crystallographic principles encountered for conventional crystals.

Induced Fit

Yan Liu
Li Li
Heng-Yi Zhang
Nankai University, Tianjin, People's Republic of China

INTRODUCTION

It is well known that the induced-fit mechanism exists widely in biological and chemical processes, and is also an important characteristic of molecular recognition in supramolecular chemistry. Based on the general concept of induced fit derived from interactions between enzyme and substrate, mainly described in this article is the induced-fit mechanism of molecular selective binding of guests by artificial receptors. including binding and assembly behaviors induced by ionic and molecular guests. as well as the thermodynamic origin of induced-fit. Therefore, the induced-fit concept is not only of theoretical interest for understanding selective molecular-binding behaviors but also of practical importance in designing novel receptors to achieve biological functions.

BACKGROUND

The induced-fit theory first described by Daniel E. Koshland. Jr., in 1958[1] is one of the most fundamental discoveries of our age and is a development of Emil Fischer's well-known lock and key theory.[2,3] it should be noted that an important characteristic of the key–lock theory is that the enzyme accommodates the substrate without having to change the shape of the active site; however, in the induced-fit model, the enzyme changes shape when it reacts, like a glove into which a hand is thrust. To visualize the concepts of induced fit and key–lock, two binding models are illustrated in Fig. 1.

Early in the development of induced-fit theory. it was mainly utilized in biological systems, especially enzymes. to describe the phenomenon of interactions between the enzyme and the substrate. In such a case. enzyme action first requires the precise orientation of catalytic groups. and then the substrate causes an appreciable change in the three-dimensional relationship of the amino acids at the active site, organizing the catalytic groups into the proper alignment.[4] This induced-fit process was validated by more experiment results,[5,6] and now it is proven that almost all enzymes show ligand-induced structural changes during interactions with substrates.[7] Along with the acceptance of induced-fit theory by numerous scientists, it was extensively applied not only for enzymes but also in the control and regulation of biological and chemical systems. One of the most important purposes of supramolecular chemistry research is to mimic the interactions between enzyme and substrate, and induced-fit theory is therefore applied to describe the phenomenon of interactions between host and guest in supramolecular systems.

CURRENT STUDIES IN SUPRAMOLECULAR CHEMISTRY

The importance of host–guest chemistry and supramolecular chemistry, developed by Cram and Lehn. respectively, from the fundamental discovery of crown ethers by Pedersen, was recognized since the 1980s. From then on, supramolecular chemistry made considerable progress, and different host molecules were employed, such as crown ethers, cyclodextrins, calixarenes, porphyrins, etc., in this field for examining their binding behaviors along with a variety of guest molecules and then for mimicking enzyme–substrate interactions. Because some of these host molecules have flexible structures and may change their conformations during guest binding, the induced-fit theory, derived from biological systems, serves as one of the basic concepts for illustrating and understanding some interesting binding behaviors in supramolecular chemistry. Induced fit can be understood in a broad sense by the way in which the introduction of the guest (substrate) induces the conformational changes of the host (synthetic receptor), and by the way the changed conforination of the host or guest becomes much fitter for guest binding.

Binding Behavior induced by Ionic Guests

The selective binding of ions by synthetic receptors (hosts) attracted significant attention over the past 30 years. Among the synthetic receptors, macrocyclic polyethers (crown ethers and csyptands) were extensively utilized to cooperate with metal ions in forming a stable host–guest complex. In the ion-binding processes of

crown ethers, the size and shape fit combination between host *and guest gives high complex stability based on the strong ion–dipole interactions of the oxygen atoms or nitrogen as well as other* heteroatoms *in the general case. For example. 15-crown-§ is* known *to fit the size of the* Na^+ *ion, and 18-crown-6 is a size* match *for the* K^+ *ion. In the case of large-sized crown ethers, such as 24-crown-8 and 30-crown-10, though their ring sizes are apparently too large to* fit Na^+ *and* K^+ *ions, they can be induced by the guest cations to give bent conformations forming three-dimensional complexes (Fig.* 2).[8] *On the other hand, in the lariat ethers possessing a side-arm group covalently bonded to a crown macroring developed by C.W.* Gokel,[9] *more recognition sites are appended, and sometimes the binding behavior cannot be explained simply by the coordination of the ring.* It *is found, consequently. that the induced-fit* mechanism *appears to play an important role in such processes of binding ion guests (Fig. 3).* Liu *and Inoue et al. reported the complexation behavior of aza-16-crown-5 lariat ethers with light* lanthanoid *nitrates and found that* the *size of the induced three-dimensional cavity of lariat ether is an important factor in binding trivalent lanthanoid* ions.[10] In *the two lariat ethers they employed (Fig. 4), a* nitrogen-*pivot 16-crown-§ 1 lariat possessing the flexible conformation showed an exceptionally high relative cation selectivity for* Nd^{3+}*, eight to nine times the neighboring* Pr^{3+} *and* Sm^{3+}*, which indicates that only the most* size-*fitting lanthanoid ion* accommodated *in the cavity of* 16-*crown-5 fully enjoys further ligation by the donating side arm with relatively large structural flexibility, making the operation of exact size-matching easy. That is to say, the host molecule* examined *could be induced to change its conformation by many kinds of guests. but the binding modes of the resulting complexes are not always as stable as the perfect induced-fit model. In the* same *way, through investigating the interaction of* polyether dicarboxylic *acids and heavy metal ions,* Hayashita *and coworkers found that a pseudo-18-crown-6 structure is formed based on the induced-fit mechanism, and it is predominant for* Pb(II) recognition.[11] *These* examples *described one important character of the induced-fit mechanism, that is, though it emphasizes the* conformational *change during the binding process in contrast to the key–lock theory,* it *also exhibits the* enzyme *specificity, similar to the* key–*lock theory to* some *extent.*

Among the ion-binding behavior mechanisms, cation–π *interaction* is *an important* kind *of driving force in molecular recognition. Even here, the induced-fit concept is reportedly an important mechanism for understanding the structures of* cation–π *complexes. Yoshida et* al.[12]

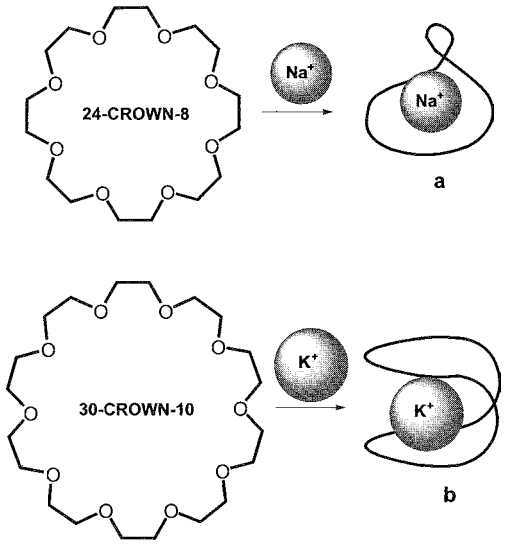

Fig. 2 *Three-dimensional complexes of (a)* 24-crown-8/Na^+ *and (b)* 30-crown-10/K^+. *(View this art in color at www. ilekker.com.)*

reported that the most stable conformation in the uncomplexed form is not always the preferred conformation of the π-complexes (Fig. 5). This is found to be the general condition in induced-fit systems, namely, there always exist several probable conformations for the host molecule, and one of them is most suitable for binding with the guest. Then, the different conformations will be induced by the guest binding to change to the complexed geometry. In this case, the action of the induced-fit mechanism breaks the original equilibrium and creates a new equilibrium distribution between the different states (conformations) of the host.

On the other hand, the induced-fit mechanism not only operates in the spontaneous process but also could be utilized for the special cases, for controlling the binding behavior. Wolte et al.[13] showed a bis-crown-ether analogue that could be induced by metal ion complexation to a conformation preorganized for binding with certain guests. In this case, induced-fit theory was expanded to a more specific understanding and became a two-step process involving an "induced step" and a "fit step" (Fig. 6). The "induced step" refers to the conformational change of receptor induced by metal ion binding. However, the "fit step" refers to the binding behavior of another guest, but not metal ion, with the same receptor. It means that three components are included in this induced-fit system by introducing an additional inducing agent (metal ion, here) besides the original host and guest.

Upon the ionic guest-induced binding behavior, most changes are caused by the direct interactions between ion and host (coodination. cation–π, etc.) but not size or shape factors. though size or shape sometimes controls the effect of induced fit to a certain degree.

Binding Behavior Induced by Molecular Guests

Molecular recognition is a central concept in supramolecular chemistry and generally refers to the selective binding of guests (substrates) by the host (receptor).

For example, the macrocyclic sugars called cyclodextrins (CDs) (see entry on *Cyclodextrins*) are important receptors for organic and inorganic guests via their hydrophobic cavities. To expand the binding ability and selectivity of native CDs, chemical modification is performed to introduce different substituents to the primary or secondary side of CDs, which provides the possibility for the operation of an induced-fit mechanism in this field. Ueno et al. reported many chromophore-modified CDs[14–16] that change fluorescence and absorption intensities upon accommodation of a guest molecule and, consequently, can be used as the photosensors. The studies indicated that the spectral variations are due to decomplexation of the chromophore moiety upon guest binding, and the induced-fit mechanism plays an important role in controlling the conformational change of the hosts. Similar examples were also found by Liu et al. concerning the binding behavior of chromophore-modified β-CDs.[17,18] These studies pointed out that conformers involving a free or a self-included chromophore tethered to CD are in a dynamic equilibrium. The addition of a guest leads to further equilibrium with the inclusion complex, as is illustrated in Fig. 7. The induced-fit mechanism herein is to choose the predominant conformation

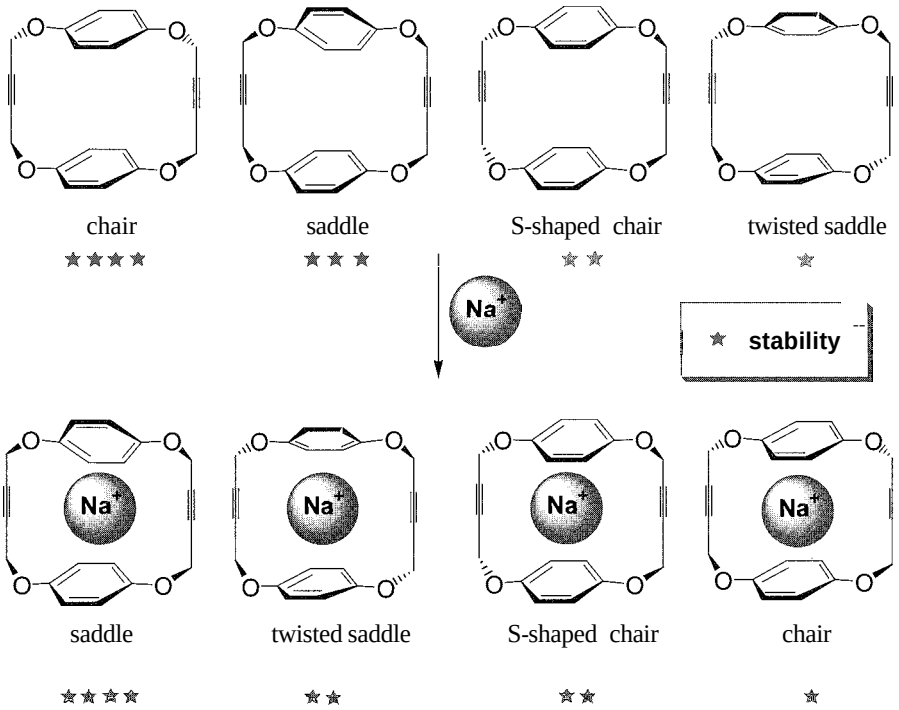

Fig. 5 Stability comparison of conformations of n-receptors and their cation–n complexes. (*View this art in color at www.dekker.com.*)

and then make the equilibrium shift. Simultaneously, it could be seen that in these instances, the size and shape of the guest become a key factor influencing the induced-fit mode finally formed between host and guest.

Recently, the induced-fit theory was utilized to explain the binding behavior arising upon the complexation of bridged *bis*(cyclodextrin)s and guest molecules. Because the *bis*(cyclodextrin)s possess two hydrophobic cavities in close proximity to one another and a relatively flexible spacer to link them together; these elements could cooperate to achieve a conformational change induced by guest binding.[19,20] For example, induced-fit behavior is exhibited by fluorescence investigations on the inclusion complexation of 2,2′-biquinoline-4,4′-dicarboxamide-bridged *bis*(β-cyclodextrin)s with sterols (Fig. 8).[21] The enhancement of fluorescence intensity of the *bis*(cyclodextrin)s proves the important function of the induced-fit mechanism. indicating that a subtle change in conformation may significantly alter the binding behavior.

The induced-fit mechanism exists not only in the molecular recognition process of cyclodextrins but also in that of other synthetic receptors. Rebek and coworkers introduced a family of receptors designed to bind adenosine derivatives within a pocket formed through induced fit.[22] Also, Schneider et al. described a configurational isomer with three different forms as a function of pH[23] (Fig. 9). On complexing with ammonium derivatives, the configurational isomer could change from one form to the other. accompanied by deprotonation via an induced-fit mechanism. Though only a few molecular recognition processes are presented, it is clear that the molecule-induced conformational change is different from the ion-induced conformational change due to the variability and complexity of the size and shape of the molecular guest. More interactions between host and guest are incorporated into the induced-fit mode formed. including hydrophobic interaction, hydrogen bond, van der Waals interaction, etc.. and thus the understanding of the induced-fit mechanism from the molecular aspect should be more helpful and give insight into the interaction between enzyme and substrate in biological systems.

Supramolecular Assembly by Induced Fit

If molecular recognition is regarded as the foundation of supramolecular chemistry for investigating the interactions between host and guest, then the molecular assembly or aggregation function could be considered to be the aim of these investigations. Because supramolecular assembly consists of many transformable factors, the induced-fit theory becomes necessary for understanding the relationships among the complicated elements forming the supramolecular assembly.

It was discussed that the lariat ether can serve as an induced-fit receptor. Gokel et al.[24] described a ditopic receptor system termed a "molecular box." in which the

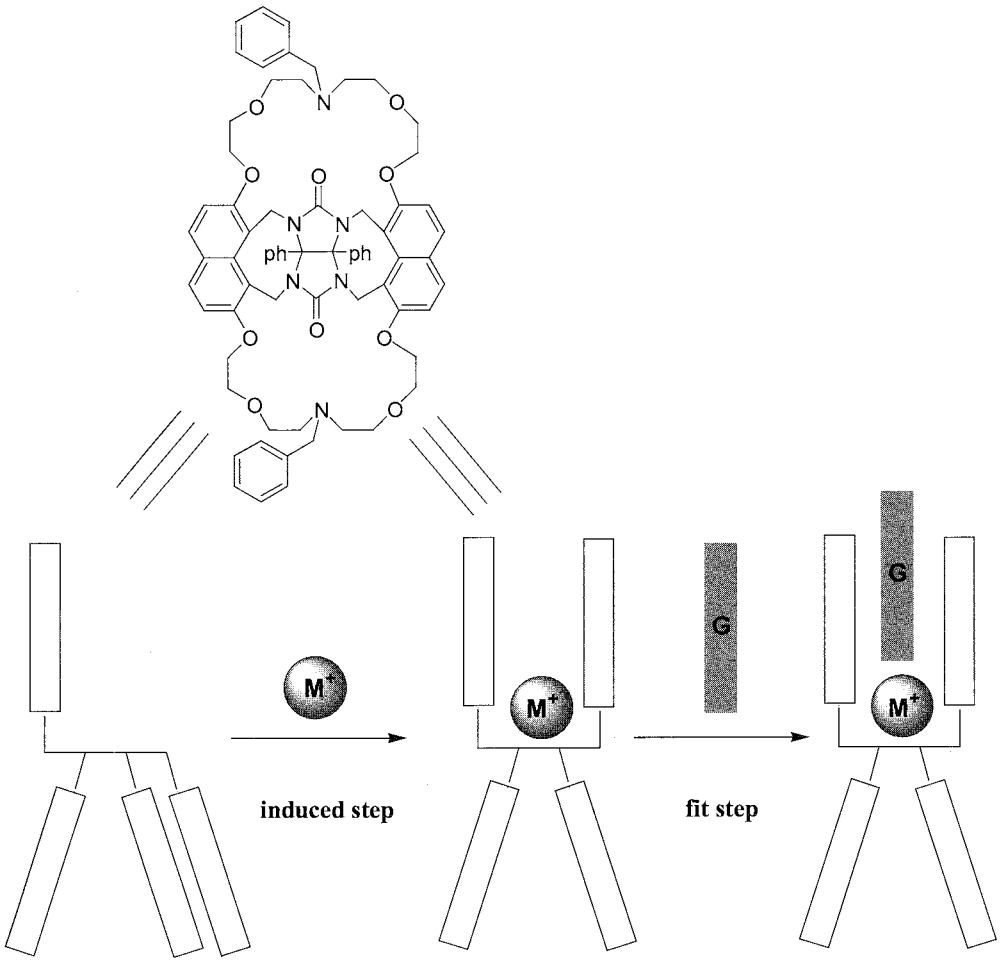

Fig. 6 The "induced step" and "fit step" of a his-crown-ether analogue in the guest-binding process. (*View this art in color. at www.dekker.com.*)

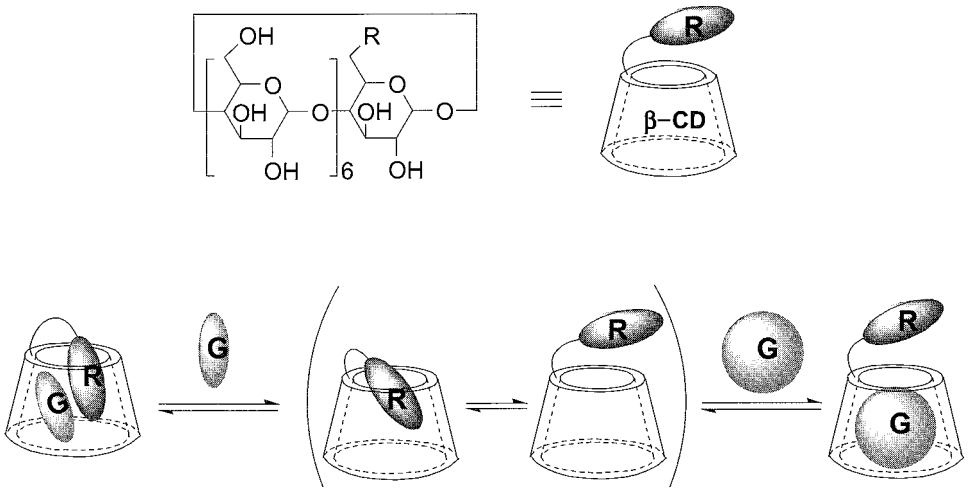

Fig. 7 Conforniational equilibria and guest-induced conformational change of modified cyclodextrin. *(View* this *art in color at www.dekker.com.*)

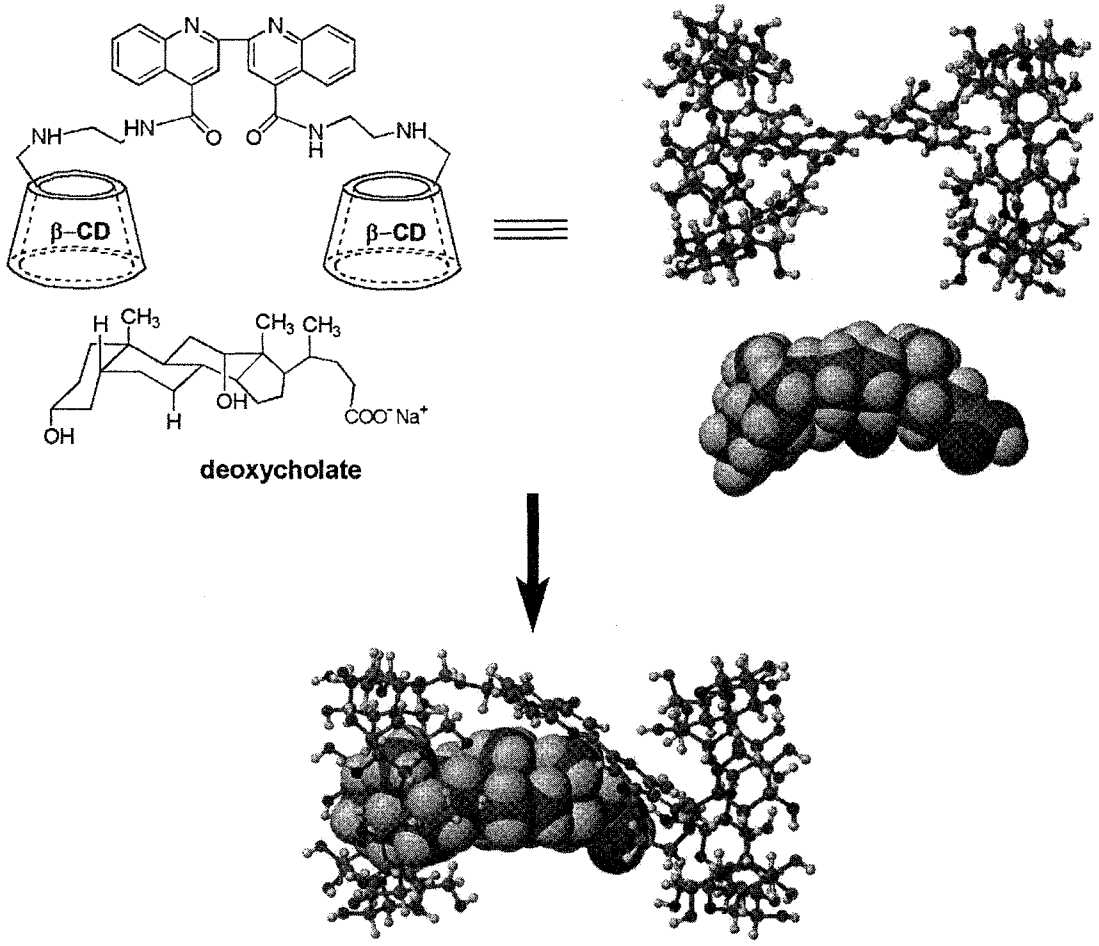

Fig. 8 The induced-fit model formed by *bis*(*β*-cyclodextrin)s and sterol.

sides of the box are Adenine::Thymine pairs, and the ends are crown ethers that serve as the induced-fit receptor. The system forms a three-component assembly in the presence of appropriately sized diammonium salts by means of an induced-fit mechanism. The compound represents a low-molecular-weight "induced-fit receptor model." As the size of a system increases. the induced fit in assembly becomes more complicated and precise due to the increased number of recognition sites. In this case, the appropriate length of the guest and the organized H-bonding or z-stacking are incorporated into the formation of the assembly. so the cooperativity of these factors should be a precondition for the good performance of the induced-fit process. In other words, it may be said that the process of assembly formation is just the process in which all components induced fit with each other in a certain mode. From this point of view, induced fit can also be utilized as a way to construct the assemblies and then to control their behavior. Chen et al. presented a K^+-induced aggregation via sandwich complexation of IS-crown-5 functionalized gold nanoparticles in a sodium-containing solution (Fig. 10).[25] Here, the crown-thiol molecule was induced to change its conformation from a 1:1 complex with Na^+ to a sandwich complex of 2:1 with K^+, again demonstrating the specificity of induced-fit processes.

In recent years, a new concept in molecular recognition, "molecular imprinting," was advanced and developed extensively. Many investigations indicate that the molecular imprinting displays characteristics of induced fit to a certain degree. It is the process in which the guest (substrate) induces the host to aggregate in accordance with guest size and shape. In this process, sometimes the host does not change its conformation, but several hosts cooperatively form a new assembly with a particular conformation different from the monomer. It could be said from this viewpoint that the molecular-imprinting technique expands the induced-fit mechanism to a more complicated and ordered system with many elements accompanied. For instance, induced fit was mentioned to occur upon the inclusion complexation between guest and

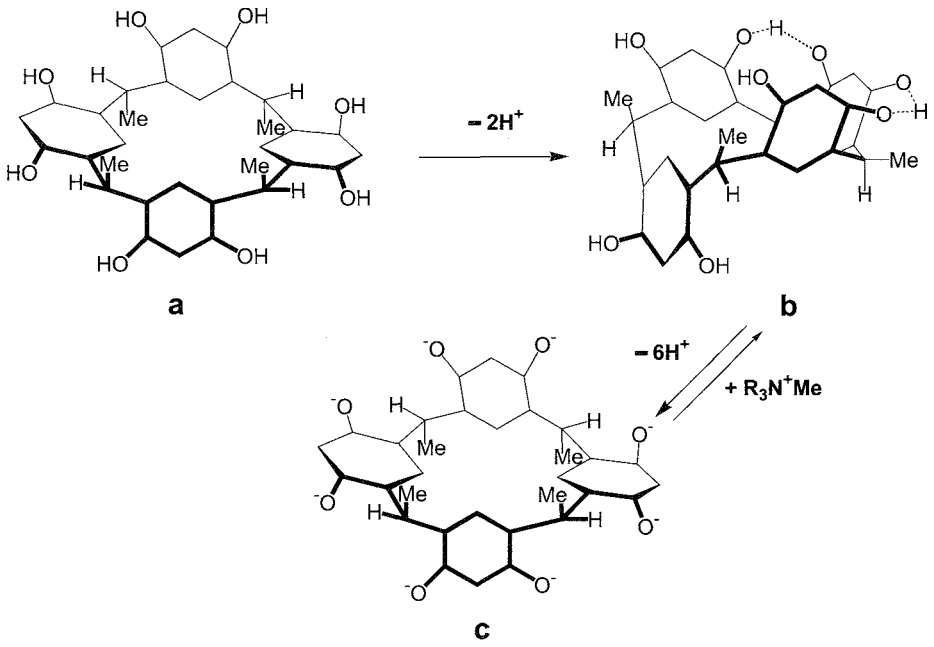

Fig. 9 The three different forms of cyclophane as a function of pH

cyclodextrin derivatives. However, for some special guests with large size and shape, even if induced-fit processes occur, the binding ability of cyclodextrin could not be improved in a general instance. However, in the molecular-imprinting process, when induced fit is worked to collect several cyclodextrins together using a large-sized guest as the template, the aggregate obtained might be favorable by virtue of recognizing the corresponding template molecule (Fig. 11).[26] It should be emphasized that the induced fit only exists in the process of preparing (assembling) the imprinting molecule but not in the recognition process. which would be more reasonably described as a lock and key recognition process.

Thermodynamic **Origin of** Induced Fit

In the classical lock and key model, complementary groups are rigidly positioned for maximal interaction with the substrate, which usually implies that the shape and nature of the cavity will provide good, close van der Waals contacts, and then the local free energy belonging to each active site will sum to the overall free energy of binding.[27] In contrast, in the induced-fit model, the complexation between host and guest is usually accompanied by the formation of a new configuration or sometimes a shift of equilibrium between different conformations of the host, and therefore, the contribution of this rearrangement to the overall free energy of binding must be entropically unfavorable. At the same time, as the result of induced fit, the rearrangement of the host conformation should achieve much stronger van der Waals contacts as well as other interactions between host and guest, such as ion–dipole, dipole–dipole, π–π, hydrogen-bond interactions. etc., which means favorable free-energy contributions from an enthalpic viewpoint. It is relatively straightforward to demonstrate the existence of entropy–enthalpy compensation effects in induced-fit binding.[28,29] Sanders and coworkers rationalized the conformational changes and binding between porphyrin hosts and *bis*-amine ligands in terms of the sum of the entropic and enthalpic contributions of each individual interaction to the overall binding energy, providing insight to the important features of the thermodynamics of conformational switching and the behavior of induced-fit enzyme models.[30] It could be deduced that the thermodynamics of induced fit involves a balance between the energetic penalty for conformational change and the gain in binding energy as a result of the chelate effect and any other favorable interactions. That is to say, only the induced-fit structure possessing the lower energetic penalty for conformational change or much larger binding energy compensated for by favorable interactions from confonnational change, displays the highest affinity. Consequently, for the formation of such a perfect induced-fit complex, a guest with suitable size and shape is necessary for complexation with a given host, which explains the specificity of induced fit thermodynamically. Furthermore. Murakami et al. presented their

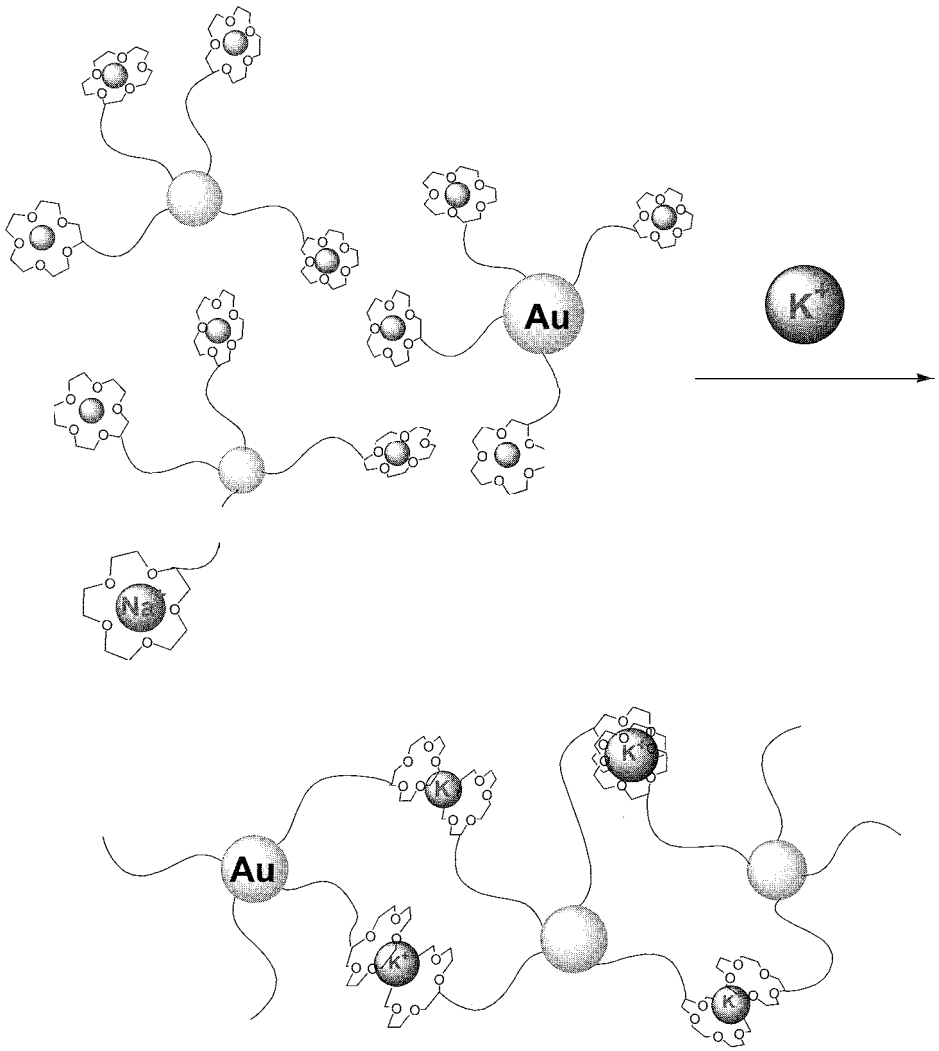

Fig. 10 The K^+-induced conformational changes of 15-crown-5 functionalized gold nanoparticles. *(View this art in color at www.dekker.com.)*

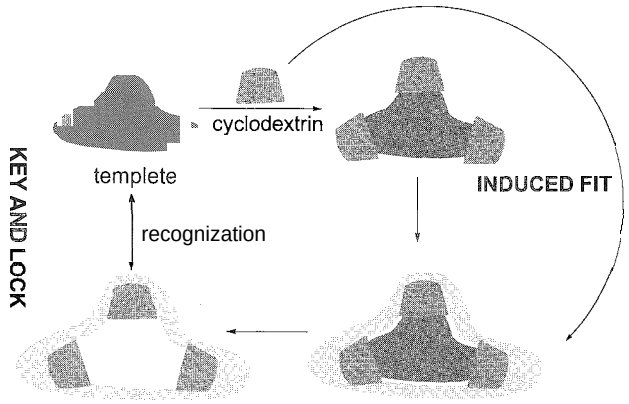

Fig. 11 The molecular-imprinting process of cyclodextrin. *(View this art in color. at www.dekker.com.)*

observations of dynamic features of an induced-fit complexation in artificial host–gueot systems,[31] which provides a useful guidepost for designing functionalized hosts as artificial receptors and enzyme models

CONCLUSION

It was demonstrated that the induced-fit concept of the interaction between an enzyme and a substrate was introduced from biological processes to supramolecular systems for explaining the molecular-binding behavior of artificial receptors, including crown ethers, cyclodextrins. calixarenes, porphyrins, etc. The induced-fit mechanism was utilized to explore the binding behavior of ions and molecules, and was adopted to accurately describe

supramolecular aggregates bearing more complicated structures. In the molecular recognition and assembly processes, when a guest (ion or molecule) induces a host (artificial receptor) to fit its size and shape, unavoidable conformational changes of the host sometimes exist; which is the essential characteristic of an induced-fit interaction. Thermodynamic investigations of induced-fit processes for molecular selective binding are not only of theoretical interest as the direct quantitative measures of the conformational change but are also of practical importance as the guiding principle in designing novel receptors to achieve biological functions.

Inelastic Neutron Scattering

Marc Bée
Université J. Fourier, Grenoble, France

INTRODUCTION

Inelastic neutron scattering is a well-established and powerful technique used to study elementary excitations in condensed matter on the atomic scale, including local vibrational modes and single-particle diffusive modes as well as collective modes such as phonons and magnetic excitations.[1–5] The theoretical foundations were developed in the 1950s. Van Hove[L6] expressed the differential scattering cross section in terms of time-dependent pair cosrelation functions, and Glauber and Zemach developed the theory of neutron vibrational spectroscopy for solids and diluted molecular gases.[7,8] Then the availability of large fluxes of low-energy neutrons from nuclear reactors permitted the design of spectrometers for accurate investigation of diffusive motions in disordered materials.[9–11] In the course of time, inelastic neutron scattering has been applied to more complex systems, such as polymers[12] and biological macromolecules.[13,14]

BASIC ASPECTS OF NEUTRON INELASTIC SCATTERING

Neutrons are particles liberated in fission of ^{235}U in nuclear reactors or by pelting heavy nuclei with GeV protons in spallation sources. They propagate with a finite velocity v. and according to the laws of kinematics, a neutron with mass rn= 1.675 10^{-24} g has a kinetic energy

$$E = \frac{1}{2}mv^2$$

Typical velocities of neutrons used in condensed matter research vary from 500–14.000 m/sec, corresponding to energies from E=1.3 meV to 1.0 eV.

At the same time, a neutron can be considered a wave, with wavelength, λ. related to its velocity by the De Broglie relation:

$$\lambda = \frac{h}{mv} = \frac{2\pi}{|\boldsymbol{k}|}$$

where h is the Planck's constant (h=6.62 10^{-34} J.s), and $\boldsymbol{k}$ is the wave vector. The kinetic energy is then

$$E = \frac{\hbar^2 k^2}{2m}$$

Neutron wavelengths are of the order of crystallographic spacings. Therefore. neutrons obey Bragg's law when diffracted by single crystals. The relationship between wavelength, λ. lattice parameters, d_{hkl}, and diffraction angle θ, is as follows:

$$\lambda = 2d_{hkl}\sin\theta$$

Experimental techniques make use of these two features to select the required energy of a neutron beam. The neutron flight time is easily determined on sufficiently large lengths: a 5 Å wavelength neutron has a flight time, τ [L(m)/v(ms^{-1})] of 1264 s m ^{1}.

The neutron energy range encompasses a wide range of dynamical processes in condensed matter. Typical energies are 100 meV (1.2 10^{13} Hz) for molecular vibrations, 0–50 meV (6 10^{12} Hz) for lattice vibrations (phonons) or spin waves in solids, 0.01–1 meV (characteristic times τ=10^{-10} 10^{-12} s) for reorientations of inner chemical groups in molecules (e.g., polymer side groups) or for whole molecule reorientations in disordered phases (liquid crystalline phases or rotator phases), and a few μeV (τ=10^{-9} s) for long-range translational diffusion of molecules in the liquid state or in intercalation compounds (zeolites).

It can be found in standard textbooks that the neutron nuclear scattering is isotropic and characterized by a single parameter, b, the scattering length, independent of the neutron energy. Theory also attributes to each nucleus a coherent bound cross section:

$$\sigma_{coh} = 4\pi b^{coh} = 4\pi\langle b^2\rangle$$

together with an incoherent bound cross section:

$$\sigma_{inc} = 4\pi b^{inc} = 4\pi(\langle b^2\rangle - (b)')$$

where the brackets hold for an average over all the isotopes and spin states.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012833

Coherent and incoherent b^{coh} and b^{inc} scattering lengths are properties of the neutron–nucleus interaction and play an important role in the analysis of the dynamics of solids and liquids. They are fundamentally different in nature. Coherent scattering is the scattering that would be observed if all the atoms of the same chemical species had the same scattering length (b). The neutron would see an average uniform potential. which could give rise to interference effects. Coherent scattering involves the correlation between the positions of different nuclei and enables the study of collective excitations like phonons or spin waves, where all atoms or spins move in concert. Because deviations from the average potential are distributed at random, they cannot yield interference effects. Incoherent scattering describes the correlation between the positions of the same atom at different times. This scattering is added to the coherent scattering to obtain the scattering of the real system. Depending on the isotopes present in the sample, it is possible to select between coherent and incoherent scattering processes. The incoherent scattering cross section of hydrogen, in particular [σ_{inc}(H)=80 10^{-24} cm^2], is larger than that of all other atoms by a factor of 20. Incoherent neutron scattering is a powerful method for investigating motions in hydrogenated organic compounds like polymers or biological macromolecules. Moreover. isotopic substitution of deuterium [σ_{inc}(D)=2 10^{-24} cm^2] for hydrogen allows some chemical groups to be hidden and can be of considerable help in the identification of observed motions.

Through its spin. the neutron interacts with the magnetic moment (spin and orbital) of unpaired electrons. Inelastic magnetic scattering probes the dynamics of spin systems like spin waves (magnons). The use of polarized neutrons and the analysis of their polarization after scattering allows the differentiation of magnetic fluctuations from positional fluctuations and separation of coherent nuclear scattering from incoherent.

The neutron spectroscopy method consists of the measurement of changes in energy and momentum of neutrons interacting with matter in order to obtain information about the dynamics and the geometry of constituent atoms. Let us denote by indexes i and f the initial and final states of the physical quantities attached to the neutron. In the scattering process, the sample transfers momentum $\hbar\boldsymbol{Q}$ and energy $\hbar\omega$ to the neutron according to

$$\boldsymbol{Q} = \boldsymbol{k}_f - \boldsymbol{k}_i$$

($\boldsymbol{Q}$ is the scattering vector) and

$$\hbar\omega = E_f - E_i = \frac{\hbar^2 k_f^2}{2m} - \frac{\hbar^2 k_i^2}{2m}$$

The general double differential cross section for neutron nucleus scattering is as follows:[1–5]

$$\frac{\partial^2\sigma}{\partial\Omega\partial E_f} = \frac{1}{\hbar}\frac{\partial^2\sigma}{\partial\Omega\partial\omega} = \frac{\sigma_{coh}}{4\pi\hbar}\frac{k_i}{k_f}S(\boldsymbol{Q},\omega) + \frac{\sigma_{inc}}{4\pi\hbar}\frac{k_i}{k_f}S_{inc}(\boldsymbol{Q},\omega)$$

The scattering functions $S(\boldsymbol{Q},\omega)$ and $S_{inc}(\boldsymbol{Q},\omega)$ measure the response of the atomic number density to the external driving potential caused by the neutron interaction. They are expressed as the space and time Fourier transforms:

$$S(\boldsymbol{Q},\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} dt \int_{-\infty}^{+\infty} d\boldsymbol{r} G(\boldsymbol{r},t)\exp(-i\boldsymbol{Q}\cdot\boldsymbol{r}) \times \exp(-i\omega t)$$

$$S_{inc}(\boldsymbol{Q},\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} dt \int_{-\infty}^{+\infty} d\boldsymbol{r} G_s(\boldsymbol{r},t)\exp(-i\boldsymbol{Q}\cdot\boldsymbol{r}) \times \exp(-i\omega t)$$

where $G(\boldsymbol{r},t)$ and $G_s(\boldsymbol{r},t)$ are the pair and self-correlation functions, respectively, according to the formalism first introduced by Van Hove.[6] The notation $G(\boldsymbol{r},t)$ represents the conditional probability for a relative displacement r of a scatterer with respect to another within time t. $G_{inc}(\boldsymbol{r},t)$ is the conditional probability for the same scatterer to undergo a displacement $\boldsymbol{r}$ within time t. Thus, the two basic quantities to be measured are ω and $\boldsymbol{Q}$ (or simply $Q=|\boldsymbol{Q}|$ in the case of isotropic samples like liquids or powders).

INSTRUMENTS IN NEUTRON INELASTIC SCATTERING

Atomic motions cause the energies of scattered neutrons to be changed. Depending on the time scale of motion, one needs to cover an energy range from *10* neV–1 eV and to span wave vectors from *0.01–10* $Å^{-1}$. This wide time scale of analysis is covered by different classes of instruments. The phase space region (ω,Q) accessible to the various types of neutron spectrometers is schematized in Fig. 1.

Any spectrometer must perform three functions:

1. The incident neutrons must be selected in a small energy range between E_i and E_i+dE_i and in a small solid angle about the direction of k,.
2. The final energy E_f of the scattered neutrons must be analyzed to determine the energy change $\hbar\omega=E_f-E_i$.

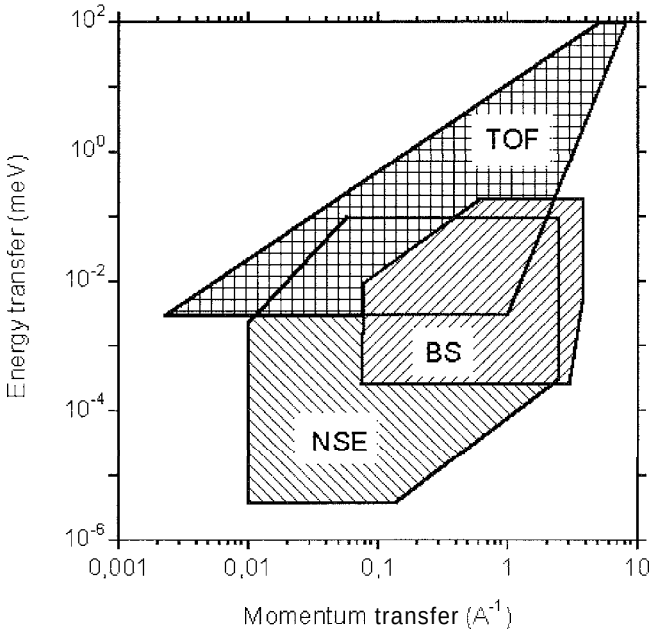

Fig. 1 The energy and momentum transfer regions accessible to different types of neutron spectrometers: time of flight (TOF), backscattering (BS). and neutron spin echo (NSE).

3. The scattering angle with respect to the incident beam and with respect to the sample orientation must be measured to determine the momentum transfer $Q = k_f - k_i$.

In practice, these three functions are achieved using the wave/particle duality of the neutron. The incident and scattered wave vectors can be determined by Bragg reflection from single crystals or by time of flight analysis of their velocity.

Triple-Axis Spectrometers

The triple-axis spectrometer (TAS) was invented by Brockhouse in 1962. This type of instrument is cominon in reactor centers. It is used to investigate well-defined excitations such as phonons or spin waves in single crystals. Since their first appearance, these instruments have changed little and can be schematically sketched as in Fig. 2. Incident and final wave vectors are determined by Bragg reflection of the neutron beam by suitable single crystals: a monochromator determines the magnitude and the orientation of the incident wave vector, k_i. Another crystal, the analyzer. determines the final wave vector k_f. Adjustment of the sample orientation allows the neutron wave vector transfer to be positioned at will in the reciprocal lattice of the sample and the phonon dispersion curves to be investigated. The best energy or wave vector resolution can be achieved in several ways. The most general method is the constant-Q mode, in which the scattering vector is kept equal to $\boldsymbol{Q}=\boldsymbol{G}+\boldsymbol{q}$, where G is a vector of the reciprocal lattice around which the dispersion curves are analyzed. Then, the initial energy can be fixed, and the final energy is scanned; conversely, the initial energy can be scanned, and the final energy kept fixed. The simultaneous collection of data over a range of (Q,ω) requires the use of a position-sensitive detector, as with DFTAS at NIST (Gaithersburg, USA[''']).

Time-of-flight and Backscattering Spectrometers

In contrast to TAS, time-of-flight (TOF) spectrometers and backscattering (BS) spectrometers are adapted to simultaneously record neutrons scattered into a wide range of wave vectors and energies. They are used to measure $S(Q,\omega)$ for liquids or disordered samples or magnetic energy spectra that vary only little with Q. A detailed review of existing instruments can be found in Ref. [16].

Neutron TOF spectroscopy is a powerful method for the study of dynamic processes over a wide dynamical range for polycrystalline and disordered solids. The continuous neutron flux is chopped into short bursts to set a time mark $t=0$ for the flight time of the neutrons. A

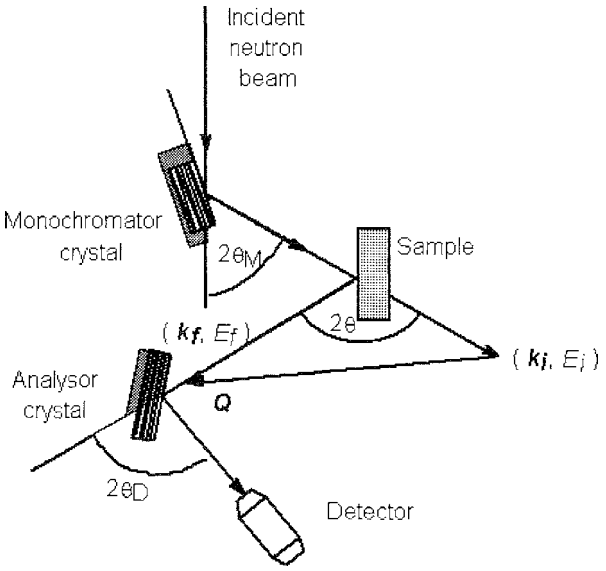

Fig. 2 A triple axis spectrometer.

large assay of several hundred detectors is placed to simultaneously collect counts for several final wave vectors in the scattering plane and also above and below. The first instrument of this type has been IN5 at ILL (Grenoble, France[17]). It uses several disk choppers separated from each other for pulsing the neutron beam and selecting a particular energy from it. Later, new TOF instruments were also built: MIBEMOL at LLB (Saclay, France[18]), NEAT at HMI (Berlin, Germany[19]), and DCS at NIST, with a number of technical improvements. Other TOF spectrometers use a crystal monochromator in combination with a Fermi chopper. Numerous instruments of this type exist for thermal neutrons. For cold neutrons, the use of focusing techniques permitted a substantial gain in intensity: IN6 at ILL. FOCUS at PSI (Villigen. Switzerland[20]), and FCS at NIST.

Neutrons inelastically scattered from the target gain or lose energy and then suffer a speed change. Obviously, the part of the spectrum corresponding to neutron energy loss is limited by the time interval between two bursts. The energy resolution of a TOF spectrometer is determined from the flight time and the energy uncertainty proportional to the burst duration. Accurate measurements are obtained with machines having large diinensions (several meters) and rapidly rotating disks.

Due to kinematic limitations: it is clear that at a constant angle between k_i and k_f, the scattering vector, $\boldsymbol{Q}$, is a function of the energy transfer, $\hbar\omega$. This point has to be taken into account in the data analysis.

Inverted TOF spectrometers are often used at spallation sources. IRIS at ISIS (RAL, United Kingdom[21]) is the first spectrometer of this type. Its main advantage is that it is flexible. with a wide dynamic range. The design of IRIS inspired many similar instruments on other spallation sources. A polychromatic neutron burst hits the sample. The repetition rate of the neutron bursts is directly determined by the period of the neutron pulses from the source. After the scattering process, crystal analyzers reflect only neutrons with well-defined energies into the detectors, where they are counted into different TOF channels.

BS spectrometers can be described as a particular case of TAS in which Bragg scattering angles on the monochromator and on the analyzers are equal or close to 90°. Differentiation of the Bragg's law gives

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta d}{d} + \frac{\Delta\theta}{\tan\theta}$$

The best resolution is obtained for $\theta = 90°$, where only the spread of the lattice spacing contributes. Typical energy resolutions of 1 μeV are obtained with $\Delta d/d$ of the order of 10^{-5}. Neutron backscattering spectroscopy is an important scattering technique for probing dynamical processes with long characteristic times. The analysis is made at constant final energy. The incident energy is varied by fast translational motion (Doppler effect) of the monochromator or by thermal expansion of the lattice parameters, the monochromator being cooled or heated in a cryofurnace. BS can operate over a wide momentum-transfer range simultaneously and can potentially access a time range between 0.01 μs and 100 ps. The resolution is mainly determined by the divergence of the neutron beam.

Molecular spectroscopy stimulated the development of especially dedicated spectrometers. At ISIS, the accessible energy range is spanned through the traditional spectroscopy region (2–500 meV) with TOSCA up to high energies (>5 eV) with eVS. The latter uses a filter technique. A filter instrument also exists at ILL (IN1-BeF) over a different energy range.

Neutron **Spin-Echo** Spectrometers

Neutron spin-echo (NSE) spectroscopy is somewhat different from the time-of-flight or BS techniques. The principle was introduced by F. Mezei in 1972.[22,23] NSE spectrometers use the Larmor precession of the neutron magnetic moment in an external magnetic field as an internal clock and directly compare the incident and scattered velocities of each individual neutron. Angular precession of the neutron spin is related to their velocities. After scattering by the sample, the direction precession axis of the spins is reversed. Analyzers measure the difference of the two precession angles and, hence, their energy exchange. The energy resolution becomes basically independent of the beam monochroinatization and

intensity. While BS and TOF spectrometer5 measure in frequency space. and thus determine $S(\boldsymbol{Q},\omega)$, neutron spin-echo spectroscopy measures in time space and directly determines the intermediate scattering function $S(\boldsymbol{Q},t)$ that is both the space Fourier transform of the pair correlation function and the inverse time Fourier transform of the scattering function:

$$S(\boldsymbol{Q},t) = \int_{-\infty}^{+\infty} G(\boldsymbol{r},t)\exp(-i\boldsymbol{Q}\cdot\boldsymbol{r})d\boldsymbol{r}$$

$$S(\boldsymbol{Q},t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} S(\boldsymbol{Q},\omega)\exp(+i\omega t)d\omega$$

In 1987 Gähler and Golub suggested a new type of spectroineter designed as "neutron resonance spin echo" or on "zero field neutron spin echo" that uses radio-frequency coils directly inspired from nuclear magnetic resonance.[24] Instruments of this type have been built at HMI and LLB or are under development (Munich).

Fourier times accessible to spin-echo spectroscopy range from 1 ps–100 ns. i.e., the energy resolution is better by two orders of magnitude than with the backscattering technique. The scientific fields under interest are polymer dynamics, glass transitions, dynamics of magnetic disordered compounds, colloids, microemulsions, or inelastic excitations (rotons in ^{3}He).

COHERENT NEUTRON SCATTERING

Phonons

Atoms in a crystal are not at rest. They execute small displacements about their equilibrium positions. The theory of crystal dynamics describes the crystal as a set of coupled harmonic oscillators. Atomic motions are considered a superposition of the normal modes of the crystal, each of which has a characteristic frequency $\omega(\boldsymbol{q})$ related to the wave vector of the propagating mode, $\boldsymbol{q}$, through dispersion relationships. Neutron interaction with crystals proceeds via two possible processes: phonon creation or phonon annihilation with. respectively, a simultaneous loss or gain of neutron energy. The scattering function $S(\boldsymbol{Q},\omega)$ involves the product of two delta functions. The first guarantees the energy conservation of the neutron phonon system and the other that of the wave vector. Because of the translational symmetry. these processes can occur only if the neutron momentum transfer, $\boldsymbol{Q}$, is such that

$$\boldsymbol{Q} = \boldsymbol{K} \pm \boldsymbol{q}$$

K being a vector of the reciprocal lattice. Coherent inelastic neutron scattering remains a powerful method for investigating collective motions in condensed matter. It allows for a complete determination of the dispersion curves in a Brillouin zone (BZ), as a function of the mode polarization. Other techniques, such as Brillouin scattering for the acoustic modes and Raman scattering for the optic modes are sensitive to phonon branches close to the Γ point in the reciprocal lattice.

Magnetic Scattering

Inelastic neutron scattering is a powerful tool for measuring inelastic magnetic excitations. Because the magnetic response is often spread over a wide energy range (from a fraction of μeV to several meV), a combination of several spectroscopy methods with different resolution (NSE, BS, and TOF) is required. Collective modes yield dispersion curves that can be investigated in detail with TAS. On the other hand, as long as the excitations are localized modes. they can be observed with TOF instruments. but dispersion smears the peaks. The study of itinerant magnetism requires spectrometers working with high incident energies (IN4 at ILL or MARI at ISIS). Recent developments in neutron instrumentation (^{3}He neutron spin filters, polarizing super-mirrors) make feasible new experiments on inelastic neutron scattering with simultaneous analysis of the polarization of the scattered neutrons.

INCOHERENT NEUTRON SCATTERING

Inelastic Scattering

Incoherent scattering is related to the self-correlation function and, therefore, does not contain any interference terms. Unlike in the case of coherent scattering. there is no momentum selection rule. Incoherent one-phonon scattering occurs for a continuous range of k_f wave vectors, each corresponding to a phonon mode fulfilling the energy conservation.

The relevant quantity is the density of states (DOS), $g(\omega)$. In the case of cubic crystals composed of a single type of atoms of mass M, measurement of the energy distribution of the scattered neutrons directly yields the DOS:

$$S(Q,\omega) = \exp[-2W(Q)] \times \left[\delta(\omega) + \frac{\hbar Q^2}{4M\omega}\frac{\exp\left(-\frac{\hbar\omega}{2k_BT}\right)}{\sinh\left(\frac{\hbar\omega}{2k_BT}\right)}g(\omega)\right]$$

k_B is the Boltzman constant. and $2W(Q)$ is the Debye–Waller factor that takes into account atomic vibrations.

For completely incoherent scatterers, such as vanadium, $g(\omega)$ is the only information about phonons that can be obtained from neutron scattering. Nevertheless, a singular behavior can be observed at critical phonon frequencies at the limits of the Brillouin zone (BZ) and in the center of the BZ. Large maxima appear in the scattered intensity, providing a rough estimation of the phonon dispersion curves.

For noncubic crystals or when there are several atoms in the unit cell, one can access only to a weighted DOS. $G(\omega)$, with a polarization term involving the polarization vectors of the normal modes with respect to the scattering vector $\boldsymbol{Q}$. This DOS can be obtained by extrapolation to small Q of the purely inelastic part of the scattering.

The theory of neutron scattering from vibrating molecules was developed by Zemach and Glauber.[8] Recently, the method was applied to complex biological substances (bovine pancreatic trypsin inhibitor).[13]

Quasi-Elastic Neutron **Scattering**

Quasi-elastic neutron scattering (QENS) is related to stochastic particle motions. Because the displacements are random, the diffusive motion of particles in liquids cannot be quantized, and the energies are continuously distributed. Unlike the case of cooperative motions like phonons in solids or molecular vibrational excitations, in the dynamic scattering function $S(\boldsymbol{Q},\omega)$, there are no δ-functions at finite momentum and energy transfers. Instead. the dynamic scattering function is centered at zero-energy transfer with a characteristic quasielastic line width proportional to the diffusivity of the particles.

One looks at the motion of an individual atom. Therefore, the relevant quantity is the incoherent scattering function. Because of the large incoherent cross section of hydrogen, quasielastic scattering is particularly suited and mostly used for the investigation of hydrogenated organic compounds with dynamical disorder, like rotator phases; liquids. polymers, and biological macromolecules.

Coherent quasi-elastic neutron scattering due to the pair-correlation of atomic motions is more complex than incoherent scattering from single particle motion. Therefore, the theory of coherent scattering function is not yet fully developed. However, approximate expressions for the coherent scattering function exist (incoherent approximation).

Translational long-range diffusion

Long-range diffusion of particles in solids and liquids was investigated for many years using the neutron scattering techniques,[11,25] and several types of descriptions were stimulated. The most simple is the continuous diffusion model according to Fick's law:

$$\frac{\partial G_s(\boldsymbol{r},t)}{\partial t} = D \cdot \nabla^2 G_s(\boldsymbol{r},t)$$

where D is the self-diffusion constant, and ∇^2 is the Laplace operator with respect to r. On the microscopic scale. it corresponds to the Brownian motion of large molecules immersed in a viscous solvent. The mean square displacement

$$\langle r^2(t)\rangle = 6Dt$$

corresponds to the Einstein free diffusion law.[26]

The incoherent scattering function $S(Q,\omega)$ exhibits a Lorentzian shape with a parabolic increase of its full-width at half-maximum (fwhm), Γ, as a function of Q:

$$\Gamma = 2DQ^2$$

At large momentum transfer, systematic deviations to this law are observed, because on distances smaller than several molecular diameters, the medium is no longer continuous, and underlying microscopic mechanisms intervene. Several jump models were developed. The Chudley–Elliott model[10,11] assumes a diffusion by successive jumps. It is successful in the description of hydrogen diffusion in metals or molecules in porous media. In their description of the dynamics of water molecules in the liquid state, Singwi and Sjolander[10,11] take into account successive oscillatory and diffusive states. At small Q values, both models yield the macroscopic DQ^2 law, the diffusion constant, D, being related to the mean residence time on a given site τ, by Einstein's relation:

$$D = \frac{l^2}{6\tau}$$

Localized motions

A large majority of solids is composed of molecules in crystal lattices or in amorphous phases. Then under the influence of thermal fluctuations, atoms can sometimes undergo displacements toward a limited number of other sites, by well-defined reorientations of chemical groups or of the whole molecule.[9,10] Also in liquid crystal phases, rotations of the molecules about their long axes were evidenced.

Because the motion of the scatterers is essentially restricted in space, the scattering function comprises a Dirac function $\delta(\omega)$ and a series of Lorentzian functions; the forms of which are directly related to the characteristic times of the relevant motions. Experimentally, one

observes a purely elastic peak with zero width (actually widened by the instrument energy resolution), superimposed on a broader quasi-elastic contribution. Their relative importance provides direct information on the geometry of the relevant motions.[10]

Numerous IQNS studies of organic chemical groups reorienting on several sites exist. Scattering laws were derived for proton two-site exchange mechanisms and rotations about symmetry axes like methyl groups or aromatic rings. When reorientation jumps occur about several axes, calculation of the scattering law is greatly simplified by using group theory. When the number of equilibrium sites becomes large, rotations approach axial or spherical rotational diffusion.

In recent years, many studies of biological samples carried out on TOF or BS spectrometers addressed the question of how the activities or functions of biological macromolecules are related to their local dynamics. It seems established that systems become active when their atoms are sufficiently mobile and the macromolecule can explore several conformational substates.[27]

Quantum tunneling

At low temperature, when the thermal energy of the rotating group becomes smaller than the energy barrier between equilibrium sites, a classical system freezes. However, there is a quantum mechanical probability of tunneling through the barrier, due to the overlap of the wave functions: the librational ground state is split due to tunneling, and direct observations of the transitions between these states are possible by high-resolution inelastic scattering. Tunnel splitting is sensitive to the mass of the tunneling atoms and to the strength of the potential. Inelastic neutron scattering permits probing of the force fields applied in molecular dynamic simulations. Earlier investigations were carried out with crystalline samples. Recently, tunneling excitations could also be observed in amorphous polymers poly(vinyl acetate) and poly(methyl methacrylate).[29]

CONCLUSION

Inelastic neutron scattering is a powerful technique for investigating atomic and molecular motions in condensed phases. Several types of instruments permit a time range from typically 10^{-13}–10^{-9} s to be covered and thus vibrations (collective or individual) as well as diffusive displacements to be investigated. The technique also provides geometrical information about the relevant motions. For the study of vibrations, it is complementary of Raman or IR spectroscopy with the advantage of an absence of selection rules, in spite of a worse resolution. For diffusive motions. it can be profitably associated to NMR, with both methods providing an inspection of the dynamical mechanisms on the same microscopic scale. Inelastic neutron scattering data are also directly comparable with computer molecular simulations. Finally, inelastic neutron scattering should benefit the development of new intense neutron sources.

Interpenetration

Stuart R. Batten
Monash University, Clayton, Victoria, Australia

INTRODUCTION

Crystal engineering is of great current interest and can be thought of as "the supramolecular chemistry of the solid state." A common theme is the analysis of crystal structures and the application of the knowledge gained to the design of new structures.

A particularly useful approach to the analysis and design of crystal structures is to reduce the structures to simple topological networks.[1,2] These networks are basically descriptions of multiply connecting nodes and the ways they connect, and are usually named after simple chemical examples of the net (e.g., diamond, NbO, α–Po) or are given numerical descriptions [e.g., (6,3), (4,4), (10,3)-*a*].

This approach is particularly useful for structures containing coordination polymers or molecules that are connected by hydrogen bonding into infinite arrays, and the structures examined here will be described in terms of their topological networks. One application of this network approach has been in the design of structures with large, open frameworks that might potentially include guest species. Often, however, this results in structures with multiply interpenetrating networks, as nature seeks to maximize crystal packing efficiency. Interpenetrating networks can be thought of as polymeric analogues of molecular catenanes and rotaxanes, and they involve the intimate entanglement of two or more polymeric networks.[1,3,4]

An important and defining feature of interpenetration is the condition that the entanglement of the topological nets is such that, although there is no direct connection between the networks, they cannot be separated (in a topological sense) without requiring the breaking of network connections. Any amount of bending or distortion of the nets is allowed: but breaking of the connections is not permitted—connectivity and not geometry is important in topological descriptions. Thus, cooked spaghetti is not interpenetrating, but links in a chain are. Alternatively, the chemical example of simple linear one-dimensional (1D) chains penetrating through the windows of a stack of two-dimensional (2D) sheets is not interpenetration if, in an imaginary, topological sense, the chains could be simply drawn out without requiring any connections of any of the networks to be broken.

Although the 1D chains penetrate the 2D networks. the 2D nets do not penetrate the 1D chains; so it is not interpenetration. If, however, the 1D nets possessed windows that were penetrated by the 2D nets (for example, if they had a ladder-like motif), then the term interpenetration would apply.

When describing interpenetrating systems, it is important to describe not just the topology of the interpenetrating networks but also the topology of interpenetration.[1,4] This is analogous to describing not only the molecular geometry in a simple molecular crystal structure but also the way the molecules pack together. The way the networks interpenetrate can have important structural consequences. For example. interpenetration of low-dimensional networks can give entanglements with the same or higher dimensions [interpenetration of 2D nets, for example, can give overall 2D or three-dimensional (3D) entanglements]. A notation for partially describing the topology of interpenetration was developed".'' and is used at various stages in the following discussion to help illustrate not only the network topologies but also the interpenetration topologies.

1D NETS

The importance of describing interpenetration topology, as well as dimensional increase through interpenetration. can be illustrated by looking at 1D networks. The structure of $[\{HO_2CC_6H_4CH_2)(Bu_2bipy)Me_2Pt\}_3(tpt)](PF_6)_3$ [*Bu_2bipy* = 4.4'-di-tertbutyl-2.2'-bipyridine, *tpt* = 1,3,5-tri(4-pyridyl)-2,4,6-triazine], consists of trimeric species connected by hydrogen-bonding carboxylate dimers to generate 1D nets that consist, topologically, of alternating windows and links.[5] The chains entangle in parallel pairs such that the links of one chain penetrate the windows of the other and vice versa, generating 1D entanglements of pairs of nets (Fig. 1a). The mean vectors of propagation of each chain in the interpenetrating pairs are both parallel and coincident, and the 1D entanglement of 1D nets is called "1D → 1D interpenetration."

The structure of $[Cu_2L_3(MeCN)_2](PF_6)_2$ [*L* = 1.4-bis (4-pyridyl)butadiyne] contains 1D ladder-like networks that interpenetrate such that each Ladder interpenetrates

DOI: 10.1081/E-ESMC 120012732

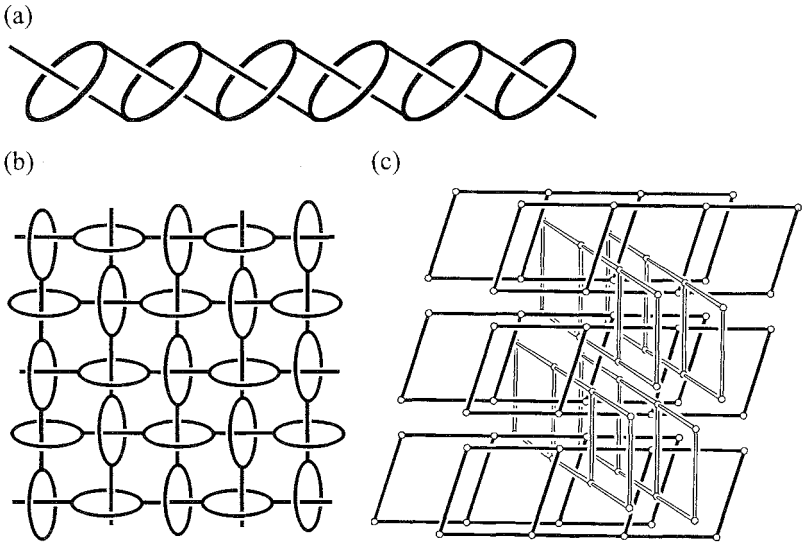

Fig. 1 Interpenetration of ID nets: (a) 1D — 1D interpenetration in the structure of $[\{HO_2CC_6H_4CH_2)(Bu_2bipy)\text{-}Me_2Pt\}_3(tpt)](PF_6)_3$;[5] (b) 1D → 2D inclined interpenetration in the structure of $Ag_2(bix)_3(NO_3)_2$;[8] and (c) 1D → 3D inclined interpenetration in the structure of $CdL_{1.5}(NO_3)_2$, *L* = 1,4-*bis*(4-methylpyridyl)benzene.[9]

with four others.[6,7] As in the previous example, the mean vectors of propagation of the interpenetrating networks are parallel; however, they are no longer coincident. As a result, the interpenetration is such that 2D layers of interpenetrating 1D ladders are formed. This is 1D → 2D parallel interpenetration.

1D → 2D inclined interpenetration is illustrated by the structure of $Ag_2(bix)_3(NO_3)_2$ [*bix* = 1,4-*bis*(imidazol-1-ylmethyl)benzene].[8] Like the example of 1D → 1D interpenetration discussed above. this structure contains 1D chains that consist of alternating windows and links. The mean vectors of propagation of the interpenetrating nets are. however, no longer all parallel but rather occur in two sets of parallel directions inclined to each other. The interpenetration results in an overall 2D entanglement (Fig. 1b). An interesting feature of this structure and the first compound mentioned in this section is that they are rare examples of structures in which there are only rotaxane-like interactions and no catenane-like interactions.

The generation of a 3D entanglement from the interpenetration of 1D networks is displayed by the structure of $CdL_{1.5}(NO_3)_2$ [*L* = 1,4-*bis*(4-methylpyridyl)benzene].[9] Each window of each 1D ladder-like net is penetrated by four other ladders at an inclined angle to the first (Fig. lc), resulting in an overall 3D entanglenlent (1D → 3D inclined interpenetration). Another possible topology of interpenetration. 1D → 3D parallel interpenetration, is yet to be observed.

2D NETS

As for 1D nets, there are a number of different ways for 2D networks to interpenetrate. The compound Ag(tcm) (*tcm* = tricyanomethanide), $C(CN)_3^-$ is a coordination polymer composed of 2D chicken-wirelike (6,3) networks.[10,11] The networks are corrugated and interpenetrate such that discrete layers of doubly interpenetrating networks are formed (Fig. 2a). The mean planes of the interpenetrating sheets in each layer are parallel and coincident, and the topology of interpenetration can be described as 2D → 2D parallel interpenetration. The topology of interpenetration can and should be described further (see Ref. [1] for further descriptions of different possible interpenetration topologies).

When the mean planes of the interpenetrating networks are parallel but no longer coincident, an overall 3D entanglement is achieved (2D → 3D parallel interpenetration). An example of this is the structure of $Cu_4(dca)_4(bipy)_3(MeCN)_2$ [*dca* = dicyanamide, $N(CN)_2^-$, *bipy* = 4,4′-bipyridine].[12] Each coordination network is polymeric in only two directions but has a certain "thickness" in the third. Each net is penetrated by four others that are parallel but offset in the third, nonpolymeric direction. Two layers penetrate the first toward the edges of the layer (one on either side), and two others penetrate toward the middle of the layer (again, one each propagating out either side). Each layer is identical; and thus, a 3D entanglement results.

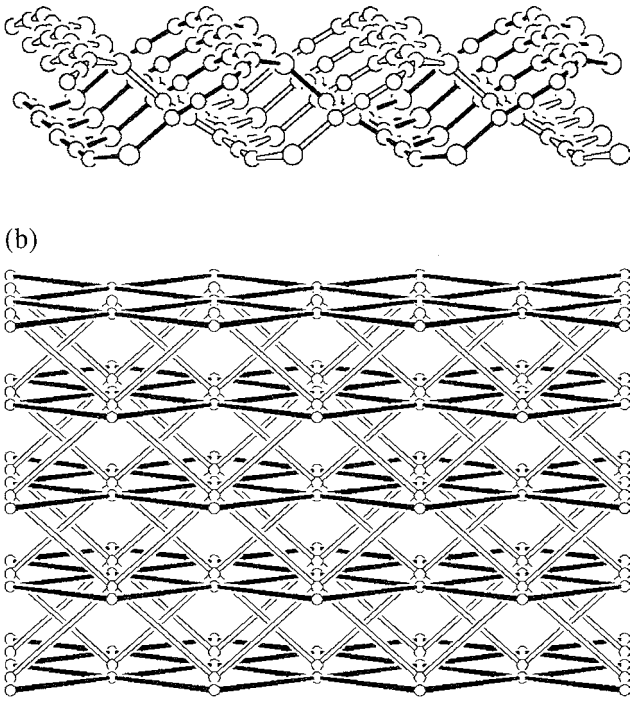

Fig. 2 Interpenetration of 2D nets: (a) 2D → 2D parallel interpenetration in the structure of Ag(tcm);[10,11] and (b) 2D → 3D inclined interpenetration in the structure of $[Zn(bipy)_2(H_2O)_2]SiF_6$.[13]

The structure of $[Zn(bipy)_2(H_2O)_2]SiF_6$, *bipy*=4,4′-bipyridine (Fig. 2b) contains two sets of parallel (4,4) sheets that interpenetrate each other at an inclined angle (2D inclined interpenetration).[13] The interpenetration is such that each window of each sheet contains a node of an interpenetrating sheet. Zaworotko[14] recently categorized three of the likely interpenetration topologies for inclined (4,4) sheets as parallel/parallel, parallel/diagonal, and diagonal/diagonal; the structure described here has the latter topology.

Another long-known example of 2D inclined interpenetration is the structure of trimesic acid (1,3,5-benzenetricarboxylic acid).[15] It contains hydrogen-bonded (6.3) sheets that interpenetrate such that each window of each sheet is penetrated by three other inclined sheets. It is also possible for more than two stacks of parallel sheets to show inclined interpenetration—the remarkable structure of $Co_2(azpy)_3(NO_3)_4 \cdot Me_2CO \cdot 3H_2O$ [*azpy*=4,4′-azo*bis*-(pyridine)] contains four separate stacks of parallel (6,3) sheets that all interpenetrate at mutually inclined angles.[16] Combinations of network and interpenetration topologies are also possible. Inclined interpenetration between (4,4) and (6.3) sheets has been reported,[17] and the structure of $[AgL_2]SbF_6$ (L = 3-cyanophenyl 4-cyanobenzoate) has 2D layers of doubly interpenetrating parallel sheets; these layers then show inclined interpenetration.[18]

3D NETS

A simple 3D network composed of three-connecting nodes is the (10,3)-*a* net.[19,20] The (10.3)-a net is inherently chiral, and this chirality has interesting consequences for interpenetration. The structure of $Ni_3(btc)_2(py)_6(eg)_6 \cdot solv$ (*H_3btc* = trimesic acid, *py* = pyridine. eg = ethylene glycol). for example, has four interpenetrating (10,3)-*a* networks, all of the same hand.[21] The structure of $Zn(tpt)_{2/3}(SiF_6)(H_2O)_2(MeOH)$ (*tpt* = 1,3,5-tri(4-pyridyl)-2,4,6-triazine), however. contains eight interpenetrating networks: four of either hand.[22] Thus, interpenetration can retain the chirality of the individual networks or can result in an overall racemic structure. The largest class of interpenetrating networks is that with the diamondoid topology. Some of the oldest examples are the structures of $M(CN)_2$ (M = Zn, Cd),[2,23,24] which contain two interpenetrating diamondoid networks (Fig. 3a). Other long-known examples of twofold interpenetration of diamond-like nets are Cu_2O[25] and certain high-pressure forms of ice.[26,27] An interesting series of compounds contains the derivatives of $Cu(DCNQI)_2$ (*DCNQI* = *N*,*N*′-dicyanoquinodiimine).[28] These materials show metal-like electrical conductivity that can be related to the way their seven diamondoid networks interpenetrate. Curiously. of all the known examples of interpenetration of diamondoid networks, all but a few[12,29,30] show the same topology of interpenetration.

The PtS network consists of equal numbers of tetrahedral and square-planar centers. Two such networks interpenetrate in the structure of $[\{Cu^{II}(tcp)\}Cu^{I}]BF_4 \cdot 17C_6H_5NO_2$ [Cu^{II}(tcp) = 5,10,15,20-tetrakis(4-cyanophenyl)-21H,23H-porphine copper(II)].[31] The networks interpenetrate in an asymmetric fashion, i.e., the second net does not lie in the center of the channels and cavities of the first, but rather lies to one side. Attractive internet porphyrin...porphyrin interactions are the likely cause, and it produces larger channels and cavities, which contain large amounts of essentially liquid solvent, than would normally be expected.

The α–Po network contains octahedral 6-connecting nodes: two such networks interpenetrate in the structure of α–$M(dca)_2(pyz)$ (*dca* = dicyanamide, $N(CN)_2^-$, *pyz* = pyrazine), as shown in Fig. 3b.[32] Another structure that can be related to two interpenetrating α–Po nets is the structure of $Zn(CN)(NO_3)(tpt)_{2/3} \cdot solv$ [tpt = 1,3,5-tri

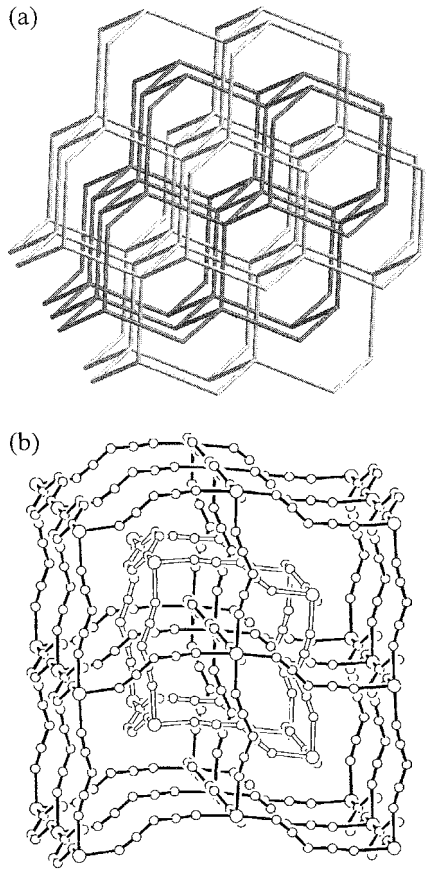

Fig. *3* Interpenetration of 3D nets: (a) two interpenetrating diainondoid networks; and (b) two interpenetrating α-Po nets in the structure of α-M(dca)$_2$(pyz).[32] ***(View this** art in color at www.dekker.com.)*

(4-pyridyl)-2,4,6-triazine].[33] The octahedral connectors are [{$Zn_4(CN)_4(NO_3)_4$}$_6$(tpt)$_8$] cages that share Zn_4-$(CN)_4(NO_3)_4$ squares with adjoining cages. Remarkably, the interpenetration of the two networks is such that the second network wraps around the aforementioned cages of the first network (and vice versa). creating large (>1290 A') completely sealed-off cavities that can contain up to 22 molecules of liquid solvent.

The Pt_3O_4 net contains four-connecting square-planar centers and three-connecting trigonal centers. The structure of $Cu_3(BTB)_2(H_2O)_3\cdot 9DMF\cdot 2H_2O$, *$H_3BTB$* = 4,4′,4″-benzene-1,3,5-triyl-tribenzoic acid contains two networks with Pt_3O_4 topology that interpenetrate in an asymmetric fashion.[''] Thus: despite the interpenetration, the structure is highly porous, containing large cavities and channels. and was shown to reversibly sorb large amounts of gases and organic solvents. The interpenetration is thought to reinforce the frameworks against structural collapse upon removal of solvent.

NETS OF DIFFERENT COMPOSITION, TOPOLOGY. AND DIMENSIONS

While the vast majority of interpenetrating structures involve interpenetration of identical networks, an increasing number of examples of heterogeneous interpenetration are being reported. The structure of $K_2[PdSe_{10}]$ contains two interpenetrating diamondoid networks, one of composition $Pd(Se_4)_2^{2-}$ and one of composition $Pd(Se_6)_2^{2-}$.[35] The Se_6^{2-} bridges are considerably more twisted than the Se_4^{2-} bridges, allowing both nets to have the same intranet Pd...Pd separation.

$[Ni(azpy)_2(NO_3)_2]_2[Ni_2(azpy)_3(NO_3)_4]\cdot 4CH_2Cl_2$ [*azpy* = 4,4′-azo*bis*(pyridine)] shows 2D inclined interpenetration of (4,4) and (6,3) sheets.[17]

The structure of $[Cu_5(bpp)_8(SO_4)_4(EtOH)(H_2O)_5]$-$SO_4\cdot EtOH\cdot 25\cdot 5H_2O$ [bpp = 1,3-*bis*(4-pyridyl)propane] contains 1D polymers that interpenetrate at an inclined angle with (4,4) 2D sheets (1D/2D→3D inclined interpenetration).[36] Two sheets penetrate each window of each 1D net. while each window of the 2D sheets is penetrated by one 1D net. The structures of $Ni(bipy)_2(H_2$-$PO_4)_2\cdot C_4H_9OH\cdot H_2O$ (*bipy* = 4,4′-bipyridine)[37] and $[Cu_2L_4\cdot 3H_2O][Cu_2L_4\cdot 2H_2O]\cdot 2H_2O$ (L = isonicotinate)[38] both contain interpenetrating 2D (4,4) sheets and 3D $CdSO_4$-like nets (2D/3D interpenetration). In the former case, both nets have the same composition, whereas in the latter example; they differ.

SELF-PENETRATION

A self-penetrating network is one in which the smallest topological circuits are penetrated by other parts of the same network.['''] The smallest topological circuits are the shortest pathways (in terms of the number of nodes) that can be taken which form a circuit that contains any two links from a given node. It is therefore important to note that the smallest topological circuits are not necessarily all the same size. For example, the smallest circuits for the 3D rutile network, which contains 3-connecting nodes and 6-connecting nodes, are four-membered rings and six-membered rings, depending on which pairs of links from which node are used to define the circuit.

An interesting series of structures based on the rutile net illustrates the relationship between interpenetration and self-penetration. The compounds are constructed using octahedral metal ions and the trigonal ligands tcm [tricyanomethanide, $C(CN)_3^-$] and dca [dicyanamide, $N(CN)_2^-$]. It is iinportant to note that dca is a smaller ligand than tcm. Thus. while the compounds $M(tcm)_2$ have two interpenetrating rutile-related networks,[39] the

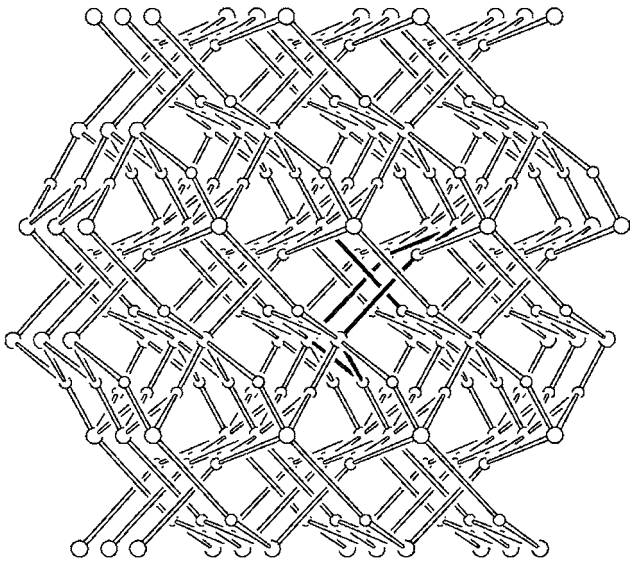

Fig. 4 The self-penetrating network of M(dca)(tcm), with the penetration of a rod through a ring highlighted.[''']

compounds α–M(dca)$_2$ have only a single rutile network.[40] In the tcm complexes, each net penetrates through the six-membered rings of the other, while the four-membered rings are left untouched. Interestingly. when only half the large tcm ligands are replaced by the smaller dca ligand. as in the structures of M(dca)(tcm), a single, self-penetrating network is formed (Fig. 4).[41] Again, it is the six-membered rings that are penetrated. this time by rods from other parts of the same network. The structure of this network is closely related to the rutile net, with the two nets having the same Schlafli notation.[1,19,20] The magnetic properties of these mixed-ligand complexes were also studied, and like their structures. their magnetic properties are a compromise between the two ''parent'' compounds.

Another self-penetrating network is the (12,3) net, of which two examples were recently reported.[42,43] If interpenetrating networks can be related to catenanes and rotaxanes, then self-penetrating networks can be considered to be polymeric equivalents of molecular knots.

CONCLUSION

Interpenetration of networks is becoming an increasingly more common phenomenon, with any structure containing networks that account for less than 50% of the crystal volume being open to interpenetration. The effects of interpenetration vary — examples were given of compounds in which interpenetration reinforced highly porous structures,[34] structures that contained unique sealed-off cavities containing essentially minute droplets of liquid,[33] or materials that had metal-like conductivities.[28]

In order to understand such systems, it is important not only to describe the network topology but also the topology of interpenetration. A number of examples of different interpenetration topologies were given above. Further details on the numerous examples of interpenetration can be found in a number of recent reviews,[1,3,4] and also on the author's Web site, which contains a regularly updated table of all known interpenetrating structures, sorted according to network and interpenetration topologies.[44]

Ion Channels and Their Models

Karycia D. D. Mitchell
Thomas M. Fyles
University of Victoria, Victoria, British Columbia, Canada

INTRODUCTION

Ion channels, which control the movement of ions across lipid membranes. are essential to the function of many biological systems.[1] Ion transport across membranes can occur via one of two broadly defined mechanisms: transport via channels or transport via carriers.[1] The former suggests a tubular or helical membrane-spanning structure that is stationary and allows ion translocation through or along the transporter. The latter suggests a smaller. encapsulating structure that forms a complex with the ion and moves through the membrane via diffusion.

In molecular terms, the movement of an ion across a membrane via a channel can best be described as a series of "hops" along the stationary channel molecule. The ion–transporter interactions that facilitate ion translocation replace ion–water interactions on either side of the membrane. The energy barrier for direct ion diffusion across the membrane is directly due to the instability of the ion in the nonpolar membrane interior. Ion–channel interactions significantly lower the barrier and thus facilitate diffusion.[1] A similar argument applies to carrier-mediated transport. with the result that channels and carriers are kinetically indistinguishable. However. activation barriers for channel-mediated diffusion are expected to be much lower than the activation barrier for carriers."' with the result that the maximum transport rates of channels are typically several orders of magnitude higher than those of carriers.

Another important distinction between carriers and channels is the ability to regulate or "gate" channels. The nature of channels is such that they could be pliysically switched "on" and "off" by altering the binding of the ion with the transporter: either through altering the conformation of the channel or by plugging the channel orifice."'

BILAYER CLAMP TECHNIQUE

Experimental deiection of the formation of ion channels is best achieved using the bilayer clamp technique.[2] In this experiment. a freestanding bilayer membrane is interposed in a small orifice separating two pools of aqueous electrolyte. The bilayer is an effective insulator. so no current is passed under applied potentials in the range of ±150 mV. An ion channel in the bilayer will significantly increase the transmembrane current in an abrupt "all-or-nothing" fashion. The resulting trace of current shows sharp transitions between a nonconducting "off" condition and a conducting "on" condition. Shown in Fig. 1 is the bilayer conductance of the peptide channel gramicidin under different applied potentials. Note that at a given potential, the step heights of the conductance changes are the same, indicating a single type of channel structure. in this case, a dimer. Step conductance changes are the unique experimental signature of channel activity; carriers provoke a general increase in the bilayer conductance but do not show abrupt "on–off" behavior. The bilayer clamp technique is a powerful method with which to elucidate ion selectivity, channel lifetime. and voltage gating properties of single channels.[1]

CHANNEL TRANSPORT MEASUREMENT

Indirect methods of measuring channel transport are based on measurements of indicators trapped within a vesicle bilayer membrane."' These measurement methods include ^{23}Na–NMR; UV/Vis or fluorescence spectroscopy of pH. metal ion concentration, or concentration of environment-sensitive indicators; radiochemical techniques; and pH stat techniques to monitor proton efflux. These methods give evidence that an active compound can alter membrane permeability, but it is difficult to establish a distinction between channel function, transport via carriers. or a nonspecific membrane disruption.[1]

NATURAL ION CHANNELS

Natural ion channels are high-molecular-weight membrane-spanning proteins that are believed to act via multiple α-helical strands that cross the membrane repeatedly.[3] While much about protein channels is still not understood, it is believed that several helices arrange into an ion-selective pore. with ion transport occurring

via the hydrated spaces adjacent to the bundles of helices. The most detailed insights into the structural origins of specificity stem from the crystal structures of the KcsA channel from *Streptomyces lividans*[4] and of *CLC* chloride channels from *Salmonella enterica* serovar *typhimurium* and *Escherichia coli,*[5] for which McKinnon was awarded the *2003* Nobel Prize in Chemistry.

The best-studied natural ion channels are peptides, which act as aggregates comprised of peptide monomers. The most well-known examples are alamethicin and gramicidin.

The aminoisobutyric acid containing peptide alamethicin[6] is a naturally occurring ion-channel compound that acts via a cluster of α-helices without the support of additional proteins. Produced by the fungus *Trichodevrna viride,* it is an antibiotic peptide, known to affect the quality of pastureland through its effects on ruminant animal stomach bacteria. Side-by-side association of several alamethicin molecules to form a barrel-stave aggregate occurs. The membrane-spanning aggregate possesses a net transmembrane dipole; thus producing voltage-gated behavior. Alamethicin pores also have short lifetimes, showing ''burst'' activity of only a few milliseconds duration.

Gramicidin[1,6] is one of the most well-studied ion channels. It is naturally synthesized by *Bacillus brevis* and derives its name from its antibiotic properties against gram-positive bacteria. Gramicidin, **1** (Fig. 1), is a pentadecapeptide derivative, composed of alternating D- and L-amino acid residues, that forms a monovalent–cation–selective tubular helix channel in lipid membranes. Ion translocation occurs via cation interactions with carbonyl oxygens on the inside of the helix. Two molecules of gramicidin span the membrane via formation of an end-to-end dimer held together by hydrogen bonding. Due to its unique mechanism, in which the ion transfer occurs within a single helix, the gramicidin channel has limited relevance to channels in the natural world, but it has inspired numerous synthetic mimics.

SYNTHETIC MIMICS

An example of such a synthetic mimic is the hydraphile channel system developed by Gokel.[13] The system is based on the 4,13-diaza-18-crown-6 macrocycle **3** (Fig. *2),* with an inner crown ether believed to be embedded in the

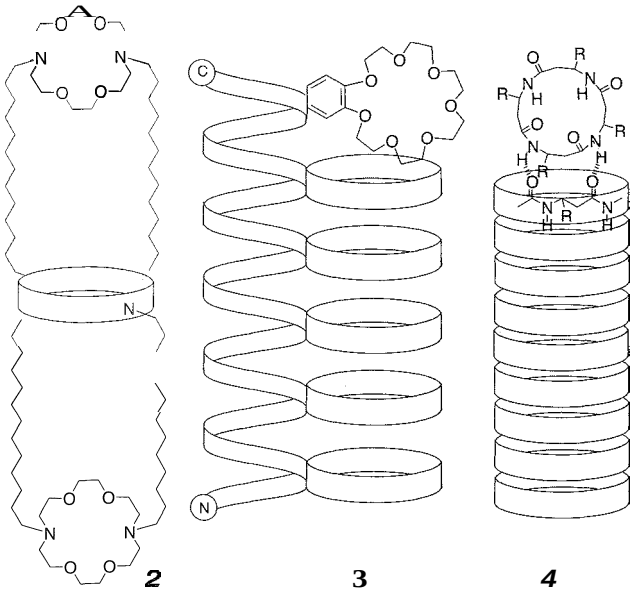

Fig. *2* Schematic structures of synthetic transporters incorporating macrocyclic ion binding units.

bilayer as the central relay group. The other crown ethers lie near the bilayer surface and can regulate cation entry to the membrane interior. The sodium transport rate of these channels is about 100-fold lower than gramicidin but substantially faster than a single crown ether acting as a carrier.

Unimolecular channel compounds have also been formed using an α-helical peptide scaffold to support an assay of 21-crown-7 moieties, **4**.[7] Models suggest that the structure formed is about 3.2 nm long, and that the crown ethers stack to form the channel. Compound 4 showed transport ability similar to that of gramicidin and displayed bilayer-dependent single-channel features.

Self-assembling transmembrane peptide nanotubes were formed from cyclic peptides composed of an even number of alternating D- and L-α-amino acids. These macrocycles adopt flat, ring-shaped conformations, with the backbone amides positioned perpendicular to the plane of the ring. Hydrogen-bonding conditions, such as adsorption onto a lipid membrane, are ideal for stacking the peptides, forming open-ended β-sheet-like tubular structures, 5. Cyclic hexapeptide channels showed transport rates for Na^+ and K^+ that rival those of gramicidin,[8,9] and larger structures will allow transport of small molecules, such as glutamate. Cyclic peptides of this type are antibacterial agents; as demonstrated against Staphylococcus *aureus*,[8] and antibiotic activity was correlated with enhanced membrane permeability to ions.

Alternatives to tubular channels are transmeinbrane aggregates that enclose a hydrophilic pore. One example is based on poly-p-phenylene oligomers bearing side arms

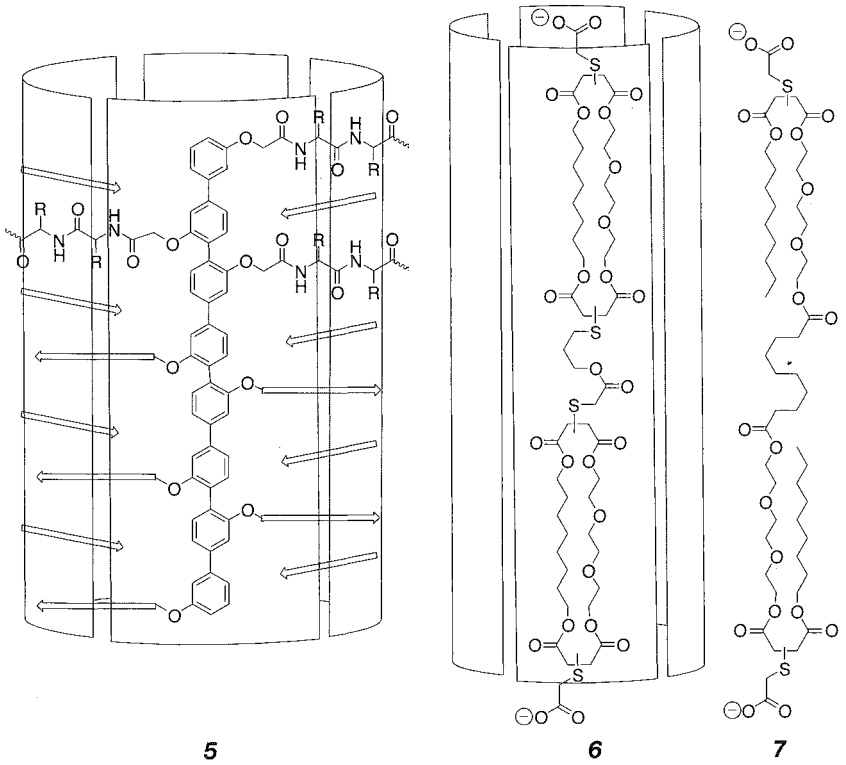

Fig. *3* Schematic structures of synthetic transporters that act via transmembrane aggregates.

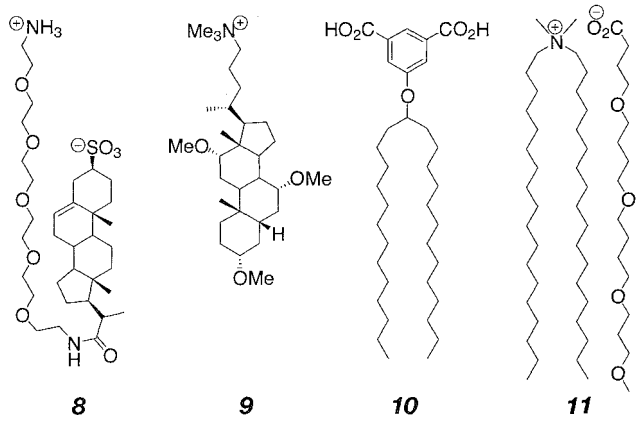

Fig. 4 Simple compounds that form transmembiane ion channels.

to promote the formation of side-to-side and tubular aggregates. 6 (Fig. 3).[10] This system produces stable hexameric pores with an "infinite" lifetime, i.e., the conductance is always in the "on" state.

Specific intermolecular interactions between components may not be essential, as macrocyclic bolaamphiphiles 4 form specific channels composed of a few molecules.[11] The association of the components is presumed to be driven by microphase separation in the lipid. Voltage-gated pores based on this system were also designed.[12] This group of compounds demonstrated a specific activity dependent on the structure of the core regions of the molecule, while ion selectivity and voltage switching appeared to be controlled by the polar head groups. The macrocyclic components are not essential for activity, as related acyclic compounds **7** are virtually indistinguishable from the bismacrocyclic compounds.[13]

Even simpler compounds form defined ion channels. Sterol conjugates 8 (Fig. 4) were prepared by steroid derivatization. as well as from cholic acid–spermine conjugates in which the hydrophilic face of each sterol was altered to incorporate methoxy. hydroxy, carbamate. or sulfate groups.[14,15] Another example is 9. a cholic-acid-based ion conductor that was altered to incorporate rnethoxy groups in place of the sterol hydroxyl groups.[16] These channel compounds were found to exist as membrane-spanning dimers, capable of Na^+ transport. with the rate of ion transport dependent on the bilayer membrane thickness. Similar structures with cholate groups appended to a resorcin[4]arene core formed long-lived K+ selective channels.[17]

The simplest compounds known to form defined ion channels are the isophthalate derivative **10**[18] and the ion-pair transporter **11**.[19] Single channels were observed for both systems, although incorporation and activity are somewhat erratic in both cases.

CONCLUSION

Attempts to mimic naturally occurring channels yielded a wide range of compounds of many shapes, sizes. and structures. Each group of cornpounds synthesized has a basic structure, which appears in every case to be subject to structure-activity control. Clearly, a wide range of basic structural types will support channel formation. making it unlikely that structurally specific interactions between the channel compound and the transient ion are essential.

Note that many of the molecules produced have few internal polar functional groups to which ions may bind. Instead, it is more likely that ion–water–channel interactions escort the ion through the pore. To that end. many of the models can then be viewed as methods to pull water into the lipidic core of a bilayer membrane and thereby stabilize ions in transport. Recent studies of molecular dynamics simulations of ion transportation in human aquaporin-1 and in the bacterial glycerol facilitator GlpF revealed the key role of water in the stabilization of ions in transit and in the molecular selectivity of channels.[8,20] Synthetic compounds form less-defined structures than these complex proteins but apparently act as efficiently as more complex natural materials. It is likely that continued study of synthetic systems will continue to reveal the general details underlying all transport processes.

Ion-Selective Electrodes

Yoshio Umezawa
University of Tokyo, Tokyo, Japan

INTRODUCTION

Ion-selective electrodes (ISEs) are among chemical methods of analysis, and one of the major chemical sensors that include bioaffinity-, gas-, ion- and other molecular sensors. A common feature for these chemical sensors is that molecular recognition of analytes takes place chemically by. e.g., bioreceptors, and various synthetic supramolecular receptors, immobilized in many cases on solid substrates. The molecular recognition process is followed by appropriate signal transductions. such as electrochemical, optical, and gravimetric methods. The YSE chemistry involves permselective transport of analyte ions from adjacent aqueous sample solutions into ionophore-incorporated organic liquid membranes. This process leads to ion-selective charge separation at the aqueous/organic interface. and the change in boundary potentials becomes a measure for the analyte ion concentrations (activities). The development of the liquid-membrane ISEs owes much to the progress of supramolecular chemistry and has played an important role in bridging supramolecular chemistry with analytical chemistry.

BACKGROUND

Methods of analysis based on immiscible aqueous/organic-solution interfaces include solvent extraction, liquid–liquid partition chromatography, and ionophore-incorporated liquid-membrane ion-selective electrodes (ISEs). A common feature for these analytical methods is partitioning of analyte ions between the two phases, aqueous and organic. Of these, solvent extraction is based on the occurrence of electroneutrality in the bulk phases. On the contrary. the ISE is based on the occurrence of ion-selective charge separation at the interface of the two phases. The analyte-ion-selective charge separation at the aqueous/organic interface occurs as a result of permselective transfer of analyte ions from aqueous to organic phases upon their complexation with the corresponding ionophore at the surface of the organic phase; it leaves hydrophilic counterions in the aqueous phase. This forms an electrical double layer at the interface, while the electroneutrality in the bulk organic and aqueous phases is still satisfied. The partitioning of the analyte ions between aqueous and organic phases is described as follows:

$$K = a_0/a_a = e^{-\Delta G\ kT} \quad (1)$$

where K is the partition coefficient, a_a the activity of the analyte in the aqueous phare, a_o the activity of the analyte ion in the organic phase. and k the Boltzmann constant. The AC is the chemical potential change of analyte ions between the two phases, as expressed

$$\Delta G = nF\phi + \Delta G_{dehyd} + G_{solv} + \Delta G_{compl} + \Delta G_{ionpair} \quad (2)$$

where n is the charge number of the analyte ions. F the Faraday constant, o the electrochemical potential, ΔG_{dehyd} the dehydration energy of the ion, ΔG_{solv} the ion-solvation energy in the organic phase, ΔG_{compl} the complexation energy of the ion with the relevant ligand or ionophore. and $\Delta G_{ionpair}$ the ion-association energy between the complexed ion and its counterion in the organic or membrane phase.

The first term in Eq. 2 is responsible for the generation of membrane potentials: the liquid-membrane ion-selective electrode targets only charged ionic analytes in contrast to solvent extraction and partition chromatography.

PHENOMENA WITH IONOPHORE-BASED ION-SELECTIVE ELECTRODES

The most representative ISEs are valinomycin (VM)-based liquid membrane ISEs. W. Simon pioneered the development of liquid membrane ISEs incorporating natural ionophores such as VM and nonactin (1967). The first VM-based ISE was constructed by dissolving VM in diphenyl-ether that was supported in a cellulose membrane. which then gave selective response to K^+ over Na^+ in the concentration range of 10^{-5}–10^{-1} M K^+ ion.

At the surface of ionophore-incorporated liquid membranes; ion-selective charge separation occurs as a result of permselective analyte ion transfer from the aqueous organic phase. This phenomenon is illustrated in Fig. 1.

Hydrophilicity of counterions is important for primary ion-dependent charge separation to occur at the interface. If counterions are more or less hydrophobic, such as

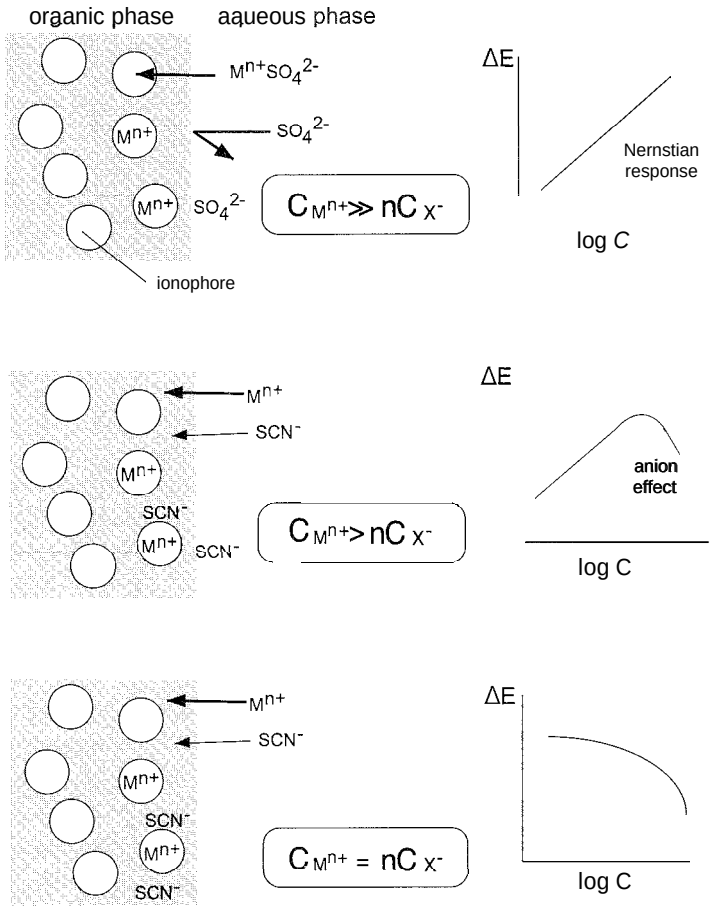

Fig. 1 Partition of metal ions and counterions at the polymer (PVC)-supported ionophore liquid-membrane/aqueous-solution interface: relation with interfacial boundary potentials. $C_M n+$ and C_{X^-} are concentrations of the ionophore-metal-ion complex and its counterions. respectively. These concentrations were measured with FT-IR-ATR to a depth of μm range in the organic phase near the interface. When $C_M n+ > nC_{X^-}$, the observed membrane potential *(AE)* exhibits a Nernstian response that meets Eq. 2. When the value of $C_M n+$ is small but still greater than nC_{X^-}, the anion effect distorted the log C–ΔE relation observed for a non-Nernstian response. When permselectivity was completely lost. i.e.. $C_M n+ = C_{X^-}$, *AE* showed no M^{n+} concentration dependence. Hydrophilic SO_4^{2-} ion and hydrophobic S C N ion made the observed difference. (From Ref. [1].) *(View this art in color* at *www.dekker.com.)*

SCN^-, ClO_4^-, *and* picrate *ions, salt extraction* (coextraction) *rather than* charge *separation results. This is called the* anion *effect, and the activity (concentration)-dependent potential changes, which are a requisite for analytical purposes, are not* fulfilled.[1]

In *the case of hydrophilic counterions. the analyte ions transported into the organic phase* form *an electrical double layer together with hydrophilic counterions left behind in the aqueous phase. The thickness of this double layer is of the order* of *50–100* Å. *From the charge density and charge distribution (Boltzmann distribution is assumed) at this electrical double layer, the membrane boundary potential is obtained from the Poisson* law.[2,3] *In thermodynamics. this process is described as follows:*

$$E = E_0 + RT/nF \log a_0/a_a \quad (3)$$

This relation is *derived* from *the free-energy change, including the term of the activity* (a_0/a_a) *dependent* free-*energy change. Eq. 4* sums *up of each free energy term in Eq. 2:*

$$\Delta G = \Delta G^0 + RT \log a_0/a_a \quad (4)$$

where ΔG^0 is the standard free-energy change.

In Eq. 3, E corresponds to the related electrochemical potential. and the standard potential E_0 corresponds to ΔG^0. When the observed potential with an ISE fulfills Eq. 4, the response is called a Nernstian response.

After the success of VM-based ISEs, *a number of synthetic ionophores were applied for the* developments *of respective* ISEs. *For alkali metal ions, crown-ether derivatives and calixarene derivatives were employed*

for developing excellent Li^+, Na^+, and K^+ ion ISEs. For alkaline earth ions, Ca^{2+} and recently Mg^{2+} ion ISEs were developed. These ISEs were applied for the analysis of serum electrolytes. For ISEs for heavy metal ions, thiocrown-ether derivatives comprise a major ionophore. The ISEs for inorganic anions, such as sulfate and chloride, are also available based on, e.g., recently developed ionophores based on multitopic hydrogen-bond interactions to these ions. For organic cations and anions, recently developed supramolecular chemistries helped in the development of many novel ISEs,[4] which include ISEs for guanosine nucleotide with a cytosine-pendant triamine derivative, dopamine cation sensing with a calix[6]arene derivative, and ATP^{4-} with a macrocyclic polyamine-derivative ionophore. The ionophore-based liquid-membrane ISEs are, in principle, applicable to any target ions, with the development of appropriate new ionophores continuing for many years.

MOLECULAR MECHANISMS FOR ISE RESPONSES

Liquid membranes for ionophore-based ISEs contain not only ionophores but also ion exchangers (ionic sites). If no ionic sites are added in the membrane, coextraction or salt extraction of ionophore/primary ion complexes with counterions occurs, thereby causing no charge separation at the interface.

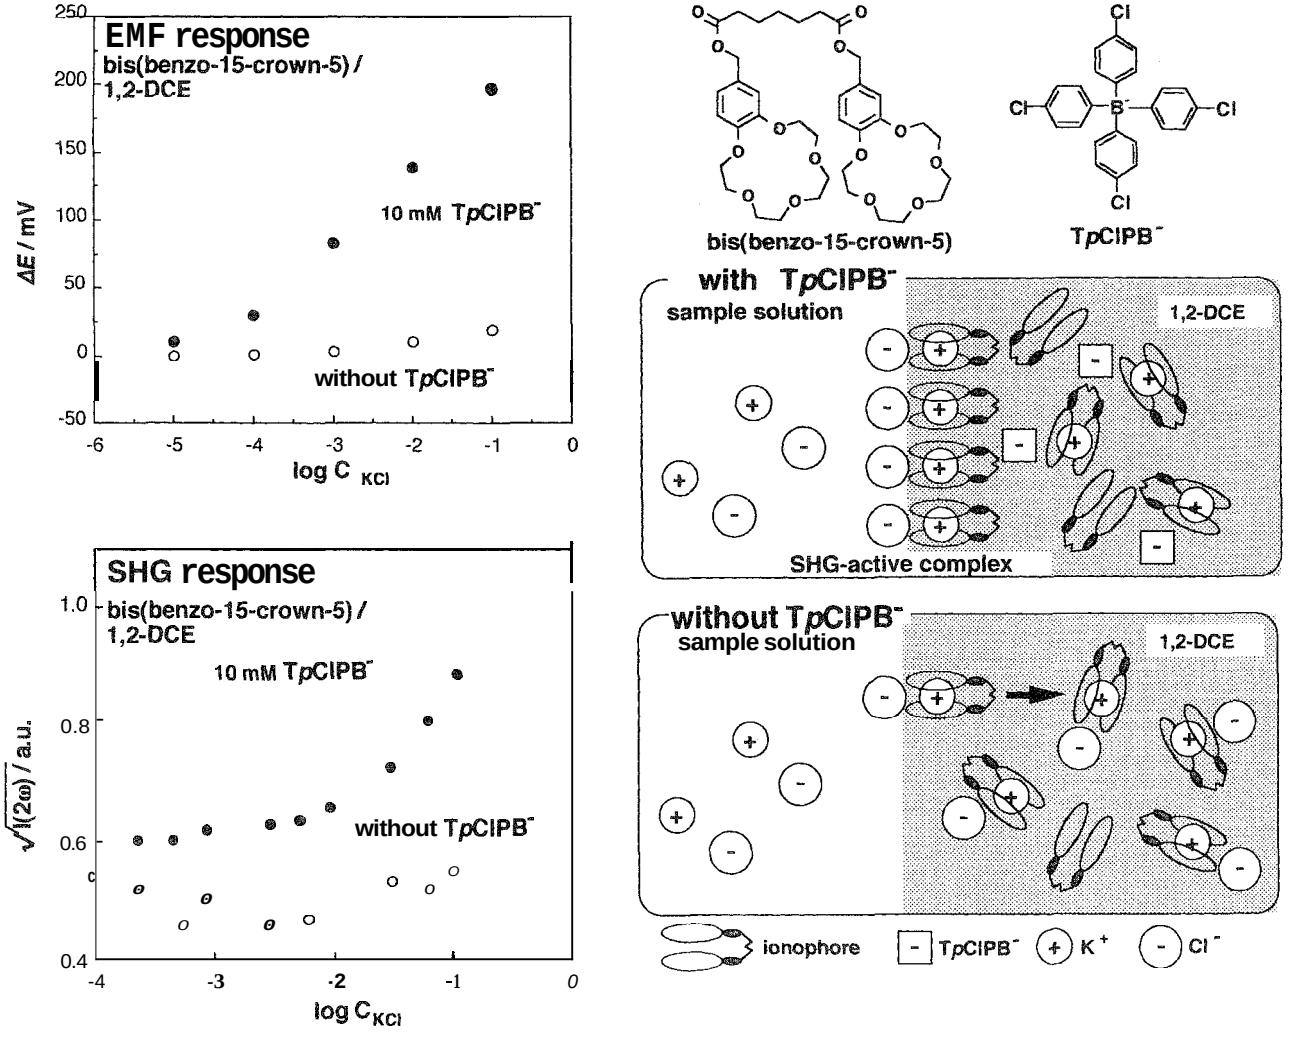

Fig. 2 Dependence of membrane potential change ΔE and second-harmonic generation (SHG) response, $\sqrt{I(2\omega)}$, on the concentration of added lipophilic anionic sites [tetrakis (*p*-chlorophenyl) borate (T*p*ClPB)] (left), and the corresponding surface model that shows orientation of SHG-active K^+-ionophore complexes across the aqueous/1,2-dichloroethane (1,2-DCE) interface in the presence of the added anionic sites in the membrane phase (right). (From Refs. [5,6].)

As shown in Fig. 2. the charge separation is the result of the occurrence of an oriented layer for ionophore/analyte ion complexes at the organic/aqueous interface in the organic side of the interface, leaving their hydrophilic counterions in the aqueous side at the interface. The extent of this charge separation is dependent on the activity (concentration) of respective analyte ions and is measurable as changes in the membrane boundary potentials.

The ionic sites [tetrakis (p-chlorophenyl) borate. T*p*ClPB$^-$] work to reject counterions from being coextracted into the organic phase and are, therefore. requisite for the generation of analyte-ion activity (concentration)-dependent membrane potential changes. This molecular mechanism for the potential response process of ISEs was recently revealed experimentally by simultaneous measurements of laser-induced second-harmonic generation (SHG) and membrane potentials, in which it was found that the observed membrane potentials originate from the SHG-active surface-oriented charged chemical species of the order of a few molecular layers (Fig. 2).[5,6]

On the basis of this mechanism, a great number of ionophore-based ISEs were developed. It should also he noted here that polyvinyl chloride (PVC) has been used since the early 1970s to support liquid membranes, and the term ''plasticized liquid membrane'' has been coined to describe these systems. In those days, the addition of ionic sites was not explicitly realized, but instead. impure ionic sites in the PVC (anionic sites) played virtually the same role. However, the membrane including such an impurity does not allow quantitative control of the optimized amounts of ionic sites, and therefore, it was supplemented later by deliberately added ionic sites.

MEASUREMENT WITH ION-SELECTIVE ELECTRODES

The performance characteristics for ISEs are evaluated in terms of ion selectivity, detection limit, dynamic range [measurable concentration (activity) range]. and response time.

The selectivity and detection limit for each ISE are basically determined by the magnitude of formation constants (K_f) of ionophores with analyte ions under otherwise identical conditions. including cornpositions of respective membrane and inner-filling solutions. In many ionophore-based liquid-membrane ISEs developed so far. the lower detection limit is reported to be around 10^{-6}–10^{-7} M.

The response time for ISEs to attain equilibrium potentials is around 3 minutes or less. Therefore, this technique is suited for high-throughput rapid analysis. The ion selectivity of ISEs is exemplified by one of the best examples involving VM-based ISEs, in which Na^+ ion

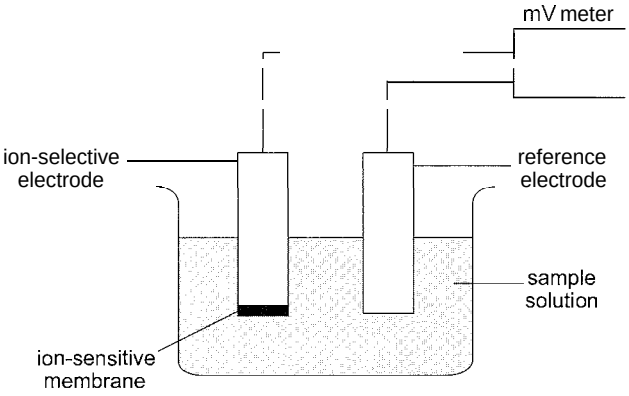

Fig. 3 Potentiometric measurement with ion-selective electrodes. (*View this art in color at www.dekker.com.*)

interference is minimized so as to allow its coexistence in up to 10' times higher concentration than K^+ ion.

To evaluate the extent of such selectivity for each ISE, the selectivity coefficient defined by the following equation is experimentally determined:

$$E = E_0 + RT/(z_A F) \ln \left[a_A + \Sigma K^{pot}_{A,B} (a_B)^{z_A/z_B}\right] \quad (5)$$

where E is the measured potential; E_0 is a constant that includes the standard potential of the electrode. the reference electrode potential, and the junction potential: z_A and z_B are charge numbers of the primary ion. A, and of the interfering ion. B: a_A and a_B are the activities of the primary ion, A, and the interfering ion, B: and $K^{pot}_{A,B}$ is the potentiometric selectivity coefficient for the primary ion *A* against the interfering ion *B*, *R*, *T*, and F have the usual meanings. If $K^{pot}_{A,B}$ is larger than 1. the ISE responds to the interfering ions more selectively than to the primary ions. In most cases, $K^{pot}_{A,B}$ is smaller than 1, which means that such ISEs respond to the primary ions more selectively than to interfering ions.

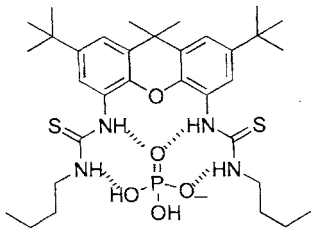
The experimental methods for measuring selectivity coefficients and the values of selectivity coefficients thus obtained are given in the references for a large number of ISEs developed during the past three decades.[7–12]

The measurements of ISEs are achieved by potentiometry. Potentiometry is an electrochemical method that measures changes relative to a reference electrode of observed potentials at the indicator electrode. ISE under a condition of no net current flow (Fig. 3).

A PROBLEM FOR LIQUID-MEMBRANE ISES

For comparison and better understanding of the ISE response, ion-channel mimetic sensing for phosphate ion using the receptor (I) was examined.[14]

A hydrogen bond-forming *bis*(thiourea) (Compound 1) is strongly bound to $H_2PO_4^-$ (K_{11}=55,000 M^{-1} for 1:1 binding in DMSO-d_6) and shows the selectivity sequence $H_2PO_4^- > CH_3COO^- > Cl^-$ by formation of hydrogen bonds to the thiourea groups of the receptor.



1

The response of the ISE with receptor 1 was highest for Cl^-, not for $H_2PO_4^-$, and the selectivity sequence was of the order of $Cl^- > SO_4^{2-} > CH_3COO^- > HPO_4^{2-} \sim H_2PO_4^-$. This leads to a high-quality Cl^- ISE.[13] The phosphate ion is located at the end in the Hofmeister series; indicating its high hydrophobicity. Pulling phosphate ion out of aqueous phases and putting it into organic phases is therefore difficult: C l ion has, on the contrary, relatively lower dehydration energy than phosphate, although its coinplex formation constant with host 1 is less than that of phosphate. As a result, the Cl^- ion is transferred from the aqueous to the organic phase, thereby generating the corresponding charge separation and membrane potential.

A receptor (1) monolayer was formed at the air–water interface and subsequently contacted with a highly oriented pyrolytic graphite electrode (Fig. 4). Horizontal touch cyclic voltammetry was performed with subphase solutions containing various electroinactive analyte anions and with $[Fe(CN)_6]^{4-}$ as the electroactive marker. The binding of analyte anions to the receptor monolayer was found to inhibit $[Fe(CN)_6]^{4-}$ oxidation. The influences of the analyte anions on the cyclic voltammograms were largest for HPO_4^{2-} and decreased in the order of $HPO_4^{2-} > F^- \sim SO_4^{2-} > CH_3COO^- > Cl^-$, in contrast to the selectivity of the ISE containing the same Receptor (1) as described above. Because the *bis*(thiourea) receptor does not bind to all potentially hydrogen-bonding sites of most of these anions, it is apparent that several of the larger anions, and in particular, phosphate and sulfate, are substantially hydrated while being bound to the interfacial receptor layer. This distinct feature of interfacial molecular recognition seems to explain why the selectivities of these ion-channel-mimetic sensors differ strongly from the selectivities for the complete anion transfer from aqueous to organic phases. as represented by the ISE selectivity.

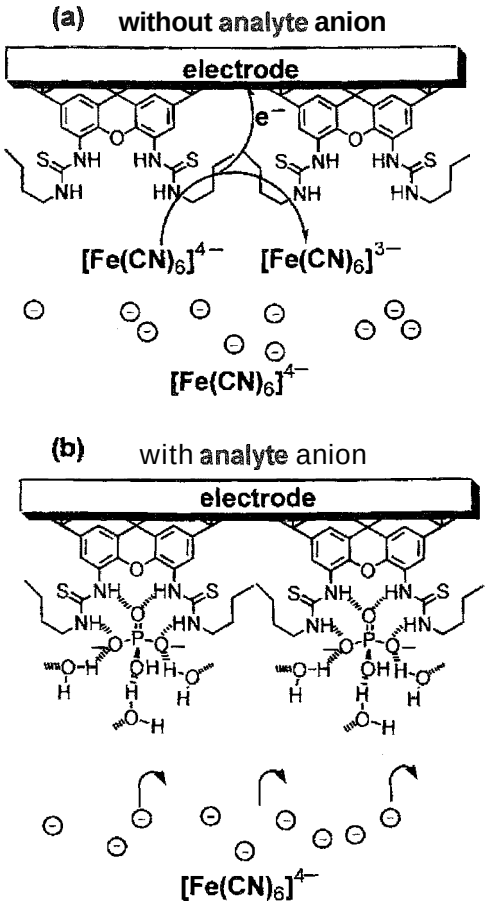


Fig. 4 The marker oxidation at the surface of an oriented monolayer of Receptor 1: (a) oxidation of $[Fe(CN)_6]^4$ at the electrode surface coated with a monolayer of Receptor I in the absence of analyte anions: (b) oxidation of $[Fe(CN)_6]^{4-}$ is hampered by the binding of the phosphate ion to the monolayer. (From Ref. [14].)

The results suggest that the ionophore-based liquid-membrane ISEs are not suited for the analysis of hydrophilic, relatively large analyte ions, for which hosts that encapsulate the analyte and remove its hydration sphere are difficult to synthesize.[14]

Ionic, Dipolar, and Interfacial Processes

Gyan P. Johari
McMaster University, Hamilton, Ontario, Canada

INTRODUCTION

Absorption of an electromagnetic wave's energy in a homogeneous liquid and solid is determined by two thermally activated occurrences: diffusion of ions and reorientation of dipolar units. These are referred to as ionic and dipolar processes, respectively. Both contribute to a measured dielectric property and are regarded as part of molecular dielectrics. When a liquid or solid is, in addition. heterogeneous. and the conductivity of inclusions is ohmic. the buildup of electrical charges at the interface of the inclusions also causes absorption of energy. This absorption process also occurs in a polycrystalline solid with abundant grain boundaries. and it is called the interfacial process or Maxwell–Wagner process. Finally, a further absorption of energy results from an accumulation of ions on the electrodes and the consequent formation of a double layer that acts like an electrical capacitor. This process is present in all dielectric measurements on homogeneous and heterogeneous materials. It is extrinsic to the liquid or solid, and its effect varies with the type of metal used as electrodes.

These four processes—diffusion, dipolar reorientation, interfacial charge buildup, and double layer formation—appear in different parts of the dielectric spectra of materials. The frequency range in which each process dominates varies with temperature and pressure, as do their magnitudes. Several monographs[1–4] and reviews[5,6] on dielectric properties and molecular structure provide brief descriptions of these processes and references to research articles on this subject. These overviews may be consulted and applied to the dielectric study of supramolecular structures. It is to be noted that dipolar processes are often ignored in the description of ionic processes in crystals and glasses, and the subject is treated as impedance spectroscopy.[7] The formalism underlying this description is also useful for interpreting the electrical properties of highly conducting supramolecular structures. But because only the capacitance and conductance are measured as a function of frequency in all cases, separate names for the spectroscopy seem unnecessary, and only the term ''dielectric spectroscopy'' will be used here.

Dielectric spectroscopy is now performed over a range of frequencies from 1 μHz to 10 THz, i.e., over 19 decades of frequency, which include the far-infrared region of the spectra.[8] The measurements yield the real and imaginary components e' and e'', respectively. of the complex relative permittivity ε^*. The term permittivity is used for c'. and the term dielectric loss is used for e''. Although the temperature and pressure can be chosen such that the spectral features arising from the ionic. dipolar, and interfacial processes and from electrode polarization appear in different frequency regions of the ε' and ε'' spectra. these features often overlap at ambient conditions. These are then analytically resolved by using formalisms specific to a process.

THE IONIC PROCESS

The diffusion of ions produces flow of a direct current through a liquid or solid. For an applied field strength given by E in Volts/m and the current density, **J.** in Amperes/m, the dc conductivity is given by the ratio, $J/E=\sigma_{dc}=\omega\varepsilon_0\varepsilon''_{dc}$, where ω is the angular frequency ($=2\pi f$, with f being the frequency in Hz), ε_0 is the permittivity of free space (vacuum) and is equal to 8.8514 pF/m, and ε''_{dc} is the loss due to dc conductivity. Thus. for a given ω. the magnitude of ε''_{dc} is directly proportional to ad,. For example, for water with $\sigma_{dc}=100$ μS/m, ε''_{dc} is 1.8 at 1 MHz frequency and 1800 at 1 kHz frequency. and for hydrated cyclodextrin with $\sigma_{dc}=1$ mS/m, ε''_{dc} is 18 at 1 MHz frequency and 18×10^3 at I kHz frequency.

In a wide variety of organic materials; σ_{dc} arises from the presence of impurity ions and is. therefore, extrinsic. In those supramolecular structures in which it is intrinsic, σ_{dc} arises from one or a combination of the following: diffusion of ions, as in hydrated crystals, gels, and liquids; transfer of protons along a hydrogen bond. as in the ices and ice clathrates, cyclodextrins, and proteins; and displacement of ions in a crystal lattice. Irrespective of its extrinsic or intrinsic origin, σ_{dc} is determined by the number of mobile ions n, electronic charge on the ions e. and their mobility μ, according to the equation, $\sigma_{dc}=ne\mu$. On decreasing the temperature T, the mobility of ions decreases and, hence, σ_{dc} decreases. In hydrated states or aqueous solution. ions can also form ion pairs, thereby

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012655

reducing their number. This decrease is described by the ion–ion-pair equilibrium constant:[9]

$$K_A = \frac{4\pi N a^3}{3000} \exp\left(\frac{z_1 z_2 e^2}{a\varepsilon_s k_B T}\right) \quad (1)$$

where N is the Avogadro number; a is the ion size parameter; z_1 and z_2 are the ionic charges; e is the electronic charge: ε_s is the equilibrium or static dielectric permittivity of the medium; k_B is the Boltzmann constant: and T is the temperature. The quantity K_A or, equivalently, the concentration of ion pairs, increases sensitively as T in the exponential term in Eq. 1 decreases, because a for an unsolvated ion is expected to remain constant with changing T. The quantity n in the equation, $\sigma_{dc}=ne\mu$, therefore, decreases on cooling when diffusing ions associate to form ion pairs. Thereby, they are effectively removed from the material. Because K_A also varies as $\exp(1/\varepsilon_s T)$ in Eq. 1, a decrease in the product $\varepsilon_s T$ of the material resulting from deviations from the Curie law (i.e., the product $\varepsilon_s T$ remains constant on cooling) would lead to a decrease in n. Such deviations from the Curie law often result from short-range interactions between the molecular dipoles. According to the Stokes–Einstein relation and Arrhenius equation.

$$\sigma_{dc} = ne^2 D_{ions}/RT,$$
$$D_{ions} = D_{0,ions} \exp(-\Delta E_{ions}/RT) \quad (2)$$

where D_{ions} is the diffusion coefficient of the ions; $D_{0,ions}$ is the preexponential factor; ΔE_{ions} is the Arrhenius energy for ionic diffusion; and R is the gas constant. It follows that σ_{dc} would decrease with T not only because D_{ions} decreases but also because n decreases.

Studies of a number of supramolecular materials showed that a logarithmic plot of their σ_{dc} against $1/T$ curves downwards, particularly at low T values, i.e., the decrease in σ_{dc} is much larger than expected. This means that σ_{dc} does not merely follow the Arrhenius variation of D_{ions} with T: other processes contribute. One such process is ion-pair formation, which decreases n.

THE DIPOLAR PROCESS

A dipolar process is described in terms of three quantities: the orientation polarization, the vibrational polarization. and the relaxation time. The first of the three is expressed as $\Delta\varepsilon=\varepsilon_s-\varepsilon_\infty$, where ε_s is as defined earlier, and ε_∞ is the limiting high-frequency permittivity. The vibrational polarization is expressed as $\Delta\varepsilon_{vib}=\varepsilon_\infty-n_{op}^2$, where n_{op} is the refractive index of the material, usually at the frequency of the Na–D line; and n_{op}^2 is a measure of the electronic polarization. These properties are described in phenomenological terms as well as molecular structure terms involving the dipole moment. any short-range interactions between the neighboring molecules and motion of molecular segments of different chemical structures, and of whole molecules.

The Orientation Polarization

In the statistical mechanical theories of a dipolar orientation process,[10–12]

$$\varepsilon_s - \varepsilon_\infty = \left(\frac{3\varepsilon_s}{2\varepsilon_s + \varepsilon_\infty}\right)\left(\frac{\varepsilon_\infty + 2}{3}\right)^2 \frac{4\pi N_d}{3k_B T} g\mu^2 \quad (3)$$

where N_d is the number of dipoles per unit volume, and μ_0 is the dipole moment of an isolated molecule, i.e, the value in the vapor phase. The quantity g is referred to as the orientational correlation factor. It is given by the following:

$$g = 1 + \sum_{j,(j\neq i)}^{\cdot\cdot} \cos\gamma_{ij}$$

where γ_{ij} is the angle between the i,j pair of dipole vectors, i and j, of the neighboring segments within a molecule or the neighboring molecules. It is a measure of the short-range interactions between the neighboring molecules that may represent intermolecular hydrogen bonding or strong dipolar forces. For a completely random arrangement of dipolar molecular segments and of dipolar molecules, $g=1$. In the extreme of an antiferroelectric arrangement, $g=0$, and in that of a ferroelectric arrangement, $g=\infty$. From the knowledge of measured ε_s and ε_∞, it is therefore possible to determine the dipolar alignment as a result of short-range interactions. For example; such an analysis showed that on cooling cyclodextrin undecahydrate crystals, the dipoles tend to align in an antiparallel manner.[13] Thus, variation in g with T also indicates the occurrence of an ordering–disordering transformation in a supramolecular structure. Short-range interactions of this type are important aspects of such structures, particularly because electrostatic interaction often determines their stability conditions as well as their practical use as intercalation compounds and templates for chemical reactions.

It was also possible to calculate g by first presuming a near-neighbor structure, as originally done for water.[14] and then to compare the calculated value from that determined from Eq. 3 by using the measured ε_s. This leads to information on the arrangement of molecules when intermolecular hydrogen bonding determines their dipole vectors, or when their dipolar segments are connected by flexible covalent bonds. Alternatively, g may be determined from the known positions of dipolar molecules in the crystal structure of a material. In this procedure, the orientation of one molecule is fixed, and the vector sum of all possible orientations of the

neighboring molecules is computed. Computation is done for all orientations of a given molecule and then for all molecules. Such cornputations for g of ice clathrates of Type I and Type II, which contain foreign molecules confined to the cages of 0.39–0.47 nm radius in their structures' hydrogen-bonded networks,[15] were provided, and the results were compared with the experimentally determined ε_s.[16] Similar computations also yielded the electrostatic field strength at a molecular site arising from its dipolar neighbor. the magnitude of increase in the dipolar moment, and the Coulombic interaction energy. The now available faster and more elegant computational procedures can help in such calculations on an irregularly shaped supramolecule in all its possible configurations. This may lead to not only their configurational thermodynamics but also the relative stability of molecular configurations at a given T and P.

The Vibration Polarization and Poley Absorption

Contribution from vibrational polarization in a material is given by the following:

$$\Delta\varepsilon_{\text{vib}} = \varepsilon_\infty - n_{\text{op}}^2 = (\Delta n_{\text{vib}} + n_{\text{op}})^2 - n_{\text{op}}^2 = \Delta n_{\text{vib}}^2 + 2\Delta n_{\text{vib}} n_{\text{op}} \tag{4}$$

$$\Delta n_{\text{vib}} = \sum (2\pi^2)^{-1} \int_0^\infty \frac{K(\nu)}{\nu^2}\,\partial\nu \tag{5}$$

where the absorptivity K at a frequency ν is given by

$$K(\nu) = -\frac{1}{l}\log_e\left[\frac{I(\nu)}{I_0(\nu)}\right] \tag{6}$$

where I_0 and I are the intensities of a radiation before and after traversing a distance l in the medium. The summation is for all absorption bands. The quantity Δn_{vib} is more when the vibrational frequencies are low, which occurs when the structure is relatively loose or floppy, and intermolecular forces are weak.

Molecules of different types confined to a regular or irregular cage-like structure, a doughnut-shaped, or a channel-like structure, undergo librations (rotational oscillations) in the THz frequency range and, hence, contribute significantly to Δn_{vib} and to $\Delta\varepsilon_{\text{vib}}$. This is similar to the effect observed for dipolar liquids at ambient temperatures by Poley,[17] which was attributed to rotational oscillations of a molecule inside a temporary. irregular cage formed by the neighboring molecules — a subject recently discussed in relation to the so-called Boson peaks.[18] A discussion of the magnitude of $\Delta\varepsilon_{\text{vib}}$ in the supramolecular structures of ice clathrates may be found in Refs. [15] and [16]. Because $\Delta\varepsilon_{\text{vib}}$ is the fastest dipolar process, its study should be useful in determining how configurational statistics of inclusion compounds, with lamellar, channel-like, cage-like, or toroidal structures, determine the chemical reactivity of its confined molecules.

The Dipolar Relaxation and its Characteristics

In general, the frequency-dependent complex permittivity $\varepsilon^*(\omega)$, and time-dependent complex permittivity $\varepsilon^*(t)$ are related by a Fourier transform according to

$$\frac{\varepsilon^*(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = 1 - i\omega\int_0^\infty \phi(t)\exp(-i\omega t)dt \tag{7}$$

where ϕ is the normalized relaxation function given by

$$\phi(t) = \frac{\varepsilon^*(t) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} \tag{8}$$

where $\varepsilon^*(t)$ describes the evolution of the apparent permittivity with time when a static electric field is removed as a step at $t=0$ from the polarized material. The magnitude of $\phi(t)$ decays from 1 to 0, in the absence of any contribution to the permittivity from ionic, interfacial: or electrode polarization effects. Therefore, a discussion of the dielectric relaxation may be carried out only after the dipolar contributions are isolated from other contributions. The function $\phi(t)$ is closely related to the dipole time correlation function, which describes the randomization of the dipole vector in time consequent to molecular motions.

The simplest form of $\phi(t)$ is a single exponential decay, $\phi(t)=\exp[-(t/\tau)]$, where τ is the relaxation time. Such a single relaxation time decay was observed for some ice clathrates, hydrogen-bonded liquids and amides, and simple molecules at high temperatures. But. in general, supramolecular structures showed a variation of ε' and ε'' that yielded $\phi(t)$ spread over a broader range than expected from a single exponential decay.[13,15] In such cases. empirical equations for the ε^* were used as described in Refs. [1–4]. These include the following:

- The Cole–Cole equation:[19]

$$\frac{\varepsilon^*(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{1}{1 + (i\omega\tau)^\alpha}; \quad \text{where } 0 < \alpha < 1 \tag{9}$$

- The Davidson–Cole equation:[20]

$$\frac{\varepsilon^*(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{1}{[1 + (i\omega\tau)]^\beta}; \quad \text{where } 0 < \beta < 1 \tag{10}$$

- The Fuoss and Kirkwood equation:[21]

$$\frac{\varepsilon''(\omega)}{\varepsilon_0 - \varepsilon_\infty} = m\frac{(\omega\tau)^{2m}}{1 + (\omega\tau)^{2m}}, \quad (11)$$

where $0 < m < 1$

- A combination of Eqs. 9 and 10:

$$\frac{\varepsilon^*(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{1}{[1 + (i\omega\tau)^\alpha]^\beta}, \quad (12)$$

where $0 < \alpha < 1$ and $0 < \beta < 1$

The shape of the ε' and ε'' relaxation spectra was also described by writing $\phi(t)$ in an empirical form; $\phi(t)=\exp[-(t/\tau)^{\beta KWW}]$, where $0<\beta_{KWW}<1$.[5,6] A wide variety of dielectric studies have attempted to determine the significance of β_{KWW}. It was interpreted in terms of hierarchically controlled dynamics of a dipolar process,[22] i.e., the existence of a strong degree of correlations between the molecular degrees of freedom, and the occurrence of dipolar reorientation in series, rather than in a parallel fashion—faster degrees of freedom successively controlling the slower ones and: thus. generating a wide range of relaxation times. More recent studies demonstrated that the distribution of relaxation times arises from microscopic heterogeneity,[23] and further. that the broadness of the spectra results from overlapping single relaxation time processes.[24] Thus, in supramolecular structures of ice clathrates, analysis of the relatively broad ε' and ε'' spectra in terms of a sum of several single relaxation time processes[15] seems to be reliable. The interpretation is that the number of dielectric relaxation times and the broadness of the ε' and ε'' spectra is a reflection of the presence in the lattice of crystallographically nonequivalent sites and energetically different orientations of the water molecules. With a decrease in temperature, thermal energy decreases. With the consequent increase in the number of energetically different orientations, the relaxation spectra are further broadened. Analysis of broad dielectric spectra observed for cyclodextrins[13] and other structures in such terms is now easily possible by using computation algorithms.

In most supramolecular structures, the temperature dependence of the characteristic dielectric relaxation time follows the Arrhenius equation, $\tau=\tau_0\exp(\Delta E_{dip}/RT)$, where τ_0 is the preexponential factor that is often of the magnitude of the vibrational time scale; and ΔE_{dip} is the activation energy of the dipolar process.[6,15] The dipolar process of the host lattice and the trapped molecules follows this behavior, but ΔE_{dip} for the trapped molecules is less than that for the host lattice molecules. In ice ciathrates, the dipolar processes of the water molecules that form the host lattice and the guest molecules inside the cages of this lattice occur at widely different time scales. This allows for a reliable attribution of the dielectric spectra features to water molecules and to the guest molecules. As an example of the magnitude of the dielectric properties of suprainolecular structures, the data on selected ice clathrates and other inclusion compounds are summarized in Tables 1 and 2.

THE INTERFACIAL PROCESS

When a liquid or solid is heterogeneous. i.e.. it consists of conglomerates of macroscopic volume elements with different ε_0 and σ_{dc} and the wavelength of the frequency

Table 1 The various properties of the dipolar processes in the two types of host lattices of some clathrate structures

Guest molecule	ε_s (233.2 K)	ε_∞ (165.2 K)	τ (233.2 K)	ΔE_{dip} (kJ/mol)	μ_0 (Debye)

used is large compared with the dimension of the congloinerates or inclusions, energy dissipation can occur by scattering of radiation at the interfacial boundaries. This is similar to the loss of energy by the scattering of light by colloidal solutions; but it occurs in the range of dielectric absorption frequencies. Maxwell's[25] treatment of this situation and Wagner's[26] and Sillars'[27] development of this subject may be found in Refs. [1], [2] and [28].

Briefly, the relaxation time and permittivity corresponding to the effects arising from interfacial boundaries from a heterogeneous material can be calculated from the knowledge of σ_{dc} and of ε_s values of the two phases in the heterogeneous system. In a general discussion of the dielectric effect arising from interfacial polarization, Wagner considered an even distribution of spherical particles of Phase 2 material with a small volume fraction f_2, permittivity ε_2, and conductivity σ_2 in Phase 1 of permittivity ε_1 and negligibly small conductivity. The expressions for the resulting permittivity and loss are then given by the following:[2]

$$\varepsilon'_{\text{interfacial}} = \chi\left(1 + \frac{\psi}{1 + \omega^2\zeta^2}\right);$$

$$\varepsilon''_{\text{interfacial}} = \left(\frac{\chi\psi\omega\zeta}{1 + \omega^2\zeta^2}\right) \tag{13}$$

where

$$\chi = \varepsilon'_1\left\{1 + \frac{3f_2(\varepsilon'_2 - \varepsilon'_1)}{2\varepsilon'_1 + \varepsilon'_2}\right\}$$

$$\psi = \left(\frac{9f_2\varepsilon'_1}{2\varepsilon'_1 + \varepsilon'_2}\right)$$

$$\zeta = \frac{(2\varepsilon'_1 + \varepsilon'_2)\varepsilon_0}{\sigma_2}$$

Because χ, ψ, and ζ are fixed quantities at a given T, the form of Eq. 13 corresponds to a frequency dependence

of the interfacial polarization process identical to that of the Debye single relaxation time process. Its spectra shifts with change with T only in as much as the quantity ζ changes with T.

Interfacial processes in the dielectric data obtained for biological systems were described by Pethig.[4] He summarized the formalisms for different shape particles and mixtures of particles in a medium, for porous heterogeneous systems, for emulsions of various types. and for the surface ion conductivity and counterion effects. Then, he compared the interfacial processes observed for synthetic polymers and biopolymers suspended in electrolytic solutions. In general, the E' and c" spectrum from an interfacial process is broadened as a result of effects arising from the particle shape, intra- and interparticle interactions, electrical and structural interactions (coalescence/division) between particles, heterogeneity of morphological and electrical properties of particles, and frequency dependence of their dielectric behavior; etc. This broadness at high frequencies makes $\varepsilon''_{\text{interfacial}}$ become proportional to $(\omega)^s$ when $\omega\zeta \gg 1$, with the empirical parameter, $s<1$. In contrast, s=1 when the dipolar process has a single relaxation time and $\omega\tau \gg 1$, and when σ_{dc} of the ionic process dominates the ε'' spectra.

The ε' and ε''contributions from an interfacial process provide no molecular insight. even though such data contain information on ε_{s} and σ_{dc} of the component phases. Often. the magnitudes of $\varepsilon'_{\text{interfacial}}$ and $\varepsilon''_{\text{interfacial}}$ are overwhelmingly large,[1–4] and need to be subtracted from the measured ε' and ε'' before attempting a molecular interpretation of the dielectric spectra.

THE ELECTRODE POLARIZATION EFFECT

In this process, ions migrate to the electrode surfaces. producing localized concentrations that increase with a decrease in ω. If a chemical reaction between the electrode material and the ions also occurs, an irreversible, nonequilibrium process sets in, and the effects of the reaction products begin to contribute. Such effects are observed in liquids and solids and are relatively small at high ω or low σ_{dc} values. But when σ_{dc} from the ionic process exceeds 1 μS/m, the electrode polarization effects begin to contribute significantly to the e' and e" values in the low-frequency part of the spectrum. and its magnitude needs to be determined.

The electrode impedance, z_{el}, resulting from this polarization is written as a complex function: $z^*_{\text{el}}=z_0(i\omega)^{-n}$, where z_0 is a characteristic of the electrode/dielectric interface. and the exponent n is usually taken to be 0.5.[2,29] This is equivalent to a constant phase element in series with the bulk dielectric properties of a material. The expression for the measured conductance G_{meas} (in Siemens), for an electrode impedance z_{el} in series with the dielectric sample,[2,29] is as follows:

$$\frac{G_{meas}}{C_0} + i\omega\varepsilon'_{meas} = \frac{(G_{bulk}/C_0) + i\omega\varepsilon'_{bulk}}{1 + z^*_{el}[(G_{bulk}/C_0) + i\omega\varepsilon'_{bulk}]}$$

where C_0 is the capacitance of the empty dielectric cell; ε'_{meas} is the measured permittivity; ε'_{bulk} is the true (bulk) permittivity from the dipolar process; and G_{bulk} is the true (bulk) conductance, which is the sum of the ionic and dipolar processes. For frequencies when $G_{bulk} \gg \omega\varepsilon' C_0$ and $|z^*_{\text{el}}|=z_0 G_{bulk}\omega^{-n}$, Eq. 14 is expanded as a Taylor series. After truncating at the first order. it was written as

$$\frac{G_{meas}}{C_0} = \frac{G_{bulk}}{C_0} - \left[z_0 \cos\left(\frac{n\pi}{2}\right)\frac{G^2_{bulk}}{C_0}\right]\omega^{-n} \tag{15}$$

and its transformation to

$$\varepsilon'_{meas} = \varepsilon'_{dip} + \left\{\left[z_0 \sin\left(\frac{n\pi}{2}\right)\right]\frac{(\sigma_{dc} + \sigma_{dip})C_0}{\varepsilon_0^2}\right\}\omega^{-(n-1)} \tag{16}$$

and

$$\varepsilon''_{meas} = \varepsilon''_{dc} + \varepsilon''_{dip} - \left\{\left[z_0 \cos\left(\frac{n\pi}{2}\right)\right]\frac{(\sigma_{dc} + \sigma_{dip})C_0}{\varepsilon_0^2}\right\}\omega^{-(n+1)}$$

In Eqs. 16 and 17, the last term is the magnitude of electrode polarization. It contributes to ε' and ε'' values. and its magnitude depends upon that of σ_{dc}. This term is evaluated by using a reiterative procedure.[30] This polarization can also be treated empirically in terms of $(\omega)^s$, the frequency dependence of the measured conductivity.[31]

CONCLUSION

In practice, electrical measurements do not distinguish between conduction and polarization currents, because only the total current that appears in Maxwell's equation, $J_{\text{total}}=J_0+(\partial P/\partial t)$, is measured. The conduction cunent J_0 and the polarization current $(\partial P/\partial t)$ need to be separated into the electrode polarization, dc conduction, and dipolar orientation contributions by using suitable procedures. This is particularly the case for a majority of highly conducting suprainolecular structures of all types at ambient temperatures, with ε' and e" data that do not show features directly attributable to a molecular dielectric process. In such cases, Eqs. 16 and 17 are used to determine contributions from electrode polarization and dc conductivity. On subtraction from the measured ε' and

ε'' data. the spectrum of the dipolar process is obtained by an analysis described earlier.[30]

Studies of the dielectric properties will certainly provide greater insight into the molecular processes that determine the applications of supramolecular structures. The onset of ferroelectric and antiferroelectric behavior and the ordering–ordering transitions in supramolecular structures. as well as the dynamics of molecular segments in such structures, can be investigated by studying their dielectric spectra.

Ionophores

Riccardo Ferdani
George W. Gokel
Washington University School of Medicine, St. Louis, Missouri, U.S.A.

INTRODUCTION

Ionophore (literally "ion bearer") is a name given to the family of compounds with the principal characteristic that is to "promote the transfer of ions from aqueous medium into a hydrophobic phase."[1–4] The Shorter *Oxford English* Dictionary gives the following definition: "An agent which is able to transport ions across a lipid membrane, in a cell." By extension, ionophores are host molecules that bind ionic guests and transport them across a membrane, such as a bulk organic phase or a phospholipid bilayer. In the latter case, the bilayer may be present in a cell or subcellular organelle.

The name was coined to describe the activity of compounds. such as valinomycin, a naturally occurring cyclic depsipeptide that transports K^+ ions across membranes efficiently and selectively.[5,6] A number of natural ion transport agents have been identified. They regulate the concentrations of the predominant biological cations (Na^+, K^+, Mg^{2+}, and Ca^{2+}).[7] Artificial ionophores were first prepared to serve as models for their natural but more complex counterparts. They now comprise a broad family of compounds that includes inter alia, podands, crown ethers. lariat ethers: and cryptands.

The name ionophore suggests a "bearer" or carrier function. Cations are typically transported across a membrane by a carrier or a channel mechanism. Channel function is less well understood but is generally thought to involve the formation of a transmembrane pore through which ions pass. Effectively, a channel is a scaffold or superstructure that facilitates this process. In contrast, the ionophores discussed here typically function by a carrier mechanism. An ionophore is usually soluble in a hydrophobic or membrane phase. The ionophore (host) captures the guest ion at the aqueous–hydrophobic interface. The complex diffuses across the hydrophobic membrane or barrier phase. At the opposite interface, guest release occurs, passing the ion into the second aqueous phase. The ionophore or host molecule then diffuses back to the opposite interface. where the process is repeated until equilibrium is reached.

In one sense, ionophores comprise a superfamily that includes all compounds that bind a charged (ionic) species, screen its charge so that transport across a highly hydrophobic phase becomes feasible, and release it at the end of the transport process. Taken together, the number of compounds that are more or less effective at transporting cations is large. We briefly describe this family below, but the reader is directed to other, more specific entries that deal with individual compound groups.

CLASSES OF IONOPHORES

Any classification scheme is necessarily arbitrary, but ionophores are often divided into two groups: naturally occurring and synthetic. A subclassification distinguishes on the basis of open-chained (noncyclic) versus cyclic. Examples of the latter typically exceed the former because binding site preorganization and geometric complementarity are usually easier to achieve or ensure in a cyclic structure when the goal is to complex a spherical ion.

Natural Cyclic Ionophores

Valinomycin

Valinomycin[8–13] is probably the best known and characterized of the natural ionophoretic, antibiotic compounds. It is a K^+-selective carrier molecule that is produced by *Streptomyces fulvissimus*.[14] It is a dodecadepsipeptide comprised of 12 alternating amino and hydroxy acids to form a neutral, macrocyclic ionophore (Fig. 1).

The macrocyclic ring of valinomycin contains 36 atoms and is flexible. It is too large to complex a K^+ ion. for which it is selective, in a two-dimensional fashion. Instead, it wraps about the cation in what has been called a "tennis ball seam" conformation. Because of the conformational flexibility, this host molecule readily binds and releases the cation. This is a critical issue for transport because both complexation at one interface and cation release at the opposite interface must take place with reasonable rates or strong complexation and fast diffusion will be to little avail.

When complexation takes place, two water molecules may be included in the K^+ coordination sphere, giving a coordination number of eight. As the carbonyl groups turn inward to complex the cation, the nine isopropyl and three

methyl groups turn outward to interact with the hydrophobic medium. This conformation effectively creates a solvent gradient from the nonpolar exterior to the polar coordination site. As such, the complex is soluble in hydrophobic membranes. and transport is effective.

Enniatins

Enniatins A (also called lateritiin I) (Fig. 2), B, C, D, E, and F[15] are antibiotics synthesized by various strains of the genus *Fusarium*.[16–20] Like valinomycin, they are cyclic compounds, but they differ in several respects. First, the enniatins are cyclohexadepsipeptides, so they are half the size of valinomycin. Second, their ring nitrogen atoms are methylated. In contrast to valinomycin, they show poor ion selectivity. The prototype of this family is enniatin B, a cyclohexadepsipeptide assembled by threefold repetition of the L-N-methylvaline D-hydroxyisovaleric acid subunit. When L-*N*-methylvaline is replaced by L-N-methylphenylalanine in this repeating sequence, beauvericin results.

Enniatins form 1:1 and 1:2 complexes with cation~. [~ Structures were obtained for the Na^+, K^+, Rb^+, and Ba^{2+} complexes. Complexation occurs as a result of carbonyl donor groups interacting with the bound cation. The conformations of Na^+- and K^+-bound enniatin B complexes differ little in overall conformation. This fact may account for the poor cation selectivity.

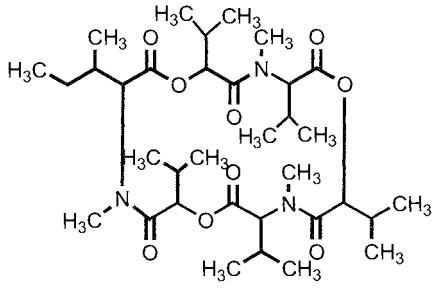
Nactins

Nonactin (Fig. 2) is a macrotetrolide antibiotic comprised of four nonactic acid groups that have alternating chirality. Nonactin is of historical interest. as its potassium complex was the first solid-state structure of an ionophore complex to be resolved.[23] The resulting structural insights were valuable in explaining the formation of such complexes and in understanding transmembrane transport. It is interesting to note that the macrotetrolides[24–29] exhibit a broad range of biological activities. including antibacterial, antifungal, antitumor, and immunosuppressive activity.

Natural Noncyclic Ionophores

Nigericin and related compounds

Nigericin, monensin, grisorixin, ionomycin, and many other compounds are structurally related and may be grouped into a family.[30–37] All are carboxylic acid ion-



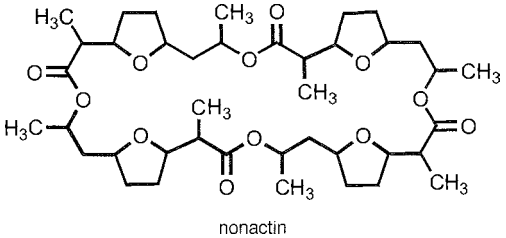


Fig. 2 Structures of enniatin A and nonactin.

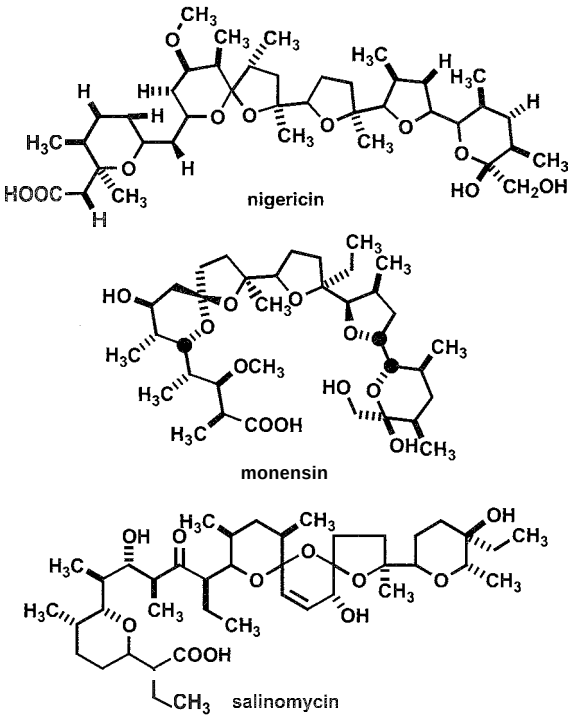

Fig. 3 Structures of nigericin, monensin. and salinomycin.

ophores that contain tetrahydrofuran and tetrahydropyran structural units. Nigericin,[38] the structure of which is shown in Fig. 3. contains three five-membered and three six-membered rings in a noncyclic array.

Although these compounds are acyclic,[39] they adopt semicircular conformations in which the oxygen heteroatoms are focused for cation binding.[40] The uncomplexed forms may adopt a cyclic conformation as a result of hydrogen-bond formation between the molecule's head and the tail. It is interesting to note that valinomycin transports cations (typically K^+) into mitochondria: the carboxylic ionophores in this family typically transport in the opposite direction. The ionophores in this group are deprotonated at physiologic pH (7.4), so their complexes with alkali metal cations are ordinarily neutral. Nigericin has 11 oxygen atoms, all of which could potentially interact with a bound cation. Typically. however, only five to seven donors coordinate. The donor number has been attributed to the lack of symmetry in these ionophores and to conformational restrictions caused by, inter alia. the spiro ring junctions.

Several other natural, acyclic carboxylic ionophores are known. Among these, salinomycin is notable for its unusual tricyclic spiroketal ring system. Further, the ester of salinomycin affords complexes that have a helical, rather than "circular," conformation.[41] Ionomycin[42] is likewise notable as the first example of a dibasic ionophore to be discovered. Ionomycin has a high affinity for divalent cations such as Ca^{2+} and Cd^{2+}, owing to the presence of an enolized β-diketone.

Artificial Noncyclic Ionophores

Crown ethers are two-dimensional, cyclic, cation-complexing agents. The corresponding three-dimensional analogues are called cryptands. The open-chained (noncyclic) analogues of crown ethers are generally referred to as podands. Like the crowns and cryptands. their structures include oxygen. nitrogen, sulfur, or other donors typically separated by ethylene units. The donors may be part of a small ring. such as tetrahydrofuran, and the ethylene or other carbon spacer units may be part of other structures. such as a benzene ring.

Polyethylene glycols

Polyethylene glycols. acyclic compounds having the repeating (OCH_2CH_2) units, have been known for many

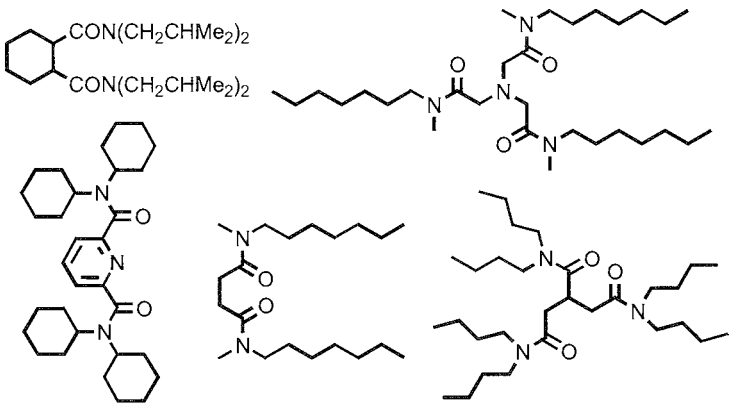

Fig. 4 Structures of open-chained ''podand'' cation complexing agents

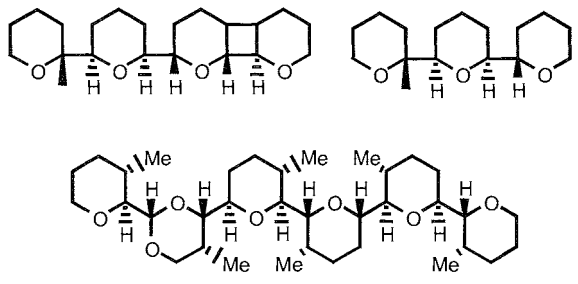

Fig. 5 Synthetic, pyran-containing open-chained ionophores.

years. The chains may be terminated by hydroxyl groups [HO-$(CH_2CH_2O)_nH$], by one alkyl group [$RO(CH_2CH_2O)_nH$], or by two alkyl residues [$R^1O(CH_2CH_2O)_n R^2$]. In the latter case, R^1 and R^2 may be the same or different, but the most common examples are mono- and dimethyl ethers. The molecular weights known for these compounds range from hundreds to millions of Daltons. The polyethylene glycols are commonly referred to as ''PEGs,'' and the methylated derivatives as ''MPEGs.'' Polyethylene glycols are available commercially under a variety of trade names, including "Carbowax," typically followed by a number indicating the molecular weight. For example, Carbowax 300 is a liquid having approximately seven repeating ethyleneoxy units. The designation PEG-2000 refers to a polymer mixture of the type $HO(CH_2CH_2O)_nH$, in which n is about 45. MPEG-2000 has the formula $CH_3O(CH_2CH_2O)_nH$, but n remains about the same.[43]

Attachment of a polyethylene glycol chain to, for example, a protein, is called ''PEGylation.'' The covalent attachment of PEG chains to drugs, peptides. proteins, and other substances often has the effect of increasing the derivative's circulation time in the bloodstream. This derivatization was also found to reduce the immunogenicity of the conjugate in some cases.[44,45]

Polyethylene glycols are similar to crown ethers except that they are linear rather than cyclic oligomers.[44] Accordingly, they can bind cationic species, just as do crown ethers.[45–47] An important difference is that crowns are preorganized in a cyclic conformation that PEGs must adopt with a corresponding entropy cost. Thus, a crown ether will typically bind a cation more strongly than will a PEG of corresponding molecular weight.[48,49]

Ion-selective, open-chained ionophores

Simon and coworkers prepared numerous novel open-chained compounds that exhibited cation selectivity.[50–57] Some of these compounds were incorporated into ion-selective electrodes. An especially successful application is their use in the detection of divalent calcium cation. Several of the structures developed in the Simon laboratory are shown in Fig. 4.

Oligotetrahydropyrans

Still and coworkers prepared a family of polytetrahydropyran derivatives such as those depicted in Fig. 5.[58–60] These compounds are preorganized by virtue of their stereochemistries into conformations that are appropriate for cation binding. These conformations confer upon them ionophoretic abilities that sometimes exceed those of crown ethers containing the same number of donor atoms.

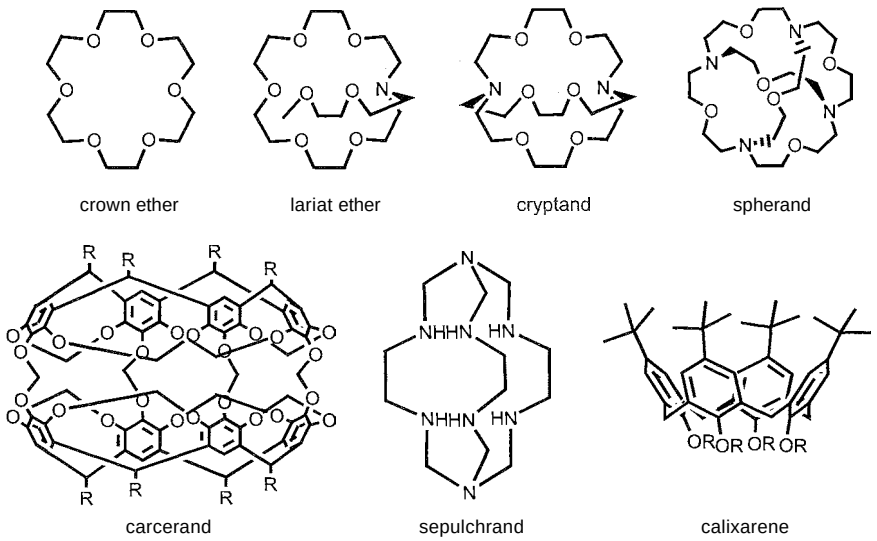

Fig. 6 Structures representing major classes of ionophores.

Compounds such as the one shown in the bottom of Fig. 5 are conformationally locked; the oxygens are held in the same geometry observed in the solid-state structure of the 18-crown-6 potassium complex.[61] Most of these compounds are chiral and are capable of enantioselectively complexing chiral ammonium ions.[62–64]

Artificial Cyclic Ionophores

The ion-bearer concept applies to cyclic and bicyclic molecules as well as to the open-chained counterparts described above. Complexing agents such as crown ethers comprise such an enormous class. however, that they are usually referred to by the more specific cognomen. This tradition applies to lariat ethers. spherands. cryptands, carcerands, calixarenes, sepulchrands, and numerous other compounds that are dealt with separately in this *Encyclopedia*. Structures exemplifying these various families are shown in Fig. 6.

CONCLUSION

Ionophores are ion-bearers. In order to bear or carry ions, they must also complex them. The complexation and transport of cations depends to an appreciable extent on the ion, the medium. the ionophore's structure, the counterion, and other variables. The reader is referred to other articles in this *Encyclopedia* for information concerning structures that encapsulate ions. For a more detailed discussion of complexation and complexing agents, the reader should consult Ref. [65] and information therein.

Isostructurality of Inclusion Compounds

Mino R. Caira
University of Cape Town, Rondebosch, Western Cape Province, South Africa

INTRODUCTION

Crystal isostructurality refers to identical or nearly identical packing arrays of chemically distinct compounds and is inversely related to the phenomenon of polymorphism, which, instead. refers to the ability of a single compound to crystallize in different packing arrays.[1] A series of isostructural inclusion compounds is typically based on a common host framework with voids that may be occupied by different guest molecules. The constant guest environment provided by such a series is a factor that facilitates interpretation of the mechanisms of processes such as thermal decomposition and guest exchange.

GENERAL SIGNIFICANCE OF CRYSTAL ISOSTRUCTURALITY

Description of Isostructurality and Its Implications in Supramolecular Chemistry

''Crystal isomorphism'' is a term used to indicate similarity in crystal morphology and, as such, is inappropriate for describing two or more crystals containing essentially the same three-dimensional arrangement of geometrically similar structural units. For such systems, the term ''isostructural'' is appropriate.[1] Crystal isostructurality of organic compounds was initially recognized as an interesting aspect of the packing of structurally similar molecules. In recent years, with the explosive increase in the number of published crystal structures, its increasing frequency of occurrence, especially among inclusion compounds, has generated renewed interest. In a strict definition, isostructural compounds crystallize with similar unit cell dimensions, the same space group, and almost identical atomic coordinates for common atoms. This implies that the entire atomic array of one crystal is virtually superimposable on the array of its isostructural partner. Crystallographers have for many years used isostructurality to advantage in the solution of crystal structures by the so-called isomorphous replacement technique.

A series of isostructural inclusion compounds presents a unique opportunity to investigate structure and property relationships, because one structural degree of freedom, namely the host arrangement, is effectively constant. If the guests are volatile, thermal analysis can be used to establish whether the guest loss event has common or widely disparate thermodynamic and kinetic parameters. Interpretation of such data can lead to postulation of a mechanism for desolvation, especially if the structure of the resulting polymorphic form has also been established. In principle, two members of a series of isostructural inclusion compounds may yield the same or different polymorphs on desolvation. Guest exchange processes are most easily interpreted in the case of isostructural inclusion compounds; because the exchangeable guests in these species occupy voids or channels of virtually identical topology, and the complicating appearance of new solid phases is eliminated.

Two isostructural inclusion compounds are most conveniently identified as such from close correspondence between their powder x-ray diffraction (PXRD) patterns. Shown in Fig. 1 are representative crystal structures of three members of an isostructural series of inclusion compounds with their corresponding PXRD patterns.[2] The angular positions of the diffraction peaks are dictated by the respective lattice constants, which for isostructural compounds frequently differ by very small percentages, resulting in near coincidence of peak positions. Peak intensity differences, however, reflect differences in the structures and orientations of the guest molecules present. These features of PXRD patterns may be exploited in developing a reference pattern for a series of isostructural clathrates, useful for identifying and characterizing clathrates of new guests of the same host unequivocally. More than one series of isostructural clathrates may exist for a given host, and their reference patterns may permit a finer level of structural characterization, including space group discrimination.

DEFINITION AND QUANTIFICATION OF ISOSTRUCTURALITY

Isostructurality and Homeostructurality

Since the 1980s, Kálmán and his rchool have been largely responsible for systematizing the notion of isostructurality for organic compounds[3] and for developing numerical

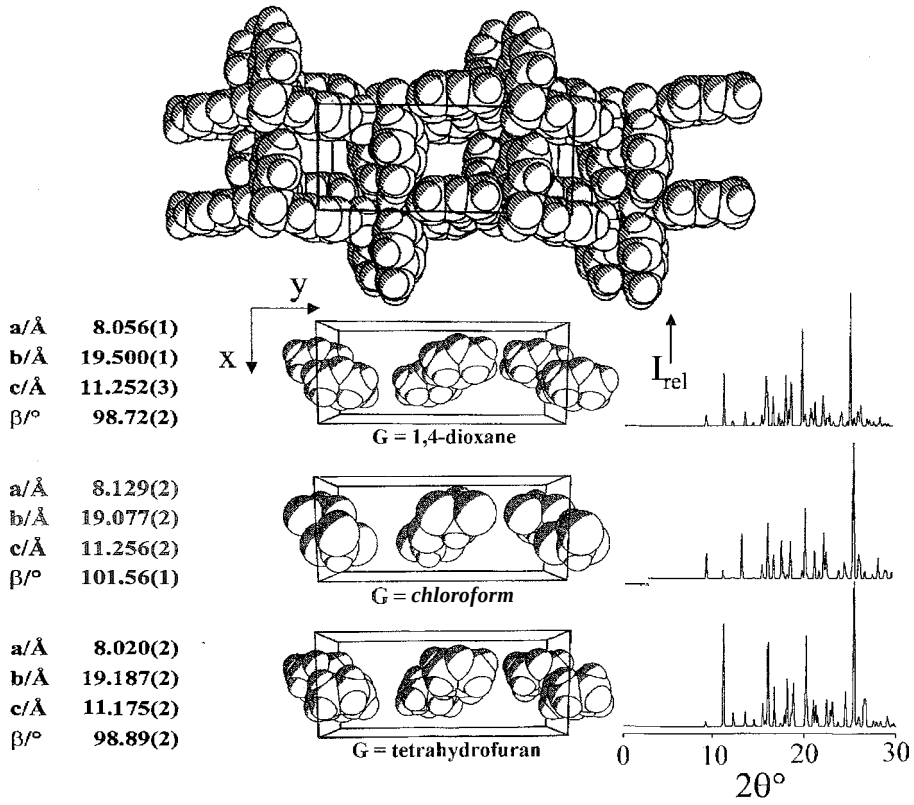

Fig. 1 Space-filling representation of the common host framework adopted by 5-methoxysulfadiazine in three isostructural clathrates (space group $P2_1/c$) and cavity occupation by the respective guests. Also shown are the unit cell data and PXRD patterns for the clathrates. (Adapted from Ref. [2] with permission from Gordon and Breach Publishing and Taylor & Francis.)

indices[i]'' with which to quantify the extent of isostructurality shared by two or more crystal structures. A synopsis of their classification follows. Distinction is made between ''isostructural'' and ''homeostructural'' crystals. In the former, crystals are characterized by having small differences on the surfaces of their respective molecules. which are otherwise isometric (''main part isostructuralism''). a pre-requisite for the formation of identical packing motifs. Small molecular differences include a substituent difference at a common site. e.g., $H \rightarrow CH_3$ substitution as in digitoxigenin→(21S)-methyldigitoxigenin,[1] or chirality differences at a common site. The term ''homeostructural'' allows for more relaxed forms of isostructurality, in which substitution occurs at more than one atomic site on the related molecules. As regards molecular associates, such as clathrates with similar host substructures but containing different guest molecules in coinmon cavities, crystal pairs of this type may be isostructural to a greater or lesser extent. and in the latter case, are included among the homeostructural cases. Ideally. classification can be based upon computed values of the various isostructurality indices available (see below), but this is not yet common practice. Instead, recent literature abounds with the term ''isostructural,'' even for systems that should properly be called ''homeostructural.'' In the absence of quantitative data for most systems, the term ''isostructurality'' is used here henceforth, but the finer distinctions recommended by Kálmán and coworkers[i]'' should be borne in mind.

Indices of Isostructurality

Indices for measuring the extent of isostructurality of two or more organic crystal structures can be applied not only to homomolecular crystals but also to molecular associates. such as inclusion compounds. A qualitative summary of these descriptors follows, and the reader is referred to a recent account for explicit mathematical definitions.[4] Earlier descriptors of isostructurality included the ''''degree of isostructurality'' $I_i(n)$ (based on the distance differences ΔR_i between the crystal coordinates of identical nonhydrogen atoms within the same section of the asymmetric units of two or more related structures); the packing coefficient increment. $\Delta(pc)$; and the unit cell similarity index Π.[3]

Recently; Fábián and Kálmán highlighted certain limitations in the above indices. proposing that the degree of isostructurality of two or more structures be based instead on the extent of their volume overlap.[4] They accordingly defined a "volume isostructurality index" represented by the ratio of the volume overlap of the two compared fragments and their average volumes. This parameter, computed over the entire unit cell, has merit in that it can be used selectively on two or more related inclusion compounds to measure the levels of isostructurality between the entire crystal structures, the hosts alone, or the guests alone.

OCCURRENCE AND CONSEQUENCES OF ISOSTRUCTURALITY

Classes of inclusion Compounds Exhibiting Isostructurality

Isostructurality occurs frequently in many classes of inclusion compounds. Here, selected examples are drawn from several classes displaying this tendency, starting with clathrate hydrates and metal-containing inclusion compounds. The inherent stabilities of many host frameworks are conducive to the formation of isostructural series. At the other extreme, however, isostructurality may also arise in situations where the host is unstable, originating only within the clathrate phase, which self-assembles in the presence of guest molecules.

Isostructurality among clathrate hydrate phases is common. the known isostructural types being based on different but well-defined combinations of polyhedral water frameworks that accommodate guest molecules of different sizes. From diffraction data, it is known that, e.g., the hydrates of N_2, O_2, and air are isostructural. belonging to "structure Type II'' with cubic symmetry ($Fd\bar{3}m$) and unit cell dimensions in the range of 17.07–17.24 Å.[5] The voids occupied by the guest molecules in this series are pentagonal dodecahedra and hexakaidecahedra. Clathrate hydrates containing substantially larger guest molecules (e.g., methylcyclohexane, t-butyl ether) belong to a different isostructural series crystallizing in the hexagonal system. These and other clathrate hydrates are known to have isostructural counterparts among the clathrasils (clathrates based on the SiO_2 host framework).

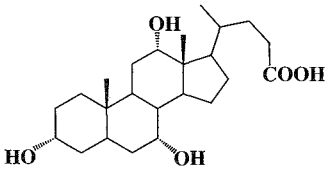
Numerous instances of isostructurality among Hofmann clathrates. $M(NH_3)_2M'(CN)_4\cdot 2G$, are known. the high frequency of occurrence probably owing to the fact that this family of inclusion compounds has been studied extensively over a long period. In addition. isostructurality can manifest itself in different ways, e.g., with either M. M' fixed and guest G variable or with M, M′ variable and a common guest. An example in the former category is the pair $Fe(NH_3)_2Ni(CN)_4\cdot 2G$ with G=benzene and pyrrole[6] crystallizing in the tetragonal system with similar unit cell dimensions. The clathrate with the more symmetrical guest, benzene, crystallizes in the space group P4/mmm, while the pyrrole clathrate crystallizes in P4/m. The isostructural host frameworks, however, share the high symmetry of P4/mmm. Isostructurality in a system of the second type occurs in the series $M(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$, where M=Mn. Ni, Cd, and Cu.[7] Here, a linear increase in the lattice constant a of the common tetragonal unit cell is observed and is attributed to the increasing ionic radius of M.

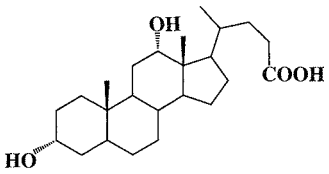
Isostructurality is maintained in variants of the classic Hofmann clathrates, in which the host ammonia ligands are replaced by N-substituted α,ω-diaminoalkanes,[8] e.g., *N*-methyl-1,3-diaminopropane (mtn). Thus, the host $H=Cd[CH_3NH(CH_2)_3NH_2]Ni(CN)_4$ forms a series of isostructural clathrates $2H\cdot G$ with no fewer than 27 guests. Isostructurality was deduced from close correspondence among the PXRD patterns, all of which could be indexed as tetragonal. based on the single crystal x-ray structure of one member of the series (G=cyclohexane). When the ligand mtn is replaced by N, *N*-dimethyl-1,3-diaminopropane and 2-hydroxyethylmethylamine, the resulting hosts form several clathrates each, also isostructural with the series based on mtn. Despite a wide variety of guests incorporated in the three host frameworks, the *a* and c unit cell dimensions for all of the clathrates are in the narrow ranges of 14.12–14.33 and 7.69–7.85 Å, respectively, suggesting that a high level of host isostructurality is maintained throughout.

Werner complexes, MA_4X_2, and their variants[9] also form numerous series of isostructural clathrates, but in contrast to the Hofmann clathrates, the host substructure comprises discrete molecules rather than being polymeric. In limiting cases, such host molecules may be so unstable that they do not exist as a separate phase but arise only inside the clathrate phase during its formation (the phenomenon of "contact stabilization''[10]). Isostructurality may also occur in such systems. A case in point is the isostructural pair $[M(Py)_4(NO_3)_2]\cdot 2Py$, M=Zn,Cd, and Py=pyridine. A common space group (Ccca) and similar unit cell dimensions were deduced for these clathrates from single crystal x-ray data.[10] The existence of the host molecules within the clathrates as well as their essential structural features were inferred by analogy with the isostructural species $[Ni(Py)_4(NO_3)_2]\cdot 2Py$ on which complete x-ray analysis had been performed earlier. Isostructurality in the space group Ccca is maintained when the nitrate ion of the previous series is replaced by cyanate to yield a series of seven clathrates $[M(Py)_4(NCO)_2]\cdot 2Py$, M=Mn–Zn,Cd.[11] Their isostructural nature was deduced by comparison of space group and unit cell data, with those for $[Ni(Py)_4(NCO)_2]\cdot 2Py$, whose

structure in space group Ccca was determined fully. These seven coinpounds represent the longest known row of isostructural clathrates of type $[M(Py)_4X_2]\cdot 2Py$ containing the same ligand X. Introduction of the slightly longer azido ligand in the hosts of the clathrates $[M(Py)_4(N_3)_2]\cdot 2Py$, M=Ni.Co leads to a change in the crystal structure from space group Ccca to Pnna, which is common to this isostructural pair.[12] This illustrates that apparently small chemical variations in Werner compounds can induce significant morphotropic shifts. The host $[Ni(MePy)_4(NCS)_2]$, MePy=4-methylpyridine, is a versatile clathrate former giving rise to cage, organic zeolite, and layered structures, and including guests ranging from rare gases to organic molecules the size of naphthalene.[9] The clathrates of, e.g., benzene, p-xylene. and MePy, form a well-known isostructural series crystallizing in the tetragonal space group $I4_1/a$. Inclusion of larger molecules (e.g., naphthalene derivatives) by the host $[Ni(MePy)_4(NCS)_2]$ involves a change in structure from tetragonal to triclinic with an accompanying change in the topologies of the voids occupied by guests.[''''] The clathrates $[Ni(MePy)_4(NCS)_2]\cdot 2G$, G=2-methylnaphthalene and 2-bromonaphthalene are isostructural, crystallizing in the space group $P\bar{1}$ with similar unit cell dimensions. Not surprisingly, isostructurality extends even to the guest molecules, and this was exploited in the structure solution of the 2-bromonaphthalene clathrate by isomosphous replacement.

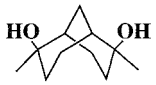
Isostructurality among inclusion compounds of organic hosts and guests occurs widely, and selected cases are highlighted here. An isostructural series derived from a specific host cocrystallizing with a range of guests represents the most common situation. The bile acids, cholic acid (CA) 1 and deoxycholic acid (DCA) 2, exemplify such hosts.[''''] Their inclusion compounds generally feature an assembly of host bilayers with the guest molecules enclosed within cavities or helical channels. CA cocrystallizes with the aliphatic esters ethylacetate and ethylpropionate to yield an isostructural pair of I:1 host–guest stoichiometry in the space group $P2_1$.[15] Inclusion of *n*-propylacetate, i-propylaceiate, and n-butylacetate results in a rnorphotropic change to a new isostructural series, again crystallizing in $P2_1$ but with distinctly different unit cell dimensions. The structural change involves a shift in the relative positions of the host bilayers, yielding channels with different cross-sectional shapes to accommodate the new guests.



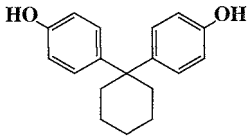


2

Synthetic diol host compounds are prolific clathrate formers.[16] Among these are the alicyclic diols (e.g., **3)** that cocrystallize with a large variety of guests to form helical tubulate inclusion compounds.[17] Here, isostructurality may occur within a series of inclusion compounds containing a common host and variable guests, while homeostructurality is evident between some clathrates in which both the host and the guest differ. Kálmán used several of these compounds as models to illustrate the use of indices to quantify individually the levels of isostructurality among hosts, guests, and the entire clathrate structures.[''] The diol 4, which was used to separate close isomers of several organic compounds,[18] forms an isostructural series with guests methanol, ethanol, 2-propanol. and n-butanol of 1:1 H:G stoichiometry in the space group $P\bar{1}$. The host framework is a double ribbon motif, and guests are located in channels formed by host layers. The unit cell parameter normal to the layers shows a steady increase from 12.9 to 14.8 Å as guests of increasing size are accommodated.

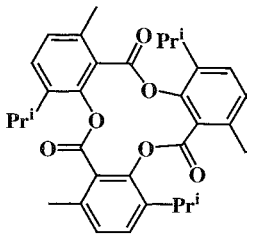


3



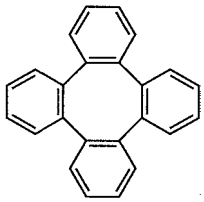
4

The host tri-o-thymotide 5 was reported to form over 140 clathrates with guests of the most varied shapes.[19] These clathrates crystallize in about a dozen isostructural series, the most populous belonging to space group $P3_121$. For several of these series, a linear relationship between unit cell size and guest molecular volume was observed.

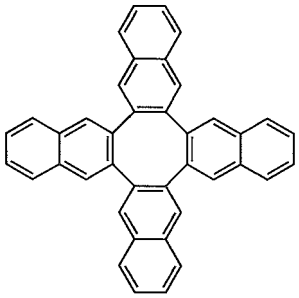


5

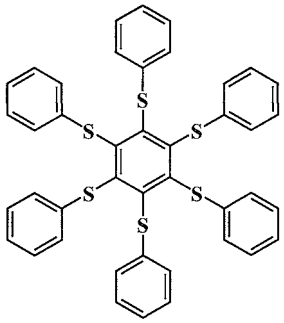
Clathrates of tetraphenylene 6 form a single isostructural series ($P4_2/n$) with H:G ratio 2:1, in which guests range in size from dichloromethane to cyclohexane.[20] Guests occupy common spheroidal cavities generated by the isostructural host framework. Elaboration of the host 6 to the more bulky tetrabenzo[*b*,*h*,*n*,*t*]tetraphenylene 4 produce, no fewer than three distinct isostructural series of clathrates (two triclinic, one monoclinic).



6

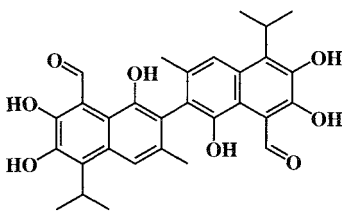


The prototype hexa-host 8 forms an isostructural series of H:G ratio 1:2 with halogenated species (e.g., CCl_4, CCl_3Br) crystallizing in space group $R\bar{3}$.[21] The latter space group and those derived by lowering its symmetry are characteristic of phenolic clathrates; isostructural series of β-hydroquinone clathrates crystallizing in R3 and R3 are familiar examples.[22]



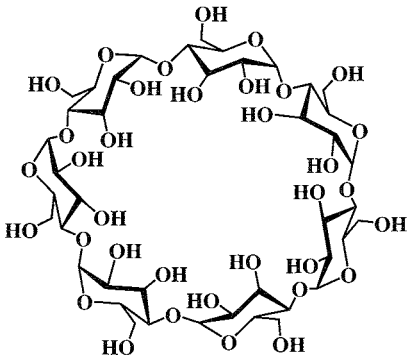
8

The yellow polyphenol pigment gossypol 9 is undiscriminating in its formation of inclusion compounds with organic guests and was recently dubbed the "universal clathrate-forming agent."[23] Over 100 crystalline forms of gossypol, including clathrates and polymorphs, have been identified. Single crystal and powder x-ray diffraction studies enabled the classification of these species into 24 groups of isostructural crystals represented in the space groups P1, $P2_1$, $P2_1/c$, C2, C2/c, and Pbcn. Such diversity in the types of supramolecular associates formed by gossypol is attributed to the presence of several polar functional groups in the molecule, as well as conformational mobility and its racemic nature. These permit the existence of a variety of centrosyinmetric host dimeric motifs from which the substructures in the various isostructural clathrate series are constructed.



9

The cyclodextrins represent another group of hosts giving rise to numerous isostructural series of clathrates. Crystalline cyclodextrin complexes are generally ternary systems, containing host, guest, and water molecules. A recent survey of crystal structures of cyclodextrin inclusion complexes with organic guests[C2] showed that for β-cyclodextrin 10, at least eight isostructural series can be identified. This host can form monomeric complexes but more frequently yields dimeric complexes in which the guest is encapsulated within a hydrogen-bonded



10

host dimer. Three of the eight isostructural series are represented by sets of monomeric complexes (all crystallizing in space group $P2_1$ but with distinctly different unit cell dimensions), while the remaining five isostructural series occur in P1, $P2_1$, C2. and $C222_1$ and are based on distinct modes of packing of dimeric complex units. Reference PXRD patterns for these and other isostructural series of cyclodextrin inclusion complexes have been generated. and their utility in identifying new complexes has unequivocally been demonstrated.[24] Shown in Fig. 2 is an empty β-cyclodextrin dimer that occurs in the isostructural series in space group $P2_1$, a cutaway view revealing the topology of the channel available for guest accommodation and channel occupation by two different guests in this series.[25] Assignment of a new inclusion compound to a particular isostructural series using PXRD is valuable. because this immediately defines the host arrangement as well as the void topology.

Isostructurality–Reactivity Correlations

Although isostructurality of inclusion compounds is frequently identified, published accounts of its role in reactivity (e.g., formation. thermal decomposition, selective enclathration, guest exchange) are generally lacking. Several topical aspects of isostrucrurality are illustrated by the following recent case studies.

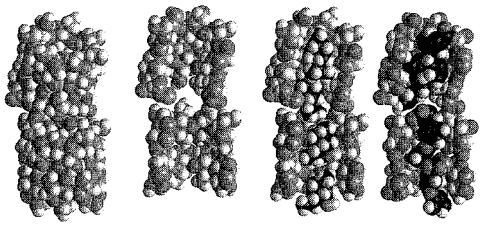


Fig. 2 Space-filling representations of (from left to right): empty β-cyclodextrin dimers, a sectioned view showing the empty channel. and sectioned views showing channel occupation by (L)-menthol and (R)-fenoprofen guest molecules in the isostructural clathrates. (Prepared from data in Ref. [25].) (View this *art in color at www.dekker.com.*)

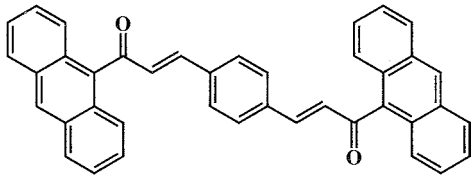
Isostructural clathrates based on certain metal molecular complexes display different thermal properties.[11] For the isostructural series $[MPy_4(NCO)_2]\cdot 2Py$, M=Mn–Zn,Cd, the thermal stability order of the first four members is Mn<Fe<Co<Ni, and they desolvate to give the host phase $[MPy_4(NCO)_2]$. The Cu clathrate, however, loses all four moles of pyridine in a single step, with no subsequent evidence for the host phase, while the Cd clathrate shows intermediate behavior. sometimes revealing the host phase during incongruent melting of the clathrate. Consideration of similar trends occurring in related series led to the conclusion that the thermal stabilities of these clathrates depend on those of the coordination bonds in the host molecule and therefore upon the nature of the metal center. Only in cases where the host phase is sufficiently stable to remain intact during all processes is clathrate stability governed by host–guest complementarity.

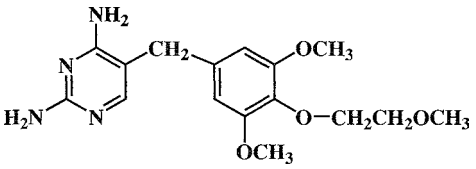
Nonuniform behavior during therinal decomposition was also reported for isostructural organic inclusion compounds. The "wheel-and-axle" host **11** forms isostructural clathrates $H\cdot(THF)_2$ and $H\cdot(1,3\text{-dioxolane})_2$, in which one set of guest molecules is sandwiched between host phenyl rings.[26] Thermal desolvation of the clathrates is a one-step process, but despite the higher volatility of the pure solvent THF, the onset temperatures for desolvation are 116 and 87°C, respectively. It was argued that in the THF clathrate, there is net stabilization due to attractive host–guest π···HC(methylene) interactions that outweigh the π···O(ether) repulsive interactions. The reverse is obtained for the guest 1,3-dioxolane with the larger complement of oxygen atoms, accounting for the lower stability of its clathrate phase.



11

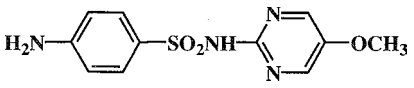
Host–guest hydrogen bonding differences underlie the anomalous thermal stabilities of the isostructural clathrates $H\cdot(MeOH)_{0.5}$, $H\cdot(EtOH)_{0.5}$, and $H\cdot(H_2O)_{0.67}$, where H=tetroxoprim **12**.[27] These likewise desoivate in a single step with onset temperatures in the order $t(H_2O)<t(EtOH)<t(MeOH)$, which is unexpected in view of the

relative volatilities of the guests. X-ray studies subsequently showed that the guest –OH group in MeOH acts as both donor and acceptor in hydrogen bonding to the common host framework, whereas for EtOH, the hydroxyl group acts as donor only. In the hydrate, guest disorder and low partial occupancy account for the weakest host–guest interactions. On the other hand, normalized enthalpy changes for desolvation increase in the order H_2O<MeOH<EtOH relative to the enthalpies of vaporization of the pure solvents. This was attributed to the increasing energy required to effect diffusion of guest molecules of increasing steric bulk through the transforming solid phase.



12

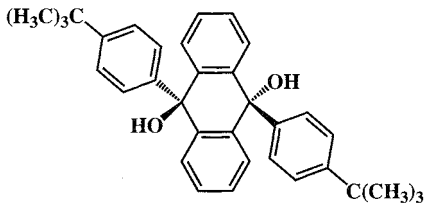
In contrast to the above cases. uniform behavior was observed for the thermodynamics as well as the kinetics of desolvation of the system shown in Fig. 1, namely, the isostructural 1:1 clathrates of 5-sulfamethoxydiazine (SMD) 13 with chlorofom, THF, and 1.4-dioxane as guests.[2] This was ascribed to the presence of uniformly weak host–guest interactions within the identical guest-filled cavities of the SMD framework and the similarities in guest steric bulk. These clathrates yielded the same SMD polymorph on desolvation.



13

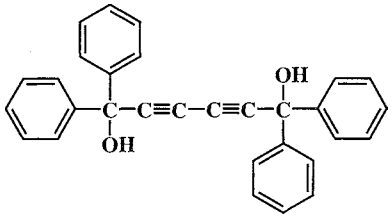
The question of the influence of isostructurality on the identity of the polymorph resulting from clathrate desolvation is an important one. because this process is a potential route for obtaining new polymorphs. One example is cited here, namely. that of gossypol 9 for which each of six isostructural groups of tubulate clathrates yields a distinct polymorph on desolvation.[23]

Unusual control of host–guest stoichiometry in isostructural clathrates of mixed guests was recently reported.[28] The diol 14 forms isostructural clathrates H·4A and H·4B (A=dimethylformamide, B=dimethyl sulfoxide). Investigation of the selectivity of H in mixtures of A and B spanning the entire concentration range $0 \leq x_A \leq 1$ yielded the stepwise competition profile shown in Fig. 3, leading to isolation of three intermediate clathrates H·3A·B, H·2A·2B, and H·A·3B, which are isostructural with those containing the pure solvents.

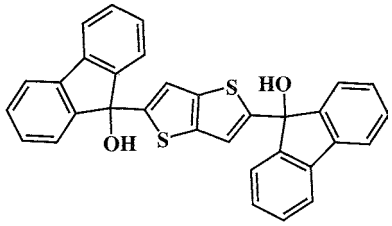


14

Exchange of similarly sized guests molecules should be facilitated if they form isostructural inclusion compounds with a particular host. This was demonstrated using diol 15, which forms isostructural clathrates H·2G [G=tetrahydrofuran (THF) and thiophene].[29] The exchange was carried out by exposing a powder of H·2THF to thiophene vapor in a closed system and monitoring the products periodically by the DSC technique. The facility of guest exchange was ascribed to the isostructurality of the clathrates and the fact that their computed lattice energies are comparable. The presence of apohost could, however, be detected during the exchange process. Guest exchange via gas–solid contact also occurs in isostructural clathrates of 16 with compositions H·$(EtOH)_2$, H·$(n\text{-PrOH})_2$, and H·$(i\text{-PrOH})_2$.[30] These clathrates contain an isostructural host framework with the guests located in channels. Exposure of, e.g., H·$(EtOH)_2$ to *n*-PrOH vapor results in gradual, but complete: replacement of ethanol by n-propanol. In this system, guest exchange does not proceed via the apohost, because pure H does not form these clathrates by a gas-sorptive mechanism. Guest



15



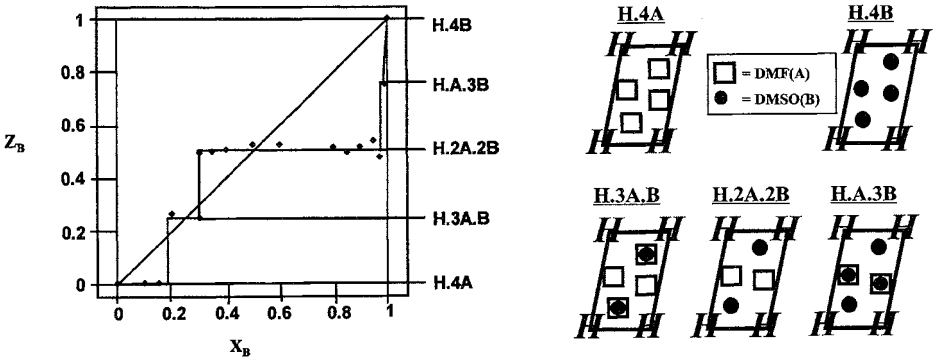


Fig. 3 Left: Results of competition experiments. The symbol X_B represents the mole fraction of Guest B in the liquid mixture and Z_B that of Guest B enclathrated in the inclusion compound. The diagonal line represents zero selectivity. Right: The five isostructural species isolated. H represents the host molecule (on a center of symmetry), and guest disorder is implied in H.3A.B and H.A.3B. (From Ref. [28]. Reproduced by permission of the Royal Society of Chemistry.)

elimination was also observed in this system. Recrystallization of host **16** from MeOH does not yield an inclusion compound but rather a polymorph of the host. Accordingly, when the three clathrates containing ethanol and the propanol isomers were exposed to methanol vapor, guest-free host solids resulted in all cases. An explanation for guest elimination is that while MeOH molecules are able to enter the crystals and displace the respective guests, their small size prevents them from stabilizing the wide channel (originally "designed" for larger guest molecules), and the structure collapses to that of the apohost.

The examples above serve to illustrate that both uniform and diverse behaviors may be observed in different series of isostructural inclusion compounds. In the latter case, anomalous behavior can often be traced to subtle host–guest interactions.

CONCLUSION

The occurrence of an isostructural series of inclusion compounds is informative, indicating the structural integrity of a particular type of host array but also reflecting a degree of flexibility to accommodate small to moderate structural modifications in the guest. This information can be carried over to the design of analogous host systems.

The finding that a new inclusion compound has an isostructural counterpart is readily achieved by the PXRD technique and represents an enormous return in terms of structural information, because it immediately defines the host substructure and the topology of the voids. This is useful for crystal structure solution of the new species by either single crystal x-ray diffraction or high-resolution PXRD. Systematic investigation of the physical and chemical properties of isostructural inclusion compounds can reveal novel phenomena in supramolecular chemistry that have practical implications for crystal engineering and polymorphism.

Kinetics of Complexation

Donal H. Macartney
Queen's University, Kingston, Ontario, Canada

INTRODUCTION

While generally overshadowed by structure determinations and the measurements of thermodynamic stability constants, the determination of rate constants and activation parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta V^{\ddagger}$) for the assembly of supramolecular host–guest complexes in solution provide vital information in understanding the properties of these systems.[1,2] These studies, which began in the early 1970s involving alkali metal ion complexation by crown ethers and cryptands, were extended in more recent years to include anionic and neutral guest molecules in a myriad of natural and synthetic hosts. Using a variety of physical and spectroscopic techniques, through kinetic investigations of host–guest formation and dissociation reactions, as a function of temperature and pressure, several reaction mechanisms in operation were identified. Extensive compilations of rate and activation parameters for host–guest complexations. along with the corresponding thermodynamic stability constants. regularly appeared in the literature.[3]

MECHANISMS

The ligand exchange and substitution reactions of the first coordination sphere of transition metal ions with unidentate ligands, with rate constants that span close to 20 orders of magnitude (10^{-10}–10^{10} s^{-1}), were well studied and are understood in terms of a range of mechanisms from purely dissociative (D), involving an intermediate of lower coordination number, to purely associative (A), with an intermediate of higher coordination number.[4,5] In a majority of ligand substitution reactions, no such intermediate is present, and a concerted interchange (I) mechanism (Eigen–Wilkins mechanism[''])>with dissociative (I_d) or associative (I,) activation, is operating. For the multistep complexation reactions of metal ions with polydentate acyclic and macrocyclic ligands, the rate of the reaction and the position of the rate-determining step in the overall mechanism are dependent on Iigand properties such as acyclic versus cyclic. the presence and placement of strong donor atoms, and the degree of substitution and flexibility of the chains.[5,6] While a flexible acyclic tetraamine permits a facile stepwise substitution of coordinate aqua ligands on a copper(II) ion, for example, the increased rigidities of the corresponding saturated tetraazamacrocycle and aromatic porphyrin ligands result in decreases of two and eight orders of magnitude, respectively, in complexation rate constants.[5,6]

For the complexation of guests by more elaborate macrocyclic ligands with preformed three-dimensional cavities, such as crown ethers, cryptands, calixarenes, etc., the Eigen–Wilkins mechanism was modified slightly to give the Eigen–Winkles mechanism.[7] In the latter mechanism, shown below (Eqs. 1 and 2), the macrocyclic ligand may undergo required conformational changes prior to the complexation process. With cryptands, for example, equilibria between *endo–endo*, *endo–exo*, and exo–exo conformers exist, with *endo–exo* species (C) being reactive toward the solvated metal ion (MS^+). A preassociation of the metal ion and the macrocycle generates a solvent-separated complex (M^+--C), from which the first metal–ligand bond formation leads to an ''exclusive'' complex, in which the metal ion is outside the macrocyclic ring. The formation of the remaining bonds between the cation and the ligand donor atoms yields the ''inclusive'' complex. $(MC)^+$, in which the metal ion resides inside the ring:[1,2]

$$*C \rightleftharpoons C \tag{1}$$

$$MS^+ + C \underset{k_{-0}}{\overset{k_0}{\rightleftharpoons}} M^+ \text{--} C \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MC^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (MC)^+ \tag{2}$$

The transformation of M^+--C to $(MC)^+$ in Eq. 2 may be further divided into individual elementary steps, $MC_{i-1}{}^+ \rightarrow MC_i{}^+$, representing the successive replacements of the solvent molecules associated with the cation by the donor atoms of the ligand.[8] As with ligand substitution reactions on transition metal ions, there are two limiting hypothetical mechanisms: dissociative and associative.[1,2] The first mechanism is a dissociative or pseudomonomolecular process with consecutive dissociation (Eq. 3) and recombination (Eq. 4) steps:

$$(MC)^+ \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} M^+ + C \tag{3}$$

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012657

$$(M)^{+*} + C \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (M^*C)^+ \quad (4)$$

The second is an associative or bimolecular exchange reaction in which the dissociation of the macrocyclic complex is initiated by a free metal cation M^{*+} present in excess (Eq. 5). This was also identified as the metal cation interchange mechanism and assigned the symbol I_M.[9]

$$(MC)^+ + M^{+*} \overset{k_2}{\rightleftharpoons} (M^*C)^+ + M^+ \quad (5)$$

$$\begin{aligned}(MC)^+ + M^{+*} &\rightleftharpoons [M^+ - - C - - M^{*+}] \\ &\rightleftharpoons (M^*C)^+ + M^+\end{aligned} \quad (6)$$

An associative exchange, accompanied by large negative entropies of activation, is primarily controlled by changes in the conformation of the macrocycle with a concerted decomplexation of one cation and partial complexation of the second cation (Eq. 6).[10]

A third mechanism, a ligand associative mechanism (Eq. 7). may be applicable to systems where a 1:2 guest:host stoichiometry is important:[1]

$$(MC)^+ + C^* \rightleftharpoons (MC^*)^+ + C \quad (7)$$

The mechanisms shown above do not consider the possibility of ion pairing between the metal ion and the spectator anion, a feature observed in relatively nonpolar solvents.[1] In solvents of low dielectric constant, the metal ion species available for complexation is not a lone solvated MS^+ cation but rather a solvated ion pair MS^+X^-. In solvents with a low Gutmann donor number. the solvent competes poorly for positions in the first coordination sphere of the metal ion. In these solvents. ion pairings of the counteranion with the metal cation (MX) and the resulting metal–host complexes become important. The complexation processes, such as the Eigen–Winkles mechanism (Eq. 2), must be modified to include ion pairing, where XM--C, XMC, and X(MC) are the solvent-separated, exclusive, and inclusive species. respectively:[1]

$$MSX + C \underset{k_0}{\overset{k_0}{\rightleftharpoons}} XM - - C \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} XMC \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} X(MC) \quad (8)$$

TECHNIQUES

There are two basic categories of kinetic experiments that may be performed on the complexation reactions in solution." [2,5] The first is the direct monitoring of the approach of the system to equilibrium. involving rapid mixing of reagents or perturbation of an existing equilibrium. The second type of measurement uses competitive methods in which excess of a competing guest or host is added, and the exchange process is monitored. The physical or spectroscopic technique most conveniently employed depends primarily on the time scale of the formation or dissociation of the guest–host complex in solution (see Table 1).[5,9–19] Three of the most commonly employed techniques for determining the kinetics of complexation of supramolecular entities are conventional and dynamic NMR spectroscopy,[10–12] a variety of stopped-flow"'' methods (conductivity,[14] variable pressure,"'' etc.), and ultrasonic absorption relaxation spectrometry.[16] Recently, techniques such as fluorescence[17] and EPR line shape analysis,[18] along with appropriate guest probes; were successfully applied to the kinetics of complexation and served to fill in the time domains that were not as easily accessible by the other techniques. Fluorescent probes, such as the fluorazophores[17] (with excited state fluorescence lifetimes in the 300–800 ns range), and persistent radical probes, such as benzyl tert-butyl nitroxide,[18] are ideal for the submicrosecond time scales commonly associated with guest complexation of the macrocyclic hosts described herein.

CROWN **ETHERS** AND **CRYPTANDS**

The complexation reactions of alkali metal cations by crown ethers and cryptands generally exhibit competition between the dissociative (Eqs. 1 and 2) and associative (Eqs. 3 and 4) processes, with the preferred mechanism determined by the nature of the solvent and the temperature of the reaction.[10,19,20] In low dielectric solvents, such as nitromethane (DN = 2.7) an associative

Table 1 Some techniques for kinetic studies of guest–host complexation reactions in solution

Technique	Time domain(s)[5,17]	*References*
Classical mixing	$\geq 10^2$	[5]

NMR — dynamic line shape analysis	10^{-5}–10^{-2}	[10,11,19]
EPR	10^{-10}–10^{-5}	[18]
Ultrasonic absorption	10^{-11}–10^{-4}	[16]
Fluorescence	10^{-12}–10^{-6}	[17]

mechanism is generally preferred, while in higher dielectric solvents such as acetonitrile (DN = 14.1) the dissociative pathway is favored.[20] Similarly, at lower temperatures the associative process is dominant. with an increase in the temperature leading to a more competitive dissociative mechanism. This may be attributed to the importance of comformational changes of the ligand during the concerted partial decomplexation of one cation and the partial complexation of the second ion in the associative mechanism.[10] In the dissociative process. the solvation of the metal ion places a major role in the barrier to complexation.[20]

Cryptands are macrobicyclic or macrotricyclic hosts, of which the cryptands [221] and [222] have been the most widely studied. The reactions of cryptands with metal cations are generally slower than observed with crown ethers because of more extensive confosmational changes, and are slow enough to allow for the use of stopped-flow kinetic methods.[14] The mechanism of the complexation reactions of cryptands depends on the natures of the cryptand, the cation and the solvent. With alkali earth cations, for example, a three-step mechanism is reported involving an initial change in the conformation of the metal-free host (*exo–exo* to endo–endo), followed by a slow external binding of the cation and a slower conversion to internal binding in the host cavity.[14] For cryptands, the thermodynamic stability constants correlate quite strongly with the dissociation rate constants, with each dependent on the structure of cryptand, the number and type of macrocycle donor atoms, and the nature of the metal ion.[21,22] It is also observed that an increase in the solvent dielectric constant results in an increase in the magnitude of k_d (decrease in K), with k_f being much less sensitive to changes in the nature of the solvent.

CYCLODEXTRINS, CALIXARENES, AND CUCURBITURILS

Cyclodextrins (CD) are naturally occuring toroidal-shaped cyclic oligimers of commonly six (α-CD), seven (β-CD), or eight (γ-CD) a-D-glucose possessing a hydrophobic interior cavity with hydroxyl-rimmed portal~.'They are capable of including a variety of guest molecules. and the kinetics of the complexation and dissociation of host–guest systems was widely investigated using many different techniques. While in general the inclusion of the guest proceeds rapidly (10^7–10^9 M^{-1} s^{-1} for many small anions and organic guests[18,23,24]), some complexation reactions are significantly slower. For the complexation of many guests in cyclodextrins, such as the well-studied aromatic azo dyes (L), a two-step mechanism is evident,[25] with the formation of a transient complex (CD·L) followed by relaxation to the final form of the guest–host speciec (CD·L), as in Eq. 9:

$$CD + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CD \cdot L^* \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CD \cdot L$$

The technique of variable-pressure stopped-flow kinetic studies, of great benefit in mechanistic investigations of ligand substitution reactions of transition metal complexes,[4,5] was recently applied to complexation reactions of α-CD by diphenyl azo dye guest molecules.[15] The inclusion of the dye in α-CD. with the sulfonate group passing through the wide rim exclusively, proceeds in the two steps, as above (Eq. 9). The rapid first step is attributed to the formation of an encounter complex between the dye and α-CD and results in partial desolvation of the sulfonate head group of the dye and a corresponding negative volume of activation [$\Delta V_1^{\ddagger} = -24 - (-8)$ cm^3 mol^{-1}]. In the slower second step, as the guest moves further through the cavity, the head group interacts with two internal "activated" waters, and their expulsion from the cavity is delayed by the primary hydroxyls on the narrow rim [$\Delta V_2^{\ddagger} = -15 - (-2)$ cm^3 mol^{-1}]. A subsequent rehydration of the sulfonate group occurs as it emerges from the cavity. With more extended guest molecules, with bulky head groups, threading of the cyclodextrin by the guest leads to the formation of pseudorotaxanes (head groups not sufficiently bulky to prevent dissociation) and rotaxanes. The threadings of α-CD by 1,10-*bis*(trimethylammonium)decane (k_1 = 1.6 x 10^{-1} M^{-1} s^{-1} at 25°C) and 1,10-*bis*(trimethylphosphonium)decane (k_1 = 2 x 10^{-7} M^{-1} s^{-1} extrapolated to 25°C) proceed slowly, with the latter guest forming rotaxanes, by the "slippage" mechanism. only above 50°C.[26]

Calix[*n*]arenes are synthetic macrocyclic oligomers formed from the condensation of phenol and formaldehyde (*n* is most commonly 4, 5, and 6). The calixarenes are easily modified on the phenolic lower rim to permit versatile recognition of cationic, anionic. and neutral guests,[1–3] with the presence of aromatic groups in the cavity walls allowing for cation–π interactions to contribute to guest–host binding of metal and organic cations. The cavities of calixarenes are less rigid than the cyclodextrins and the calix[4]arenes, for example, exist in four conformations with the interconversion of the conformers proceeding via the partial cone structure. The alkali metal cations form a complex exclusively with the cone conformation of the tetramethoxy calix[4]arenes, with cation exchange following a dissociative mechanism.[27] The low stability constants of these calixarenes, compared with crown ethers or cryptands, originate mainly in a poor preorganization of the ligand for the complexation.[1] The sulfonated calix[5]arene and calix[6]arene are exceptional uranophiles in terms of their stability

constants ($\approx 10^{19}$ M^{-1}) and selectivity for the UO_2^{2+} cation.[28] The complexation reactions. however. are very slow, owing to the energy barrier between the initial exo (the UO_2^{2+} lies flat on the calixarene rim) and final *endo* conformers of the complexes.

Cucurbit[*n*]urils (CB*n*, *n* = 5–10) are macrocycles, prepared by the condensation of gycoluril and formaldehyde under acidic conditions, which were only recently studied in detail.[29] The rigid cavity of CB6 (5.5 Å wide by 6 Å in depth), which is capable of including nonpolar guests through van der Waals interactions, is accessible through 4 Å portals, surrounded by two rims of six carbonyl oxygen atoms capable of complexing cations through hydrogen bonding and ion–dipole interactions. To date, kinetic studies of the complexation of cucurbiturils were limited to CB6 and a series of alkyl- and arylammonium cations; with a dissociative mechanism operative.[29,30] The rate constants for the formation of inclusion complexes with alkylammonium cations [e.g., $\geq 10^6$ M^{-1} s^{-1} for cyclopropylmethylamine[29] versus 8.8×10^{-4} M^{-1} s^{-1} for cyclohexylmethylamine[30] at 40°C], but not the thermodynamic stability constants. correlate with the molecular diameters of the cations and are slower than the corresponding complexation reactions with cyclodextrins and calixarenes, which possess larger and unobstructed openings to their cavities. The rate constants for the reaction of CB6 with cyclohexylmethylamine exhibit a pH dependence attributed to two inclusion pathways. The unprotonated amine guest is able to pass directly through the portal into the cavity. whereas the protonated ammonium guest initially forms an association complex with the CB6, which positions the methylcyclohexyl group away from the portal, necessitating a slower. rate-determining "flip-flop" of the group through a distorted portal. With the advent of new methods for synthesizing and separating the larger CB7 and CB8 hosts (analogous to β- and γ-CD, respectively). kinetic studies of the cucurbiturils with a wider range of guests are warranted.[31]

LARGE-CAVITY ENCAPSULATING HOSTS

The efforts to synthesize host molecules with larger. noncollapsing cavities for specific guest molecules resulted in the production of several families of hosts, including the cavitands, hemicarcerands. carcerands, cryptophanes, and calixarene capsules. etc.[32] These molecules have well-defined portals for entry and exit of the guest molecules and the possibility of functionalization of the cavity interior to control the orientation and fluxionality of the guest, and the binding forces for complexation. While the cavitands provide no steric hindrance to complexation and decornplexation processes and the carcerands permanently entrap guest molecules, the hernicarcerands contain equatorial portals for guests to slowly enter and exit the host cavity.[32] In addition to the numerous modes of noncovalent interactions between guest and the interior of the host cavity, an additional form of binding termed "constrictive binding" was coined by Cram.[33] Defined as the difference between the activation energy for dissociation and the free-energy of complexation (intrinsic binding), the constrictive binding free-energy term represents the physical barrier to escape of the guest from the hemicarceplex. Constrictive binding of guests to the hemicarcerands is comparable to the process of "slippage" described above for the assembly of cyclodextrin pseudorotaxanes.[27]

The majority of kinetic studies was performed on hemicarcerands and related molecular capsules in which the two halves of the host are joined by variable bridging units. The rate-determining processes of the entry and exit of guests in hemicarcerands rely on conformational changes in the bridging units to open and close the "gates," respectively.[34] Varying the number, length, flexibility, and composition of the bridging units allows for control of the shapes and sizes of the gates, and this may be correlated with the decomplexation rate constant~.~'" ~Houk proposed two gating processes, a '-sliding door" (increased separation between the bridges) mechanism and a "French door" (bridge components swing open) mechanism, to account for the conformational changes involved in guest complexation and decomplexation.[36] For hemicarcerands containing o-xylyl gates, the "sliding door" pathway is important for all guests, while the contribution of the "French door" mechanism is dependent on the steric nature of the guest. More recently, Stoddart and Cram designed dynamic hemicarcerands containing diimine bridges capable of reversible formation/hydrolysis allowing a "bar-opening1 bar-closing" mechanism to provide entry and escape (with a decrease in the decomplexation half-life by an order of magnitude) of a fesrocene guest.[37]

CONCLUSION

Several mechanisms, based on dissociative and associative limits, were identified for the guest complexation reactions with a variety of cyclic host molecules. Kinetic studies have considerable potential for providing greater insight into the details of these mechanisms. Further investigations of the hosts described above and others, using a wider range of guests, will allow for a greater understanding of the processes that lead to the selective formation of the guest–host complexes and the forces that hold them together. The use of variable-pressure kinetic methods and the advent of new guest probes for accessing

specific time domains. along with continued design and syntheses of new hosts and guests, will assist in this ongoing endeavor.

Lariat Ethers

George W. Gokel
Washington University School of Medicine, St. Louis, Missouri, U.S.A.

INTRODUCTION

Lariat ethers *are crown-ether derivatives in which one or* more *side arms is appended to the macrocycle. The term* ''lariat *eiher" was coined in* 1980,[1] *but a number of macrocyclic* compounds *that possessed side arms were prepared* previously.[2] *The purposes inherent in these earlier* preparations *varied considerably. The early development of lariat ethers had a specific goal.*

Crown ethers readily complex a variety of metals. The binding of spherical cations generally occurs within the hole of the crown ether. The latter is "doughnut" shaped, i.e., *essentially two-dimensional with a central void. Entry and egress of the cation are sterically unencumbered. The complexation process may be represented as follows: crown + cation* $\leftrightarrows$ *complex. The position of the equilibrium* is *given by the equilibrium constant, K. sometimes written as* K_{eq}. *The value of* K *depends on the two rate constants that characterize the forward and reverse rates symbolized by the arrows. Thus,* $K = k_f/k_r = k_1/k_{-1} = k_{complex}/k_{release}$. *Typically, the rates for crown* complexation *and release are fast. Thus, the equilibrium or binding constant (also written as* K_S) *may be modest. but cation complexation and release* may *both be rapid. For three-dimensional* complexing *agents such as cryptands: the cornplexing and release rates are typically slower. As a result, the binding constant is greater for cryptands than for crowns. but the* dynamics *of the process are typically slow.*

The transport of cations across membranes requires binding at the first interfacial boundary. diffusion of the complex *across the barsier, and release of the cation at the other interface.* If *cation release is slow, transport will be inefficient. The natural ionophore valinomycin binds* K^+ *selectively* and *transports it effectively.* Valinomycin *is a* cyclododecadepsipeptide. It *is a 36-membered ring comprised of amino and hydroxyacids. It seems to be* too *large to effectively* complex K^+, *but* it *does so by folding over to* assume *the shape of a tennis ball seam. Thus,* K^+ *is solvated three-dimensionally by the host, but the* complexation *and release processes remain dynamic owing to the macrocycle's inherent flexibility.*

Lariat ethers were designed to incorporate a *macroring and* one *or more side arms. The crown ether was expected to provide binding and some selectivity. The flexible side arm was designed to augment the complexation by positioning a donor group in a third dimension. This would* mimic valinomycin *in the sense that the host is flexible but it can complex the cation in a three-dimensional arrangement. Because the side-armed* macrocycles *resembled a looped rope in overall shape, and because the ring and side* arm *could "rope and tie" the cation: the* name *"lariat'' ether seemed appropriate.*

When more than one arm *was present, the Latin word for arm,* i.e., *bracchium, was used in the name.* Two-*armed and three-armed lariat ethers were called* bibracchial *and tribracchial lariat ethers, respectively. These names were shortened to* BiBLEs[3] *and* TriBLEs.

Related complexing agents for inorganic ions were also developed in the 1970s and 1980s. These compounds generally contained nitrogen atoms as donors and were often described as "macrocycles having pendant arms." Although coinage and transition metals were the complexation *targets: many of the concepts are* similar *to those developed in the lariat ether area. Kaden reviewed this work in* 1984.[4]

SYNTHETIC ACCESS TO LARIAT ETHERS

Flexibility and *rigidity are important elements of the lariat ether concept,* and *each* may *be used to advantage, depending on the situation. The means by which the side arms are attached is, therefore, an important consideration. For a compound such as 18-crown-6. the side arm can be attached only at carbon. The carbon junction is inherently inflexible. because carbon is noninvertable. Carbon is chiral so attachment of a side arm to the* macroring's *ethyleneoxy unit introduces stereochemical issues. The lower flexibility and the fixed stereochemistry may be desirable properties in certain situations.*

These two issues can be circumvented, however, by replacing one ring-oxygen by nitrogen and attaching the side arm *to* it. *Nitrogen undergoes facile inversion. so* the *side-arm stereochemistry is not fixed. Further, side arms attached at nitrogen have higher overall mobility than do arms attached at carbon. The attachment atoms were called "pivots," and C- and N-pivot lariat ethers are shown in Fig.* 1.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012706

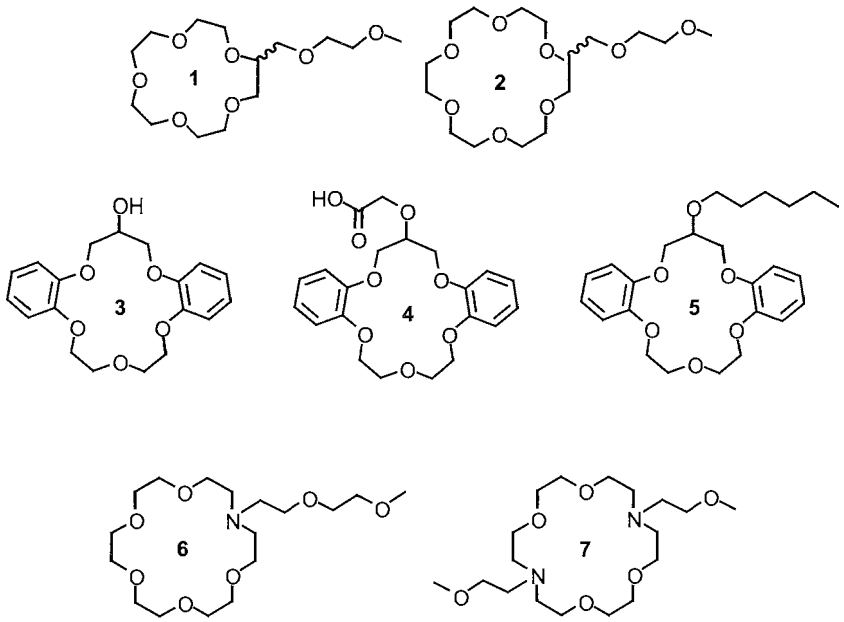

Fig. 1 Examples of one- and two-armed lariat ethers. The wavy line in structures 1 and 2 indicates that the sidearm may occupy isomeric positions.

Two types of C-pivot compounds were prominent during the past decades. These are shown in Fig. 1 as compounds 1–2 and 3–5. Both classes use glycerol as the pivot element, but in 1 and 2, the side arms are attached to the 1- and 2-positions, respectively. The former group was developed independently by Okahara and Gokel and their coworkers. The coinpounds represented by the 16-crown-5 structures 3–5 were studied extensively by Bartsch and his colleagues. The importance of the glycerol subunit for K^+ binding was recently demonstrated in the 16-crown-5 case.[5]

The earliest work by Okahara and colleagues involved cornpounds that possessed side arms but did not necessarily contain donor groups.[6] Okahara also developed approaches to N-pivot compounds at an early stage[7] and to C-pivot compounds in which the side arms bore geminal substituents.[8,9]

The syntheses of C-pivot molecules are generally accomplished by opening the epoxide residue of epichlorohydrin with an aliphatic alcohol or phenol. This affords a substituted diol of the type RO–CHOH–CH_2OH. Reaction of the diol with, for example, tetraethylene glycol ditosylate, TsO($CH_2CH_2O)_4$Ts, under basic conditions will afford 15-crown-5, in which one ring carbon is substituted by CH_2OR. The carbon to which the side arm is attached is chiral. Both enantiomers are typically formed. Pentaethylene glycol. which would lead to 18-crown-6 derivatives, is less readily available than is tetraethylene glycol, the 15-crown-5 precursor. This and the stereochemical issue limit the versatility of carbon-pivot molecules of this type.

Bartsch and coworkers developed an alternate approach to C-pivot lariats. Epichlorohydrin is treated with a *bis*(phenol) in aqueous base to give lariat ethers in which a hydroxyl group is attached to the crown-ether ring.[10] This is a single-step process in which one phenoxide opens the epoxide ring to form an ether, while the epoxide reforms on the other side. The newly formed three-membered ring is then opened by the other phenoxide to form the macrocycle **(3).** The hydroxyl group may be capped by an alkyl substituent **(5)** or by another functional group (4). Nearly 50 examples of this family were recently reported by Bartsch and coworkers.[11] Synthetic and conformational studies on asymmetric dibenzo-16-crown-5 derivatives were undertaken by Kim, Bartsch, and Ramesh.[12] This group also described synthetic approaches to a large family of dibenzo lariats having pendant *N,N*-dialkyl oxyacetamide residues.[13] Marchand and Chong reported "cage-functionalized diaza(17-crown-5) ethers" that were used to complex alkali metal picrates (see below).[14]

One-, two-, and three-armed derivatives of azacrown ethers were formed by relatively straightforward synthetic approaches. Alkylation of diethanolainine. HN(CH_2CH_2 OH)$_2$ with an alkyl or benzyl group gives RN(CH_2CH_2 OH)$_2$. Treatment of RN(CH_2CH_2OH)$_2$ with TsO(CH_2-$CH_2O)_3$Ts or TsO($CH_2CH_2O)_4$Ts gives an alkylaza-15-crown-5 or -18-crown-6 derivative.

The molecule is flexible because of nitrogen's rapid inversion; this also obviates the potential stereochemical issue.[''''] A single-step condensation affords two-armed, diaza-18-crown-6 derivatives such as 7.[3] An alternate approach affords 18- and 15-membered ring BiBLEs.[16]

Although the family of simple lariats was developed early, numerous variants were reported that were designed for a variety of purposes. The N-(2-methoxy-I-naphthy1)-methyldiaza-18-crown-6 BiBLEs were produced by templated reactions and complexation was confirmed by x-ray analysis.[17] Pyridine side chains[18] and 8-hydroxyquinoline[i''''] side chains were incorporated. and binding strengths and selectivities as well as chromophoric properties were studied. In another study, five single-armed. chiral D-glucose-substituted aza-15-crown-5 ethers having a phosphonoalkyl side chain were developed for potential use in phase-transfer catalysis.[20]

EVIDENCE FOR SIDE-ARM PARTICIPATION

Early studies in the lariat ether area required confirmation of the design principles. There were several key questions concerning side-arm participation. The first was simply whether or not the side arm(s) interacted with the ring-bound cation in accord with the design. Second, if the side-arm interaction occurred. to what extent was binding enhanced? Third, was there evidence that this arrangement was more flexible than the corresponding cryptand?

Confirmation that the side arm participated in complexation when appropriately placed was obtained by comparing the complexation strengths of 8 and 9. Sodium cation is bound in the center of the macrocycle. The side arm of 8 or 9 can reach over the ring, but only 8 has an oxygen donor (methoxy) positioned appropriately to interact. The equilibrium binding constant (K_S) for Na' by 15-crown-5 at 25°C in methanol solution is 1860. Because complexation constants can be large. especially in less-polar solvents, they are usually expressed as decadic logarithms. Thus, $\log_{10}K_S$ for this reaction is 3.24. The binding constant for 8 is 3.27, or no different from 15-crown-5. This appears to contradict the concept of side-arm participation. However, the 4-isomer (9) has a binding constant of only 2.90, identical to the 3-isomer (not shown). It was concluded[1] that although the presence of the side arm engendered some hindrance, a side arm having an appropriately placed donor enhanced binding.

An alternate demonstration of side-arm interaction involved ammonium cation, NH_4^+. In this case: the more flexible azacrown compounds were used. Molecular models suggested that when tetrahedral ammonium ion formed three hydrogen bonds to macroring donors. the fourth N–H bond would be perpendicular to the ring's plane. The three N–H to macroring bonds would be optimal for 18-membered crowns and poorer for the smaller 15-membered rings. Models suggested that the fourth N–H bond would interact optimally with the distal oxygen when the side arm was $-(CH_2CH_2O)_2CH_3$. This is shown in Fig. 2. All of the required lariat ethers were prepared. and these expectations were confirmed by measuring ammonium ion bisiding constants.[21]

Convincing as these results were, solid-state structural evidence was sought for confirmation.[22] Two structures are shown in Fig. 3. At the top is the KI complex of *N*-(2-methoxyethyl)aza-18-crown-6, abbreviated $CH_3OCH_2CH_2\langle N18)$. The potassium cation is 8-coordinate and fonns a hexagonal bipyramid. One apical position is occupied by the side-arm oxygen and the other by iodide anion. The lower structure is of the NaI complex of *N,N'-bis*(2-hydroxyethyl)-4,13-diaza-18-crown-6 ($HOCH_2CH_2\langle N18N\rangle CH_2CH_2OH$). In this case, Na^+ is 8-coordinate, and the side arms interact with the bound cation from the same side. Iodide anion. an excellent donor. is excluded from the cryptate-like solvation sphere.

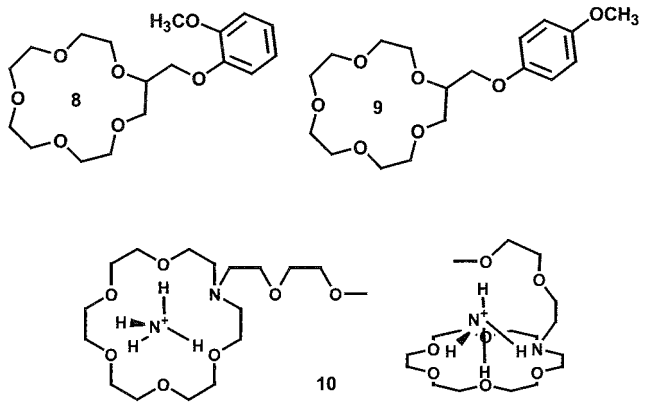

Fig. 2 Lariat ether compounds used to demonstrate side-arm participation in guest binding.

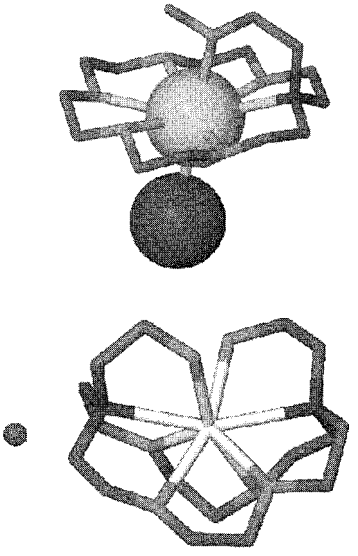

Fig. 3 Solid-state structures of 1- and 2-armed lariat ethers showing sidearm participation in cation complexation. (*View this art in color at www.dekker.com.*)

Numerous solid-state structures are available of 1- and 2-armed lariat ether compounds. Extensive structural data were obtained as part of an effort to demonstrate that side-arm participation occurred as inferred from solution studies.[23] More recently, structural data for the 16-crown-5, C-pivot lariats were reported. Liu and coworkers reported the preparation of a derivative of 3 in which the hydroxyl group (OH) was elaborated to OCH_2CH_2-OCH_3.[24] Data showed side-arm participation in binding for Na and Pb complexes.

The final issue of overall flexibility was addressed by use of NMR.[25] Longitudinal relaxation times (^{13}C-NMR, T_1) were determined for C- and *N*-pivot lariat ethers alone and in the presence of Na^+, K^+, and Ca^{2+}. Structural changes that occur when complexation takes place are reflected in the relaxation times. It was found that the macroring in C-pivot compounds became more rigid. suggesting a greater importance in cation complexation. The *N*-pivot compounds became more uniformly rigid, suggesting a nearly equal contribution to binding by ring and side arm(s). The dynamics of the side-arm interaction were also confirmed by ultrasonic relaxation studies.[26]

A single-armed lariat ether. N-heptylaza-18-crown-6, was crystallized as its *KSCN* complex. Although the side arm was aligned in a vertical arrangement, its lack of donors precluded a secondary donor interaction.[27] The two dodecyl side arms of *N,N'-bis*(dodecyl)-4,13-diaza-18-crown-6 were found not only to align but also to form an extended bilayer in the solid state when complexed to sodium cation. The bilayer formed could be correlated to the formation of liposomes by this compound in aqueous suspension.[28]

In recent work, x-ray crystal structures were obtained for La(III), Ce(III), and Pr(III) complexes of *N,N'-bis*(2-salicylaldiminobenzyl)-4,13-diaza-18-crown-6. The deprotonated host afforded a dianionic, 10-coordinate *syn*-side-armed arrangement for the cations.[29] Lariats were used as the experimental vehicle to demonstrate cation-x complexation with alkali metal ions.[30]

APPLICATIONS

The key difference in applications between crown ethers and lariat ethers is that the side chain(s) may possess residues that confer unique properties on the system. The crown ether continues to be important as a complexation site, but the chemistry of the molecule may actually be dominated by the side-arm substituents.

Complexation

The original goal in developing lariat ethers was to obtain a cooperative interaction between the ring and side arm to enhance binding strength and selectivity. For the aza-crown compounds. binding was dependent on the total number of donors rather than on their arrangement. *N*-(2-Methoxyethyl)aza-18-crown-6 ($CH_3OCH_2CH_2\langle N18\rangle$) contains one nitrogen and six oxygen atoms that can serve as donors to bind a cation.

The same number and types of donors are available in 12-, 15-, and 18-membered rings, which have three. two, and one side-arm donors, respectively. The binding profiles for there compounds are shown in Table 1 along with all-oxygen crowns. Nitrogen is a poorer donor for an alkali metal than is oxygen. Still, the Na^+ binding constants for all of the lariats exceed the values observed for the corresponding side-arm-free macrocycles. The

Table 1 Cation cornplexation constants determined in CH_3OH at *25°C*

Macrocycle	log K_S Na^+	log K_S K^+
12-crown-4	1.7	1.74
15-crown-5	3.24	3.43
18-crown-6	4.35	6.08
$\langle 12N\rangle(CH_2CH_2O)_3CH_3$	3.64	3.85
$\langle 15N\rangle(CH_2CH_2O)_2CH_3$	4.54	4.68
$\langle 18N\rangle CH_2CH_2OCH_3$	4.58	5.67

differences are generally less dramatic for K^+ binding, but side-arm enhancement of cation complexation is clear. Extensive binding studies were reported for N-pivot lariat ether compounds.[31]

Cation binding was also studied in detail for the 16-crown-5 family of *C*-pivot lariats. Inoue and coworkers studied the effects of donor groups in 1,4,7,10,13-pentaoxacyclohexadecane (16-crown-5), which lacked benzo substituents.[32] As with some other C-pivot lariats, it was found that although cation extractabilities were improved by the presence of a side arm, stability constants showed less effect. Similar mixed results were observed for 19-crown-6 derivatives.[33] A series of G-pivot [3_n-methylene-(3_n + 1)-crown-n (n = 5,6,7)] lariat ethers having an oxyquinoline as the side-arm donor was found to exhibit considerable cation selectivity. As might be expected, this was dependent on ring size and side-arm position.[34] Alkali metal, alkaline earth, and ammonium ion complexation selectivities were measured for nearly a dozen dibenzo-16-crown-5 compounds bearing a variety of side arms. These compounds were adapted for use in ion-selective electrodes.[35,36] Two studies reported lariat ethers that possess Ag^+ ion selectivity.[37,38] Bartsch recently reviewed metal ion separations accomplished by use of proton-ionizable lariat ethers.[39] Complexation thermodynamics were assessed for two-armed dibenzo-15-crown-5 lariats[40] and for azalariats.[41] A recent report described the complexation behavior of lariat ethers in supercritical CO_2.[42] Finally, urea complexation by lariat ethers has been studied.[43]

Mass spectrometry proved to be a fast and reliable method for assessing coinplexation by crowns when appropriate controls are done. This proved to be the case for lariat ethers as well, especially using electrospray (ES-MS) techniques.[44,45] The dibenzo-16-crown-5 compounds were the focus of these studies. Related compounds were examined by Brodbelt, Bartsch, and their coworkers using the ES-MS method.[46] In the latter case, selectivity data obtained in the gas and solution phases were compared. A combination of HPLC and ES-MS was proposed as a method for rapidly screening host metal-binding selectivities in various mixtures.[47]

Chromoionophores

Ionophores are compounds that transport ions. Compounds that have this capability and exhibit spectroscopic changes on binding are called chromoionophores. A cation is typically bound in the macroring that does not contain spectroscopically active groups. Fluorescent or UV-active side arms are positioned so that they may interact with the bound cation in a fashion that induces spectral change. Misumi,[48] Vögtle,[49] Takagi,[50] and Shinkai[51] reported chromogenic crown ethers at about the same time. Takagi and coworkers were especially important contributors in this area and reviewed it in 1984.[52] An example of an azalariat that exhibits complexation-induced UV shifts is shown as **11**[49] in Fig. 4. Recent chromoionophores include macrocycles having pendant phenanthridine units,[53] *N*-pivot lariats complexing luminescent Eu(II),[54] and 2,2′-bipyridine lariat calix crowns that complex Eu(III) and Tb(III).[55]

Chemical Switching

Chromogenic lariat ethers show cation-induced shifts upon complexation. The binding is often enhanced by

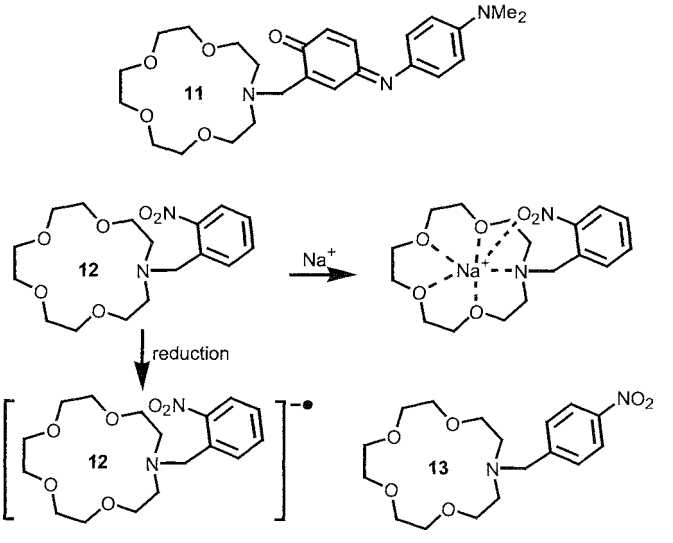

Fig. 4 *Lariat ethers with chromophonc and redox-switchable side arms.*

the side-arm interaction, but this is a benefit rather than a goal of the design. It is possible to use the side arm to enhance binding. Dibenzo-lariat 4 accomplishes this by loss of a proton. The carboxylate group may serve as a donor for the ring-bound cation when it is appropriately positioned. If the position is inappropriate for complexation, the carboxylate may still serve as an internal counterion.[39]

An alternate means for enhancing side arm binding efficacy is shown for **12**. The nitro group of **12** is positioned to interact with a ring-bound cation, whereas **13** is not. Some binding enhancement for **12** is expected, but nitro is a weak donor. When reduced to the nitrobenzene radical anion. however: the nitro group's binding potential is greatly enhanced. Moreover. complexation can be reversed on demand by oxidation. which restores the nitro group to its weaker. neutral state.[56]

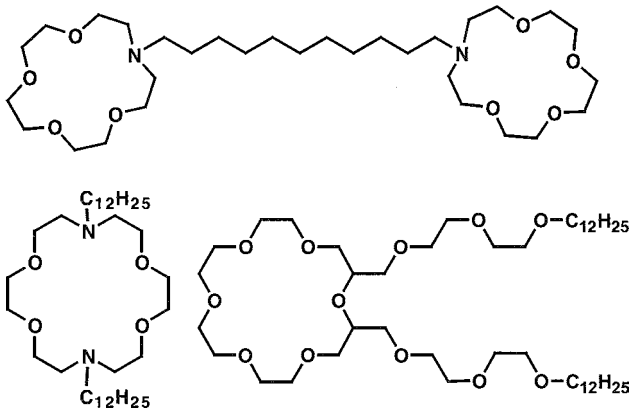

Fig. 5 Lariat ethers that form aggregates in water.

Membrane Formation

Crown ethers are polar and are known to interact effectively with water. When a hydrocarbon tail is appended. the lariat ether becomes amphiphilic. Typically. amphiphilic lariat ethers do not possess donor groups in the side arm (tail), as this would make the latter more polar. When a hydrocarbon tail of sufficient length is present. the lariats will organize when suspended in water. They may form micelles. vesicles. or other aggregates with structures that are more difficult to define. A miceile is typically a loosely organized. 100 Å structure in which the hydrocarbon tails interact with each other, and the head groups form the boundary by interacting with water. Micelles are usually small, dynamic structures of ill-defined size and shape. Vesicles (also called liposomes) normally have diameters greater than 100 Å and an aqueous compartment bounded by an amphiphile bilayer.

Vesicles may be characterized by light scattering, which gives the distribution of their sizes. by electron microscopy, and other methods. Once formed, vesicles will often be stable for significant time periods, although they may collapse or fuse to form larger structures. The membrane of a vesicle encloses space. so it is important to demonstrate encapsulation. Vesicles may be formed in the presence of a fluorescent dye such as carboxyfluorescein. Exchange of the aqueous solution in which the vesicles are suspended leaves only the dye present within the liposomes. If the dye is detected after rupture of the vesicles, it must have been encapsulated. Three examples of vesicle-forming lariat ethers are shown in Fig. 5.

A wide variety of vesicles (liposomes) were formed and characterized to varying degrees.[57] The factors that control whether micelles or vesicles form, what sizes will result, and how stable they will be are not completely understood. Much remains to be explored in this area.

Other **Applications**

As noted above, a goal of the lariat ether work was to develop compounds that might function in a fashion similar to valinomycin. A dozen crown ethers, including two 1.3-xylyl-21-crown-6 macrocyclic polyether 2-carboxylic acid lariat ethers, were prepared and tested in vitro for biological activity. Several of the compounds showed activity and are thought to be functional mimics of ionophore antibiotics.

Crown and lariat ethers formed the basis of several synthetic channel model systems. These involved multiple crown ethers separated by fixed spacers and macrocycles having flexible side arms. Polymers and peptides were also used as backbones to organize multiple crowns that inserted into phospholipid bilayers.[58]

Lariat ethers proved to be an effective vehicle for demonstrating alkali metal cation–π interactions. When either Na^+ or K^+ is bound in the macroring, interactions are possible with neutral side arms. Indole. benzene, and phenol were studied. because these arenes are present on the side chains of tryptophan, phenylalanine, and tyrosine. respectively.[30] Additional studies were reported of cation–x interactions between neutral double and triple bonds with these same alkali metal cations.[59] Lariat ethers were also explored as ion-regulated DNA cleavage agents. Monomeric propargylic sulfone-armed lariat ethers were found to cleave DNA. Modest increases in DNA cleavage efficiency were observed in the presence of Na^+ and K^+.[60]

CONCLUSION

The lariat ethers are a *growing branch of the crown ether family. The appended side arms may cooperate with the macrocycle or may perform important independent* functions. *The study of lariat ethers* is *an active area. and this is expected to remain the case* for *the foreseeable future.*

Layered Supramolecular Solids and Their Intercalates

George K. H. Shimizu
University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

The number of examples of functional extended solids based upon weaker interactions increased dramatically in recent years in the scientific literature. This is more of a reflection of a change in perception of the potential functionality of "soft" solids rather than any single chemical breakthrough. The predominant thinking in the past. certainly among inorganic chemists. equated the utility of a framework with its structural rigidity and thermal stability. The explosion of research in the domain of coordination assays yielded exquisite examples of extended metal-organic networks. In this research domain, the "Holy Grail' ` is largely regarded as a permanently porous solid with functionality beyond that offered by a zeolitic analogue, whether the enhancement is in respect to pore size,[1–3] chiral catalysis,[4] or tunability.[5] The cited recent works demonstrate these properties, however, this science is not yet at a stage of growth where these desirable qualities may be selected a priori from the components of a framework.

To continue along the same avenue of thought. that is, extended solids based upon weaker interactions. one arrives at frameworks that do not possess high thermal stability and are not rigid in their structures. These are solids based on weaker metal–ligand interactions or even noncovalent interactions. By the criteria of, for example, metal oxide chemistry, these compounds would be described as lacking potential utility. A different frame of reference is required for these "softer" extended solids. If one considers that a living animal relies upon weak interactions for its abilities to grow, think, and reproduce. the validity of these interactions in the construction of functional extended architectures becomes self-evident.

There are undoubtedly benefits to a solid with a more flexible structure. Prospects range from selective sorbents, which can be dissolved to liberate included guests, to networks. which swiich between distinctly different physical forms upon inclusion. To elaborate on the latter point. a flexible network may possess one form, where magnetic centers are in proximity, yielding a ferromagnetic response. This signal could then be lost upon guest inclusion as a result of conversion to a second structural form, either antiferromagnetic or simply paramagnetic.[6] Similar prospectus may be discussed for conductivity, optical activity. luminescence, or any other physical response that may be incorporated into a solid network.[7] Thus. extended solids based upon weaker interactions can be viewed as complements to highly robust inorganic solids, rather than replacements.

This short review deals with supramolecular intercalates. Supramolecular intercalates is a term open to considerable breadth of definition. Within the scope of this article. the author chose to focus on two-dimensional solids. based upon weak interactions, that demonstrate intercalation ability. An emphasis is placed on frameworks that demonstrate flexibility of structure and the benefits of such compounds. This short review is not meant to be comprehensive, as many systems that may fall under the broad umbrella of "supramolecular intercalates" were reviewed elsewhere.[8–14] This review is meant simply as an overview of some examples in this topical field that readily illustrate the potential of soft networks.

ORGANIC LAYERED SOLIDS AS HOSTS

Guanidinium Sulfonates

The most extensively studied intercalation solids based upon weak interactions are the guanidinium sulfonate (GS) frameworks of Ward et al.[14,15] These structures are assembled into undulating layers, describable as cross-linked ribbons: via the complementary charge-assisted hydrogen bonding between the NH_2 groups of guanidinium cations and the oxygen atoms of organosulfonate anions (Fig. 1). A structural comparison may be drawn between this family and metal phosphonates.[8] In metal phosphonates, a rigid and robust inorganic backbone serves as a scaffolding for a wide range of organic groups, the pendant group of the phosphonate. In a homophosphonate structure. space for guest inclusion is minimal due to the efficient packing of phosphonate R groups. One of the main assets of the GS system is that the guanidinium cation is considerably larger than a metal ion, and hence. at hydrogen-bonding distances. the sulfonate organic groups are situated in a inanner to welcome guest inclusion. Two framework types are typically observed in this family, a bilayer motif and a continuous layer, depending on the nature of the included guest and sulfonate R group. With

the skeleton being maintained by noncovalent forces, the solid has an inherent flexibility. In general, for the GS networks. this flexibility is manifested as ''accordion-like'' puckering of the cross-linked ribbons and ''turn-stile-like'' rotation of the organic pillars. This is a good recipe for a network capable of adjusting to accommodate a wide range of guest molecules. Indeed, the number of variations of host and guest in this family number in the hundreds. Remarkably, despite the dependence on weak interactions, in these numerous compounds. the basic structural unit persists. Recently, Ward reported GS inclusion frameworks that exhibit second harmonic generation.[16] The optical properties of the framework result from ordering guests within a polar channel resulting from ''banana-shaped'' sulfonate pillars.

The most significant feature of the GS family cannot be ascertained from any single compound. The body of work illustrates the role of subtle intermolecular interactions in dictating structure, as well as how a material can be tuned to exploit these features to advantage. A tantalizing prospect is that of a highly selective bulk separations agent, where the guest and host need only be partitioned between organic and aqueous phases for quantitative separation and recovery of all components. The extent of structural variation was pushed to a new extent with the recent report of tubular GS arrays formed.[17]

Secondary Ammonium/ Tricarboxylate Assemblies

Keeping with organic solids, Zaworotko et al. reported a series of intercalate complexes based upon hydrogen bonding between secondary ammonium cations and trimesate or trimellitate anions.[18,19] In these complexes, the tricarboxylate anions form a layer and are linked by hydrogen bonds to the protons of the dialkyl amsnonium salts. The organic moieties of the ammonium ion are projected above and below the hydrogen-bonded plane to ''pillar'' an interlayer region. Guest inclusion is highly dependent on the nature of the organic group of the ammonium cation. For dibenzylammonium. the resultant interlayer is lined with aromatic groups, and accordingly. the framework has a tremendous ability to include aromatic guests. ranging from nitrobenzene to pyrene. Shown in Fig. 2 are two views of a typical dibenzylammonium–trimesate assembly. As with the GS compounds, the flexibility of the scaffolding once again allows for the network to adjust to accommodate different guests of varying steric and electronic properties.

An analogy was made of this family of compounds to clays. This is a good illustration of the complementarity of soft networks to metal oxides mentioned in the introduction. Whereas clays typically consist of anionic, aluminosilicate layers, these ''supramolecular laminates'' represent a neutral alternative. Clays. owing to the array of oxygen atoms lining the interlayer, favor inclusion of polar species. In contrast. the Zaworotko networks represent a system that favors inclusion of nonpolar aromatic guests. For the Zaworotko structures, in the absence of guests, the interlayer is compacted with benzyl groups interdigitated. Thus, as in clays, the framework can swell to accommodate guests. If the benzyl groups are substituted for straight-chain alkyl groups, neither swelling nor guest inclusion take place, as the solid remains in a compact interdigitated form. This observation illustrates

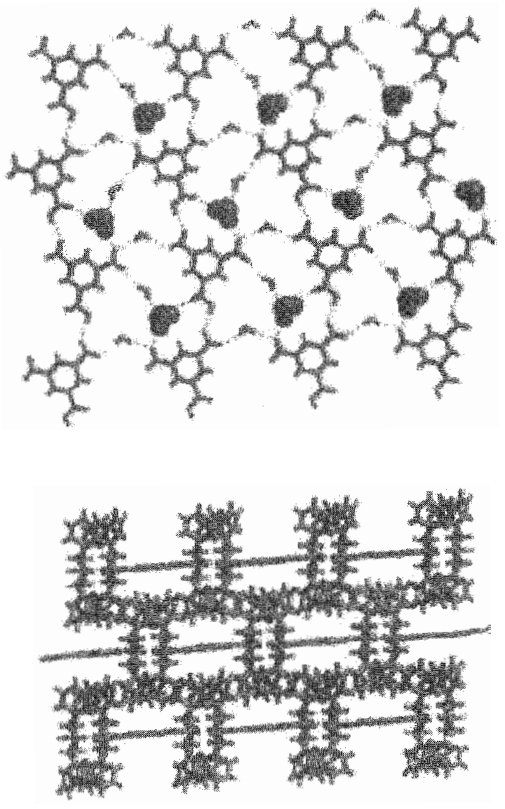

Fig. *2* Views perpendicular (top) and parallel (bottom) to a single layer showing trimesate–ammonium units hydrogen bonding in the Zaworotko clay mimics. Interlayer guests are shown in a space-filling representation. In the lower figure, the 8.3 A separation is between layers. as depicted in the upper figure. Reprinted with permission from Ref. [19]. the potential for adjustable framework properties with the softer network.

A Catalytic Bisresorcinol Host

The two previous examples concerned organic frameworks sustained by charge-assisted hydrogen bonds. Aoyama et al. reported a system of interacting neutral organic molecules chat form a layered network that functions as a catalytic host.[20,21] The complementary interaction in this case is a self-association between anthracenebisresorcinol units. Initially, the authors observed that this system had the ability to include different types of guest molecules within its cavities simultaneously, for example, ethyl acetate and benzene. In an elegant extension of this work. the authors generated the same host network in the presence of an acrylic ester and 1.3-cyclohexadiene, in place of ethyl acetate and benzene, respectively (Fig. 3). The relevance of these included components is their ability to undergo intermolecular Diels–Alder reactions. The product of the cyclization is a bicyclooctene isomer. where endocyclic and exocyclic products are possible with respect to the orientation of the ester group. Of major significance is that the host framework enhances selectivity for the endoisomer over the exoproduct. In the absence of the host, these reactions typically proceeded with a preference for the endoisomer (87:13). but in some cases, the presence of the host would push the selectivity to the point where virtually only the endoisomer was obtained.

LAYERED COORDINATION SOLIDS AS HOSTS

A Highly Guest-Selective Metal–Trimesic Acid Network

Yaghi et al. reported a copper(II) network with trimesate as the counterion,[22] isolated via a slow diffusion of pyridine into an ethanolic solution of $Cu(NO_3)_2$ and trimesic acid. As might be expected with a trigonally symmetric building block. this compound adopted a layered honeycomb structure. The axial coordination sites on the Cu center, not bound to the trimesate ions, were ligated by pyridine and directed into the interlayer region. Typically, a monodentate pyridine ligand may be readily removed upon heating. In this example. that was not the case, as the stability of the pyridine molecules was

augmented by interpyridine n-stacking interactions. These supramolecular interactions served to pillar the interlayer and, along with the trimesate core as a spacer, generated cavities for inclusion of other extensively hydrogen-bonded guest pyridine molecules (Fig. 4). The truly remarkable feature of this network was that the guest pyridine molecules could be liberated. while the ligated pyridine molecules were retained. This generated a porous interlayer lined with aromatic groups from the coordinated pyridine units and the benzene cores of the trimesate anions. The work was extended to show that the partially desolvated network was then selective for the uptake of aromatic over structurally similar. nonaromatic guests.

Tunable Frameworks Based upon Silver Organonitrile interactions

The Lee group reported some elegant and thorough work on networks hinged on silver(I) nitrile interactions. Even relative to other interactions used to form coordination solids. the silver nitrile interaction can be considered weak. Additional structural stability in these networks is undoubtedly imparted by the observed layer formation, which essentially functions as an extended chelate. Lee et al. synthesized a family of layered honeycomb structures with tris(nitrile)benzene organic cores linked by silver(I).[23] Channels in these solids include a range of organic guests. The elegance of the Lee work is illustration of the variety of modifications, both with respect to the dimensions and functionality of the organic skeleton. which could be tolerated in a solid sustained by presumably weaker interactions.[24] In Fig. 5, the range of functionality is shown, including chiral groups for enantioselective separations that were incorporated into the honeycomb nets. Impressively. this system even includes an example (esterification of a pendant alcohol group) where functionalization of the organic skeleton was after assembly of the silver framework. Thus, in addition to thermal stability. this postassembly modification demonstrated that the system possessed chemical stability. In

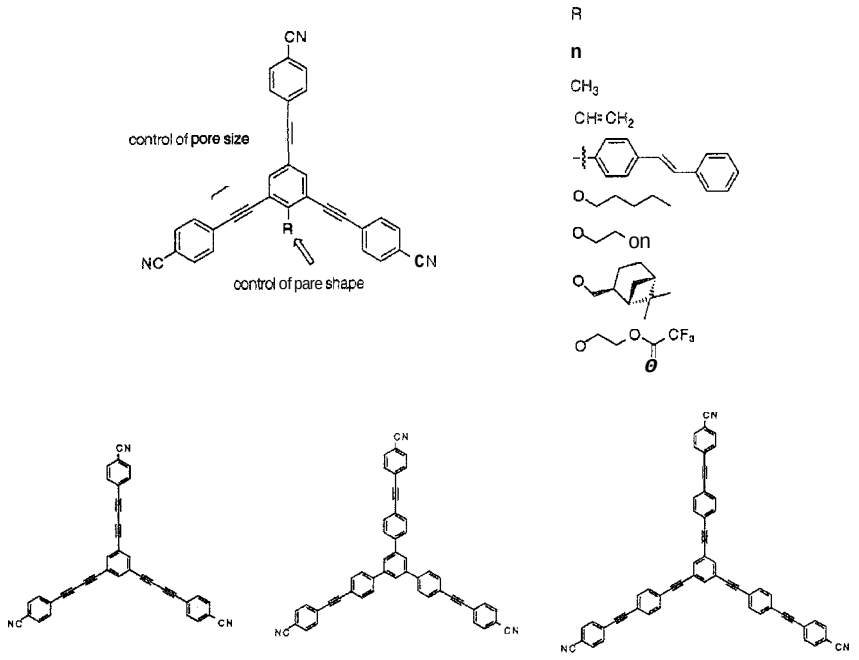

Fig. 5 Designed diversity in the silver organonitrile frameworks of Lee while still maintaining a honeycomb-type layered structure. Reprinted with permission from Ref. [24]. Copyright 1999 by American Chemical Society.

more recent work, Lee extended these studies to append longer chains of a well-defined hydroaffinity to a series of different organonitrile cores and used hydrophobic interactions to assemble different structural motifs.[25] This example of soft chemistry exists in a domain interinediate to block copolymer chemistry and surfactant-templatea inorganic synthesis. It is an excellent illustration of the complementary status of this science relative to existing materials.

Chloroanilic Acid Networks

Kitagawa et al. reported layered coordination polymers based upon chloranilic acid which exhibit intercalation phenomena.[26,27] These frametvorks have a formula $\{[M(CA)(H_2O)_2](guest)\}_\infty$, where $M = Fe^{2+}$, Co^{2+}, Mn^{2+}, Cu^{2+}. The chloroanilic acid adopted a doubly chelating coordination mode to the metal ions to form a one-dimensional ribbon. The metal ions were all six-coordinate and contained two sites not occupied by the CA ligands. These two sites were ligated by water molecules, which were in a cis or a *trans* orientation, depending on the nature of the complex. The extension of the ribbon to a layer is the reason for the inclusion of this system in this review. The ribbons were further joined via hydrogen-bonding interactions between one hydrogen atom of each metal-bound aquo ligand and the oxygen atoms of the CA^{2-} ligands of the adjacent ribbon, thus forming supramolecular layers. The remaining hydrogen atoms of each aquo ligand also functioned as a hydrogen-bond donor to a range of intercalate guest molecules. Guests that were intercalated included phenazine. dimethylpyrazine (Fig. 6). and water. With regards to materials properties, an appealing prospect is that the metal centers in these structures are, for the large part. paramagnetic. Thus, the size of the intercalate could regulate the degree of interlayer interaction and, hence, the extent of ferromagnetism. Interestingly, using these building blocks. frameworks of general formula. $\{(guest)[M(CA)_2(H_2O)_2]\}_\infty$, were also attainable.[28] The key alteration is that the ratio of divalent metal to CA^{2} . which was I:1. is now halved, resulting in an overall anionic framework. Thus, the regulation of the structures was achievable by the variation of countercations rather than neutral guests.

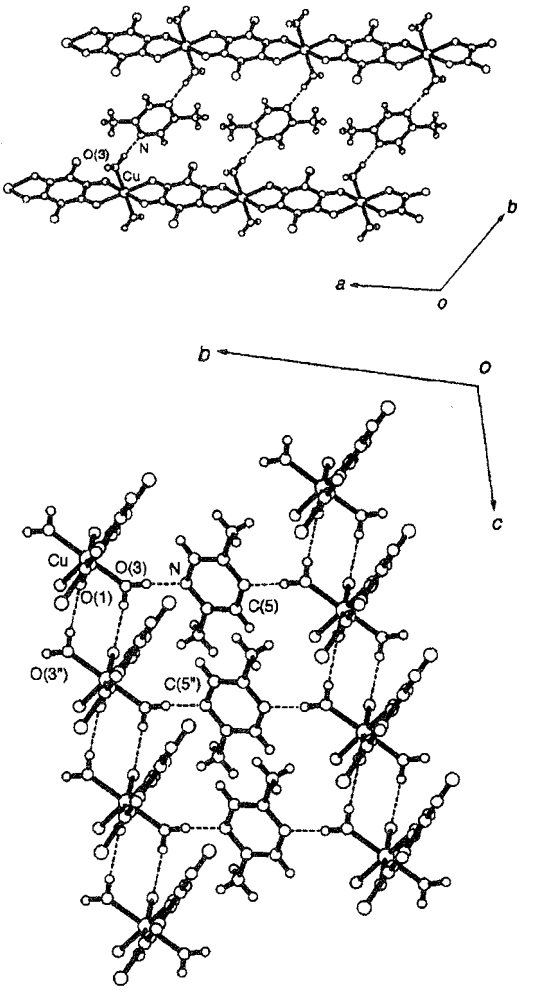

Fig. 6 Structure of a copper chloranilic acid framework reported by Kitagawa. The top figure shows the intercalation of dimethylpyrazine. and the bottom figure shows hydrogen bonding between Cu(CA) units to form the layers. Reprinted with permission from Ref. [26]. Silver Sulfonate Frameworks

Our research group has been studying the chemistry of silver(I) sulfonate frameworks. These two components offer an interesting compatibility with respect to structural pliancy. Silver(I) is noted, among transition metal ions. for having a flexible coordination sphere due primarily to its d^{10} electronic configuration. Sulfonate ions can bridge metal centers in modes ranging from bonding to a single metal to μ^6. Sulfonates are largely ignored in transition metal coordination chemistry owing to the perception that they are weakly interacting ligands. While this is true. when this fact is coupled with their potential for multiple interactions: the silver sulfonate interactions have potential as useful synthons in a supramolecular sense. With simple organosulfonate groups, silver sulfonates exist as layered solids structurally reminiscent of metal phosphonates,[29] which typically form rigid inorganic layers with a broad range of R group on the phosphonates.[8] In contrast to their divalent cousins, silver sulfonates hate more flexible layers. For example, going from R = phenyl to tolyl results in a change of the sulfonate bridging mode from μ^6 to μ^5. This led us to draw the

analogy of the sulfonate group to a "ball of Velcro" when considering its interactions with silver(I).

An example of a silver-sulfonate-layered network with intercalation properties is that of silver triflate ($CF_3SO_3^-$). In studies of layered metal phosphonates, intercalation typically requires thermal pretreatment of the solid to generate a site on the metal by liberating a coordinated solvent.[30] At this stage, the compound is usually highiy air and moisture sensitive. Silver triflate. in contrast, underwent facile coordinative intercalation of straight-chain alcohols under ambient conditions in air.[31] No thermal pretreatment was required, and no hypersensitive intermediate was generated. This was enabled due to the ''ball of Velcro" coordination ability of the sulfonate group. Whereas the phosphonate group is rigidly fixed in its bonding. the sulfonate group simply reorients to accommodate the alcohol group. This flexibility does not come at a sacrificial price with respect to lamellar stability, as the intercalation of straight-chain alcohols was topotactic over the range from ethanol (C_2) to eicosanol (C_{20}).

A second example of silver sulfonate interactions facilitating a supramolecular intercalation event is the complex, Ag(3-pyridinesulfonate). This framework existed as a dense pure compound and also as an acetonitrile intercalate.[32] The acetonitrile intercalate can be viewed as one-dimensional 24-membered rings linked in one dimension to form layers, as represented on the left side of Fig. 7. Upon desorption of the MeCN guests, the framework converted to a dense three-dimensional structure shown on the right side of Fig. 7. The reintroduction of acetonitrile was facile. as was the reconversion of the network to the layered structure. In virtually all extended solids, this structural reversion comes with a loss of long-range order reflected in broadening of peaks in the powder X-ray diffraction pattern. In this fi-amework. as all the connectivities lost and regained were weaker contacts (i.e., Ag–O bonds ranging from 2.6–2.8 Å), it was a facile process for the network to reorient and find its energetic minimum. Notably, no broadening of peaks was observed, even after 20 sorption/desorption cycles. Another significant observation concerning this system was the selectivity with which the guest inclusion took place. It was coordination of MeCN to the metal center that triggered the structural reorganization. Therefore, larger nitriles were excluded on a steric basis. while poorer Lewis bases, such as methanol, were excluded, as they likely did not displace the sulfonate group from the silver center. While it is difficult to describe a solid as porous when it never actually contains a void, this framework exhibits selective and reversible guest sorption. it may be stated that the most selective pore is. in fact. the pore that only exists in the presence of the guest.

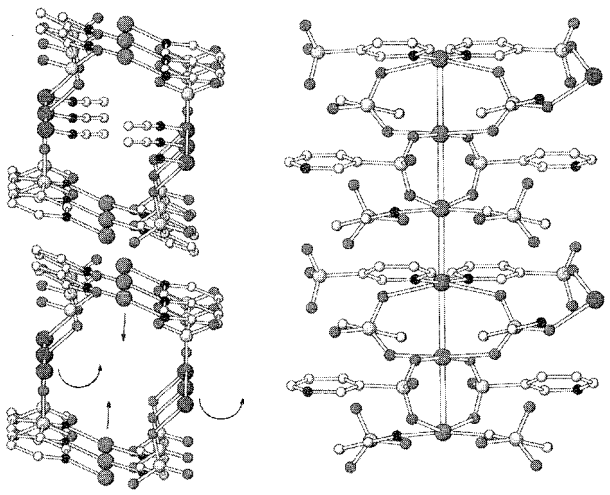

Fig. 7 Interconversion of MeCN intercalated (left) and the dense form (right) of silver 3-pyridinesulfonate, enabled by a "ball of Velcro'. rotation of the sulfonate group. CONCLUSION

This short review has not. by any means, been meant as a comprehensive survey of layered solids and intercalates or supramolecular inclusion, as there are many studies that have not received mention here. Within the context of this review, the focus was specifically on two-dimensional solids. where the structure is sustained, in whole or in part, by weak interactions and that exhibit some intercalation phenomenon.

The incorporation of organic units into an extended structure cannot but bring more structural diversity. This point is indisputable. The cloud to this silver lining has always been the question as to whether frameworks incorporating organic moieties can possess the stability to enable any functionality. This point is even more poignant for two-dimensional architectures. as they are inherently less stable than their three-dimensional counterparts. The examples discussed in this review illustrate the potential utility as materials of networks based upon weaker interactions. These soft frameworks can be thought of as solids that bend but do not break. They offer more options for tunable diversity, and this will ultimately translate to greater and, importantly, different functionality. Thus. the point that cannot be overemphasized, is that soft solids should be perceived as a complement to existing inorganic materials rather than as an alternative. In an article prophesizing materials challenges for the twenty-first century, W. M. Tolles. the former Director of Strategic Planning for the U.S. Naval Research Laboratory.

is quoted as saying; *"The field of chemistry evolved by understanding the consequences of bonding forces, leading to a vast array of materials today. An extension of the same approach to weaker ,forces is envisionecl. Materials having properties not heretofore available may he expected."*[33]

Light Scattering

Robin E. Westacott
Heriot-Watt University, Edinburgh, United Kingdom

Carolyn A. Koh
King's College London, London, United Kingdom

INTRODUCTION

Light and matter interact in such a way that the electric field of the light induces an oscillating polarization of the electrons in the constituent atoms or molecules of the matter. These interactions cause the light to be scattered by the atoms or molecules with and without absorption of energy by the material. This scattering causes frequency shifts, angular distribution, and changes in polarization and intensity of the light, all of which provide information on the size, shape, and interactions of the material. This information, when combined with classical electrodynamics and statistical mechanics, provides details on the structure and molecular dynamics of the system. The structure and dynamics of a wide range of systems such as solids,[1] liquid crystals,[2] gels,[3] solutions of macromolecules,[4] simple fluids and electrolyte solutions,[5] dispersions of microorganisms,[6] viruses,[7] membrane vesicles,[8] and colloidal dispersions[9] can be investigated using light-scattering techniques. Light-scattering has seen a rapid increase in use and applicability over the last 20 years due to the dramatic advances in laser technology.

THEORY

When a monochromatic beam of light is incident on a sample, the light is scattered at an angle θ with respect to the incident beam. The volume defined by the intersection of the incident and scattered beams is called the scattering volume. Atoms and molecules in the scattering volume experience the electric field of the incident light, and charged species are accelerated due to the force they experience. The accelerated charge emits light, which can be collected by a detector placed at the scattering angle, θ. The light reaching the detector is the sum of the light scattered by all the charges in the scattering volume and is thus dependent on the position of the scattering bodies (see Fig. 1).

Atoms or molecules in the scattering volume are constantly moving, so that the total scattered electric field constantly changes and therefore looks like noise. But, it contains all the information, structural and dynamic, on the atoms and molecules in the scattering volume. If the wavelength of the incident light is large compared to the size of the scattering bodies, the same electric field is experienced by each body. Destructive interference of the scattered waves leads to most of the transmitted light being observed in the same direction as the incident light, and only very small amounts of scattered light can be observed. The intensity of light scattered over directions other than that of the incident light increases with increasing size of the scatterer. For scatterers of larger dimensions, this leads to the well-known Tyndall effect observed when light is passed through an emulsion or solution of macromolecules.

If the scattering volume is composed of many small units, where each unit is small compared to the wavelength of the incident light, the total scattered electric field is the sum of the scattered electric fields from each unit. If the optical properties of each unit are different, then light is scattered in directions other than forward, otherwise light is only scattered in the forward direction.

When monochromatic light is incident on a single molecule having anisotropic polarizability α, a dipole moment is induced that varies with time:

$$\mu(t) = \alpha \cdot \mathbf{E}(t) \tag{1}$$

A time-varying dipole moment emits light. The light scattered from a collection of molecules is simply the sum of the amplitudes of light scattered from each of the individual molecules, i.e., proportional to

$$\sum_j{}' \alpha_j(t) \exp i\mathbf{q} \cdot \mathbf{r}_j(t) \tag{2}$$

where j indicates each individual molecule, q is the scattering vector, r_j is the position of the center of mass of molecule j, and the $'$ indicates that the sum is only over the molecules in the scattering volume. The intensity of the scattering field is then proportional to

$$I(\mathbf{q}, \omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathrm{d}t \exp^{-i\omega t} I(\mathbf{q}, t) \tag{3}$$

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012814

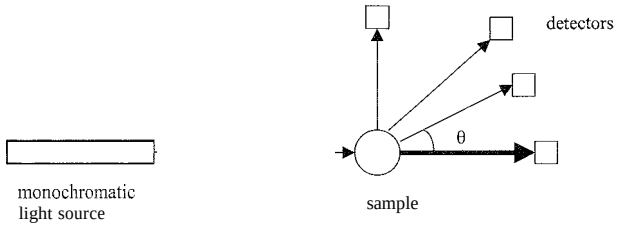

Fig. 1 Simplified light-scattering experiment. Commonly, there is a focusing lens between the light source and the sample.

where

$$I(\mathbf{q},t) = \langle \partial\alpha_j^{*}(\mathbf{q},0)\partial\alpha_j(\mathbf{q},t)) \tag{4}$$

and

$$\partial\alpha_j(\mathbf{q},t) = \sum_{j=1}^{N} {}'\alpha_j(t)\exp^{i\mathbf{q}\cdot\mathbf{r}(t)} \tag{5}$$

is the spatial Fourier component of the polarizability density,

$$\partial\alpha_j(\mathbf{r},t) = \sum_{j=1} {}'\alpha_j(t)\partial(\mathbf{r}-\mathbf{r}_j(t)) \tag{6}$$

This approach is only approximate, because the incident light is directed on a collection of molecules rather than a single molecule. These molecules are subject to collisions with one another, and this causes disturbances in the electric field around the molecules, which persist for as long as it takes for the molecules to separate to a distance outside the influence of each other's electric fields.

The polarizability term in Eq. 5 can be split into two terms: a polarizability term for the nuclear configuration and a term dependent on vibrations. The expression for intensity contains four terms: rigid molecule polarizability, two linear cross terms for vibrational modes. and one quadratic cross term for vibrational modes. The linear terms generally average to zero. The quadratic term leads to the vibration-rotation Raman spectrum. Light scattering is only concerned with those terms that contain the pure rotations and translations of molecules with the rigid molecule polarizability. often referred to as Rayleigh–Brillouin scattering.

Difficulties arise in understanding results when applying light scattering to complicated systems. Thus, model systems are used to aid interpretation. The simplest example of this is the use of spherical molecules. because the induced dipole moment is always parallel to the incident electric field, and exact solutions can be derived. Model solutions can also be derived for dilute solutions and low-density gases when the sizes of the particles being analyzed approach the wavelength of the incident light, and the interior and surface of the particle are different, such as during crystallization. Again. exact solutions are available for simple model systems such as spheres (Mie theory[10]), and some are available for cylinders. Light scattering was also used to study the mobility of microorganisms.[11] The reader is referred to the text of Berne and Pecora,[12] and references therein, for further details of the uses of light scattering.

APPLICATIONS

Some recent examples of light scattering in fields of supramolecular chemistry are provided in the remainder of this article.

Moradian-Oldak[13,14] studied amelogenin proteins, which are hydrophobic in nature and exhibit reversible temperature coacervation (gel conversion from a translucent state at 4°C to an opaque form at room temperature). The bulk of the amelogenin is enriched in amino acids: Pro, Leu, His, and Gln, while the terminal region is composed of a sequence of hydrophilic-charged amino acids. Amelogenin distribution in the extracellular matrix of enamel is believed to be due to alternative splicing of primary mRNA transcript as well as the presence of the proteolytic product. Interestingly, the amelogenin structure self-assembles to generate nanosphere structures, which were recognized as being the main structural component of secretary-stage enamel matrix. The self-assembly of amelogenin proteins to form a supramolecular structural framework is a major extracellular event in enamel formation. Dynamic light scattering was used to study the amelogenin self-assembly process, which is one of the key factors in controlling some processes of the crystal growth of enamel. The light-scattering measurements detected nanospheres of 5-100 nm diameter.[13] These nanospheres are considered the basic building blocks of the amelogenin matrix and may be the supramolecular st uctures responsible for organizing this matrix. These measurements also indicated that the self-assembly process is hydrophobically driven and is sensitive to the pH and temperature of the solution.

In particular, temperature variation studies gave the following results:[14] at low temperature (5–25°C) and pH 8, full-length recombinant amelogenin forms aggregates in a narrow size distribution between 15 and 18 nm. Between 27–35°C, the size distribution becomes bimodal and multimodal. with average particles having up to four times the hydrodynainic radius of those at the lower temperatures . At higher temperatures (37–40°C), particles are larger and better defined. suggesting that amelogenin changes conformation and reassembles in a new arrangement.

Modified amelogenins, with systematic domain deletion or substitution. were also investigated.[15] This work showed that there are substantial differences in the size distributions of the aggregates, depending on the modifications made to the pure amelogenin. Time-dependent dynamic light-scattering measurements also showed that altering the hydrophillic B-domain in the amelogenin sequence results in a significant shift in the size distribution of the amelogenin nanospheres.[13]

There is increasing interest in DNA suprainolecular complexes for nonviral gene therapy. Nonviral DNA complexes may be important as alternative gene-delivery vectors for treating genetic disorders. Most studies of nonviral gene-delivery systems focus on new condensing agent synthesis, expression vector development, and characterization and structure of the supramolecular complex. In contrast, there have been few studies on the formation kinetics of this supramolecular complex. Understanding the kinetics of the complexation process is important to achieve an optimal formulation of the DNA complex dispersion (i.e., having an optimal size and composition). Lai and van Zanten[16] used time-resolved multiangle laser light scattering to measure the kinetics of formation of a DNA/poly-L-lysine polyplex and to monitor the time evolution of the supramolecular complex. as well as changes in the mass and geometric size. The light-scattering results showed that the primary polyplexes of a smaller geometric size than individual DNA molecules in solution form rapidly when DNA is mixed with poly-L-lysine. After a certain tiine, the primary polyplexes then aggregate into larger structures. where the size is dependent on the relative conceritration of DNA to poly-L-lysine. It was found that at relatively high or low DNA/poly-L-lysine mass concentration ratios. the polyplex mass and geometric size remain almost constant with time after initial aggregation. The results also indicated that aggregation is rapid and yields polyplexes that remain stable for at least a few hours.

Resonance light scattering (RLS) is a valuable technique for detecting and characterizing extended aggregates of chromophores. Scattering intensities of such species are significantly enhanced at or near the wavelength of absorption when strong electronic coupling exists among chromophore units. This means that RLS is extremely sensitive and selective for monitoring such molecular assemblies and for studying their sizes and shapes. However. the interpretation of data obtained from RLS are complicated by the large amount of absorption present. Collins et al.[17] reported an empirical method for making absorption corsections to RES spectra obtained using a 90° fixed scattering angle spectrofluorimeter. The supramolecular assembly of the chromophore, tetrakis (4-sulfonatophenyl) porphine (H_4TPPS), was studied using RLS by considering the absorption and scattering of the sample: thus separating the extinction measurement into the individual components.

Chromic materials are present in many materials, such as drugs, dyes. nucleic acids, and antibodies. The driving force for self-association of these chromic molecules in aqueous solution is enthalpically driven. with attractive interactions occurring between π-systems leading to the formation of stacks of molecules. A well-known assembly of this kind is formed by certain cyanine and merocyanine dyes. also known as J-aggregates, because they give a sharp optical absorption band (*J*-band) shifted to longer wavelengths compared to the long wavelength absorption band of monomers. This unusual spectroscopic phenomenon was attributed to a stacking of the chromophores into polymer-like assemblies. The relationship between molecular structure and the mesoscopic properties of these materials is complex. In addition, their aggregation number, geometric size, and morphology are not well understood. Light scattering was used by von Berlepsh et al.[18] to characterize 5,5′,6,6′-tetrachlorobenzimidacarbocyanine dyes with 1,1′-dioctyl and 3,3′-*bis*(3-carboxypropyl) substituents that form distinct supramolecular aggregates in solution. The light-scattering results revealed that there was nonuniformity in aggregate diameter. The particles in solution were rod-shaped. Small-angle light-scattering measurements also showed that the scattering behavior was unchanged over the whole accessible scattering vector range down to Q of around 5×10^{-3} nm^{-1}, suggesting that particles remained a particular length. which could be on the order of a few microns.

Alloisio et al.[19] used light scattering to investigate a soluble polydiacetyiene (PDA), poly[1,6-*bis*(3,6-dihexadecyl-*N*-carbazoyl)-2,4-hexadiyne]. It was possible to create thin films of some of this polymer that have good optical quality. Dilute solutions of this polymer in benzene and toluene were characterized using light scattering. which showed that this specific polymer behaves differently than other soluble PDAs. Specifically, the results indicated that the polymer behaves as a rod-like chain. and it is this property that potentially allows preparation of thin films with good optical quality using spin coating. Gelatin forms a physical rather than a chemical gel; that is, direct chemical cross-linking of the polymer strands does not occur. This process is well understood. but chemical cross-linking of gelatin is required for some applications, such as surgical absorbents and drug capsule casings. In order to understand the effects of chemical cross-linking. Sharma and Bohidar[20] used light scattering to study the interactions between glutaraldehyde and gelatin in aqueous solution at concentrations less than that required for physical gelation or gelatin. The results suggest that there are two possible supramolecular structures for the gelatin–glutasaldehyde

complexes—a random coil with glutaraldehyde bound to lysine *residues in the gelatin chain and also pairing of gelatin molecules using glutaraldehyde bridges.*

Andjelić *and* Richard[21] *used depolarized light scattering to study* the *effects of* γ-irradiation *on the crystallization of ultrahigh* molecular *weight polyethylene. This material is important, as it is used for the manufacture of bearings in human total joint replacements. Recentiy, it was shown that the method of sterilization of the joint replacements has a significant effect on their wear characteristics, because free radicals* that *are produced can react with oxygen. leading to weakening, but if they react with each other, it* can *actually strengthen the bearing. Depolarized light scattering showed that the* nonirradiated *polymer is characterized by individual* spherulites *and their clusters, whereas for the irradiated samples. there was no evidence of ordered* supramolecular *structures.*

Zeng et al.[22] *studied the* self-assembly *of dendrimers based* on *tetraacid systems. Eight scattering allowed* them *to determine the molecular weight of the dendrimers, with results* that *compared well with other methods. including size exclusion chromatography. mass* spectrometry, *and vapor pressure* osmometry.

Eecollinet et al.[23] *investigated the self-assembly of tetraether glycolipid analogues representative of those found* in *the membranes of archaehacteria. and they used light scattering to show the stability of vesicles produced.*

Larger Systems—Crystallization

Light scattering was also used to study crystal growth. In *particular, size distributions for crystals growing* in *the nascent liquid were obtained. This is of particular interest in the pharmaceutical industry. where controlling particle size is often important. However, in many applications, dilution of the suspension is required, as the concentration of particles often exceeds the limits of conventional* light-*scattering equipment. One* method *to avoid this is to use* spectral *extinction that can cope with higher* concentrations.[24] *One field of particular interest in the area of* supramolecular *chemistry is that of clathrate (or gas) hydrates (for more* details *on clathrate hydrates. see the article Clathrate Hydrates and Ref.* [25]). *Several researchers* in *this area measured particle sizes, but the technique* is *notoriously* difficult *to use for these systems.* Monfort[26] used laser light *scattering to monitor* cyclo*propane hydrate* formation *and observed particles in the* 6–564 μm range. Yousif[27] also *used light scattering, but* only *to detect the* onset *of crystallization. which gives rise* to *a spike* in *the scattered light intensity. Moh and* Westacott[28] *also used* dynamic *light scattering to study the effect of chemical inhibitors on the* THF *hydrate formation process.* Nerheim[29] indicated *a critical* cluster *size* for *Structure* II *hydrates* in *the range* 3–80 nm *using dynamic light scattering. More recently, Bishnoi and* coworkers[30] *used light scattering to study the nucleation and growth of ethane hydrate on latex spheres. The approach has the advantage that hydrate* nucleates *on the* latex *particles, which overcomes some of the difficulties associated with water and hydrate having similar refractive indices. However, it complicates the issue by having an extra component in the system, and* more *work will need to be performed to increase the understanding of this system.*

CONCLUSION

Light scattering is clearly an important *tool for studying the structural characteristics and kinetics of formation of a wide range of materials, including proteins, polymers, chromophores. microorganisms. and inclusion compounds. such as gas hydrates. More specifically, information on particle size distributions of aggregates can be* determined from *laser* light *scattering. Depending on the* system *being studied, particle sizes of about a few nanometers to a few microns can be detected as a function of time, temperature. and composition. Such* information *is important in a* wide *range of industrial and medical applications, including self-assembly of amelogenin proteins, which is a major stage in enamel formation: crystallization of* ultrahigh-molecular-weight *polyethylene, which is used in bearings in* human *joint* replacements; *and control of crystal growth of gas hydrates, which is important in gas production and transportation.*

Liquid Clathrates

Scott K. Spear

Robin D. Rogers
The University of Alabama, Tuscaloosa, Alabama, U.S.A.

INTRODUCTION

Clathrates are a class of crystalline compounds formed from two different stable compounds that exhibit no covalent bond between them. A clathrate can be obtained when one compound. the host, crystallizes in such a way that holes or cavities within the lattice trap a second compound, the guest. This concept of a host matrix trapping a guest molecule can easily be extended from solid to liquid phases. Since their initial discovery in 1969, liquid clathrates have proven to be an interesting and growing area of research.''''

In the following sections, the distinction between air-sensitive and air-stable liquid clathrate systems will be discursed. We will also present typical synthesis and characterization procedures as well as a number of interesting applications for these nonconventional solvents.

BACKGROUND

''Liquid clathrate'' is a term coined by Professor Jerry L. Atwood, then at The University of Alabama.[4] This term was used to describe the serendipitous discovery of the biphasic behavior of a wide selection of salts with aromatic solvents. such as toluene and benzene. These semiordered liquids containing complex salt hosts and aromatic hydrocarbons represent the most common examples of liquid clathrates.[2]

The first examples of materials that supported liquid clathrate phase formation, in contact with aromatic hydrocarbons, were highly reactive air-sensitive salts containing alkylaluminum anions, first described by Atwood.[1,2] Their applications for separations of aromatics from hydrocarbons[5] and in coal liquefaction[6] were extensively explored. However, a drawback of the initial systems studied was their air-sensitivity and reactivity.

More recent research established that a much greater range of organic salts can form liquid clathrates when contacted with aromatic solvents,[3] including liquid salts now known as ''ionic liquid.''[7] Formation of liquid clathrates is observed most often with halide and pseudohalide anions. Regardless of cation or anion, these materials can be expressed as ''nonstoichiometric liquid inclusion compounds'' forming complexes in conjunction with aromatic solvents ranging between 1.3–42.2 molecules of solvent.[3]

Liquid clathrate phases are formed when large regions of liquid order exist, in which cations and anions exhibit strong interactions with aromatic molecules. Aromatic molecules acting as guests within the salt ions serve to support and stabilize the structure resulting from the cation–anion packing interactions. With too little interaction between aromatics and cation–anion hosts, the salts are simply completely miscible or immiscible with the aromatics, whereas, if the ion–ion interaction5 are too great, then the salt will simply crystallize. Provided in Fig. 1 is a simplistic view of the phenomenon.

SYNTHESIS, ANALYSIS, AND EXAMPLES OF LIQUID CLATHRATES

Preparation of the First Liquid Clathrates

Liquid clathrates may be prepared by two different methods. These methods can best be illustrated by the preparation of $K[Al_2(CH_3)_6N_3]$.[8] In an N_2 atmosphere dry box, approximately 0.010 mol $Al(CH_3)_3$ was added to 0.005 mol KN_3 to give solid $K[Al_2(CH_3)_6N_3]$ (1). The addition of toluene (0.10 mol) to 1 produced the liquid clathrate $K[Al_2(CH_3)_6N_3] \cdot 3.8\ C_6H_5CH_3$.

A second method for the production of liquid clathrates involves the addition of 0.005 mol KN_3 and 0.010 mol $Al(CH_3)_3$ to 0.10 mol toluene in an N_2 atmosphere dry box. This procedure yields a liquid clathrate identical in composition to the one prepared in the previous method. Note that liquid clathrate formation is a visually dramatic event. As the reaction proceeds, separation of two distinct liquid layers becomes obvious.

Analysis of Aromatic Stoichiometries

Molar miscibility and saturation point measurements describing liquid clathrate behavior are commonly analyzed by the integration of NMR spectra. In most cases. the aromatic stoichiometries are the average of three preparations and integrations with an acceptable standard deviation result of ±0.2 molecules. A common feature of all liquid clathrate NMR spectra is the shifting of the entire spectrum 0.2–0.5 ppm downfield relative to the pure aromatic substance.

Encyclopedia of Supramolecular Chemistry

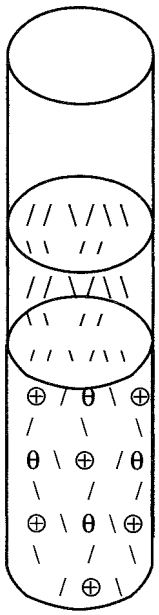

Fig. 1 Excess aromatic molecules (top phase) with a liquid clathrate (bottom phase).

Air-Sensitive Liquid Clathrates

Since the initial discovery of liquid clathrate systems, hundreds of compounds having the structure $M[Al_2R_6X]$ were found to exhibit liquid clathrate behavior.[1,2] While these highly reactive air-sensitive salts are useful in such applications ranging from separations of aromatics from hydrocarbons to coal liquefaction. their air-sensitivity and reactivity posed drawbacks to further study.

Liquid clathrate systems are characterized by a maximum aromatic-to-parent compound ratio (A/A ratio). The A/A ratio has proven to be constant for each liquid clathrate system. regardless of the presence of excess aromatic. In order to illustrate three important trends of liquid clathrates, a partial listing is shown in Table 1.

Table 1 Some representative alkylaluminum liquid clathrates"

Compound	A/A Ratio[b]
$K[Al_2(CH_3)_6N_3]$	5.8
$Rb[Al_2(CH_3)_6N_3]$	6.1
$Cs[Al_2(CH_3)_6N_3]$	7.4
$K[Al_2(CH_3)_6NO_3]$	7.0
$Cs[Al_2(CH_3)_6NO_3]$	12.0
$[N(CH_3)_4][Al_2(CH_3)_6Cl]$	8.1
$K[Al_2(CH_3)_6N_3]$	3.8[c]
$[N(CH_3)_4][Al_2(CH_3)_6Cl]$	5.6[c]

"From Ref. [2].
[b]Maximum aromatic-to-parent compound ratio for benzene.
[c]Maximum aromatic-to-parent compound ratio for toluene.

From such data as shown in Table 1, Atwood suggested the following observations:[2,3]

- For a given anion and aromatic. the larger the cation, the larger the A/A ratio.
  For a given cation and anion, the larger the anion, the larger the A/A ratio.
  For a given anion and cation. the larger the aromatic, the smaller the A/A ratio.

These observations appear to hold for all known alkylaluminum-based liquid clathrates. For example, a selenonium ion-based liquid clathrate having the inclusion formula $[(CH_3)_3Se][ClAl(CH_3)_2(Cl)Al(CH_3)_3]$.(aromatic solvent), can accommodate 8.5 benzene molecules or 8.3 toluene molecules per parent compound.[9]

Extensive research was conducted on liquid clathrates formulations using crown-ether complexes of oxonium ions.[3] One such reaction of interest arises from the interaction of 18-crown-6 with HCl in toluene with a little moisture. which results in a liquid clathrate layer having composition $[H_3O \cdot 18\text{-crown-6}][HCl_2] \cdot 3.6\ C_6H_5Me$.[10] While having a "measurable" stability, these liquid clathrates eventually deposit crystals over hours or days, and crystals of $[H_3O \cdot 18\text{-crown-6}1[HCl_2]$ were isolated.[10] Listed in Table 2 are several oxonium ion-liquid clathrates along with their reported A/A ratios and corresponding reference.

Air-Stable Liquid Clathrates and Ionic Liquids

For a rationalization of the similar physical behavior of liquid clathrate formation with aromatics. for a chemically dissimilar set of materials. Zaworotko et al.[16] suggested that liquid clathrate formation was chiefly dependent on the physical properties of the organic salts. rather than on their chemical natures. Thus, an approach to developing other systems capable of sustaining liquid clathrates would be to investigate organic salts with low melting points (or even salts that were liquid at room temperature). This is clearly a description of ionic liquids.[17,18]

In studies to determine the miscibility of ionic liquids with aromatic solvents, Holbrey et al. found that ionic liquid-aromatic mixtures form liquid clathrate systems.[7] For example, ionic liquids of current interest, such as hydrophobic 1-alkyl-3-methylimidazolium salts ($[C_n$-mim]X) with hexafluorophosphate, *bis*(trifyl)imide, and tetrafluoroborate anions were observed to form liquid clathrates with benzene. toluene, and xylenes (Fig. 2). In

the system [1-butyl-3-methylimidazolium][*bis*(trifyl)imide] ($[C_4mim][NTf_2]$)/benzene, the upper phase is wholly benzene, whereas the lower ionic liquid clathrate phase contains ca. 1:3.5 ratio of ionic liquid:benzene, i.e., has an excess of aromatic solvent.

Other air- and water-stable liquid clathrates based on boronic acid derivatives were also shown to possess water-dependent liquid clathrate formation.[19] These phosphonium cyanoborates. *bis*(methyltriphenylphosphonium)*B*,*B*′-dicyano-*B*,*B*′-hexamethylenebis(9)-borata-bicyclo[3.3.1]nonane, when anhydrous, did not dissolve in furan, but adding one equivalent of H_2O and warming resulted in rapid formation of a yellow liquid clathrate below a colorless furan layer. Some average A/A ratios included benzene (0.8), o-, *m*-, p-xylene (all 0.3), and mesitylene (0.2).

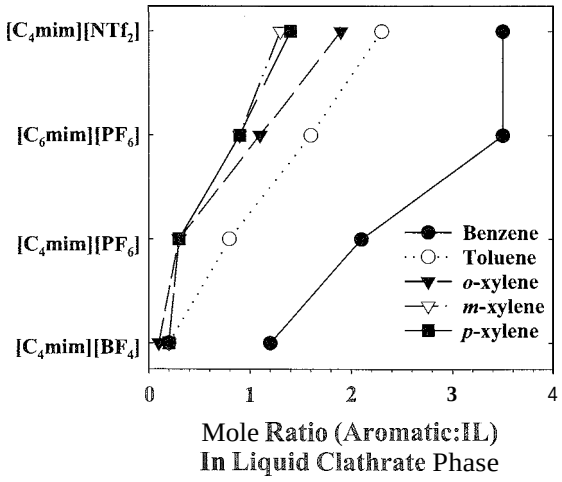

Fig. 2 Ratio of aromatic to ionic liquids in the lower phase of the liquid clathrate biphasic systems. The data shown for *n*-alkyl-methylimidazolium ionic liquids is from Ref. [7]. Connecting lines are a visual guide to changes in the liquid clathrate phase composition.

APPLICATIONS

Separations

The potential application of liquid clathrates to separation science is of continuing interest. in particular, the separation of closely related aromatic hydrocarbons such as benzene and toluene, or o. *m*. and p-xylene [2] Organic nonquaternary clathrate salts were successfully applied as useful materials for separating hydrocarbon feed streams into aromatics-rich fractions and aromatics-lean fractions [5]

Coal Liquefaction

Another interesting application of liquid clathrates that was explored is in coal liquefaction. This patented application resulted in the rapid partitioning of 23% of the coal mass into the liquid clathrate phase of a toluene-based liquid clathrate system at 50°C.[6] It is reported that no chemical reaction is believed to occur between the liquid clathrate and the coal.[2]

Catalysis

The liquid clathrate phase will dissolve substances that act as olefin hydrogenation catalysts, creating homogeneous hydrogenation catalysts.[2] Polymerization catalysts comprised of stable liquid clathrate aluminoxane, aromatic solvents. and organic. inorganic, or organometallic compounds were described.[20,21] Liquid clathrate compositions comprised of a metal halide, a quaternary ammonium salt, a quaternary phosphonium salt. or a ternary sulfonium salt: an aluminum trihalide; and an aromatic hydrocarbon have proven useful as reusable aluminum catalysts in Friedel–Crafts reactions.[22]

The support for liquid clathrate formation under biphasic conditions in ionic liquid-aromatic systems is an important and underrecognized phenomena. As the use of ionic liquids as solvents and catalyst immobilization phases for transition metal catalyzed reactions becomes increasingly commonplace, the importance of understanding liquid clathrate formation as an activation and

separations tool will become crucial. Differences in chemistry can be achieved in IL-aromatic biphasic systems and IL-hydrocarbon, or other biphasic systems, are almost certain, because the former example supports formation of liquid clathrate phases, whereas in the latter, the biphases are truly ionic liquid-molecular liquid.

It was recognized that Lewis acid Friedel–Grafts alkylation of benzene in $Cl/AlCl_3^-$ containing ionic liquids was occurring under liquid clathrate conditions. and that from the reactive chemistry perspective, these systems were identical to liquid clathrates that formed with higher melting alkylammonium salts. Liquid clathrate formation with ionic liquids was also applied as a separations technique for aromatic/aliphatic hydrocarbon mixtures,[23] with the advantage that all components are liquid at room temperature, which precludes formation of precipitants. Most recently, Dixneuf and coworkers described olefin metathesis reactions catalyzed by ruthenium allenylidene catalysts under biphasic ionic liquid-toluene systems, that is in a liquid clathrate supporting reaction media.[24,25] The authors reported that the biphasic systems formed were stable. with the ruthenium catalysts remaining in the lower (salt-rich) phase, allowing facile product extraction by transfer of the upper, toluene phase. It would be interesting to compare reactivity in this system with an analagous ionic liquid/hexane or other aliphatic upper-phase system to examine whether the reaction productivity and mass transport effects are enhanced in a liquid clathrate system over a solely ionic liquid biphasic system.

Crystallizations

Liquid clathrates as crystallization media have resulted in many new structures. Crystals of crown ether,[26,27] cryptand,[28,29] and tetramethylethylenediammonium and triphenylphosphonium[30] complexes were prepared. Presented in Table 3 is a short list of some oxonium ion crown-ether crystal complexes which deposited from the liquid clathrate mixture. Oxonium ion complexes with crown ethers from a liquid clathrate media were formed of a suitable size and shape to crystallize lanthanides and actinides.[31]

CONCLUSION

Liquid clathrates represent an interesting area of supramolecular chemistry. Over the years. the move from air-sensitive to air-stable liquid clathrate systems greatly simplified their handling procedures. Also, with the emergence of air-stable liquid clathrate systems, their possible applications broadened beyond early useful applications of coal liquefaction and hydrocarbon separations to include aqueous separations and catalytic systems.

The field of liquid clathrates can also aid in our understanding of new fields; such as ionic liquids, where many ionic liquid compositions are being observed to behave as liquid clathrates. The ionic liquid researchers are searching for new and varied liquid salt compositions, and thus, one may predict that a plethora of new liquid clathrate hosts will soon appear in the literature. It will be incumbent on researchers in liquid clathrates and ionic liquids to make the connections between the two fields.

The hock and Key Principle

Anatoly K. Yatsimirsky
Universidad Nacional Autónoma de México, Mexico City, Mexico

INTRODUCTION

More than one century ago, Emil Fisher introduced the lock-and-key analogy for the specificity of enzyme action, thus providing the first description of the molecular recognition phenomenon.[1–3] In terms of modern concepts, the lock-and-key principle describes the binding strength and specificity as a result of a number of complementary interactions between rigid preorganized host and guest molecules. Discovery of high flexibility of proteins and observations of significant conformational changes accompanying binding of ligands to proteins led to an extension of the lock-and-key principle by the induced fit mechanism, which was initially proposed to explain some anomalies in the catalytic action of enzymes transforming sugar substrates.[''] Binding via the induced-fit mechanism may be accompanied by free energy losses due to the shift of the receptor conformation from that which corresponds to the energy minimum. On the other hand, the induced-fit mechanism gives a way of understanding such important phenomena as allosteric regulation and cooperativity. Organic ligands also undergo substantial conformational changes upon complexation, which also may be energetically unfavorable due to such factors as restrictions of internal rotations, induced torsional strain, etc. These energy losses will be minimal if the ligand is prepared in a rigid binding conformation and, therefore. will interact with the receptor by the lock-and-key mechanism.

PROTEIN–PROTEIN AND PROTEIN–LIGAND ASSOCIATIONS

A large number of x-ray structures of proteins and protein–ligand as well as protein–protein complexes accumulated since the mid-1970s. In some cases, e.g., for complexes of proteolytic enzymes with small protein inhibitors as well as for the first reported structure of an antigen–antibody complex,[5] the results agree with the classical lock-and-key principle. but in general. modest to strong conformational changes in protein and ligand molecules are observed.[6,7] Recent analysis of 39 pairs of structures of protein complexes and respective individual proteins revealed that the general model of binding is induced fit. In many cases, however, conformational changes are relatively small and often do not involve functionally important residues, so it is suggested that the binding can be considered in terms of the lock-and-key principle as a first approximation.[8]

Detailed analysis of protein–ligand binding was performed for interaction of Fab fragments of affinity-matured antibody 28B4 and its germline precursor with hapten **1**.[9] The affinity-matured antibody forms ca. 1000 times more stable complex with **1** than the germline antibody: $K_d = 37$ nM and 25 μM, respectively. Shown in Fig. 1 are structures of haptene complexes with both antibodies. Comparison of these structures with those of respective unligated proteins shows only minor differences in the case of 28B4. consistent with the classical lock-and-key mechanism, but significant binding-induced changes in the structure of the germline antibody in accordance with the induced-fit mechanism. However, lower affinity of the germline antibody probably is not due to a possible energetic cost of the induced fit. As one can see from Fig. 1, there are several mutations in the active site of the affinity-matured antibody that provide additional binding interactions with the hapten. As a result, the hapten gains two additional hydrogen bonds to the phosphonate group with $Lys53^H$, which substitute $Asn53^H$ of the germline antibody, and a higher degree of stacking interaction with the aromatic groups of $Trp95^H$, $Phe50^H$, and $Tyr32^L$, the first of which substitutes $Asp95^H$ of the germline antibody. The mutation of $Trp95^H$ to Asp in the affinity-matured antibody reduces its affinity essentially to the level of the germline antibody ($K_d = 20$ μM). And, the germline antibody with mutations $Asn53^H$Lys/$Asp95^H$Trp has the affinity increased to a level that is only three times less than that of the affinity-matured antibody ($K_d = 110$ nM). It seems, therefore, that at least in this case, the number of pairwise binding interactions is more important than preorganization.

The problems of optimum geometry, conformational rigidity/flexibility, and binding mechanism of organic ligands to proteins are extensively studied with respect to the design of new drugs.[10,11] We will discuss some of these aspects, taking as an example detailed studies reported on thermolysin phosphonamide inhibitors.[12,13] In Fig. 2, the structures of inhibitors and the dissociation constants of their complexes with thermolysin are shown.

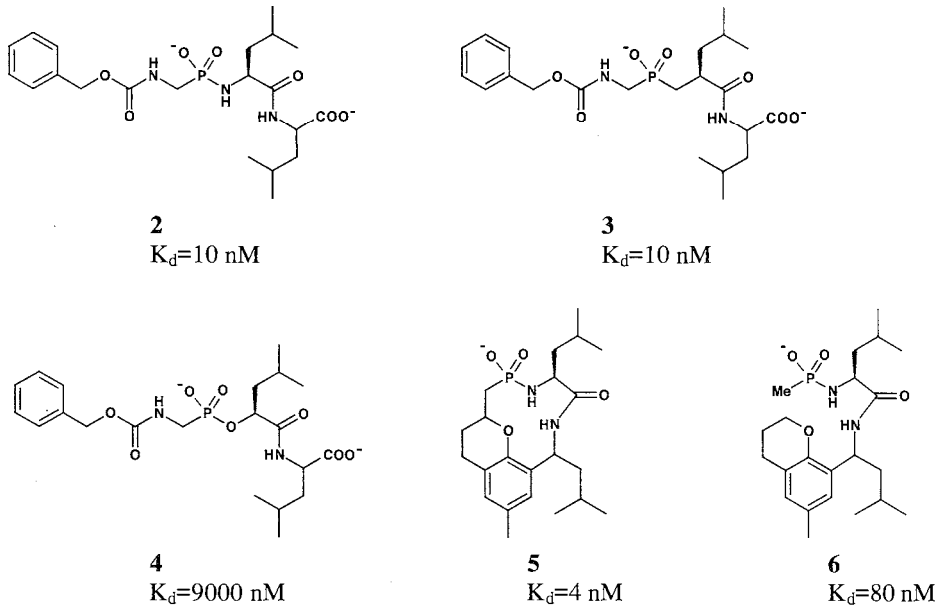

Fig. 2 Therrnolysin phosphonamide and analog inhibitors with dissociation constants of enzyme-inhibitor complexes

The binding site of the enzyme involves a Zn(II) cation, which interacts with an anionic phosphate group, and a number of functional groups, which participate in hydrogen bonding. In particular, the carbonyl oxygen of Ala-113 forms a hydrogen bond with the phosphonamidate NH group in 2. Substitution of this NH group with CH_2 in **3** does not affect binding, but the phosphonate 4 in which this group is substituted with O has much lower affinity. The structure of the thermolysin complex with 4 is the same as with 2. Therefore. the negative effect of oxygen replacement can be attributed to the repulsive interaction of partial negative charges on oxygen atoms of 4 and Ala-113. (In other cases, the replacement of an amide group of the ligand with an ester group leads to a misfit between guest and host molecules and to a strong inhibitory effect. For example, this was observed in the comparison of structures of vancomycin complexes with N-Ac-D-ala and O-Ac-D-lac.[14] This simple and efficient '.mutation'' of the ligand structure is used by bacteria to develop resistance to the vancomycin antibiotic.) Similar stability constants for 2 and **3** were interpreted as a result of hydration effects: the methylene group of inhibitor **3** does not form a hydrogen bond with the enzyme or with a water molecule, in contrast to the NH group of 2; therefore, the balance of ruptured and formed hydrogen bonds is the same for both inhibitors.

Cyclic inhibitor (S,S)-**5** was designed on the basis of the structure of the enzyme complex with 2 in such a way that it would adopt the conformation observed in the crystal structure but would be conformationally rigid and avoid unfavorable steric interactions with the enzyme.[13] Also, chemically and conformationally similar, but acyclic, inhibitor (S)-**6** was prepared. Crystal structures of the complexes between these inhibitors and thermolysin confirmed the anticipated mode of binding. The stability of the thermolysin complex with rigid (S,S)-**5** is 2.5 times stronger than with 2 and, more importantly, 20 times stronger than with acyclic analog (S)-**6**.

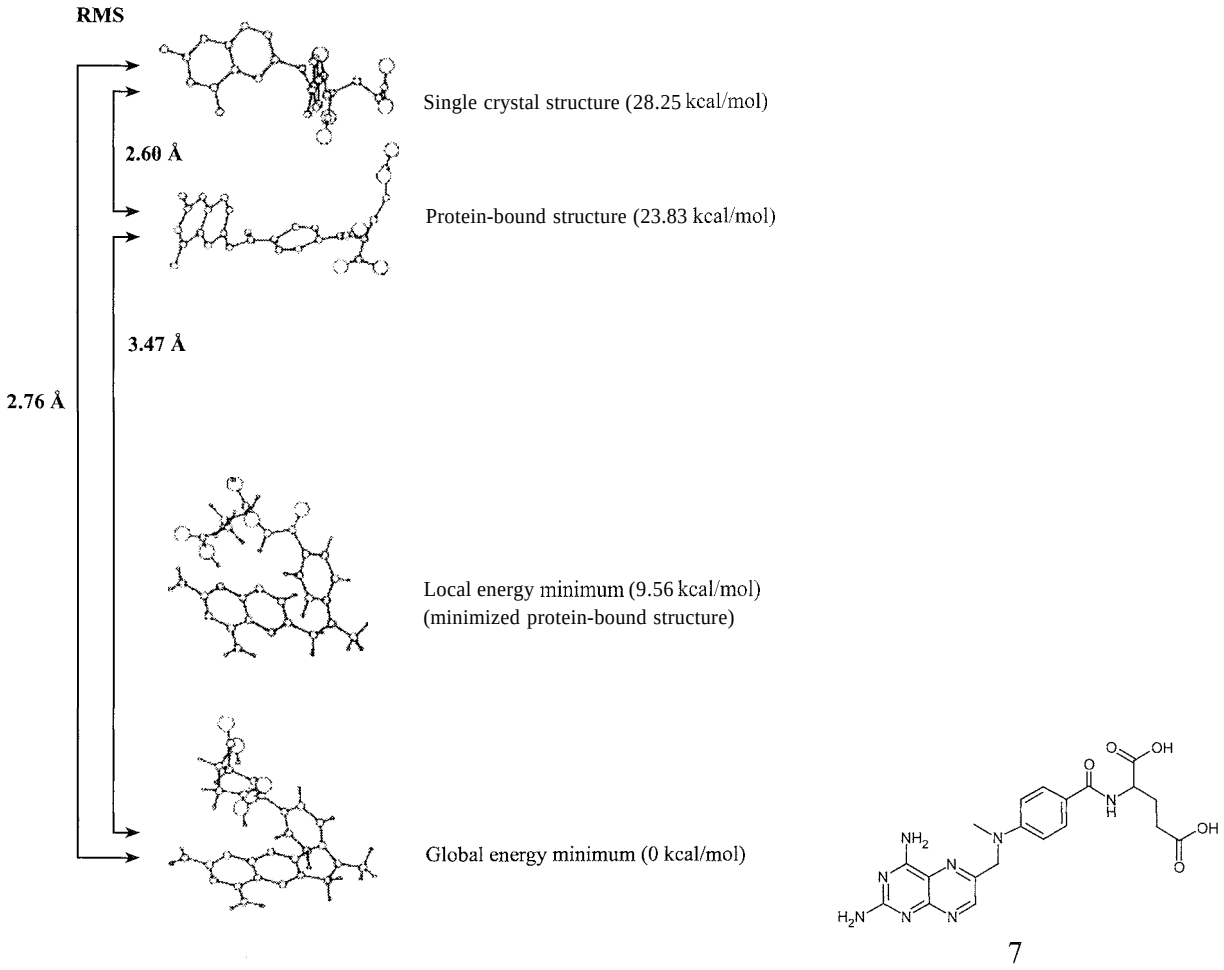

Fig. 3 Conformational changes of methotrexate **7**.[16] Reprinted from Ref. [16]. Copyright 1995, with permission from Elsevier

It is worth noting that rigidification of a flexible ligand often leads to the loss of affinity,[10] but the reason for this is the fixing of a conformation different from the optimum for binding or the appearance of some repulsive steric interactions with fragments used for rigidification. Another factor, which should be taken into account, is that some flexibility of the ligand and the receptor persists even in their complex, reducing interaction enthalpy but increasing the entropy.[13] For example; the binding constant of 2-[(4′-hydroxyphenyl)azo]benzoate to streptavidine increases from $7.3 \times 10^3\ M^{-1}$ to $2.0 \times 10^5\ M^{-1}$ and then to $1.2 \times 10^6\ M^{-1}$ on going from unsubstituted dye to its 3'-methyl and 3′,5′-dimethyl derivatives, exclusively due to the increase in the complexation entropy.'''' High-resolution x-ray structural studies suggest that the positive complexation entropy is due to two factors: displacement of water from the binding site and retention of ligand flexibility in the bound state. Therefore, rigidification is expected to improve the interaction enthalpy but may be unfavorable for the interaction entropy.[13]

Interesting results were obtained by molecular mechanics calculations of conformational changes of small molecules accompanying their binding to proteins.[16,17] The analysis of crystal structures of 33 small molecules as pure compounds and as protein-bound compounds showed considerable differences in their conformations.[16] Both conformations are also different from the global energy minimum conformation. and the degree of deformation depends on the number of bonds around which free rotation exists. Interrelations between different structures of a ligand are illustrated in Fig. 3 for methotrexate (**7**).[16] Both pure compound and protein-bound compound structures are well above the global minimum structure and do not correspond to a local energy minimum structure. However, the important question is how essential are these differences for binding? Comparisons of minimized solution conformations and protein-bound conformations of 10 small molecules showed that if the criterion is the values of torsion angles, the structures can be considered different, but if one compares the positions of ''anchor points'' (several key atoms responsible for tight binding), they appear to be similar in the free and bound ligand conformations.'''' On this basis, it was concluded that despite obvious conformational changes. the binding essentially follows the lock-and-key mechanism, and the low-energy structure in solution correctly represents the positions of importance for binding groups.

HOST–GUEST ASSOCIATION

Synthetic receptors of different types (crown ethers. podands, cyclophanes, calixarenes) possess large degrees of conformational mobility. The binding mode to these receptors is the induced-fit mechanism that. in particular, leads to a possibility of allosteric regulation of the ligand binding to these receptors. This aspect and the respective conforinational changes are discussed in the article. *The Allosteric Effect.* Rigidification of these receptors, usually considered preorganizaiton. in several instances was found

to improve the binding selectivity and affinity, see, e.g., Refs. [18,19]. The binding mode to such preorganized receptors is essentially the lock-and-key mechanism.

Cyclodextrins are an important class of rigid receptors. although molecular modeling predicts some degree of flexibility.[20] A modified mono-*altro*-β-cyclodextrin, in which one of the seven glucose units is changed to an altrose. was prepared to achieve the induced-fit mechanism of binding.[21] Complexation of adamantancarboxylate to this host induced a conformational change in the altropyranose unity.

It was pointed out that the degree of complementarity between interacting atoms and the losses due to restrictions of internal rotations depend on the interaction strength, and for weak and nondirectional interactions, such as ion pairing and hydrogen bonding. may be small.[22,23] The conclusion was based on observations that the association constants between dicarboxylate dianions and diamides (hydrogen bonding) or between dicarboxylate dianions and diammonium cations (ion pairing) are insensitive to the rigidity of a spacer between the interacting groups, e.g., the difference in the association constants with isophthalate and glutarate dianions is only ca. 50% in favor of the rigid isophthalate. Nevertheless, even pure ionic binding may lead to fairly strong shape selectivity in molecular recognition. Shown in Fig. 4 are logarithms of the association constants of a series of tricarboxylate anions with two protonated forms of macrocycle **8**.[24] There are several points of interest in these results. Binding of all rigid tricarboxylate anions is stronger by two to three orders of magnitude than that of flexible citrate. The binding of rigid carboxylates is strongly shape dependent. in particular. for isomeric cyclohexanetricarboxylates. The degree of discrimination increases with an increase in affinity — going from a less-charged tetraprotonated receptor to a highly charged heptaprotonated macrocycle. Apparently, for stronger interacting host and guest species, the geometrical requirements become progressively important. and the binding mode becomes closer to the lock-and-key model.

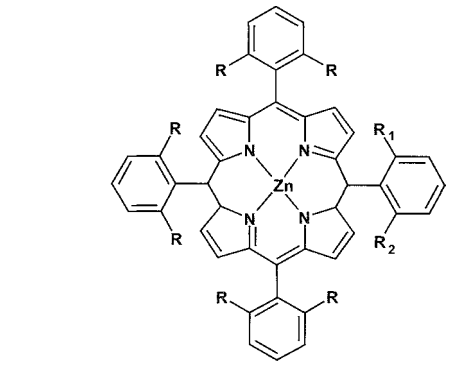

Fig. 5 Chemical structures and molecular models of shape-selective receptors for recognition of amine guests.[25] Reprinted with permission from Ref. [25]. Copyright 2000 by American Chemical Society.

Shape selectivity of molecular recognition is one of the direct consequences of the lock-and-key mechanism. It may result from complementarity of interacting atoms: as is the case in the system described in Fig. 4, or from steric restrictions in the binding pocket of the receptor. The latter principle is illustrated by shape-selective binding of amines to Zn(II) porphyrin complexes shown in Fig. 5.[25] The binding of three groups of ligands was studied with these sterically encumbered porphyrins and with sterically undemanding Zn(II) tetraphenylporphyrin [Zn(TPP)]: aliphatic primary and secondary amines, alicyclic secondary amines. and aromatic amines. Within each group of ligands, binding constants vary unsystematically and in limits of only one order of magnitude for Zn(TPP). Some steric discrimination is observed for $Zn(Si_6PP)$, and stronger selectivity is observed for $Zn(Si_8PP)$: binding constants vary in limits of three to four orders of magnitude for ligands of different structures. Molecular models shown in Fig. 5 explain the difference in steric requirements for these two guests.

CONCLUSION

In many cases, ligand binding to proteins and low-molecular-weight receptors follow, at least at first approximation. the lock-and-key mechanism. A more general binding mechanism is induced fit. Binding-induced conformational changes in the receptor are important for the allosteric regulation and cooperativity, but they may be unfavorable for the binding free energy. Similarly, ligand flexibility can be unfavorable due to losses of internal rotations and induced torsional strain. In several instances, the "freezing" of a ligand in its binding conformation by rigidification. e.g., via cyclization, significantly improves binding, which proceeds in this case by the lock-and-key mechanism. In general, however. it is difficult to give a real estimate of losses due to flexibility of the ligand and the receptor; in particular. taking into account solvent effects. It should be noted that the importance of the lock-and-key principle extends beyond the ligand–receptor complexation discussed above. It applies to a certain degree to all types of supramolecular interactions, e.g., one easily recognizes the lock-and-key principle in self-assembly of synthons in crystal engineering."" in chiral discrimination,[27] and in zeolite catalysis.[28]

Luminescent Materials

Suning Wang
Corey Seward
Queen's University, Kingston, Ontario, Canada

INTRODUCTION

Luminescence is the emission of light from any substance and involves electronic transitions from excited states (excitons) to the ground state. Luminescence is formally divided into two categories, fluorescence and phosphorescence, depending on the nature of the excited state.[1] Luminescent materials are capable of performing certain tasks/functions via emitting light, changing the emitted light (intensity or energy), or converting light to other energy forms, such as chemical energy. There are three classes of luminescent materials — inorganic solids, organic polymers, and small molecules. Supramolecular luminescent materials involve mostly small organic or coordination molecules. The most important current applications of supramolecular luminescent materials are their uses as sensors and probes for certain chemicals or biological molecules, and as emitters or hole/electron transport materials in light-emitting diodes.

CLASSIFICATION OF LUMINESCENT MATERIALS BASED ON THE ORIGIN OF THE EMISSION

bigand-Based Emission

This category contains two classes of lnolecules (organic molecules and coordination compounds) in which the emission involves electronic transitions of the ligands. There are many luminescent organic molecules, most of which are aromatic molecules. Examples include 9,10-diphenylanthracene, 1,4-*bis*(5-phenyloxazol-2-yl)benzene, perylene, acridine, and fluorescein.[1] Many luminescent main-group coordination compounds are luminescent due to electronic transitions that involve ligands only. Typical examples are Alq_3 (q = 8-hydroxyquinolinolato), $Al(POP)_3$, (POP = 2-(5-phenyl-1,3,4-oxadiazolyl)phenonate), BPh_2q and BPh_2(2-py-azain), (2-py-azain = 2-(2-pyridyl)-7-azaindolyl).[2,3] The common features of these main group complexes are that they all contain chelate ligands that are luminescent and that the complexes are all much brighter emitters than the corresponding free ligands. Enhancement of the luminescent efficiency is attributable to the chelation of the ligand to the central atom. increasing the rigidity of the chromophore, and hence, the emission efficiency. A number of luminescent zinc(II) complexes also belong to this category.

Metal Center-Based Emission

This category consists of two classes of molecules: I) molecules that emit color due to electronic transitions localized on one metal center; and 2) molecules that emit color due to electronic transitions involving more than one metal center:

1. A few transition metal complexes such as Mn^{2+} and Cr^{3+} complexes are known to display luminescence that originates from d → d transitions. However, the most important class of luminescent molecules involving a single metal center-based emission is that of lanthanide compounds. Many lanthanide ions with a partially filled *4f* shell are emissive due to $f \rightarrow f$ transitions. Depending on the lanthanide ion, blue, green, or red emission can be achieved. Lanthanide luminescence is usually weak due to the forbidden nature of the $f \rightarrow f$ transitions. In order to achieve relatively bright luminescence, ligands that can function as activators for lanthanide emission are required.[" The role of the ligand is to harvest photons and transfer the energy of the photons to the lanthanide center. The requirement for the ligand is that its band gap be greater than the band gap of $f \rightarrow f$ transitions of the lanthanide ion, and the triplet energy level of the Iigand should be comparable to that of the excited state of the lanthanide ion. Many lanthanide complexes that display bright luminescence, facilitated by ligands, are known. Two well-known examples are Eu(tta)$_3$(phen), a red emitter and Tb(benzoate)$_3$, a green emitter.
2. Luminescent complexes that involve multiple metal centers are most well-known for dinuclear and multinuclear Au(I) complexes, where weak metal–metal bonding interactions are present.[5] Examples

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012502

are $[Au_2(dppm)_2]^{2+}$, where *dppm* = *bis*(diphenylphosphino)methane, and $[Au_3(dmmp)_2]^{3+}$, where *dmmp* = *bis*(dimethylphosphinomethyl)methylphosphine, both of which have emission bands in the 570–590 nm region that were attributed to the transition of Au–Au σ^* $(d–d)\leftarrow$Au–Au σ $(p–p)$. A number of $d^{10}–d^8$ mixed metal complexes, such as $[AuIr(CH_3CN)_2(dppm)]^{2+}$, display a similar luminescence due to the Au–Ir σ^* $(d–d)\leftarrow$Au–Ir σ (p–p) transition.[6] The most impressive are heteronuclear molecules that involve both $5d^{10}$ and 6s' metal ions:[7] two examples are $[Tl(OPPh_3)_2][Au(C_6F_5)_2]$ and $Au_2Pb(mtp)_4$, where *mtp* = $(CH_2P(S)Ph_2)^-$. While neither of the molecular components in $[Tl(OPPh_3)_2][Au(C_6F_5)_2]$ are emissive. the linear solid-state aggregate with alternating Tl···Au units is luminescent. a consequence of weak Tl···Au bonding interactions. The luminescence of $Au_2Pb(mtp)_4$ changes dramatically from solution (λ = 555 nm) to the solid state (λ = 752 nm) due to the formation of infinite one-dimensional Au···Pb···Au chains in the solid state. A trinuclear Au(I) complex, [Au3(MeN = COMe)$_3$], was recently demonstrated to exhibit an unusual phenomenom termed solvoluminescence. When the solid of the complex is irradiated with near-UV light, it appears to undergo a charge separation. When contacted by a solvent in which the complex is soluble, the separated charge recombines. and a yellow light with $\lambda \cong 560$ nm is emitted. It is currently unclear, however, exactly where the emission originates.[8]

Intramolecular Charge-Transfer Emission

Charge-transfer emission refers to luminescence originating from electronic transitions from one center to another. This can occur within a molecule (intramolecular charge transfer. ICT) or between molecules (e.g., exciplexes and excimers).[1] Compounds that display intramolecular charge-transfer emission belong to two categories: 1) charge transfer within the ligand and 2) charge transfer between ligand and metal centers. Many organic molecules that display charge-transfer emission belong to the first category. The well-established examples include (4-dimethylamino)benzonitrile, arylanilines, carboxamide quinoline derivatives, and biaryls. ICT emissions are often solvent dependent. Charge-transfer emissions that involve a metal center and a ligand can originate from metal-to-ligand transitions (MECT) or ligand-to-metal transitions (LMCT), depending on the relative energy levels. The most well-known examples of MLCT emissions are $[Ru(bpy)_3]^{2+}$and $[Ru(bpy')_3]^{2+}$ complexes, where bpy = 2,2′-bipyridine, bipy' = derivatives of 2,2′-bipyridine.[1] The highest-filled orbital in the Ru(II) complexes is mostly *d* character, while the lowest unoccupied empty orbital is ligand-based π^* orbital. A number of Pt(II) diimine complexes also display MLCT emission.[9] Cp_2TiX_2, $Cp^*_2TiX_2$, $CpTiX_3$, and Cp^*TiX_3, where Cp = cyclopentadienyl anion, Cp^* = substituted cyclopentadienyl anion: and X = halide known to display charge-transfer transitions from the filled *Cp* or Cp^* π orbital to the empty d orbital of the Ti(IV) center.[10]

Intermolecular Charge-Transfer Emission

Two commonly used terms for intermolecular charge-transfer emission materials are exciplex and excimer. The former refers to an excited state charge-transfer complex and the latter to an excited state dimer. For example, anthracene and diethylaniline form an exciplex that has a broad emission band at $\lambda \cong 485$ nm. The best-known excimer is pyrene, which displays an intense excimer emission band at $\lambda \cong 470$ nm in a relatively concentrated solution ($\sim 10^{-3}$ M). Excimers formed by aromatic molecules such as pyrene typically display a stacked dimer structure.[11] Excimer and exciplex emission are useful for probing morphology and intermolecular interactions of luminescent molecules.

APPLICATIONS OF LUMINESCENT COMPOUNDS

Luminescent compounds have versatile applications in many different areas of materials sciences. Below is a brief summary of some of the important applications of luminescent compounds.

Displays

Intense research efforts for the past two decades were devoted to the development of light-emitting diodes (LEDs). The ultimate goal of LEDs is their use in display devices, such as computer and TV monitors. LEDs are based on electroluminescence, where excitons are created through electron and hole injections and charge recombination processes. LEDs are devices that convert electrical energy to light and typically have a three-layer structure, i.e., hole-transport. emitter, and electron-transport layers. Traditionally, inorganic semiconductors (Group 14 elements, Group 13/15 compounds) were used for this purpose. Small luminescent molecules (organic or coordination compounds) and organic polymers were recently demonstrated to be useful emitters in LEDs.[12,13] The display devices based on molecular compounds (small molecules or polymers) can be fabricated readily and relatively cheaply in comparison to semiconductor-based devices. In addition, large and flexible display

devices, which are difficult to achieve by using inorganic semiconductors, are possible by using molecular compounds. Alq_3, $Eu(tta)_3(Phen)$, and $Ir(ppy)_3$ (*ppy* = 2-phenylpyridine) are among the most widely used molecular emitters in LEDs. The structure of a typical three-layer light-emitting device is shown in Fig. 1.

Sensors and Probes

Luminescent sensors and probes (see also fluorescent sensors and luminescent probes) are based on the change of luminescent signal upon interaction with an analyte (Fig. 2). Analytes can be metal ions, oxygen molecules. organic molecules, or biomolecules, and the change can be intensity or energy. The intensity change can be an increase or decrease of emission intensity. The increase of emission intensity is often observed in lanthanide compounds, where the analyte enhances the energy transfer to the lanthanide center via specific interactions with the coordination sphere of the lanthanide ions, and, hence, increasing the emission intensity from the lanthanide center. This type of interaction was used for the detection of benzene by lanthanide compounds.[14] The more commonly used strategy in chemical sensing is fluorescent quenching by the analyte via direct or indirect interaction of the analyte with the chromophore. Direct nonbonding interactions between benzene molecules and an aromatic chromophore in a trinuclear Zn(II) complex were demonstrated to be responsible for the highly selective detection of benzene.[15] Similar nonbonding interactions were also used for probing the structure of DNA molecules and for fluorescent labeling of DNA molecules.[16,17] Many examples of indirect interaction of the analyte with the chromophore that results in the quenching of luminescence involve photoinduced electron transfer (PET). The commonly used system for sensors based on PET involves a chromophore that is attached to a

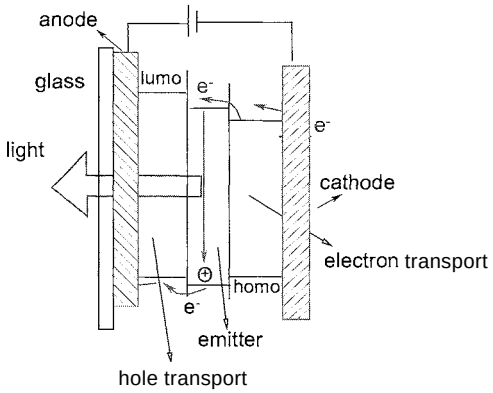

Fig. **I** A typical three-layer light-emitting device. (*View this art in color at www.dekker.com.*)

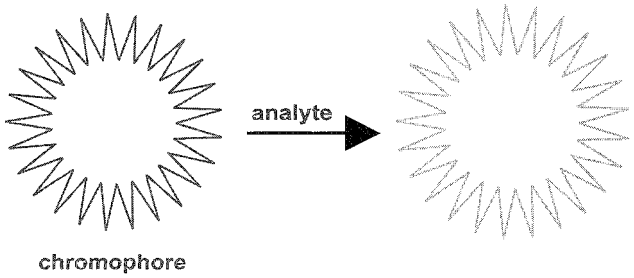

Fig. **2** Luminescent sensors/probes. *(Weir this art in color at www.dekker.coin.)*

nonemissive macrocyclic or multidentate ligand.[18] The binding of a metal ion or a proton to the nonemissive ligand induces the PET process and fluorescent quenching, hence the detection of the metal ion or protons. Long-range PET processes were also used in the investigation of DNA structures by using Ru(II) complexes as the probes.[19] The change of emission energy upon interaction with the analyte is a common occurrence when the analyte forms a covalent bond or a coordination bond with the chromophore, due to the change in energy levels. Formation of an exciplex or excimer between the chromophore and the analyte is also known to lead to a dramatic change of emission energy. Due to the large separation of excitation and emission energy in Eu(III) and Tb(III) compounds and their persistent luminescence in aqueous solutions, Eu(III) and Tb(III) compounds were demonstrated to be useful probes, stains. and markers for biological systems.[20] When Eu(III) or Tb(III) compounds are used as reagents for luminescent imaging of tissues, the background fluorescence from the tissue can be readily eliminated. For example, several classes of Tb(III) complexes were demonstrated to be effective contrasting reagents in the fluorescent imaging of cancer tissues.[21] Luminescent compounds are also widely used as imaging reagents for mechanical structmes such as airplanes and for the study of fluid-flow dynamics.[22]

Switches

Molecular switches based on luminescence are devices that change the luminescent signal reversibly by an external input, such as change of pH, variation of redox potential. or illumination (Fig. 3) (see also molecular switches and molecular logic gates).[23] A typical molecular switch contains a control unit that exists in two states of comparable stability. which can be interconverted reversibly by an external input. Each state interacts to a different extent or in a different manner with another active subunit of the system via bonding interaction/isomerization, of electron or energy transfer processes. The different

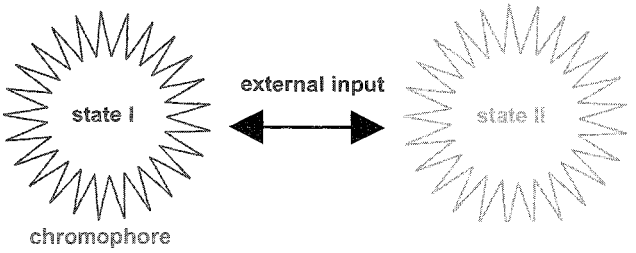

Fig. **3** Luminescent switches. (*View this art in color at www.dekker.com.*)

extent or different manner of interaction between the control subunit and the active subunit in each state provides the on/off function of the molecular switch. Redox switches modulate the luminescence by changing the oxidation state of the metal ion, an example of which is a Ni(II) complex of a naphthalene-containing macrocyclic ligand. The complex undergoes a reversible one-electron reduction process that switches the fluorescence of the naphthyl component off and on via electron transfer.[24] Switches modulated by illumination were demonstrated by a phosphorus(V) porphyrin compound with an axially bound azobenzene subunit. Irradiation by light causes a reversible $Z \leftrightarrow E$ isomerization of the azobenzene subunit, which leads to the modulation of the fluorescence from the basal porphyrin chromophore.[25]

PHOTOCHEMICAL REACTIONS

Numerous luminescent compounds were demonstrated for their potential uses as centers/catalysts for photochemical syntheses—syntheses catalyzed by light (see also photochemical techniques and supramolecular photochemistry). Catalysts for photochemical reactions and syntheses are devices that convert photon energy to chemical energy (Fig. 4). In order to achieve a working photochemical system, several key components are required, such as a chroinophore for electron-hole creation, antennae for harvesting and transferring photons. and redox couples, etc. The most well-known example is the photochemical splitting of water using derivatives of $[Ru(bpy)_3]^{2+}$ as the catalysts.[''''] A number of derivatives of Pt(II) complexes of diimines and dithiolates were recently shown to be promising candidates for photochemical reactions.[9] The research in effective photochemical systems remains to be one of the most challenging and potentially most rewarding areas in sciences.

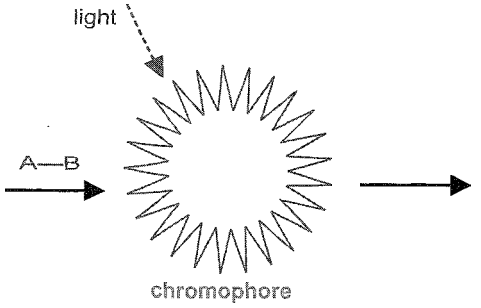

Fig. **4** Photochemical reactions. (*View* this art *in color at www.dekker.com.*)

CONCLUSION

In summary, the combination of luminescence and supramolecular structures gives luminescent supramolecular materials many advantages over other types of materials. By controlling the supramolecular structures. it is possible to achieve selective and highly effective guest–host interactions that can be recorded or monitored by luminescent signal change. Using supramolecular interactions, it is possible to assemble luminescent molecules or charge transport molecules to form the desired molecular layers and architectures on an appropriate substrate so that the resulting surface can perform the desired optoelectronic or photonic functions effectively. These are perhaps some of the most exciting and most challenging tasks in supramolecular materials research.

Luminescent Probes

Dmitri B. Papkovsky
Tomás C. O'Riordan
University College Cork, Cork, Ireland

INTRODUCTION

Luminescent probes represent a substantial segment of supramolecular structures. They are widely used in the design and investigation of physicochemical and structural properties of supramolecular compounds and in various bioanalytical applications based on luminescence detection. In general, a luminescent probe contains a luminophoric structure, functional moiety, ancillary units (such as linkers connecting these fragments), and peripheral groups used to adjust properties of the probe as a whole. Such a probe produces a traceable luminescent signal, and it may also respond to certain events involving the probe or its environment, such as the presence of particular compounds, recognition processes, conversion into different conformations, chemical and spectral forms, changes in environment, etc.

The main advantages of luminescent probes and detection include the following:

- High selectivity due to efficient wavelength discrimination (excitation and emission). which can be further enhanced by lifetime discrimination: potential for multiplexing.
- High sensitivity, down to single-molecule detection, and a broad range of concentrations measurable by luminescence spectroscopy.
- Multiple detection formats, including spectral, intensity, lifetime, polarization. quenching, energy transfer, time-resolved, and phase-resolved measurements.
  Imaging capability with submicrometer spatial resolution. two- and three-dimensional (with confocal optics); sensitive visual detection.
- Temporal resolution spanning from picosecond to second scale for studies of inter- and intramolecular dynamics and processes.
- On/off switching by means of an excitation source.
- Low hazard, chemical stability, robustness, low cost.

Below we describe the basics of luminescence and examples of some common types of luminescent probes, their organization and functioning, applications, and information obtainable with such probes. A general outline of a luminescent probe is given in Fig. 1.

PRINCIPLES AND PARAMETERS OF LUMINESCENCE

The photophysics of photoluminescence (other types of luminescence are outside the present scope) is represented in Fig. 2, commonly called a Jablonski diagram.[1] The absorption of light by a molecule promotes its electrons from the ground singlet state S_o to the vibrational levels of excited singlet states (S_1, S_2,...). In this excited state, the molecule will quickly lose its energy to the lowest vibrational level of the first singlet state. Some molecules can change their spin to the triplet state (T_1) by the process known as intersystem crossing. These processes are rapid and proceed on a scale of 10^{-15}–10^{-12} s. At this point, nonluminescent molecules will lose energy nonradiatively by internal conversion to vibrational levels of the ground state overlapping with excited state levels or as heat in collisions with solvent molecules (external conversion). For luminescent molecules, a substantial energy gap between the excited and ground states limits radiationless deactivation pathways, such that return to the ground state partly occurs via the emission of photons: as fluorescence ($S_1 \rightarrow S_o$) or phosphorescence ($T_1 \rightarrow S_o$).[2]

Excitation and Emission Spectra

These allow for the identification of luminophores and their selective detection in complex mixtures using spectral discrimination. Main spectral characteristics are location, shape, width, peak wavelength of excitation and emission bands, and spectral integrals. For simple molecular structures, excitation spectra are close to their absorption spectra, while emission spectra resemble a mirror image of the excitation spectrum (Frank–Condon rule)[3] and are independent of the excitation wavelength. Because some energy is lost before a molecule can emit light (see Fig. 1), the emission spectrum is shifted toward longer wavelength (Stokes' shift). For more complex structures, spectra of individual chromophoric moieties usually superimpose and reflect photophysical interactions between them, such as internal quenching, complex formation, and energy transfer. Spectral changes may indicate chemical or physical transformations occurring with the luminescent probe or changes in its environment.

Luminescence **Intensity**

Luminescence intensity (I_L) is the main measured parameter that depends on a number of factors related to the instrument, measurement conditions, luminophore characteristics, and sample properties. In dilute solutions, its relationship with the concentration of luminophore is as follows:

$$I_L = I_o * k * \phi * \varepsilon * l * [C] + I_b \quad (1)$$

where **I,,** = intensity of excitation: k = instrumental factor; o = emission yield: E = molar absorptivity: 1 = optical path; [C] = concentration; and I_b = background signal on the photodetector (i.e., without the luminophore). Luminescence intensity is measured in arbitrary units, but measurements performed on different instruments can be easily compared using appropriate standards or relative values. The product of E and Φ is called the "absolute spectral sensitivity." and it estimates the efficiency of different luminophores.[2]

Emission Yield

The emission yield *(h)* defines the quantum efficiency of luminescence: the ratio of the number of emitted and absorbed photons ($0<o<1$). Changes in emission yield can indicate quenching and other photophysical and chemical processes occurring with the luminophore.

Luminescence Lifetime

The luminescence lifetime (τ) is a kinetic characteristic that gives an estimate of luminescence duration and time profile once the excitation source is switched off:

$$I(t) = I_o * \exp(-t/\tau) \quad (2)$$

where t is the time after the excitation pulse. Luminescence lifetime relates to the structure of the luminophore and the presence of other processes (quenching. RET, see below). Compared to the steady-state (averaged) luminescence intensity, lifetime measurements provide additional information about luminescent supramolecular structures and their intra- and intermolecular interactions. Most fluorescent dyes have nanosecond lifetimes. Phosphorescent dyes have millisecond lifetimes and even longer. Such long-lived excited states are prone to nonradiative deactivation and quenching processes, and for many dyes; phosphorescence vanishes at room temperature. A few compounds have bright long-decay luminescence at room temperature. including transition-metal complexes (lanthanides, ruthenium(II), osmium(II)) erythrosine, metalloporphyrins, with lifetimes 1 μs–1 ms. Probes on their basis are becoming increasingly popular, as they allow sensitive time-resolved luminescence detection and some special applications.[4]

Luminescence Quenching

This originates from various internal and external processes involving luminescent probes and other molecular structures called quenchers. Changes in molecular organization, dynamics, environment affecting the luminophore-quencher interactions; or chemical transformations can cause luminescence quenching. Physical quenching encompasses two mechanisms. Static quenching includes formation of a dark complex between the quencher and the luminophore. Dynamic quenching proceeds via collisions of quencher molecules with luminophore excited states deactivating them and also quenching the emission lifetime. Both processes are described by the Stern–Volmer equation:

$$I_o/I = 1 + K_{s-v} * [Q] \quad (3)$$

For static quenching. K_{s-v} corresponds to the binding conrtant. whereas for dynamic quenching. K_{s-},$=k\tau_o$, where k is the bimolecular quenching rate constant. and τ_o

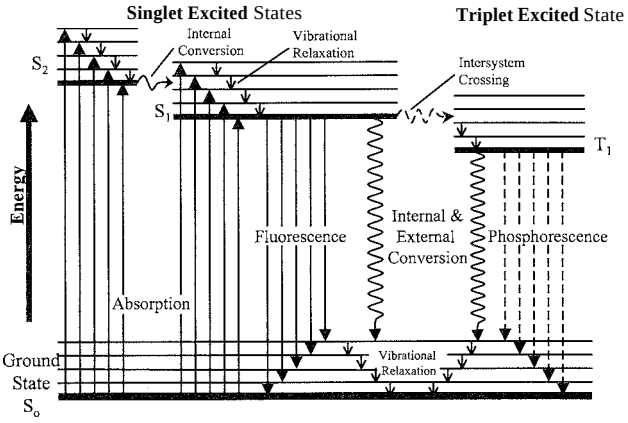

Fig. 2 Jablonski diagram showing transitions giving rise to absorption. fluorescence, and phosphorescence spectra

is the emission lifetime in the absence of the quencher. Long emission lifetime, high temperature, and low solvent viscosity favor dynamic quenching but not static. The opposite process, luminescence enhancement, is usually associated with the elimination of quenching or with the transfer of energy from other specie to the luminophore. Quenching facilitates the study of various nonluminescent structures with luminescent probes.

Polarization of Luminescence

This is the consequence of photoselective excitation of luminophores by polarized light, which selectively excites a population of molecules oriented with respect to the electrical vector of excitation. Emission also occurs with the light polarized along a fixed axis in the luminophore. The angle between these moments determines the maximal polarization of fluorescence.[5] Luminescence polarization is defined as follows:

(4)

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of the vertically and horizontally polarized emission, respectively. Rotational diffusion occurring during the lifetime of the excited state is the most common cause of depolarization of luminescence. Even short-lived fluorescent probes of small size are almost completely depolarized in solution; but their binding to macromolecules or translocation to viscous environments, such as lipid membranes, can partly restore their polarized emission. For these reasons: fluorescence polarization is widely used to study (bio)molecular interactions and molecular and conformational dynamics.

Resonance Energy Transfer

From the excited state of a luminophore, resonance energtransfer (RET) can occur as a result of dipole–dipole interaction with another chemical structure (acceptor). The RET proceeds without the emission of a photon by the donor, and its efficiency is determined by the spectral overlap between the donor emission and absorption of the acceptor and by the distance between them.[6] Distance dependence of RET efficiency is as follows:[7]

$$E = \frac{R_o^6}{R_o^6 + r^6} \tag{5}$$

where R_o is the distance at which RET efficiency is 50%, called the Forster radius. Remarkably. for the majority of donor–acceptor pairs, R_o is about 30–50 Å, which is comparable with the size of molecules including DNA and proteins. The steep distance dependence of RET facilitates its use as a "spectroscopic ruler''[8] with which to measure distances between chemical and molecular structures and to monitor intra- and intermolecular interactions, molecular dynamics, etc.

These features provide luminescent probes with versatility and a broad range of applications. A variety of luminescent dyes and probes were described (e.g., *Molecular* Probes) and the number continues to grow rapidly. A small cross section of common luminescent structures is given in Table 1 and Fig. 3. Examples of typical luminescent probes, their organization, and their properties are discussed below.

MAIN CLASSES OF LUMINESCENT PROBES

Natural Fluors

The majority of naturally occurring compounds are nonluminescent, including nucleic acids (DNA/RNA), mono- and polysaccharides, lipids, and most of the small biomolecules. Proteins contain in their structure three amino acids — phenylalanine, tyrosine, and tryptophan — that fluoresce in the UV range. Due to its long-wave emission and relatively low abundance, tryptophan is commonly used as an intrinsic luminescent probe to study proteins. Tryptophan also exhibits phosphorescence at room temperature.

Some natural pigments, including chlorophylls, porphyrins. riboflavin. bilirubin, carotene, NADH, and FAD. have strong fluorecence in the UV and visible ranges. They were exploited for studies of enzyme active sites (NADH, FAD), enzyme kinetics, photosynthesis, and electron-transport processes (chlorophylls. porphyrins).

Luminescent Labels

Fluorescent compounds are commonly used as labels, which allows other molecules and structures to be traced and quantified by luminescence spectroscopy. Such labels, which usually do not change their luminescent characteristics during the assay, are conjugated to the molecules of interest via functional groups of the latter, such as $-NH_2$, -OH. -COOH, and -SH groups. To facilitate the conjugation. the fluorophore is often functionalized with reactive groups: aldehyde, isothiocyanate, sulfony! chloride, *N*-hydroxysuccinimide for labeling via amino groups; and iodoacetamide and malemide for labeling via sulfhydryl residues. Other groups such as carboxylic acids may require additional activating or condensing reagents for conjugation.[9] Fluorescently labeled reagents are used for the detection of DNA. proteins, hormones; cells, etc., in applications such as binding assays (immuno, hybridization, and receptor based): fluorescent microscopy,

fluorescence in situ hybridization (FISH), and fluorescence-activated cell sorter (FACS).

For complex samples. the presence of proteins and other fluorescent compounds results in high optical background, basically in the range of 250400 nm. Probes working in this spectral region are prone to interference and limited sensitivity. Therefore. research focused on the design of luminophores with long-wave spectral characteristics (above 500 nm). large Stokes' shifts, and long luminescence lifetimes. Such Iabels can overcome interference by scattering and autofluorescence and provide higher selectivity and sensitivity.

Fluorescein isothiocyanate (FITC) and dansyl-chloride were among the first extrinsic fluorescent labels for proteins used for immunofluorescence microscopy and polarization measurements.[10,11] Fluorescein and rhodamine labels were extensively employed due to their bright emission in the visible range. These probes have drawbacks: including hydrophobicity, small Stokes' shifts, and sensitivity to pH and photobleaching, which led to the development of new dyes such as Alexa, Bodipy, and cyanine dye families (see Table 1). These dyes cover a broad spectral range and are represented by derivatives with various functionalities and physical chemical properties suitable for conjugation to various molecular structures.

The phycobiliproteins are a group of light-harvesting proteins derived from algae and composed of a polypeptide chain enclosing the chromophoric bilin (open-chain tetrapyrrole) groups. The *R*-phycoerythrin and allophycocyanin, which display large extinction coefficients and emission yields, long-wave absorption and emission, and high photostability, were exploited as labels in immunoassays[12] and flow cytometry.[13]

Green fluorescent protein (GFP) is a conserved polypeptide fragment isolated from the bioluminescent jellyfish *Aequorea Victoria.* It displays bright visible fluorescence upon processing of the polypeptide structure, where a β-sheet conformation encloses a central α-helix, which forms the fluorophore. Such polypeptide labels can be produced by recombinant techniques and used as "intrinsic tags," both in vivo and in vitro. The sequences encoding the polypeptide can be incorporated into donor DNA. which is then translated to a protein-bearing GFP tag. Several variants of GFP were developed, giving a

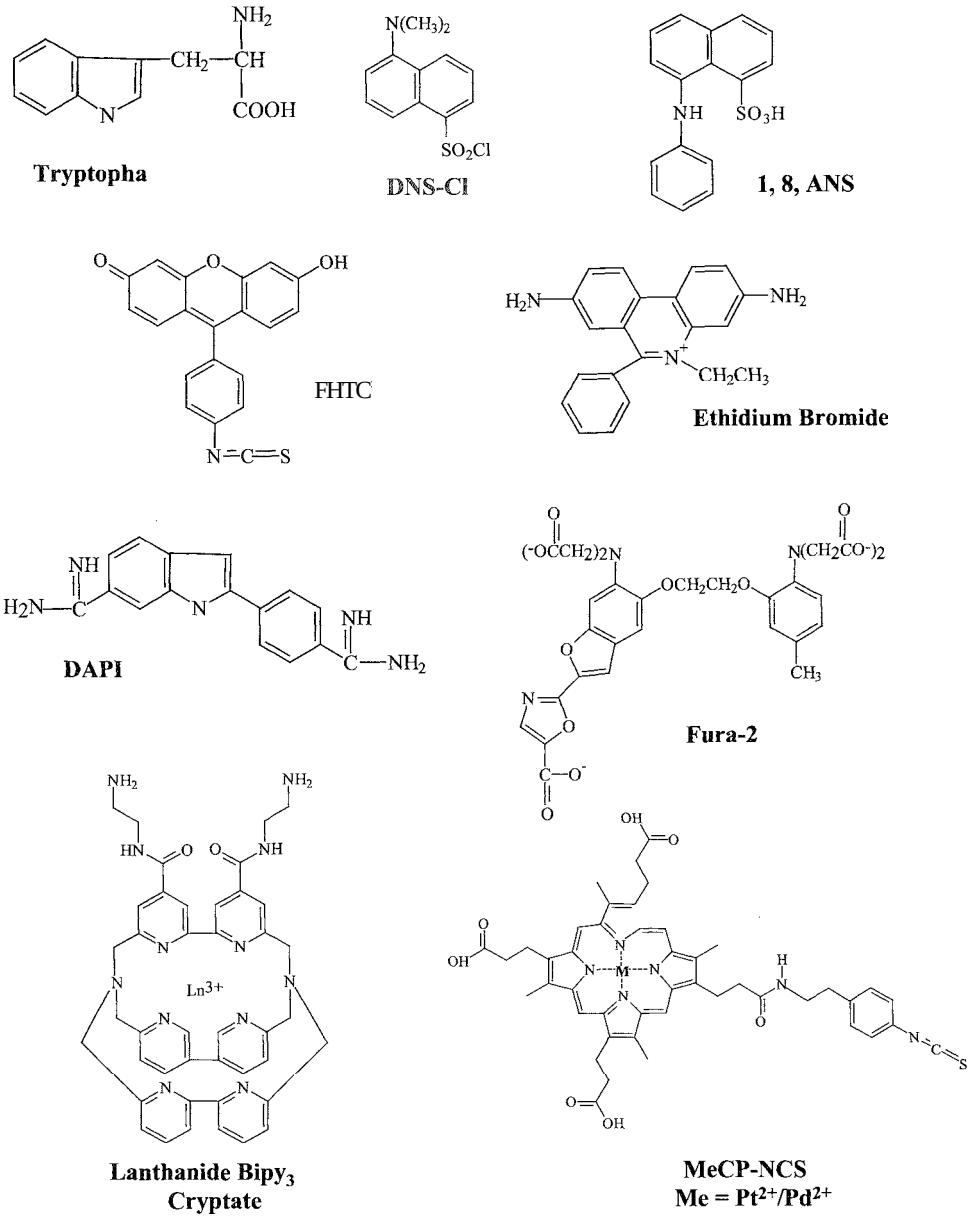

Fig. 3 Chemical structures of some fluorescent and phosphorescent compounds.

color palette of fluorescent proteins (see Table 1) available as labeling reagents and tags. They are actively used to study gene expression, synthesis and localization of protein markers, co-localization using FRET pairs, and multicolor detection.[14,15]

Probes for Micro- and Macroenvironments

The complex photophysics of luminescence makes luminophores sensitive to their immediate and macro-environments, so they can change emission characteristics in response to minor changes in the environment. Intrinsic fluorescence of amino acids was used to monitor the conformational dynamics and protein folding in vitro. Hydrophobic tryptophan residues tend to be buried within the core of folded proteins, thus shielded from an aqueous environment. Unfolding exposes tryptophan residues to an aqueous environment, which quenches their emission. These effects may be augmented by the presence of quenchers located within protein structures, e.g., a methionine residue, or a second tryptophan[11,16] or external quenchers present in or added to the sample.[17] The dynamics of protein folding, conformational change, or interactions with other molecules can be monitored in this way by measuring intensity, lifetime, or polarization of tryptophan fluorescence.

Similarly, 1-anilinonaphthalene-8-sulfonic acid (ANS) only emits in a hydrophobic environment, being almost completely quenched in aqueous solution. ANS and some other dyes, including 6-(*p*-toluidinyl)naphthalene-2-sulfonate, pyrene, 1,6-diphenyl-1,3,5–hexatriene, fluorescein, and rhodamine derivatives attached to long acyl chains or to fatty acids that localize in the cellular membranes were used as probes for hydrophobic sites in proteins, protein folding, imaging of membranes of the cell, and solvent polarity. Pyrene-labeled fatty acids were used to detect the fusion of two membranes. When prcscnt in a membrane at sufficiently high concentrations, pyrene excimers (excited-state dimers) are formed that emit at 470 nm. Upon fusion with other membranes, probe concentration decreases, and excimer fluorescence is replaced by monomer fluorescence at 400 nm. This process can be monitored by ratiometric detection of pyrene labels.[18]

The dyes that alter their emissions on binding to nucleic acids have high utility in molecular and cell biology. The mechanism of binding is intercalation of the planar aromatic dye structure into double-helical DNA, which is favored and stabilized by multiple electrostatic and hydrophobic interactions between the two matching chemical structures (see Fig. 4). Such an interaction has significant impact on the electronic structure of the dye,

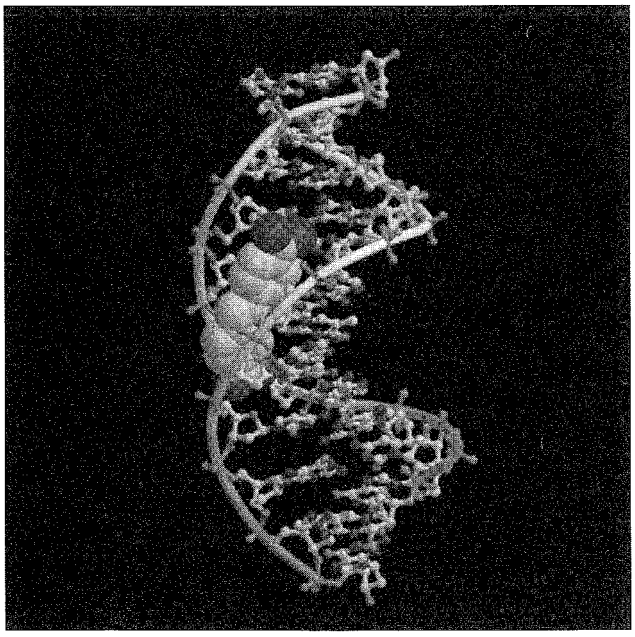

Fig. 4 X-ray crystal structure of DAPI intercalating with DNA. The image was obtained from the Protein Data Bank (*www.rcsb.org/pdb*, Nucleic Acids Res., 2000, 28, 235–242, no. PDR 1D30) with permission. The original structure was described in J. Biomol. Struct. Dyn, 1989, 7, 477. *(View this art in color at www.dekker.com.)*

its microenvironment, and its availability to quenchers, thus causing changes in luminescence. Ethidium bromide, a common fluorescent DNA stain, displays weak fluorcscscence in solution. On binding to double-stranded DNA, there is a 30-fold increase in intensity, with an increase in lifetime from 1.7 ns to approximately 20 ns. Some other fluorescent stains for DNA, RNA (acridine orange, Hoechst, DAPI), proteins (MDPF, SYPRO), and specific proteins (albumin blue 580) have found use for the detection and imaging of these biomolecules, e.g., in electrophoretic gels under UV excitation and in fluorescccnce microscopy.

Luminescent indicators

Luminescent indicators were used for a quantifying variety of biological and chemical specie and also ions such as $H^{\cdot}$, Ca^{2+}, K^{+}, I^{-}, Mg^{2+}, Cl , and Na^{+}. The basis of such probes is a change in luminescence properties in the presence of the analyte, which affects the luminophoric moiety.

Fluorogenic dyes are used as probes and reagents for particular chemical compounds. Nonfluorescent fluorescamine, when reacting with free amino groups, gives highly fluorescent products. A variety of fluorogenic enzyme substrates were also developed, such as β-methylumbelliferryl-β-D-galactopyranoside, which is cleaved by β-D-galactosidase enzyme, releasing highly fluorescent umbelliferrone. Such probes are employed in the detection of amino acids, proteins, sugars, and enzyme activity, with high sensitivity.

The ion-selective probes usually exist in two interchangeable chemical and spectral forms (free and bound) having different luminescent charactcristics. By determining the ratio of the two forms by luminesccncc measurements, the analyte concentration in a sample can be quantified, based on the known binding constant and probe concentration. Such indicators usually have limited dynamic range, which is detcrmincd by the binding constant:

$$0.1{*}K_{\mathrm{d}} < [C] < 10{*}K_{\mathrm{d}}$$

Fluorescent pH indicators are based on the protonation of some dyes. The phenolic moiety of fluorescein derivatives, such as 2′, 7′-*bis*-carboxyethyl-5(6)-carboxyfluorescein (pH range 6.5–7.5) is in the anionic form at higher pH, resulting in a longer wavclcngth absorbance band. On protonation of this group, the absorbance maximum is shifted to lower wavelengths. Other fluorescent pH indicators, such as the seminaphthorhohafluors and scminaphthofluoresceins (pH ranges 6.0–8.0 and 7.2–8.2, respectively), display changes in absorption and

emission maxima on protonation. Fluorescent pH indicators respond to minor changes in pH within the range of protonation (pK_a).[19]

Fluorescent indicators for ions are based on corresponding chelators. The Ca^{2+} indicators usually mimic the structure of ethyleneglycol-*bis*(β-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), which also contains an adjacent fluorophore moiety affected by the binding. The most popular intracellular Ca^{2+} indicator, Fura-2, displays a shift in excitation maximum between 300–400 nm when monitoring emission at 510 nm, thus allowing ratiometric measurements. Calcium Green displays an increase in emission at 530 nm on addition of calcium but displays no spectral shift. Other fluorescent calcium indicators with different affinities and spectral characteristics are available that allow for the measurement of Ca^{2+} from nano- to submillimolar concentrations.[19]

Long-decay luminescent dyes and probes that are effectively quenched by molecular oxygen can be used for its quantitation. Examples of such probes include ruthenium(II)-*tris*(diphenyl phenanthroline) and phosphorescent platinum(II) porphyrins. Their long emission lifetimes facilitate quantitation by lifetime or intensity measurements.[20] Other chemical specie, such as heavy-metal ions and heterocyclic compounds, can be quantified by luminescence quenching, according to Eq. 3.

Molecular Switches

Some probes containing luminophoric fragments may be switched into "on" or "off" luminescence modes in the presence of certain analytes. such as H^+, Cu^{2+}, and Ca^{2+}, by a process termed photoinduced electron transfer (PET). This sensing mechanism of such molecular switches uses the ability of certain chemical structures to quench the excited states of adjacent luminophoric moiety by electron transfer. On the recognition and binding of the analyte, the PET process may be curtailed, resulting in fluorescence off-to-on switching, or initiated, resulting in on-to-off switching. Molecular switches bearing two recognition sites for the same analyte facilitate production of off-on-off switches. Where PET is initially occurring, low concentrations of analyte terminate the process, and higher concentrations cause it to resume.[21] Potential applications for such probes include molecular electronics, computing, and data storage systems.

Polyfunctional and Long-Decay Luminescent Probes

A luminescent probe may contain more than one luminescent. functional, or chemical moiety in its structure. For example, for monitoring chemical specie intracellularly, it is essential to have a cell-permeant probe that can easily be loaded into the cell and then stay inside it. This is achieved with acetoxymethyl derivatives of the fluorescent indicators (AM-esters), which are nonluminescent and hydrophobic and tend to accumulate in cell membranes. where the ester groups are cleaved by cellular esterases, producing a water-soluble fluorescent probe that is trapped inside the cell.[22]

Dual-labeled luminescent probes contain pairs of dyes attached to a functional chemical or biological structure, such as specific oligonucleotide or peptide sequence. The detection is based on the monitoring of close-proximity quenching of the reporter dye, which is dependent on the probe conforination. Chemical or biological recognition or transformation alters the effective distance and the degree of interaction between the dyes, thus producing positive or negative luminescent response.

The molecular beacon probe contains an internal oligonucleotide sequence specific to target DNA, short self-complementary sequences at both 3'- and 5'-ends, and the donor and quencher dyes attached to these ends. Such a probe exists in two main conformations. In the absence of a target, it forms a hairpin structure ("dark" complex), with the dyes close to each other. The self-hybridization and quenching can be eliminated by the target sequence, which hybridizes to the probe with greater affinity, or by exposing the probe to high temperatures (melting). Opening the hairpin structure increases the distance between the two dyes, thus eliminating proximity quenching. Such probes were coupled with DNA amplification in polymerase chain reaction (PCR), so that they produce a luminescence response proportional to the amount of a target DNA. Such closed-tube format is called real-time PCR.[23] Mechanism of action of these probes is shown in Fig. 5.

Similar principles are employed in the fluorogenic peptide substrates and TaqMan® DNA probes, in which the luminescent label is quenched due to close proximity of the other dye. Enzymatic cleavage of the probe during the assay separates the two dyes. thus causing enhancement of the luminescence of the reporter. Pairs of single-labeled RET probes are used for sensing molecular interactions in solution, such as immuno, receptor, or DNA-binding assays.[23] Similar approaches were used for cell-based assays for proteases, such as proapoptotic caspases. where the fluorphor and quencher are conjugated on opposite sides of a specific amino acid recognition sequence. Upon cleavage, energy transfer terminates. and the signal is enhanced. Luminescent labels employed for these schemes include xanthene dyes (FITC, rhodamines, TAMPRA), coumarin derivatives, and lanthanide chelates.

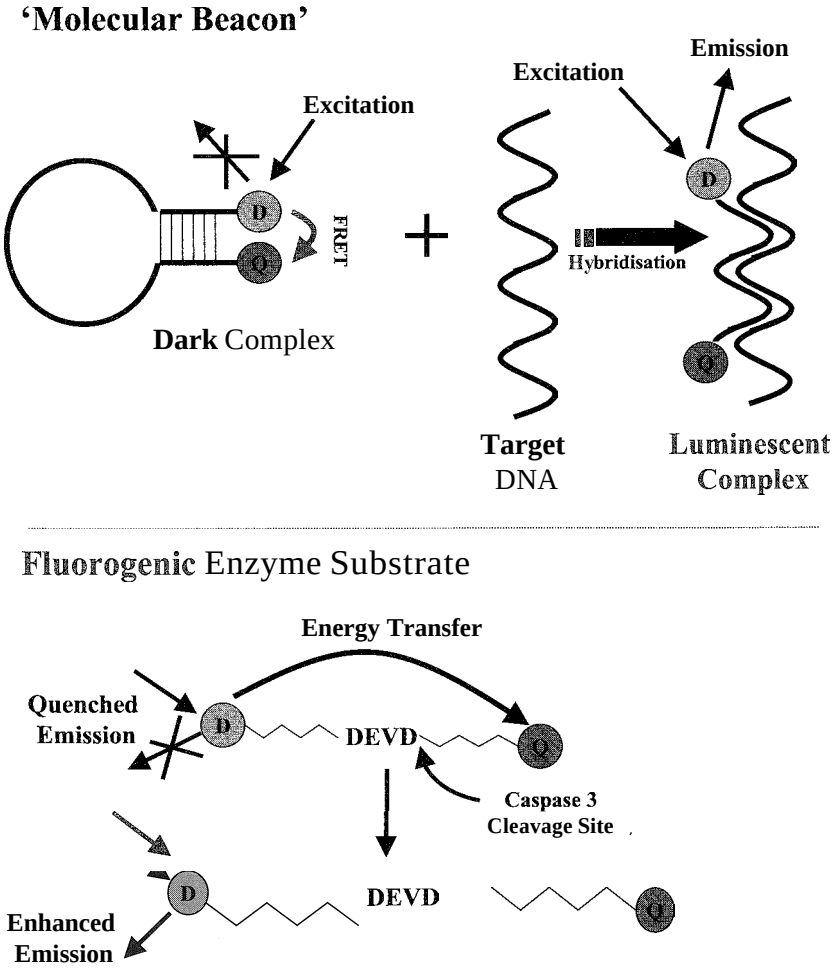

Fig. 5 Two RET-based sensing schemes. A molecular beacon structure with a fluorescent donor (D) and a quenches (Q) enhances emission upon target hybridization. A protease substrate with donor and acceptor conjugated to an amino acid recognition sequence (DEVD) enhances emission upon enzymatic cleavage. (*View* this *art in color at www.dekker.com.*)

Probes based on long-decay luminescent complexes of lanthanides (Eu^{3+}, Tb^{3+}, Sm^{3+}) and transition metals (Ru^{2+}, Os^{2+}) usually contain a central metal ion responsible for luminescence but with weak intrinsic absorbance; aromatic ligands serving as "light antennae" that absorb UV-light and transfer its energy via their excited triplet states to the metal ion; ancillary chemical groups and ligands shielding the luminophore from quenching by water and other molecules; and a linker arm, a functional chemical group for covalent attachment, and a chemical or biological moiety that recognizes the target analyte.[4,24] In contrast, the luminescence of metalloporphyrin dyes originates from the tetrapyrrolic macrocycle, but it is greatly affected by the nature of the central metal ion coordinated by the porphyrin ring and by axial ligands.[25] Pt^{2+}- and Pd^{2+}-porphyrins are particularly interesting because of their bright short-decay phosphorescence at room temperatures, and practically no fluorescence. They were used as sensitive labels for binding assays based on time-resolved luminescent detection[12] and as probes for oxygen sensing.[20] Other porphyrin complexes can be fluorescent (metal-free, Mg^{2+}), fluorescent and phosphorescent (Zn^{2+}, Al^{3+}), or nonluminescent (Fe^{3+}, Co^{2+}, Ni^{2+}). Structures of lanthanide chelates and metalloporphyrins are given in Fig. 3.

CONCLUSION

Overall, luminescent probes provide a powerful and versatile tool for studying supramolecular structures and their practical uses. Multiple intrinsic and extrinsic parameters of chemical and biological samples are measurable by their means. Accompanying multiple detection formats facilitate the collection of large amounts of information about supramolecular structures, their macro- and micro-

environments, and their interactive processes. Such probes allow for a variety of (bio)analytical applications, and they are actively being exploited in many areas of research and human practice.

Macrocycle Synthesis

Bernard Dietrich
ISIS—Université Louis Pasteur, Strasbourg, France

INTRODUCTION

Over the past decades, the number of macrocyclic compounds have increased in an explosive manner. This fast-growing phenomenon is due to the discovery of an impressive number of new macrocyclic families of natural. seminatural, or artificial origins: porphyrins, phthalocyanins, cyclodextrins, calixarenes, coronands, cryptands, spherands. etc. Special mention has to be given to the impressive number of natural bioactive macrocycles isolated from soil bacteria and, more recently, from marine organisms. The importance of these metabolites may be illustrated by their medical applications as antibiotics (nonactin, erythromycin), immunosuppressants (cyclosporin, FK506), and an anticancer agent (cytovaricin), to mention just a few. Thus. the macrocyclic type of structure is constantly supplied by two main sources: 1) the supramolecular chemistry field. for which the macrocyclic arrangement is of fundamental importance and which still plays a major role in the design of specific (macrocyclic) targets; and natural sources: which give access to new macrocycles, usually exhibiting complicated chemical skeletons and requiring sophisticated tools for elucidation of their structures. The most extravagant and the a priori most complicated target molecule will invariably fascinate some (high-rank) chemists who do not hesitate to rush in the gambling of total synthesis. As an almost general rule in macrocycle synthesis, the methodology consists of a step-by-step building of a linear precursor, followed by the macrocyclization event, which usually takes place in one of the final seeps. The necessity of obtaining a high yield in this crucial step has been, and still is. the major stimulus for efforts to improve existing macrocyclization methods or to discover new ones.

In this article, we will first present some general considerations of cyclization and then concentrate on some of the various synthetic approaches. The synthesis of macrocyclic families will not be covered here. as this topic is treated in detail in other entries of this Encyclopedia (see articles on calixarenes. cyclodextrins, porphyrins, etc.)

HISTORY

The emergence of macrocyclic chemistry came surprisingly late and was beset with difficulty, because for a long time, it was a common belief that macrocyclic compounds did not exist. The story of the macrocycle started at the beginning of the nineteenth century when Walbaum isolated from natural musk the odor principle, which he called muscone, and then a few years later, Sack isolated the odor principle from civet (civetone). But elucidation of the chemical constitutions of these compounds was accomplished only in the mid-1920s by L. Ruzicka, who presented in his Nobel Lecture a description of the difficulties he encountered: ''I was hindered less by the caprices of the substance itself than by the general prejudice, shared by myself, against the probability of the existence of a 15- and a 17-membered ring.''[1] The above-mentioned compounds were indeed identified as being 15- and 17-membered macrocyclic ketones.

Shortly after these investigations. he described a method for the synthesis of macrocyclic ketones by thermolysis of thorium or cerium salts of dicarboxylic acids. Unfortunately, the yields were poor. Between 1930 and 1950, several efficient methods were devised: the use of high dilution conditions (K. Ziegler); depolymerization methods (W. H. Garothers); and acyloin condensation (V. Prelog, M. Stoll). With the start of the supramolecular chemistry field in the 1960s, and the simultaneous growing interest in natural macrocyclic compounds, a large number of new synthetic methods were developed. A select and, due to space limitations. restricted number of procedures will be described here.

GENERAL CONSIDERATIONS

For the past 70 years or so. the cyclic compounds have been divided into four families depending on the number (n) of atoms in the ring: small rings ($n = 3,4$); normal rings (n = 5,6,7); medium rings ($n = 8$–11); and large rings or macrocycles ($n \geq 12$). This classification is the result of several empirical and experimental facts. The ease (or

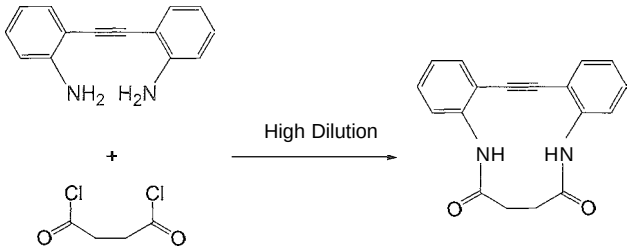

Fig. 1 First macrocycle synthesized in 1912 by the high dilution method.

difficulty) of cyclization as a function of ring size was recognized a long time ago, and the first classification was based on these results. More elaborate is the classification established from the heats of cornbustion of cycloalkanes per CH_2 group. with cyclohexane acting as the reference. These values reflect the ring strain, which is maximum for small rings (angular strain) and high for medium rings (transannular repulsive interactions). It should be noted that in macrocycles, there is no more ring strain, and the difficulty of the syntheses rests on other factors, as will be shown below.

HIGH DILUTION

The story of this fundamental technique used in many macrocycle syntheses is odd. In 1912, P. Ruggli was interested in the synthesis of cyclic compounds containing a triple bond in their ring. He realized that because of the intrinsic properties of a triple bond, the ring had to be large. He estimated that a 12-membered ring would be appropriate to fulfill his expectations. So, trying to afford such a 12 membered ring, he discovered that operating in ''normal conditions'' leads essentially to an insoluble polymer, and that in order to obtain the target molecule, the reaction should be carried out in high dilution conditions[2] (Fig. 1). This publication came too early and did not attract attention, mainly because at that time. nobody was interested in macrocycles.

Elegantly, in a large footnote of one of his publications K. Ziegler admitted that he ''rediscovered'' the high dilution principle 20 years later.[3]

In the reaction described in Fig. 1. the reactants are bifunctional, and the first step is intermolecular and does not present any difficulty. The problems arise in the second intramolecular step (see Fig. 2a). The long chain formed by the first connection between X and Y can be assumed to exist in a large number of shapes, but the specific conformations required for ring closure are limited. Expressed in another way, one has to assume that in a long chain there exists only a low probability of encountering the two remaining reactive centers X and Y. Therefore, in order to allow this reaction to occur, the competitive intermolecular reaction should be avoided. This can be achieved by operating in high dilution conditions, i.e., leaving the reactive molecule ''alone'' for the time necessary for the intramolecular encounter of the reactive ends X and *Y*. This type of high dilution reaction involving bifunctional reactants was largely used, for example, for the first cryptand synthesis. The one-component cyclization (Fig. 2b) is another common alternative that was used, for example, in the amide formation from a carboxylic acid and a terminal amine. This is the type of reaction mainly used in the synthesis of the elaborate natural compounds. Here again, high dilution will favor the intramolecular reaction between X and *Y*, thus affording a single macrocycle and minimizing the intermolecular reactions leading to a dimer or various oligomers. A schematic summary of the two major types of macrocyclization methods requiring high dilution conditions is given in Fig. 2.

One may note that in both methods, valuable side products can be obtained (formation of larger rings by 2+2 or 1+1 condensations in Fig. 2a and 2b, respectively). In a more practical viewpoint, several comments have to be made. In the one-component cyclization the two reactive centers are present on the same molecule. What arises, therefore, is the need to hide the reactivity of the two centers (or at least one of the centers) until the ultimate moment. This is usually realized in the following way: 1) one end of the reactive center is activated, while the other center is maintained in an unreactive form; 2) then, a solution of the linear precursor is slowly added to a well-stirred solution containing the substance that is able to activate the protected site (bases often play this role). For

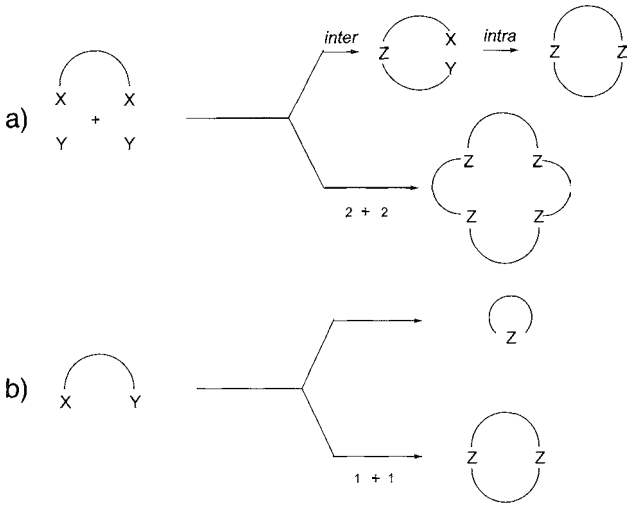

Fig. 2 Two-components (a) and one-component (b) cyclizations.

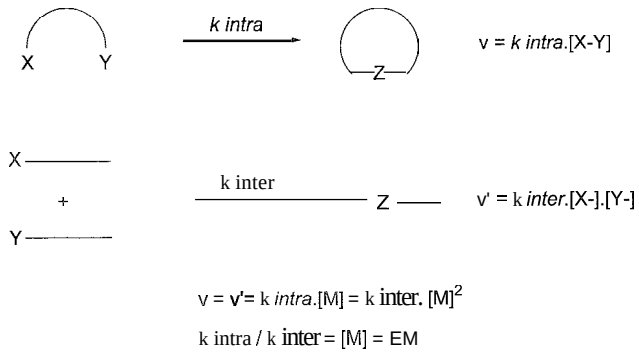

Fig. 3 Intramolecular cycliration and intermolecular reaction between two model reactants—the effective molarity (EM) definition.

the two-components cyclization. the procedure is simpler: solutions of the two reactants are introduced into two precision dropping funnels, and the two solutions are added very slowly to a well-stirred large volume of solvent. As noticed above, the two-components method becomes, after the initial intermolecular reaction, a one-component reaction with its specific requirements. We will, therefore, concentrate our attention on this type of reaction.

Going more deeply into the subject, the first question we can ask is: what is really a reaction conducted in high dilution conditions? Rigorous studies are rare, so we will mention one of the most studied, developed by Mandolini and Illurninatti. in which they introduce the concept of effective molarity.[''] They defined the effective molarity (EM) as being the concentration at which the rate of intramolecular reaction is similar to the rate of intermolecular reaction (Fig. 3).

Thus, at this concentration equal amounts of cyclic and open products are formed. A significantly more diluted solution will, therefore, give predominantly the desired macrocycle. Conversely, a solution that is too concentrated will afford almost exclusively polymers. This rigorous procedure is, in practice, not used, and the cyclization reactions are conducted on the basis of more empirical considerations that, nevertheless, respect the necessity to operate in low concentrations.

Several other factors also play a role: the presence of heteroatoms (oxygen, nitrogen, sulfur) in the chain or the presence of rigid groups (aromatic ring) usually favors the formation of macrocycles.

We will turn our attention toward the synthesis of macrocyclic lactones, macrocyclic lactams, cyclopeptides, and macrocarbocycles, which are abundant in nature. Retrosynthetic cleavage of the lactone function, lactam function, and cycloalkanes provides an ω-hydroxy-acid, an ω-amino-acid, and an open-chain hydrocarbon derivative, respectively, which can therefore be considered a good precursors for the formation of the parent cyclic compounds (Fig. 4).

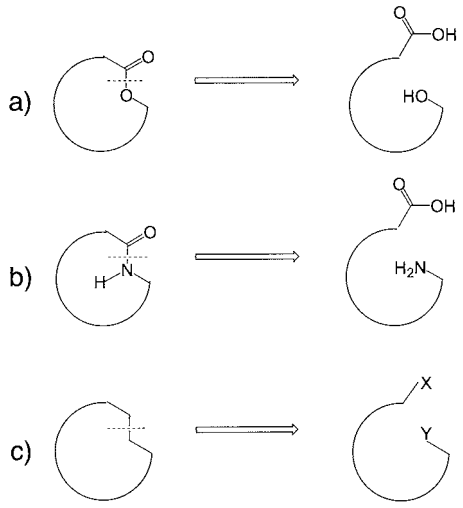

Fig. 4 Retrosynthetic cleavage of (a) rnacrocyclic lactone, (b) rnacrocyclic lactam, and (c) macrocarbocycles.

The intramolecular esterification of simple ω-hydroxy-acids (for example, those containing only a saturated hydrocarbon chain) or of its ω-halogeno derivative can be realized easily (Fig. 5), but the harsh reaction conditions are not compatible with the numerous sensitive functions present in the seco ω-hydroxyacids of natural origin. The necessity to perform the lactonization in a smoother way has been an efficient motor for progress. The same considerations apply for the macrolactamization or the formation of macrocarbocycles of natural origins.

The development of activating groups for acid and alcohol functional groups led to great advances in macrolide chemistry.[5] Many such activating groups for acids or alcohols were developed to improve macrocyclization. Some examples of activating groups for carboxylic

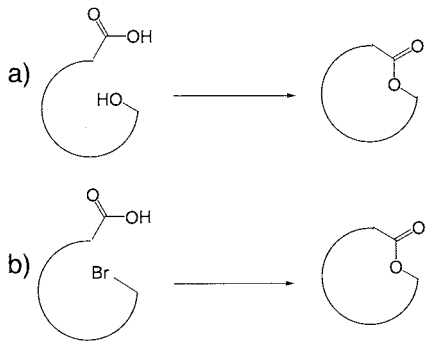

Fig. 5 Lactone synthesis from (a) ω-hydroxy- or (b)ω-bromo-acids.

acids are given in Fig. 6: thiol esters (1,2): 2-acyloxypyridinium or 2-acyloxybenzothiazolium (3,4); and mixed anhydrides (5,6). One may be surprised by the large number of activating groups. But, the screening of total synthesis of natural macrolides reveals that in each case. one group is the most efficient. This may be due to the stereochemistry of the linear precursor, which plays a crucial role. The best conforination of the linear precursor is the conformation that brings the two reactive sites in close proximity. Nevertheless. the conformation is an intrinsic property of the precursor. on which the operator has little influence (by change of solvent, for example). Also important are the relative orientations of the interacting sites, the steric hindrance, the lipophilicity, etc. The prolific production of activating agents has been realized by talented chemists such as Corey, Nicolaou, Mukaiyama, Masamune. Roush, and Yamaguchi among many others.

Two other important methods are described in Fig. 7. The first is a macrolactonization mediated by the Mitsunobu reaction. In this case, in contrast with the preceding examples. the hydroxyl functional group is activated, and the carboxylate group behaves as a nucleophile. The reaction of the hydroxy acid with diethyl azodicarboxylate and triphenylphosphine leads to ring closure via an alkoxyphosphonium carboxylate intermediate (Fig. 7a).

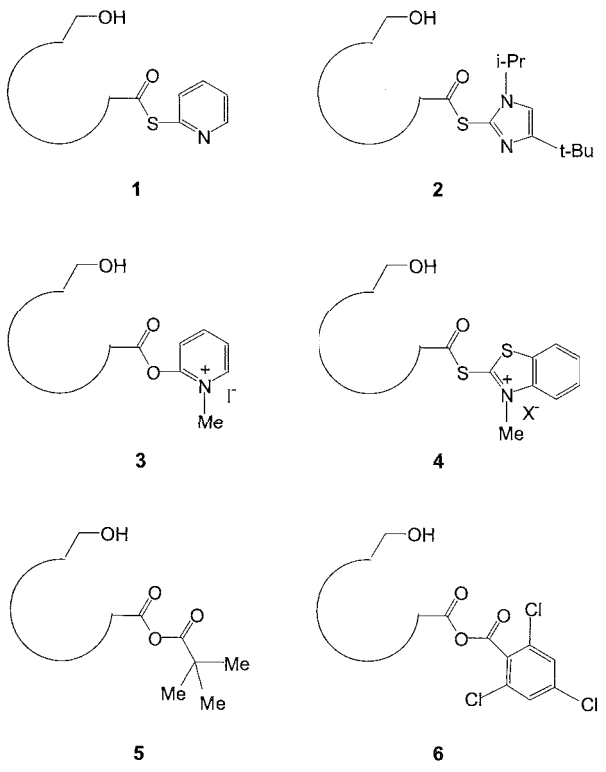

Fig. 6 Activating groups for an acid functional group: 1 and 2, thiol esters; **3,** 2-acyloxypyridinium; 4, 2-acyloxybenzothiazolium: and **5,** and 6, mixed anhydrides.

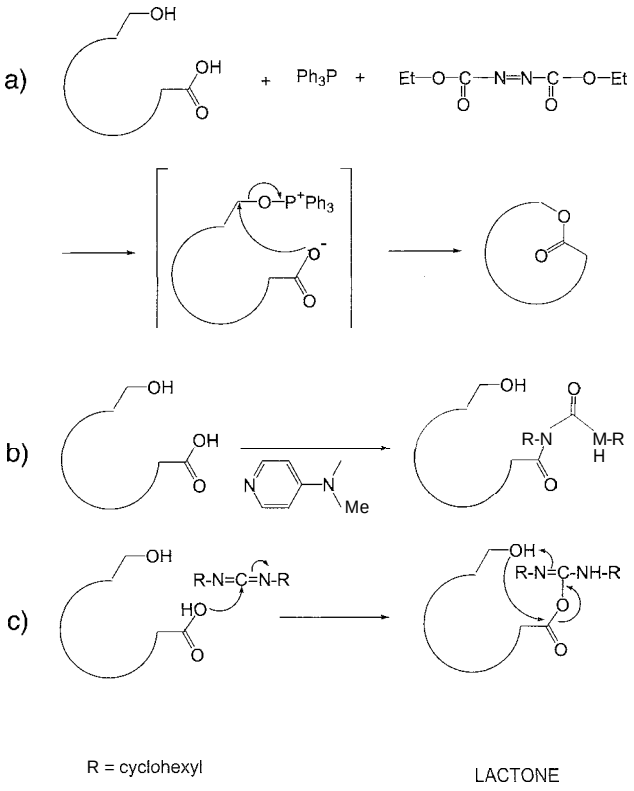

Fig. 7 Macrolactonizations mediated by (a) the Mitsunobu reaction; (b) the Steglich esterification run in the presence of DMPA, which gives only an urea derivative; and (c) high yields of lactones, which are obtained in the presence of a proton source (DMPA, HCl).

The second example is based on Steglich esterification, for which it was shown that the yield of esterification reaction using dicyclohexylcarbodiimide is greatly increased by the addition of 4-dimethylarninopyridine (DMPA). However, in the case of w-hydroxyacids under these reaction conditions, the N-acylurea derivative is formed almost exclusively (Fig. 7b), with almost no lactone formation. The reason for this failure appears to lie in the proton-transfer steps. By operating in the presence of a proton source (DMPA-HCl), the lactonization occurred in excellent yield (Fig. 7c).

Many other activating groups have been elaborated. and further examples can be found in a review on synthesis of natural macrocyclic compounds.[6]

The lactam functional group is encountered in numerous macrocyclic lactams like, for example, the inacrocyclic polyamine alltaloids and the ansamycin antibiotics. Lactam formation can be achieved by intramolecular reaction between acyl chloride and amine functional

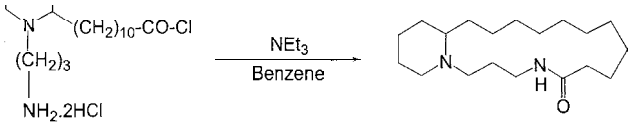

Fig. **8** Macrolactam synthesis by intramolecular reaction of an ω-acyl chloride-amine

groups. Tne reaction can be carried out by slow addition of the precursor **1** into a large volume of benzene containing triethylamine (Fig. 8).

Several methods of activation of the acid functional group have been described (hydroxypiperidine, thiophenol, thiazolidine-2-thione.).[7] Mixed anhydride methods (phosphonic, phosphoric. sulfonic, carbonic anhydrides) have been used in the final steps of many impressive total syntheses (rifamycin S for example).

The biological importance of cyclopeptides is widely known (oxytocin. vasopressin: cyclosporin, etc.). During the syntheses of these compounds. several problems were encountered. In particular, good protecting groups are needed for the amino acid side chain functionality, and efficient coupling methods are needed.[8] The general principles governing macrocyclization, which were covered extensively above, can be applied in this case (Fig. 9). The methodology consists of constructing the linear precursor step by step. At this point, the acid moiety is activated using classical reagents for peptide synthesis, while keeping the amine moiety protected (by

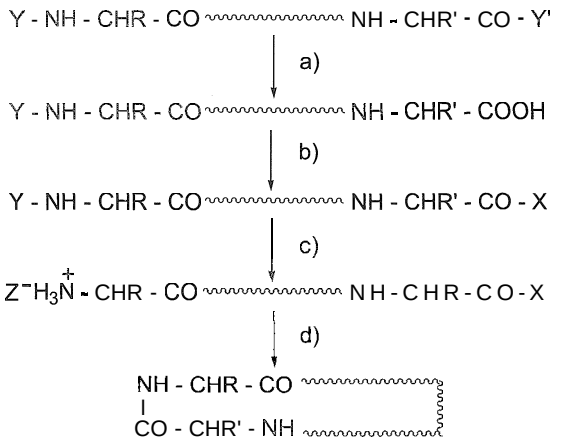

Fig. **9** Macrocyclopeptide synthesis: *Y*, Y are protecting groups; X is an activating group. (a) Deprotection of the carboxyl group; (b) activation of the carboxyl group: (c) acidic deprotection of the terminal amine; and (d) cyclization in a basic medium. The high dilution conditions are obtained by the slow addition of the protonated amine into a large volume of pyridine.

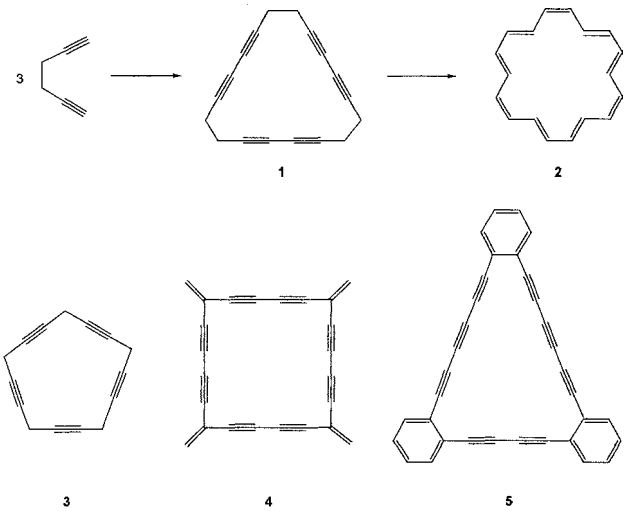

Fig. 10 Formation of carbomacrocyles by oxidative coupling of diacetylenes. 2: [18] annulene: **3.** 4, and **5,** macrocyclic-oligoacetylenes.

protonation) after removal of Y. The cyclization reaction takes place during the slow addition of the activated precursor to a basic medium (pyridine, for example).

Among compounds containing only carbon atoms in the macrocyclic framework, the macrocarbocycles, we will first mention the annulenes that were important synthetic targets in the 1960s. An important method

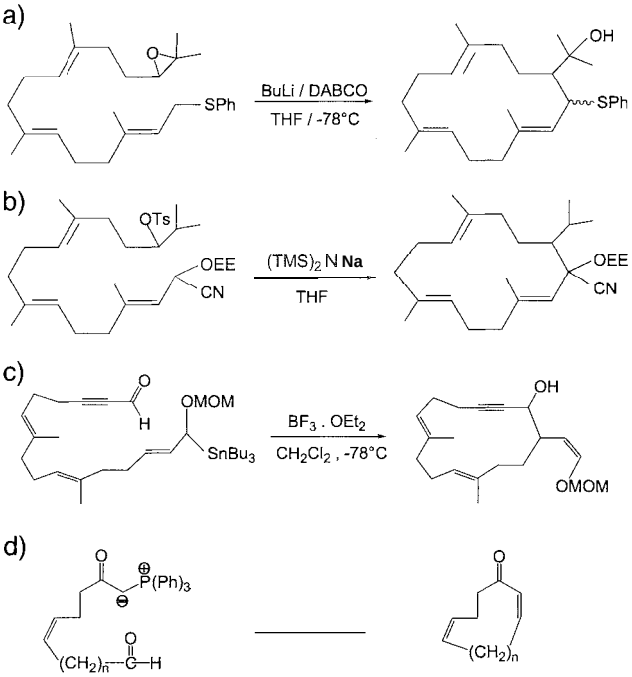

Fig. 11 (a–d) Natural macrocpcles syntheses via carbon–carbon bond formations.

allowing the preparation of macrocarbocycles relies on the oxidative coupling of terminal diacetylenes in the presence of copper acetate (Fig. 10). Thus, the coupling of the hexadiyne gave the cyclic trimer **1,** which on rearrangement and partial hydrogenation afforded 2. This method was extended to the formation of many annulenes. In recent years, the field of macrocyclic oligoacetylenes has exploded. Hundreds of these compounds have been synthesized by carbon–carbon bond formation often using the oxidative coupling described above or closely related reactions[9–11] (3. 4, and *5,* in Fig. 10). The interest in these compounds rests on their potential applications as advanced materials.

In the field of synthesis of natural macromolecular carbocycles, macrocyclization through formation of a carbon–carbon bond has been intensively investigated. We will give just a few examples: the alkylation of carbanions (Fig. 11a, 11b); the addition of allylstannane to aldehyde (Fig. 11c); and the intramolecular Wittig reaction (Fig. 11d).[6 9–11]

Powerful methods make use of metal-catalyzed macrocyclization. We mention the following: the allylic alkylations catalyzed by palladium[12] (Fig. 12a); the reductive coupling of dicarbonyl compounds[13] (Fig. 12b); the Stille coupling[14] (Fig. 12c); and ring closing metathesis[15] (Fig. 12d).

SOLID-PHASE SYNTHESIS

The macrocyclizations using the high dilution method described above were carried out in an homogeneous medium. Heterogeneous conditions have also been explored. A long-known example is the acyloin cyclization developed by Prelog and Stoll. The diester was added to a suspension of liquid sodium in boiling xylene and was efficiently stirred (Fig. 13a). The high yields were attributed to coordination of the diester to the surface of the metal, hence, isolating the molecules from each other and bringing the chain ends in close proximity.

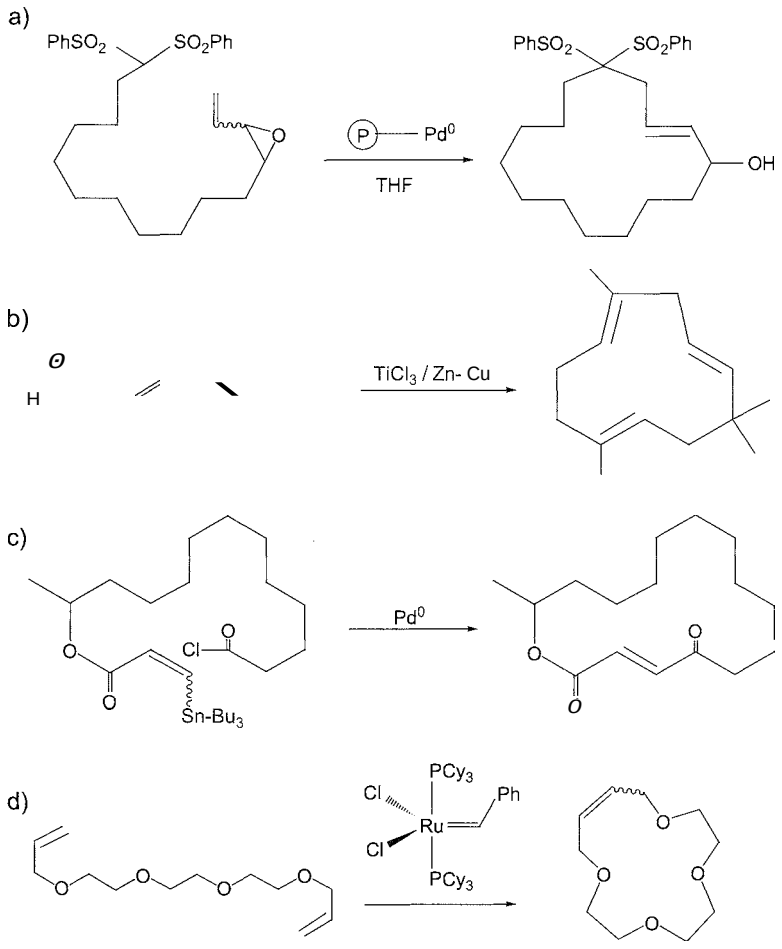

Fig. 12 (a–d) Examples of metal-catalyzed macrocyclizations.

Solid-phase synthesis[16] offers a more rational approach toward high dilution in a solid–liquid heterogeneous medium by using a polymer support to bind the reactant, which leads to site isolation on a solid matrix (Fig. 13b). The loading of the beads should be accomplished in order to ensure real site isolation. Solid-phase synthesis was initially designed for peptide syntheses, and the solid-phase methodology was largely used in the preparation of cyclopeptides.[8] The principle of the procedure is illustrated in Fig. 13c. The first step consists of binding amino acid 5 (which had to be trifunctional, such as glutainic acid: asparagine, tyrosine, serine, and cysteine) onto the polymer. By using the amine and carboxylate functional groups of 5, two linear chains are elaborated in parallel to afford polypeptides having amino acids 1 and 9 at the two chain ends as end-products. This is followed by cyclization and then cleavage of the cyclopeptide from the polymer support.

The necessity to have practically quantitative coupling is required, because the separation of the target peptide from the side products is almost impossible when the number of peptide residues becomes large. This requirement is still a significant problem in the synthesis of the numerous existing cyclosporins which are characterized by a large number of N-methyl amino acids that have weak reactivity toward activated acids due to their steric hindrance. One may note that in this series of compounds, the cyclization was not accomplished on the resin but on the linear undecapeptide precursor after its cleavage from the resin.[17]

In recent years, combinatorial synthesis has become a powerful tool in organic synthesis, in particular; in the field of drug research.[18] This methodology has also been efficiently applied on solid-phase support. Two examples make use of the intramolecular Heck reaction, and large libraries of peptides or nonpeptides have been prepared. The first example (Fig. 14a) concerns the synthesis of various derivatives containing the Arg-Gly-Asp (RGD) sequence—a biologically important tripeptide unit.[19] In the second example, a large number of macrocycles of the type described in Fig. 14b were obtained in good yields.[20] In both cases, the libraries were elaborated by

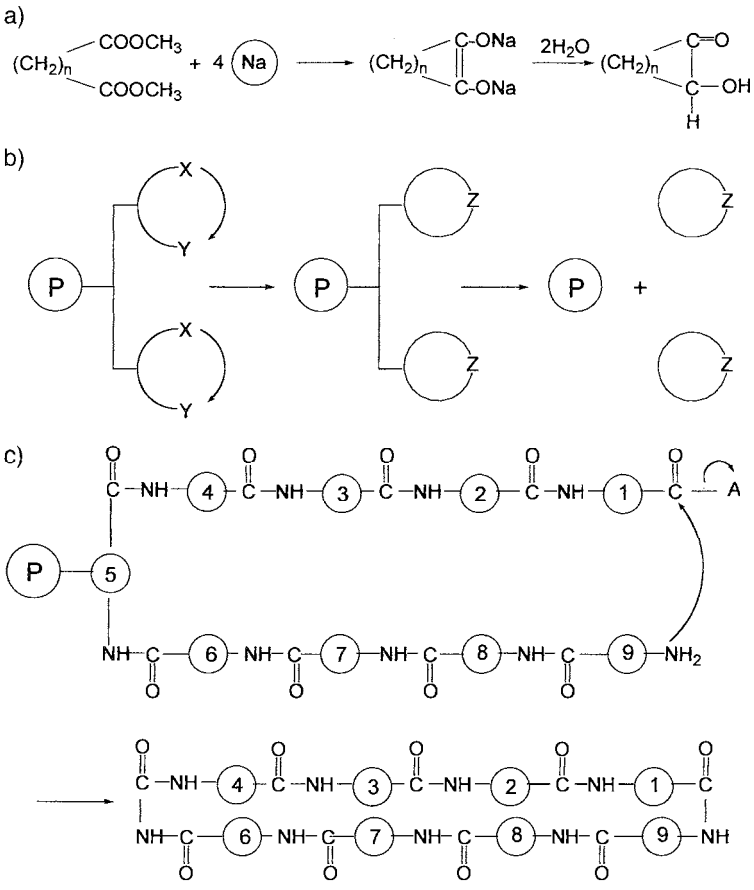

Fig. 13 (a) Acyloin cyclization, an example of macrocyclization in an heterogeneous medium: (b) scheme for cyclization on a polymer support; (c) and synthesis of a cyclopeptide on a polymer support.

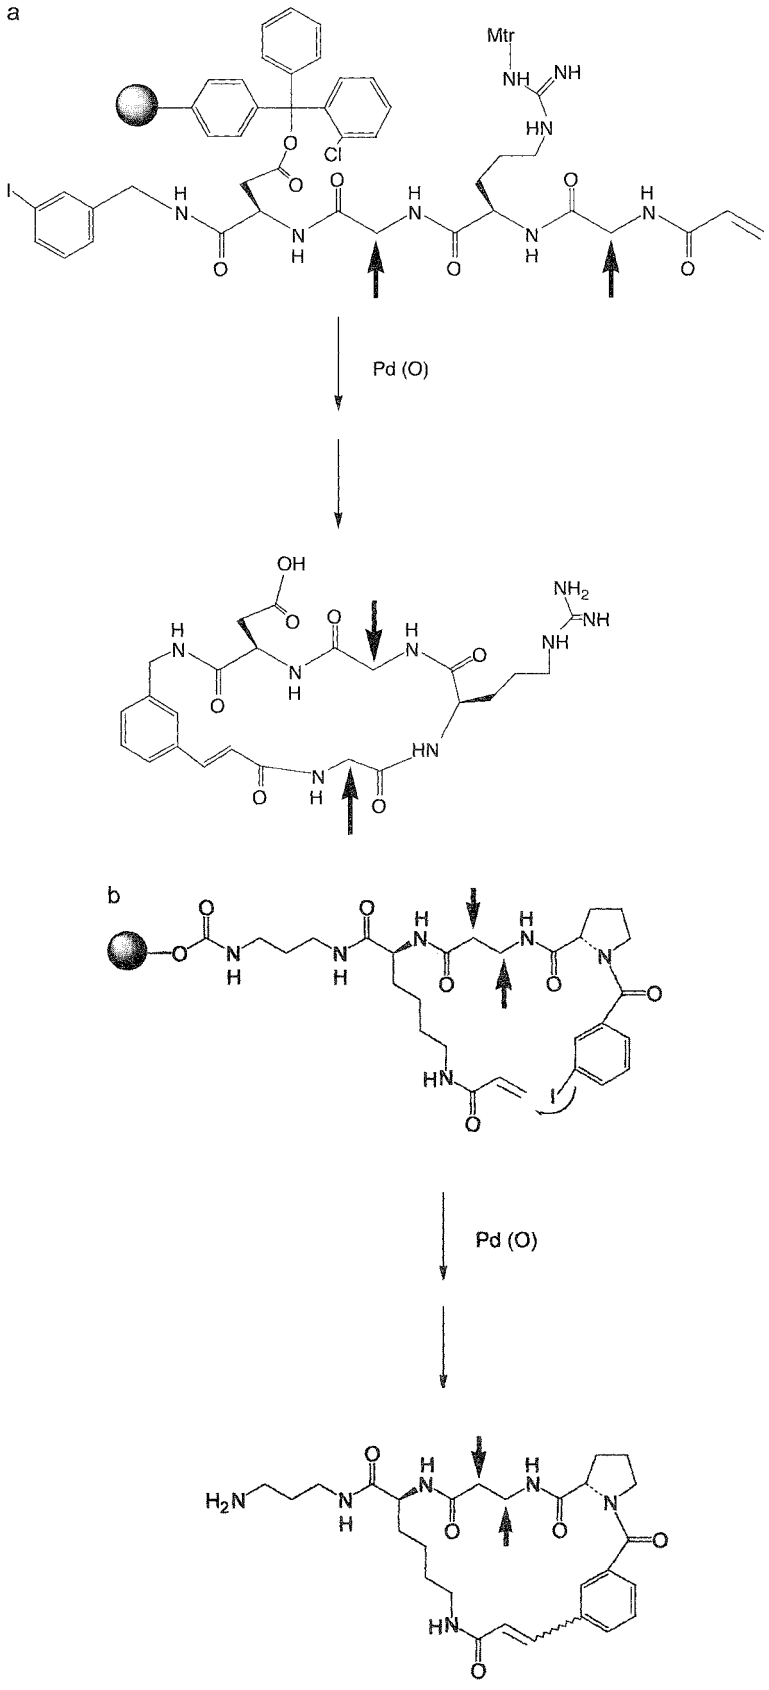

Fig. 14 (a,b) Intramolecular macrocyclizations on a solid support using the Heck reaction.

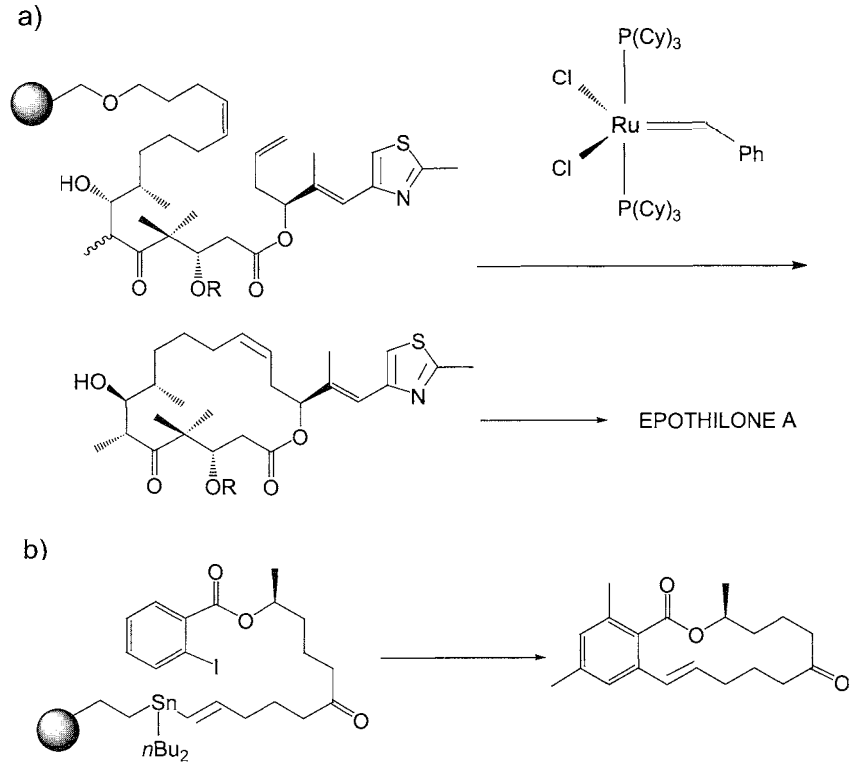

Fig. 15 Examples of cyclorelease: (a) ring-closing metathesis (this reaction afforded several macrocycles, among which we describe only one) and (b) Stille coupling.

the introduction of various substituents in the positions indicated by arrows.

To complete this short treatment on solid-phase synthesis, let us be mention the efforts made by several groups to obtain methods that allow a cyclorelease (also called cyclative cleavage) of the macrocycle, in other words. the cyclization reaction and the release from the polymer support occur simultaneously. The methods developed so far involve the metathesis reaction (Fig. 15a);[21] the Stille coupling (Fig. 15b);[22] and sulfur ylides (Fig. 16a).[23]

In the strategy described in Fig. 16b, the linear precursor is not built on the polymer, but the final cyclization reaction using the Suzuki–Miyaura coupling takes place on a polymer. The aryl boronic acid is captured on a Dowex ammonium hydroxide resin. leading to the polymer ionically bonded borate, which is subsequently treated in the appropriate conditions to give the final macrocyle. This methodology is called "resin capture–release.."[24]

PHASE-TRANSFER CATALYSIS

In classical phase-transfer catalysis (PTC), the catalyst (often a quaternary ammonium salt) transfers the reagent (the associated anion) from the aqueous phase into the organic phase containing the substrate. Another alternative is the solid–liquid phase-transfer catalysis in which the insoluble salt incorporating the active anionic species is in suspension in the organic solvent containing the substrate and the phase-transfer catalyst. This method has been applied to the synthesis of macrolides. The catalytic cycle affording various lactones is shown in Fig. 17.

It should be noted that this reaction is a special case of solid–liquid catalysis, because the anionic species, solubilized by the catalyst, is both reactant and substrate. Also of importance is the fact that because the tetrabutylammonium salt is used in catalytic quantities, the concentration of active species (the tetrabutylammonium carboxylate) remains very low throughout the reaction, which is therefore conducted in high dilution conditions. As expected, the yields are excellent.[25] Another type of PTC is the triphase catalysis,[26] having as a peculiar feature, the catalyst immobilized on a polymer (solid phase), which is in contact with the aqueous and organic phases containing the reactant and the substrate. respectively. This method presents the major advantage of avoiding the problem of catalyst and product separation. Various macrolides have been synthesized by this procedure.

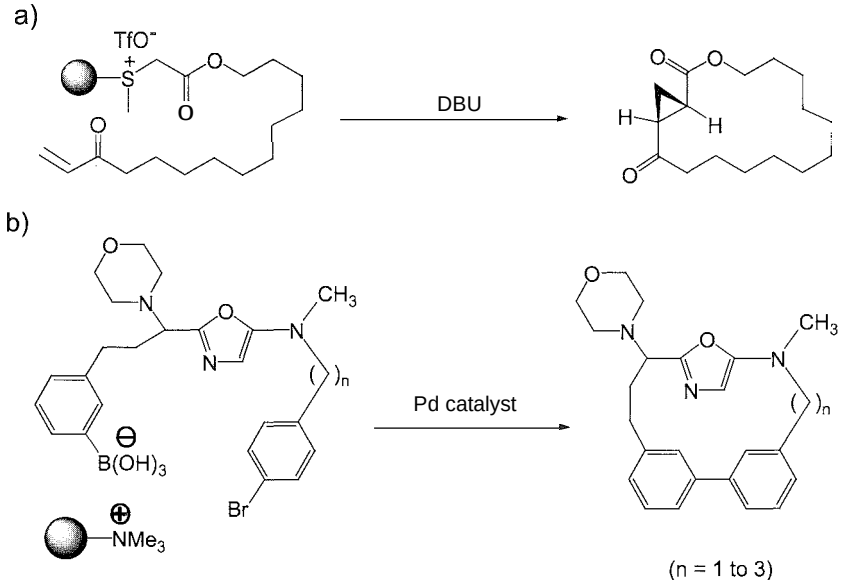

Fig. 16 (a) macrocyclic lactone synthesis by cyclorelease via a sulfur ylide and (b) macrocyclization via intramolecular Suzuki–Miyaura coupling: an example of resin capture–release.

HIGH PRESSURE

High-presrure chemistry has been applied in many fields, including organic synthesis. The method is based on the volume of activation $\Delta V^{\neq}$ that characterizes each reaction. Depending on the type of reaction. $\Delta V^{\neq}$ can be positive, negative, or close to zero. Reactions occurring with a negative volume of activation are favored by an increase of pressure. Formation of a quaternary ammonium salt from a tertiary amine and an alkylating agent is a reaction with a negative $\Delta V^{\neq}$. Jurczak et al. made use of this property in the synthesis of cryptands (Fig. 18a). The yields of diquaternary salts are very high (80–100%), and the demethylation step occurs in lower yields (50–90%).[27] High-pressure conditions were applied more recently to the synthesis of chiral macrocyclic tetraamides (Fig. 18b). These compounds are obtained in various yields (7–61%) by reaction of chiral diesters with α,ω-diamines under 10 kbar pressure.[28]

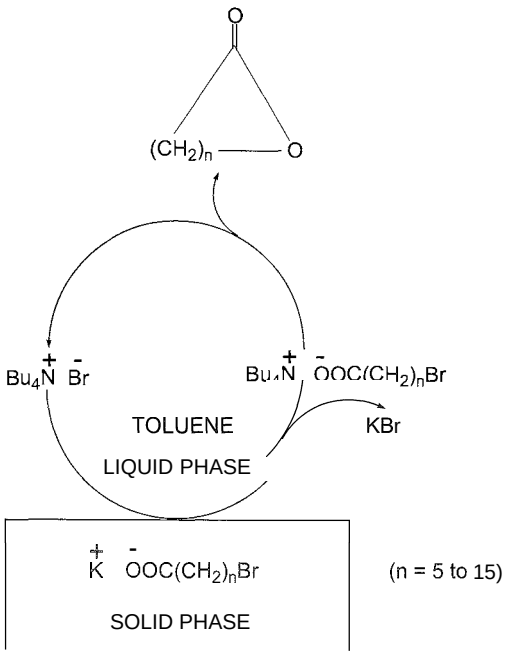

Fig. 17 Lactone synthesis by solid–liquid phase-transfer catalysis.

The Diels–Alder reaction has a negative $\Delta V^{\neq}$, and high-pressure conditions are particularly well adapted for this reaction. Using these conditions, Stoddart et al. synthesized, by successive Diels–Alder reactions, a[14] cyclacene derivative (Fig. 19).[29]

TEMPLATED MACROCYCLE SYNTHESIS

The synthesis of a macrocyclic ligand in the presence of a metal cation has been used since the mid-1960s. N.F. Curtis and D.H. Busch should be mentioned as pioneer workers in the field.[30] The so-called "template effect" is simple to understand. The presence of a metal cation leads to positioning of the reactants (by virtue of the presence of coordinating sites) such that macrocyclization is highly favored (Fig. 20).[30]

(d) Key-steps of the formation of the trefoil knot: formation of the double-helix 3, and cyclization by reaction of the diido compound—the coupling should occur between the phenol functions 1 and 4. 2 and 3. respectively. (The author thanks J.-P. Sauvage and C.O. Buchecker-Dietrich for supplying these figures.)

An elegant extension of the template effect is catenane (interlocked macrocycles) synthesis, which is based on the formation of a stable tetrahedral precursor complex between Cu(I) and the diphenolic derivative of 1,10-diphenylphenanthroline. This property has been used in the construction of a catenate, as shown in the synthetic scheme of Fig. 21a.

The key step in this approach is the formation of the precatenate **1** from the diphenolic derivative of 1,10-diphenylphenanthroline in presence of Cu(I). It can be seen that in structure **1,** the four phenol groups are in good position for subsequent attack and hence cyclization by the diiodo compound giving the catenate 2 (Fig. 21b). The Cu(I) ion can be easily removed by treatment with potassium cyanide, affording the catenane.[31] The tridimensional template effect induced by Cu(I) was extended to the formation of a trefoil knot (Fig. 21c,d).

Finally, dynamic combinatorial chemistry (DCC) opens new perspectives for templated syntheses. Early work was accomplished by the late M. Nelson, who studied in detail the condensations between diamines and 2.6-diacetyl-pyridine in the presence of various metal cations. To conclude, he found that the macrocyciic compounds formed depend on the overall proportions of the reactants and the type of cation used as the template. Related studies were accomplished using pyridine dialdehyde and several diamines (Fig. 22).[32]

The macrocyles formed depend on the overall proportions of 1 and 2, the diamine chain length and the type of cation used as the template. Of importance is the fact that the imine formation is a reversible reaction. Expressed in the DCC sense, one can say that all products. the macrocycies and the nonrepresented oligomers and polymers. are in constant equilibrium. and that all the species represented in Fig. 22 constitute a virtual combinatorial library (VCL). From this library, the high proportion of a specific macrocycle can be obtained by the use of the appropriate conditions (type of metal template, relative proportion of reactants).[32]

To conclude this part on dynamic combinatorial chemistry, we will mention the use of a polymer bound N-methyl ammonium ion as a template. The library is generated from the pseudopeptide building block mPro, which gives a dynamic library of hydrazones (Fig. 23). Depending on the conditions, the following will be formed at equilibrium: in the absence of a template, 85% of the cyclic dimer and 7% of the cyclic trimer: in the presence of the template BTA, 47% of the dimer and 50% of the trimer; and in the presence of the immobilized template. 40% of pure trimer can be isolated by washing the resin.[33]

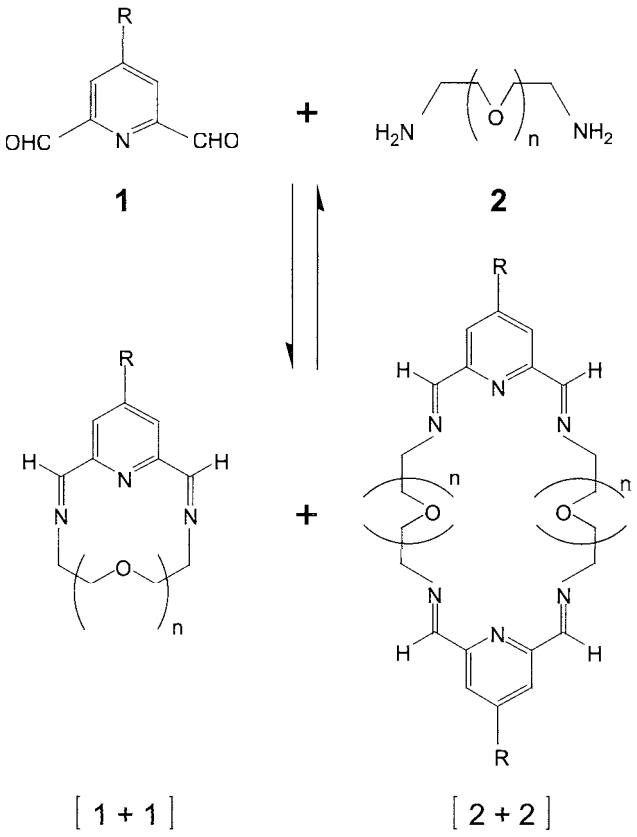

Fig. 22 Condensation of diamines with a dicarbonyl compound. The size and nature of the macrocycles thus obtained are strongly related to the relative overall proportion of the two reactants, the chain length of the diamine, and the template cation used.

CONCLUSION

Before concluding this limited survey of macrocyclic synthesis, the author would like to mention a few other aspects. For several important purposes. the syntheses of isotopically labeled macrocycles have been described.[34] Strategies leading to very large macrocycles were developed.[35] And, promising perspectives can be expected by elucidation of the biosynthetic mechanisms of the numerous natural macrocyclic compounds.[36,37]

INTRODUCTION

Recent breakthroughs in catalyst synthesis resulted in the development of a number of novel methodologies for the preparation of mesoporous inorganic materials with extremely high surface areas and ordered mesostructures. These "nanostructured" materials are of great interest to scientists in many disciplines, with potential applications as catalysts, separation media. and advanced electronic materials. Although improvements and new variations continue to be developed for all of the methods described below, the range of applicability and pace with which new mesoporous materials were described in the past decade are evidence of interest in this area as a continuing source of new, technologically relevant materials.

BACKGROUND

Briefly reviewed in this article are the current methodologies available for preparing mesoporous inorganic materials other than silicon oxides and their properties. Currently. the most important general synthetic approach utilizes mixtures of aqueous surfactants or amphilic block copolymers to create high-surface-area solids containing organized arrays of mesoscopic channels. This method, commonly referred to as "surfactant templating" or "liquid crystal templating" is the main focus of this article. A brief survey of mesoporous materials other than oxides is also included at the end of this article. For more comprehensive overviews of this area, the reader is directed to several reviews and monographs that recently appeared.[1–5]

The preparation of mesoporous silicas and aluminosilicates using aqueous mixtures of surfactants and solgel chemistry was first described by scientists at Mobil Oil.[6] The essence of this new methodology involves the use of molecular assemblies of surfactants or related substances as structure directors during formation of oxides. The mechanism for the organization of such mesostmctures involves electrostatic interactions and charge matching between micellar assemblies of quaternary ammonium cations and anionic silicate oligomer species.[5] Complex mesoscopic silicon oxides are produced by fluctuating chemical affinities and local perturbations of self-assembled surfactant molecules at the organic–inorganic interface during oxide formation processes. Here, the surfactant assemblies are used as scaffold-like templates to direct mineralization along. around, and between the organic–inorganic interfaces through "organized reaction fields." Illustrated in Fig. 1 is a simplified view of the original mechanism for synthesizing mesoporous silicon oxide based on this method.[7] From this mechanism, it can be seen how the principal methodology can be extrapolated to prepare mesophases with different metal oxides. as long as there is an interacting complementarity between the inorganic ions in solution and the surfactant head groups.

Stucky and coworkers proposed a general model for surfactant templating based upon the cooperative organization of inorganic and organic molecular species into three-dimensional mesoscopic arrays.[7] They divided the global surfactant-directed ordered porous material synthesis process into three reaction steps: multidentate binding of the inorganic oligomers to the cationic surfactant assemblies, preferential polymerization of the inorganic species in the interface region. and charge density matching between the organic and inorganic interfaces. The interaction between inorganic precursors and organic surfactants is not limited to electrostatic interactions but also includes hydrogen and dative bonding interactions or may be mediated by countercharged ions. The surfactants used in synthesis can be cationic, anionic, or neutral, depending on the charge of the inorganic precursors. Basic guiding principles in rationally synthesizing mesoporous metal oxide materials were developed.[7] In general, there are six main methodologies for synthesizing high-surface-area mesoporous metal oxide materials:

1. I^-S^+, where positively charged surfactant (S^+) interact with negatively charged inorganic (I^-) oxide precursors via coulombic interactions.
2. I^+S^-, where negatively charged surfactant interact with positively inorganic oxide precursors via coulombic interactions.
3. $I^+X^-S^+$, where positively surfactant molecules interact with positively charged inorganic oxide precursor, through a negatively charged mediator (X^-).

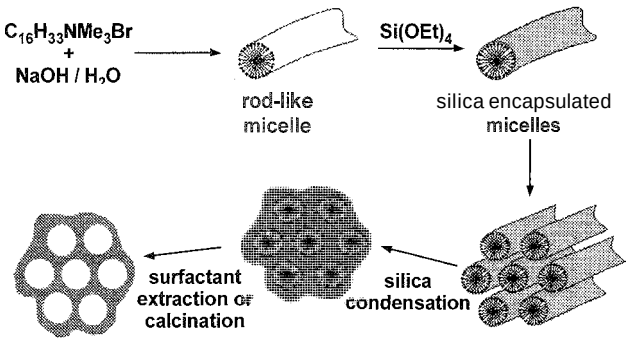

Fig. I Simplified illustration of the process of surfactant ternplating of silica based sol-gels. (*View this art in color at www.dekker.com.*)

4. I←S. where inorganic precursors interact via dative bonds with surfactant templates.
5. I^0S^0, where neutral template molecules such as amine and block copolymer surfactants interact with inorganic oxide precursors via hydrogen bonds or coordination bonds.
6. Phase transformation from a lamellar materials.

The as-synthesized mesostructures obtained from these six methods consist of spatially and chemically well-defined arrays containing inorganic species and organic template molecules which are not porous. Ordered pore structures result when the surfactant templates are removed from the channels between metal oxide domains. Removal of the surfactant templates is commonly achieved by calcination at 400–800°C or by extraction with solvents that have high solubilities for the corresponding surfactant templates. When porosity is maintained, calcination provides a measure of the chemical and thermal robustness to the matrix.

The ordered structures formed in the case of metal oxides other than silica are more susceptible to the collapse of pore structures with high-temperature treatments. This destruction of the ordered mesoscopic structures was ascribed to the crystallization of the metastable amorphous metal oxide phase, frequently leading to solids with no ordered mesophases. Although a majority of the metal oxides can be prepared in high-surface-area mesoporous forms with the above methodologies, few robust. ordered mesoporous materials with crystalline wall structures have been obtained to date. Accordingly, one of the remaining challenges in this area is to develop generally applicable synthetic approaches that yield thermally and chemically robust mesoporous metal oxides.

A second synthetic challenge is to make the walls of mesoporous materials out of mixed oxides (binary and ternary oxide systems). The key difficulty associated with syntheses in this case lies in control over different hydrolysis rates of the different metal species, which may cause the sequential precipitation and phase segregation. In addition to the mixed oxides, the mixed valent mesoporous metal oxides are also interesting because of their unique semiconducting and catalytic properties. So far, these oxide materials are derived from the corresponding parent mesoporous metal oxides through redox reactions.

In all of the methodologies listed above, the basic components of each system consist of a metal oxide precursor, similar to those used in solgel syntheses, a surfactant templating agent, water, and frequently a cosolvent. The size and organization pores in the final material can be predicted and controlled through a consideration of the molecular properties of the surfactant and its phase diagram in aqueous solutions. The size of the micelles is the most important factor defining the position of the pore size maximum. Within a series of similar surfactants having different tails, the pore size maximum increases with tail length. The addition of nonpolar, "swelling" reagents provides one means of adjusting the pore size maximum over significant ranges without changing surfactant.[5]

The most commonly observed ordered pore arrangements are lamellar and hexagonal close packed, both of which have nonintersecting mesopores (Fig. 2), and a cubic arrangement of intersecting pores that has overall cubic symmetry. Less-ordered "wormhole" arrangements of mesopores are sometimes observed in systems involving nonionic surfactants. It should be borne in mind, however, that surfactant-templated solids do not display the same order as crystalline microporous zeolites. The walls of the pores, whether crystalline or amorphous, frequently exhibit significant microporosity, presumably due to the presence of cracks and defects in the walls that can connect mesopores within the solid. Furthermore, the diameter along the length of the mesopore may have irregularly spaced bottlenecks or bulges, which effect access and transport in the matrix.

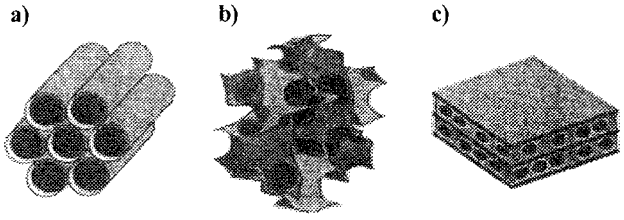

Fig. 2 Illustrations of mesoporous M41S materials: (a) hexagonal MCM-41, (b) cubic MCM-48. and (c) lamellar MCM-50.[1] *(View this art in color at www.dekker.com.)*

Although fundamentally the same approach is used to prepare mesoporous silica and aluminosilicates, what distinguishes the syntheses of mesoporous metal oxides from silicas is that the hydrolysis and condensation rates involved in the formation of the oxide phase are much faster and thus more difficult to control. Developing methods and adjusting conditions (e.g., amount of water present, pH. complexing agents) that bring these two processes under control so that continuous, robust oxide matrices are formed around the micelles was a ''rate-limiting'' step in the general development of mesoporous metal oxides. In the following. we try to summarize the recent results in using the above six methodologies to synthesize nonsiliceous mesoporous materials.

SYNTHESIS METHODOLOGIES FOR MESOPOROUS NONSILICEOUS METAL OXIDES

Nonsiliceous Mesoporous Materials via Cationic Surfactants (I^-S^+)

As is clear from the suggested mechanism, the interacting inorganic precursors should be negatively charged. Accordingly, the reaction pH values involved in this methodology should be above the isoelectric points of the corresponding oxides.[8] The hydrolysis reactions under these conditions are usually very fast, so that only powder morphologies are obtained. The most common cationic surfactants used in this inethodology are alkylainmonium salts such as cetyltrimethyl ammonium halides $(C_{16}H_{33}NMe_3)X$ (X = Cl, Br). An earlier example of synthesizing mesoscopic metal oxides using cationic surfactant templates is the work by Stucky and coworkers.''] They showed that anionic metal oxide clusters [e.g., ammonium metatungstate $(NH_4)_6H_2W_{12}O_{40}$] can interact with cationic surfactant templates to form the hexagonal mesoscopic composites. The metal oxide precursors usually do not form a connected oxide framework. Accordingly, removal of the templates by calcination usually results in the collapse of the mesopores, as found in the case of tungsten oxide. Su and coworkers''' recently successfully obtained mesoporous zirconium oxides with the I^-S^+ methodology. consistent with an earlier investigation by Knowles and Hudson.[10] The calcined mesoporous zirconium oxide exhibits mesopores with wormhole-like channels. Thermally stable zirconia (sulfate and oxophosphate) was also prepared through the use of cationic ammonium-based surfactants.[11] Mesoporous iron oxide was prepared using CTAB and sonochemical acceleration of the reaction.[12] Sayari and coworkers succeeded in preparing the mesoporous hafnium oxide in the presence of a cationic surfactant (CTAB).[13]

Suib and coworkers demonstrated that a mesoporous mixed-valent manganese oxide can be successfully synthesized by the direct precipitation of manganese hydroxide precursors in basic conditions.[14] The ordered mesoporous structure with crystalline pore walls was retained after calcination: as confirmed by powder x-ray diffraction (XRD) and transmission electron microscope (TEM). Such mixed-valent mesoporous oxides are semiconducting and possess catalytic activity in the oxidation of alkanes. The mixed oxidation states of manganese (III/IV) in these materials were introduced by the direct oxidation of the metal precursor [Mn(II)]. Both hexagonal and cubic phases of such mesoporous materials can be synthesized.

Ozin and coworkers recently extended the supramolecular I^-S+ assembly into the synthesis of binary mesoporous yttrium oxide-stabilized-zirconium oxide materials.[15] These materials were synthesized by a modified sol-gel method under basic conditions. where zirconium ethoxide and yttrium acetate were used as the precursors for the transition metal oxides. and CTAB was used to form the supramolecular templates. The use of ethylene glycol with coordinating capability as a cosolvent may play a role in controlling the hydrolysis rate and solubility of zirconium(IV) and yttrium(III). This synthesis strategy is similar to that of so-called polymerizable-complex method, which was widely used to prepare multicoinponent single-phase oxides.[16] The yttrium content in these binary materials can be tuned from 12–56 wt%, and no phase segregation of yttrium and zirconium oxides was observed. These materials could be applied in designing new solid oxide fuel-cell electrode materials.

Nonsiliceous Mesoporous Materials via Anionic Surfactants (I^+S^-)

In contrast to the above methodology. pH conditions used in this synthesis methodology should be below the isoelectric point of the corresponding oxides and above the pK_a of the anionic surfactant for strong interaction on the interface between the anionically charged template and the developing positively charged oxide. Because most of the oxides have significant solubilities in low pH conditions. this methodology requires more control over synthesis conditions. Typical surfactants used in this methodology are dodecyl sulfate[17] and phosphate.[18] Huo et al. synthesized mesostructured lead and iron oxides by the supramolecular assembly of iron and lead polycations and anionic surfactants (dodecyl sulfate).[7] Mesoporous zirconium oxide. yttrium oxide,[19] and rare earth oxides[20] were synthesized using dodecyl sulfate and dodecyl phosphate as templates. In several cases. however, no ordered mesostructures were observed via TEM and XRD studies after calcination.

This destruction of the ordered mesostructures can be attributed to the crystallization of zirconium oxide in the calcination step.

Nonsiliceous Mesoporous Materials via Mediated Coloumbic Interaction ($I^+X^-S^+$)

Stucky and coworkers[17] proposed that under certain conditions (usually strongly acidic), an electrical double layer develops between the surface of the oxide and surfactant head groups (i.e., $I^+X^-S^+$). The templates used in this synthesis methodology can be cationic surfactants or neutral surfactants with hydrophilic head groups that can be charged through protonation under strong acid conditions. Syntheses are, therefore, conducted below isoelectric points, and the rate of hydrolysis reactions can be tuned to be slow so that thin films or other morphologies (e.g., monoliths) can be synthesized via this methodology. Because the surface charge on the oxide is balanced by the presence of the mediating anion (X halide), removal of the surfactant does not require replacement by a new cation. Therefore, the surfactant template can be effectively removed by simple leaching with solvent rather than calcination, but both methods are used.

There are many well-documented examples of the methodology having been applied to nonsiliceous mesoporous materials. For example, mesoporous aluminophosphates using CTAB in acidic media were described.[21] Recently, Bhaumik and Inagaki successfully used a similar methodology to prepare ordered mesoporous titanium phosphates.[22] The ammonium-based surfactant templates were removed via ion-exchange processes. The unique property of the resulting mesoporous materials is their ion-exchange capability. Similar mesoporous materials can also be synthesized by the S^-I^+ methodology.

One of the most versatile methodologies for the preparation of nonsiliceous ordered mesoporous materials involves the use of nonionic, block copolymer surfactants in alcoholic or mixed solvent systems under highly acidic conditions. This general procedure is thought to involve a combination of electrostatic, H-bonding, and van der Waals forces as the forces behind the self-assembly and templating process. Stucky and coworkers described that over 25 nonsiliceous, ordered mesoporous metal, and main group oxides were prepared using this approach.[23] In general, metal chlorides or metal alkoxides were used as metal oxide precursors that, when contacted with alcoholic solutions of a variety of block copolymers, formed mesostructured solids. To limit the rates of hydrolysis and condensation, the above mixtures were simply allowed to stand in air for variable times (1–30 days), whereby moisture was absorbed, thus providing a "controlled" source of water. High surface area (100–800 m^2/g), thermally robust, mesoporous (3–12 nm pore diameter maxima) samples of pure and mixed metal oxides were obtained using this method. All retained mesoporosity and long-range order in their mesopore structures after calcination. Shown in Fig. 3 is a TEM image of a typical mesoporous titanium oxide prepared by this methodology.

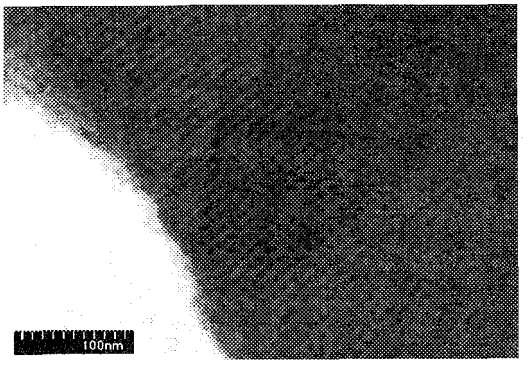

Fig. 3 TEM image of mesoporous TiO_2 synthesized at ORNL. *(View this art in color at www.dekker.com.)*

This methodology enjoys the merits of other approaches and exhibits several additional advantages: 1) it has proven applicable to a wide range of transition metal and main group oxides; 2) the metal precursors studied so far are readily available, being either alkoxide or halide complexes; 3) in many cases, syntheses can be run in alcoholic solvents in essentially nonhydrolytic conditions, which aids in controlling hydrolysis and condensation rates; 4) the critical micelle concentrations required for polyethylene-oxide–polypropylene-oxide di- and triblock copolymers are usually much lower than the concentrations needed for ionic surfactants;[5] and 5) because of the neutral, nonaqueous conditions used in these preparations, control of pH is not required, and the surfactant can be removed from the mesostructured material by calcination or milder solvent extraction methods with nonpolar solvents.

Two recent variations of this methodology are the synthesis of single crystals of mesoporous niobium and tantalum oxides[24] and the rapid preparation of titanium dioxide solids using sonochemistry.[25]

Nonsiliceous Mesoporous Materials via Complexing Surfactants (I^0S)

An approach that does not rely on electrostatic interactions between charged groups at the oxide–surfactant interface involves precomplexing surfactant ligands to the oxide precursors before exposing them to water. The metal precursors are generally alkoxide complexes [e.g., $Ti(Oi-Pr)_4$, $Nb(OEt)_5$] that are typically mixed with the surfactant in alcohol solution. Control of the mesostructure phases can be accomplished by adjusting the

surfactant:metal ratio. while the rate of hydrolysis can be controlled by regulating the vapor diffusion rate of water into mixtures. Both neutral (aliphatic amines such as dodecylamine) and charged (e.g., alkylphosphates) amines proved successful in this "ligand-assisted" methodology for preparing mesoporous oxides of titanium, niobium, and tantalum.[26–28] Although amine surfactants are usually preferred due to the ease with which they can be removed cleanly by simple solvent extraction. carboxylate surfactants were also used with sonication to shorten reaction times.[29]

Nonsiliceous Mesoporous Materials via Neutral Surfactants (I^0S^0)

The interactions between surfactant and oxide responsible for mesostructuring are primarily hydrogen bonding or simply hydrophilic/hydrophobic interactions between the various polymer blocks of the copolymer. An important drawback of this methodology is that the mesostructures of the resulting materials frequently exhibit long-range order. Instead, they have mesopore assemblies that resemble disordered, interconnecting, wormhole-like channels. Examples of this methodology include the preparation of mesoporous alumina,[30] aluminophos-phates,[21] and tungstated zirconia.[31]

Tilley's group recently showed that this method of surfactant templating can be extended to high-temperature pyrolysis of organometallic silicates to produce mesoporous, high-surface-area, metal–silicon oxides with narrow pore size maxima.[32]

Nonsiliceous Mesoporous Materials via Phase Transformation from a Lamellar Phase

Neeraj and Rao demonstrated an interesting lamellar-to-hexagonal-to-cubic phase transformation for an as-synthesized zirconium oxide ternplated by a neutral amine surfactant.[33] This methodology is based on the facile precipitation synthesis of the lamellar oxides in basic conditions and subsequent removal of some of the surfactant templates. The latter process induces the curling of the surfactant bilayer in order to minimize the surface/interface energy, as shown in Fig. 4. This mechanism is similar to the formation of mesoporous silica FSM-16.[34] The curled surfactant bilayers gradually change to cylindrical rods, which further assemble to the ordered hexagonal mesostructures.

This elegant methodology can be exploited to synthesize other nonsiliceous mesoporous materials. In fact. Yada et al. observed several similar transformations of lamellar yttrium-based mesophases teinplated by dodecyl sulfate to the corresponding hexagonal phases.[19] In this case, no cubic inesophases were observed. even after long reaction times Mesoporous magnetic materials based on rare earth oxides[20] and a binary mesoporous yttrium aluminium oxide[17] were also successfully synthesized through this phase transformation methodology

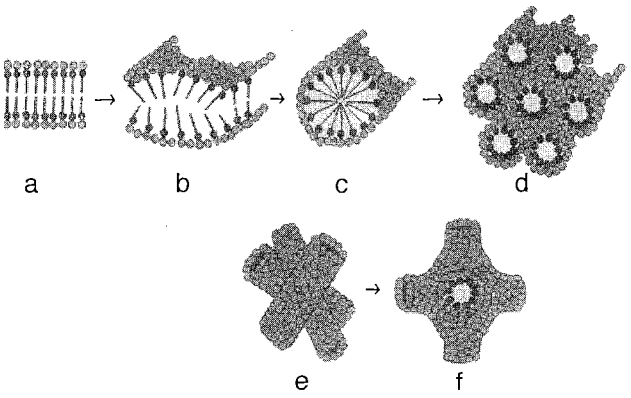

Fig. **4** Schematic representation of lamellar 4 hexagonal phase transforination (a through d) and the hexagonal 6 cubic transformation (e and f). The shaded circles around the surfactant aggregates represent the inorganic species (generally metal alkoxides or other metal-oxo species).[33] (*View* this *art in color. at www.dekker.com.*)

MESOPOROUS MATERIALS OTHER THAN METAL OXIDES

The micellar template approach to mesoporous oxides was generalized to make nonoxide mesoporous materials. Attard et al. prepared mesoporous metals with hexagonal ordered structures, where redox reactions and the general mesoscopic templating synthesis were employed to generate the metallic mesosti-uctures. The materials are typically obtained as powders composed of nanoparticles. Attard et al. also succeeded in adapting the above methodology to synthesize mesostructured metallic thin films through the electrodeposition under liquid-crystal environments.[35] More recently, a high-surface-area graphitized carbon with uniform mesopores was synthesized by the group of Jaroniec through a colloidal imprinting methodology.[36,37]

A recent approach that uses mesoporous silicas to produce mesoporous replicate templates of other materials appears to hold some promise as a general methodology in this area. In essence, a precursor to the desired material is diffused into the pores of ordered mesoporous silica and then chemically transformed into a homogeneous solid filling the pores. The silica is then removed by exposing the solid to HF or NaOH solutions. leaving a porous solid that is an "inverse replica" of the original pore structure of the silica. Mesoporous carbon solids were prepared via this method using a variety of simple precursors. such as sucrose. furfuryl alcohol, or in situ

polymerized phenol resins as the carbon precursors.[38–41] Carbonation is accomplished by heating the filled pore silicas to ~ 1000°C. The mesoporous carbon replicates exhibit surface areas; pore size distributions, and pore orderings that closely resemble those measured in the original silica matrix. as long as the original silica pore system is interconnected though pore intersections or via micropore channels between mesopores. A similar approach starting with platinum and other metal precursors led to intertwined platinum and other metal wire assemblies,[42–44]

CHARACTERIZING MESOPOROUS MATERIALS

The general characteristics of a material's porosity and pore ordering are determined via three types of measurements: isothermal gas adsorption behavior, small-angle x-ray scattering (SAXS) experiments, and electron microscopy. The overall surface area of the solid, the pore volume, and pore size distribution information are provided by gas adsorption measurements.[45] After removal of the surfactant, templated, mesoporous solids exhibit well-defined maxima in their pore distribution curves between 2–50 nm with widths (half-height) typically less than 1 nm. Mesoporous metal oxides usually have total surface areas from 100 to over 1000 m^2/g. When the pores of a templated inaterial are ordered (e.g., hexagonal or cubic ordering): SAXS data will show Bragg diffraction peaks that characterize the ordering and can give values for the interpose separation. SAXS measurements can be done on mesostructured material before removal of the templating surfactant to determine if pore ordering survives calcination. Finally. because of the size range for mesopores, TEM was used extensively to image pores in templated materials and can provide an independent measurement of pore ordering and wall thickness. Simultaneous electron dispersive x-ray (EDX) measurements can also be used to provide spatially resolved elemental analysis data on these solids.

CONCLUSION

The general field of nonsiliceous mesoporous materials is still in its infancy. A variety of surfactant-templating approaches were developed that can be used to prepare a wide variety of mesoporous metal oxide solids. Early problems concerning the thermal stability of these porous materials are slowly being overcome but remain obstacles in some cases. Promising replicate-templating procedures where the pore systems of ordered. mesoporous silicas are used to produce mesoporous carbons and metals were recently described. Although few applications of non-siliceous mesoporous materials have appeared to date,[3 46 47] the field is young and holds great promise.

Mesoporous Silica and Silica–Organic Hybrids

Abdelhamid Sayari
University of Ottawa, Ottawa, Ontario, Canada

INTRODUCTION

Since the breakthrough discovery of the so-called M41S *family of silica* mesophases some 10 *years ago.[1] research on periodic mesoporous inaterials grew so dramatically that it developed into a distinct field. During this short period of* time, *remarkable progress was achieved in many directions, including synthesis* strategies. *materials diversity. and innovative applications. The original work described three silica mesophase structures,* namely, *MCM-41 (hexagonal, p6mm*), *MCM-48 (cubic,* I*a3d*), *and* MCM-50 *(lamellar). They were* synthesized *via a supramolecular templating mechanism under basic conditions using long-chain alkyltrimethylammonium surfactants. Currently. periodic* mesoporous *silicas* may *be readily synthesized under a wide* range *of pH and temperature conditions. in the presence of a large* variety *of* amphiphile *molecules, including cationic, anionic, neutral. zwitterionic,* bolaamphiphile, *geinini.* and diva*lent surfactants. as well as many* commercially *available* oligomers *and block copolymers. This effort led to* the *discovery of numerous* new silica *mesophases including* SBA-1 *and* SBA-6 (*Pm3n*), *SBA-2 and SBA-12* ($P6_3/mmc$), SBA-8 (*cmm*), *SBA-11* (P*m3m*), *SBA-16* (I*m3m*),[2] *disordered* HMS,[3] MSU-n,[4] *and* MSU-V. *Extensive* work was *also carried out to develop strategies for controlling the pore size. the morphology. the surface properties, and the hydrothermal stability of such materials. In addition to* silica-based mesoporous *materials, the* supramolecular *templating approach was extended to numerous other materials, including transition* metal *oxides[1] and* chalcogenides,[6] organosilicates,[7,8] metallophosphates,[9] *metals.* alloys,[10] *and zeolite* nanocrystals.[11,12] *Furthermore. silica* meso*phases were. in turn, used as* templates *for the synthesis of a variety of other materials. such as* nanoporous *carbons[1] and polymers. and* metallic[14] and semiconductor[15] *nanowires. This extensive* effort *in the area of synthesis was paralleled by the* development *of innovative applications. not* only in *conventional areas such as adsorption, separation. and catalysis,[1,19] but also as advanced* materials *such as electrodes for solid oxide* fuel cells,[20] *or as hosts* for *quantum dots* and *sensing species for electronic and optical* applications.[21,22]

The short review *will be* limited *to periodic* mesoporous *silica and silica–organic hybrids. Because of their relevance to the subject of the current Encyclopedia, the supramolecular templating mechanisms leading to ordered mesoporous materials will be one of the* main *thrusts of this contribution. Authoritative reviews on nonsilica periodic* mesoporous *materials are available in the* literature.[5,10,22]

SYNTHESIS MECHANISMS OF PERIODIC MESOPOROUS MATERIALS

Synthesis of Periodic Mesoporous Silica Under Basic Conditions in the Presence of Alkyltrimethylammonium Surfactants

The synthesis mechanism of M41S *silica mesophases was originally referred to as the liquid crystal* templating mechanism. *This may erroneously suggest that silica mesophases are simple replicas of preexisting liquid crystalline phases. While direct transcription of existing* liquid *crystals may occasionally take place under high concentrations of* surfactant,[23] *in practice. this* is *seldom the case. The following observations are consistent with the fact that the occurrence of a liquid crystalline phase is not a prerequisite for the* formation *of the corresponding silica mesophase: 1) it is possible to synthesize any of the three* M41S *silicas only by changing the relative amount of silica precursor. everything else being the same: 2) mesoporous materials* may *be prepared using surfactant concentrations well below those required for the formation of liquid crystals, and even below the* critical *concentration for the formation of rod-like micelles; 3)* MCM-41 *silica inay be synthesized in the presence of short-chain surfactants, such as* $C_{12}H_{25}N(CH_3)_3OH$, *that do not form rod-like micelles in water: 4) MCM-41 and MCM-48 silicas may* form *at temperatures above* 70°C, *where rod-like micelles are not stable.*

Stucky et al.[24] *provided* compelling *evidence that in addition to amphiphile molecules. inorganic species play a key role in driving the supramolecular* assembly *process to take place. As shown* schematically *in Fig. 1,*

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012759

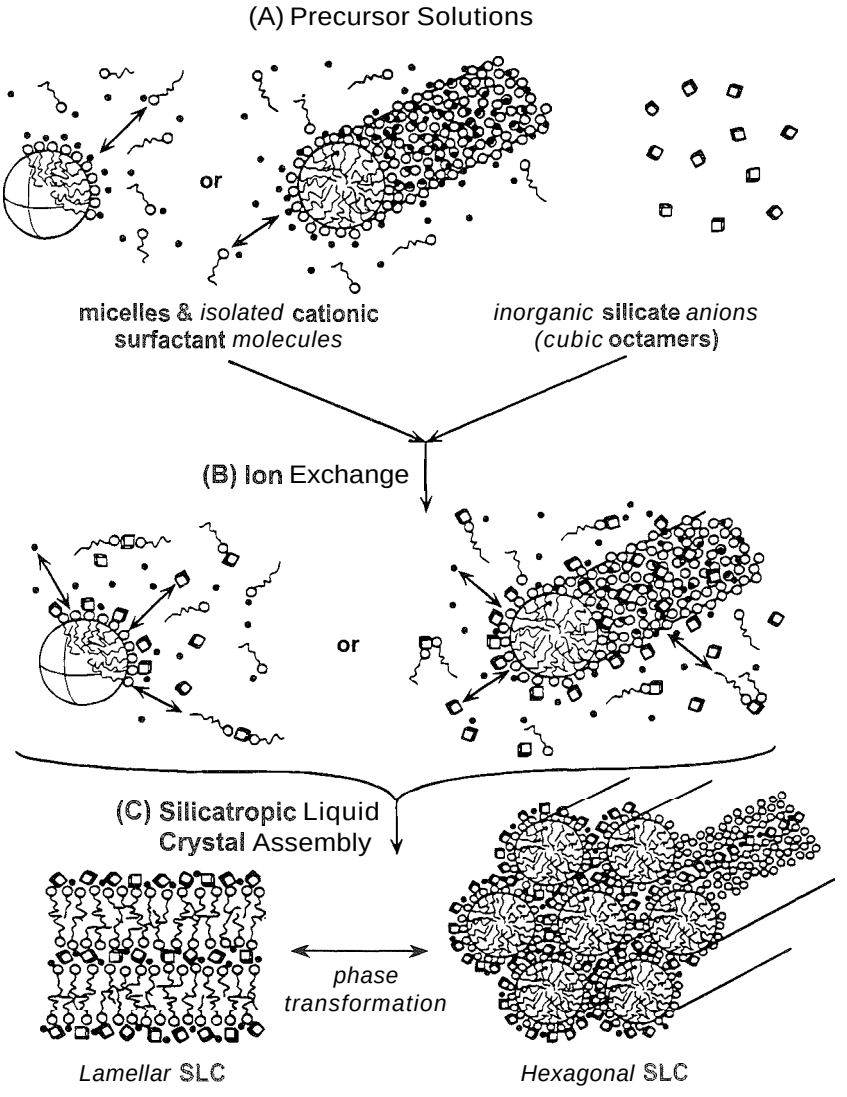

Fig. 1 Cooperative templating mechanism. (From Ref. [24].)

this so-called cooperative organization mechanism is a three-step process. The first step, driven by electrostatic interactions, is the displacement of the surfactant counterions by polydentate and polycharged inorganic anions leading to organic–inorganic ion pairs. The latter then self-organize into a liquid crystal-like mesophase with a structure that depends ultimately on controllable synthesis parameters such as the composition of the mixture. the pH. and the temperature. The final step is the cross-linking of the inorganic species, giving rise to a rigid shell with a structure that is a replica of the underlying liquid crystalline phase. The structure of such a mesophase is determined by dynamic interplay among organic–inorganic ion pairs: the charge density, coordination. and steric requirements of organic and inorganic species at the interface are the main controlling factors.

As a first approximation, the mesophase structure can be linked directly to the packing factor $g = V/a_0 l$, where V is the total volume of the surfactant chain plus any cosolvent organic molecules between the chains, a_0 is the effective head group area at the micelle surface. and 1 is the kinetic length of the surfactant tail. As the g value decreases. transitions to higher curvature mesophases occur at the following critical values: g = 1 (lamellar mesophase), $1/2 < g < 213$ (cubic. $Ia3d$), g = 1/2 (hexagonal, $p6mm$), and $g = 1/3$ (cubic, $Pm3n$). This factor was introduced earlier to rationalize the

aggregation behavior of ainphiphile molecules in water. Despite its simplicity. the concept of packing factor proved to be very useful not only to explain experimental findings but also; more importantly. to design mesoporous materials via direct manipulation of the g factor. For example, the addition of cosolvents or polar molecules was found to increase the volume V of the hydrophobic tail.[25] In turn. this decreases the packing factor and affects the nature of the mesostructure obtained. Another simple and effective way to fine tune the packing factor is through the use of surfactant blends. In a recent study, Kim et al.[26] prepared high-quality silica mesophases having two-dimensional hexagonal ($p6mm$), three-dimensional hexagonal ($P6_3/mmc$), and cubic ($Im3m$) structures through systematic variation of the effective head- and tail-group sizes via appropriate mixtures of amphiphilic block copolymers.

Generalization sf Electrostatically Driven Synthesis Mechanisms

The cooperative organization mechanism driven by electrostatic interactions described above is not limited to ion pairs between cationic surfactants (S^+) and anionic inorganic species (I^-), but can be generalized to include three other routes.[27] Pathway S^-I^+ involves direct electrostatic interaction between anionic surfactants and cationic inorganic species. The synthesis of mesostructured antimony or tungsten oxide under acidic conditions is a typical example for this pathway. In the two other routes. the interactions occur between similarly charged organic and inorganic species with the mediation of small counterions of opposite charges. These pathways are referred to as $S^+X^-I^+$ (X^- = Cl^-, Br^-) and $S^-M^+I^-$ (M^+ = Na^+, K^+). The synthesis of silica mesophase at pH < 2, and that of mesostructured zinc oxide at pH>12.5, are examples of these two routes, respectively.

Other Supramolecular Templating Mechanisms

Pinnavaia et al.[3,4] introduced a neutral (N^0I^0) and a nonionic (S^0I^0) templating mechanism using alkylamines and polyethyleneoxide surfactants, respectively. The obtained silicas. referred to as HMS and MSU-n. respectively, exhibited nonordered systems of cylindrical nanopores with narrow size distributions. Instead of the electrostatic interactions. in the presence of neutral surfactants, hydrogen bonding becomes the predominant factor in pairing organic and inorganic species. As seen in Fig. 2. the neutral species formed by partial

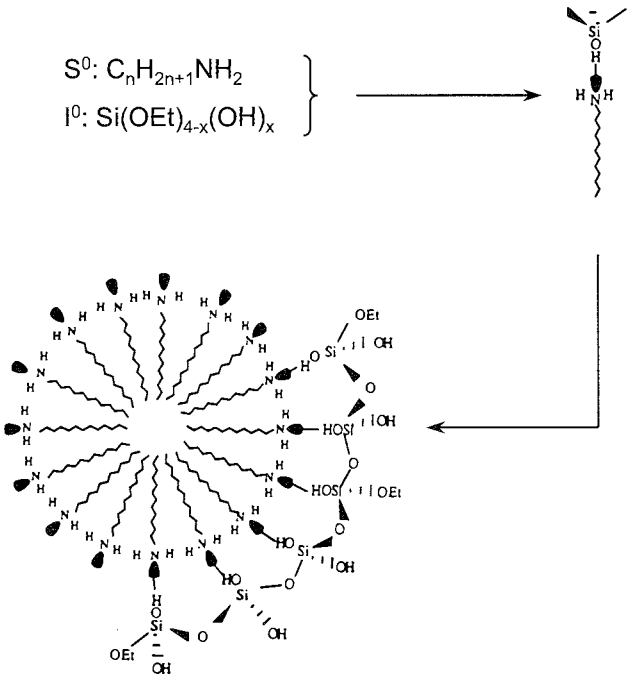

Fig. *2* Neutral templating mechanism. (From Ref. [3].)

hydrolysis of tetraethyl orthosilicate interacts with the surfactant amine head group via hydrogen bonding. The obtained organic–inorganic complex may be considered as an amphiphile with a bulky head group leading to a small packing factor. As mentioned earlier, decreasing the g value increases the likelihood for the forination of high-curvature micelles such as rod-like micelles. which exhibit a natural tendency to self-assemble into a hexagonal lyotropic mesophase. This is followed by condensation of silanol groups and formation of rigid silica walls.

For completeness, it should be mentioned that in addition to the electrostatically driven cooperative assembly pathways, and the nonionic routes based on van der Waals interactions, Antonelli and Ying[28] introduced the so-called ligand-assisted templating mechanism to explain the formation of a number of periodic mesoporous transition metal oxides. This mechanism is based on the formation of a covalent bond between organic and inorganic species. Using the synthesis of mesoporous Nb_2O_5 for illustration (Fig. 3), it is seen that the initial step, which takes place in the absence of water. is the formation of a Nb–N covalent bond between $Nb(OEt)_5$ and the long-chain amine surfactant. This is followed by intermolecular condensation of these species in the presence of water with simultaneous self-organization into micelles. and ultimately into a mesophase (Route *a'*, b' in Fig. 3). Alternatively. the

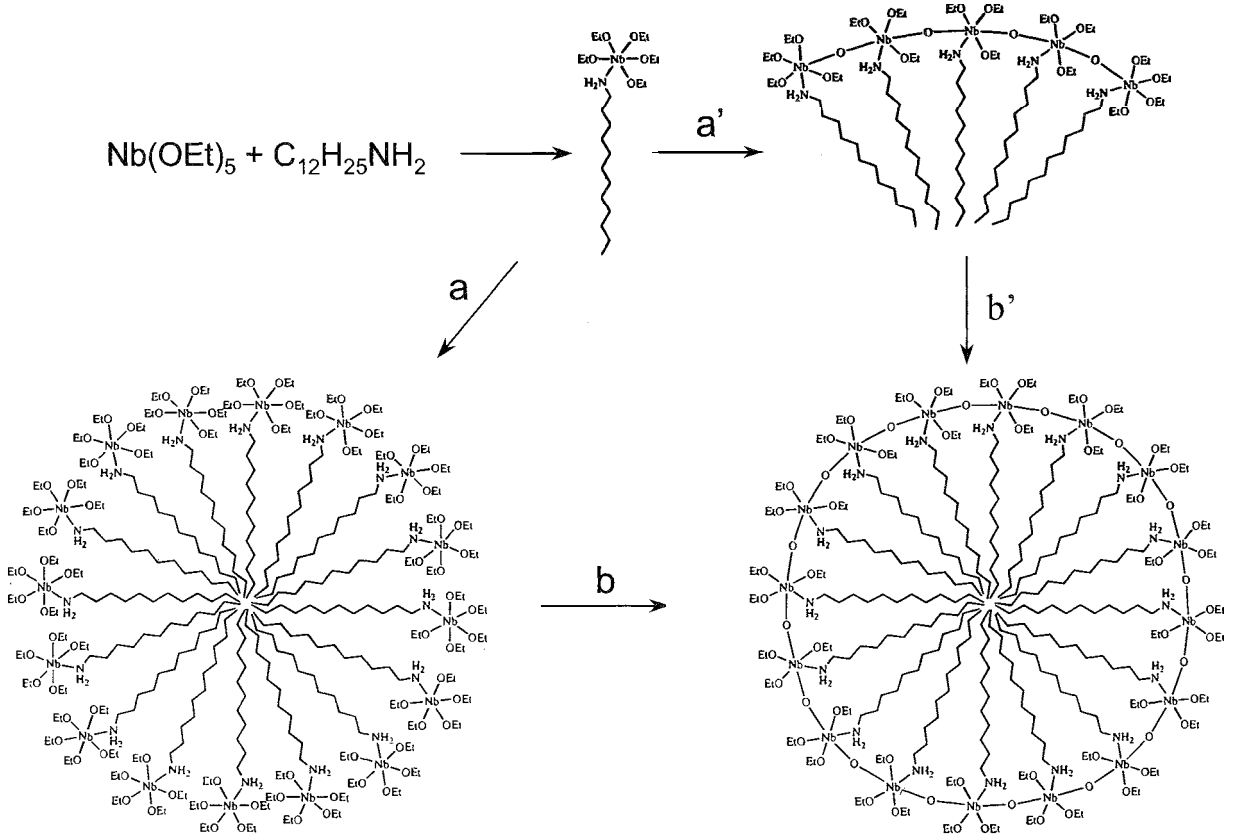

Fig. 3 Ligand-assisted templating mechanism. (From Ref. [28].)

formation of the micelles may precede the condensation step (Route *a*, *b* in Fig. 3). The key feature of this mechanism, i.e., the formation of a covalent M–N bond, was inferred from nuclear magnetic resonance (NMR) studies on 100% ^{15}N-enriched dodecylamine niobium ethoxide precursor in [D_8]toluene and the corresponding as-synthesized Nb_2O_5 mesophase.[28]

CHARACTERIZATION OF PERIODIC MESOPOROUS SILICA-BASED MATERIALS

Characterization of periodic mesoporous silicates involved a wide range of techniques. One of the first realizations made was that despite their long-range order, these materials were amorphous in nature. as conclusively demonstrated by Raman spectroscopy, solid-state NMR, and other techniques.[1,17] As a result, their x-ray diffraction (XRD) patterns were dominated by a limited number of peaks at low angles (Fig. 4), often providing insufficient information with regards to the structure of the materials under investigation. In this respect, transmission electron microscopy (TEM) (Fig. 5) and, more importantly, electron crystallography[29] played a key role in elucidating the structure of various silica mesophases. Because they are readily available to most researchers, adsorption techniques were, along with XRD, the most frequently used methods for characterizing periodic mesoporous materials.[30] This simple technique provides essential information regarding structural and textural properties of mesoporous materials, such as the surface area, the pore volume, the pore size distribution, the occurrence of micropores, the surface hydrophobicity, etc. Moreover, in combination with XRD data, nitrogen adsorption measurements provide an estimate for the pore wall thickness. In Fig. 6. a representative example of nitrogen adsorption–desorption isotherms for a MCM-41 silica is shown. Such isotherms are usually of Type IV in the IUPAC classification and exhibit characteristic steps on both branches, corresponding to the condensation and evaporation of the adsorbate from mesopores with narrow size distributions. They are usually reversible for MCM-41 silicas with mesopores less than ca. 4 nm in diameter and exhibit hysteresis loops of different shapes for two-dimensional hexagonal (*p6mm*) silica with pores larger

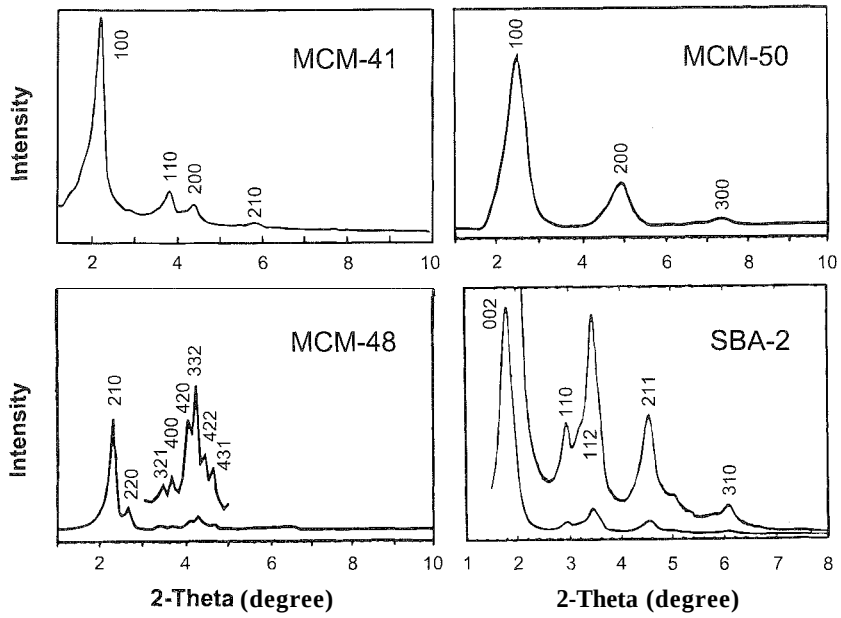

Fig. 4 X-ray diffractograms for typical silica mesophases. (From Refs. [1, 25].)

than 4 nm, mesocellular silica foams, ac well as the three-dimensional hexagonal ($P6_3/mmc$) and the cubic ($Im3m$), such as *SBA-2* and *SBA-16,* respectively, which both exhibit cage-like mesopores

PERIODIC MESOPOROUS SILICA–ORGANIC HYBRIDS

Combining organic and inorganic species within the same periodic mesoporous material offers added flexibility to control an extended range of surface properties such as catalytic activity, hydrophobicity, and hydrophilicity, as well as bulk properties such as density, dielectric constant, hardness, and mechanical strength. Sayari and Hamoudi[7] divided these materials, based on their structures, into five categories, namely: I) as-synthesized amphiphile/silica mesophases; *2)* expanded mesoporous silicas; *3)* mesoporous silicas with organically modified surfaces; 4) mesoporous organosilicates; and 5) mesoporous silicas with occluded organic materials such as polymers. This contribution will deal only with surface

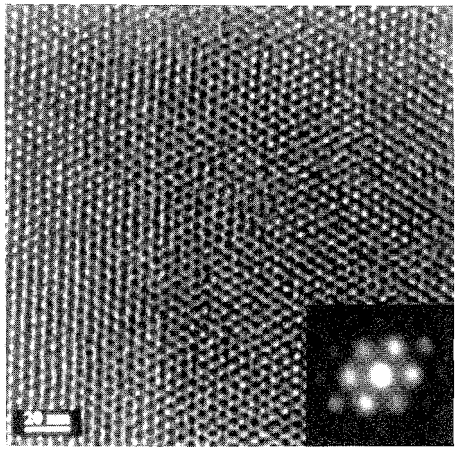

Fig. 5 TEM image and the corresponding electron diffraction pattern for a typical MCM-41 silica.

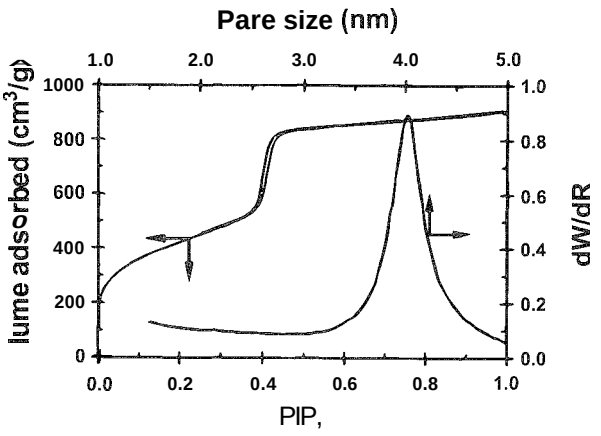

Fig. 6 Typical nitrogen adsorption–desorption isotherm and pore size distribution for MCM-41. (From Ref. [17].)

and framework organically modified silicas, i.e., Classes 3 and 4 silica–organic hybrids. As for the other categories of hybrid materials, the reader rnay refer to two recent reviews.[7,8]

Periodic Mesoporous *Silicas* with *Organically* Modified Surfaces

Surface modification of periodic mesoporous silicas via covalent bonding of organic molecules may be achieved using a postsynthesis procedure or directly via cocondensation procedures. In addition to the obvious changes in chemical properties of the inaterials upon surface modification with organic functionalities, improvement of physical properties may also occur. It was reported that surface silylation of inesoporous silica improves not only the chemical stability of the hybrid materials against moisture, but also enhances mechanical stability compared to their pure silica counterparts. Moreover; incorporation of $-CH_2-CH_2-$ groups within the walls of the silica mesopores was found to increase the Young's modulus and hardness of the material, and decrease its dielectric constant.

The two-step method was described in the Mobil group's early work.''' It consisted of coupling a suitable organosilane reagent with the silica surface hydroxyl groups using an appropriate solvent under reflux. This could be followed by higher-order modifications that involve further reactions to create new functionalities. To achieve selective functionalization of the internal surface. it was suggested to first passivate the external surface using dichlorodiphenylsilane Ph_2SiCl_2, then carry out the grafting process. In some instances. surface-functionalized mesoporous silica may also be prepared using the as-synthesized silica mesophase by simultaneously removing the surfactant and grafting the organic species. The two-step approach to organically surface-modified mesoporous silica was used to incorporate many functionalities. including alkyl groups, amine. thiol, and sulfonic acid functions, as well as more elaborate structures such as coordination complexes and chiral ligands.

As an alternative to the two-step approach, mesoporous silica with organic moieties covalently linked to their internal surface could be obtained in a single-step cocondensation of siloxane and organosiloxane precursors using similar supramolecular templating techniques as those for the synthesis of pure silica. Successful one-step syntheses of MCM-41 silicas modified with alkyl, phenyl, vinyl. cyanoethyl, amine. thiol, and propylsulfonic acid moieties were reported in the literature.[7] Similar preparations were extended to MCM-48 silica and to mesoporous materials prepared via nonionic and polymeric surfactants. i.e., HMS, MSU, and SBA-15 silicas.

Surface-functionalized mesoporous materials were characterized using numerous techniques. Solid-state ^{29}Si-. ^{13}C-, and ^{1}H-MAS-NMR (MAS = magic angle spin) measurements were used to investigate changes in the local environment of silicon atoms and to determine the degree of surface functionalization of mesoporous silicas. infrared spectroscopy. sometimes in combination with ^{1}H-NMR. was used to monitor the consumption of silanol groups and the functionalization of the silica surface through the development of characteristic vibrations. Thermogravimetric analysis was used to probe the thermal stability as well as the hydrophobic or hydrophiiic character of the hybrid materials. Structural ordering of organically modified mesoporous silicas was characterized by TEM, XRD, and nitrogen adsorption measurements. These studies revealed that postsynthesis surface modification had limited effect on the periodic structure of the starting material. However, the structural ordering of hybrid mesoporous silicas synthesized in a single step via cocondensation, was found to decrease progressively as the relative amount of the organic precursor present in the synthesis mixture increased. The upper limit for the organosiloxane-to-tetsaethoxysilane (TEOS) ratio in the synthesis gel, above which no structural ordering occurred, was typically 10–25%.

Periodic Mesoporous Organosilicates

Unlike surface-fiinctionalized silica. in periodic mesoporous organosilicates (PMOs), the organic component is built in the pore walls instead of protruding from the surface into the internal channels. This recent development in the area of periodic nanoporous materials opens a wide range of new and exciting opportunities for designing materials with controlled surface properties at the molecular level. The fact that the organic moieties constitute an integral part of the inesoporous framework allows the formation of pure silica–organic hybrids using bridged silsesquioxanes without addition of any other source of silica. This is in contrast with surface-functionalized mesoporous silica prepared via cocondensation. which requires large amounts of silica precursor, such as TEOS for the formation of rigid walls, to take place. In the latter case, the TEOS to organotrialkoxysilane is typically higher than 75%.

Mesoporous organosilicates are synthesized using similar self-assembly approaches as pure silica mesophases: the main difference being the silicon-containing precursors that consist of bridged silsesquioxanes, $(RO)_3Si-R'-Si(OR)_3$. Different types of amphiphile molecules, including cationic (alkyltrimethylammonium),

anionic (dodecylsulfate), nonionic (Brij-56), and block copolymer (P123) surfactants were used as supramolecular templates. Successful syntheses of periodic mesoporous organosilicates with organic spacers R' originating from methane. ethane. ethylene, acetylene, butene, benzene, toluene, xylene, dimethoxybenzene, thiophene, bithiophene, and ferrocene were reported in the literature. Similar to silica mesophases, the formation of mesoporous organosilicates was found to occur under acidic and basic conditions. The removal of the templating surfactants was generally performed by acid solvent extraction. Most organosilicates reported in the literature exhibited cubic, and two- or three-dimensional hexagonal structures.

X-ray diffraction, nitrogen adsorption, SEM, TEM, and solid-state NMR are some of the techniques used for characterizing periodic mesoporous organosilicates. Of particular importance was the role of NMR spectroscopy in confirming the preservation of the Si–R′–Si unit's integrity during the precipitation process, thus providing direct evidence that the organic–inorganic moiety constituted the building block of the mesoporous channel walls. For instance, ^{29}Si-MAS-NMR for ethane–silica mesophases showed mainly two peaks at $\delta \approx -57.0$ and -66.0 ppm attributable to T^2 [C*Si*(OSi)$_2$(OH)] and T^3 [C*Si*(OSi)$_3$] Si species covalently bonded to carbon atoms. Similar chemical shifts were also obtained for the methylene–silica material. The T^2 resonance was observed at -75 and -71 ppm. for ethylene and phenylene–silica mesophases, respectively: whereas the corresponding T^3 resonances occurred at -83 and -78.2 ppm, respectively. In all cases. no Q^n [*Si*(OSi)$_n$OH$_{4-n}$] species were observed. indicating that no Si–C bond hydrolysis took place. Likewise. ^{13}C-CP-MAS-NMR for surfactant-free materials were consistent with these conclusions. For example, the ethane–silica mesophase exhibited a peak with chemical shift at ca. 5–6 ppin assigned to methylene convalently bound to Si as in Si–CH_2CH_2–Si. The ethylene–silica materials exhibited a strong resonance at ca. 145 ppm, while the phenylene-bridged system gave rise to a ^{13}C resonance at 133.4 ppm. The methylene-containing material generated a single peak at ca. 0 ppm. All these data indicate that the Si–R′–Si units were preserved during the organic–inorganic mesophase formation.

APPLICATIONS OF PERIODIC MESOPOROUS SILICA-BASED MATERIALS

These materials were found to be useful in many potential applications. particularly in the areas of catalysis.[16–18] Catalytically active acid sites were generated using different approaches, including framework modification with trivalent cations as in aluminosilicates; surface modification. for example. with propylsulfonic acid; and addition of acid ingredients such as heteropolyacids. More recently. highly stable mesoporous materials were prepared via supramolecular templating of strongly acidic zeolite *Y*, β, and ZSM-5 nanocrystals. All these types of materials were found to be effective acid catalysts. Al-MCM-41 was used in oligomerization of propene, alkylation of bulky aromatic molecules, cracking of cumene, and straight run naphtha, as well as in hydroisomerization and hydrocracking of n-hexadecane. Phosphotungstic acid containing mesoporous aluminosilica was found to be more efficient than H_2SO_4 or bulk phosphotungstic acid in liquid-phase alkylation of 4-tert-butylphenol by isobutene and styrene. Similarly, sulfonic acid containing MCM-41 silicas exhibited excellent performance in acid-catalyzed reactions involving large molecules. such as esterification of glycerol with fatty acids. Materials with SAB-15 structure prepared via assembly of MFI aluminosilicate nanoclusters were also found to be powerful catalysts for the cracking of cumene and 1,3,5-triisopropylbenzene.[12] Similar progress was made in the area of base-catalyzed reactions. Mesoporous materials with basic properties were prepared via Na^+ or Cs^+ ion exchange using MCM-41 aluminosilica as starting materials, or via grafting of organic moieties containing basic functions such as amines. Such materials were found to be effective catalysts in esterification, Knoevenagel condensation, and Michael reaction.

Like their zeolitic counterparts, mesoporous titano- and vanadosilicates were also found to be excellent catalysts for selective oxidation of organic substrates, such as alkenes, ketones, aromatic or aliphatic hydrocarbons, and fatty esters, using dilute hydrogen peroxide or tert-butylhydroperoxide, under mild conditions. Because of their large pores. they had the added advantage of being able to accommodate bulky molecules. Further silylation of periodic mesoporous titanosilicates was found to improve their activities and selectivities. Another important catalytic application of functionalized mesoporous silica is chiral catalysis. For example, optically active secondary alcohols. often used for the manufacture of drugs and other biologically active compounds, were obtained in very high yield via asymmetric addition of diethyl zinc to benzaldehyde using MCM-41 and SBA-15 silica modified by prolinol-based ligands. In many instances. capping unreacted surface siianol groups with hexamethyldisiiazane was found to improve the catalyst selectivity.[7]

In addition to catalysis, mesoporous silicas were used as hosts for a wide variety of advanced materials, such as metallic and semiconductor nanoparticles and

nanowires with unique optical and electronic properties. They were also employed as templates for the synthesis of porous polymers and carbons. Another important area of application, particularly for surface-functionalized mesoporous materials, is protection of the environment. For example, mercaptopropyls bearing MCM-41, HMS, MSU, and SBA-15 silicas were successfully tested for scavenging heavy-metal cations such as mercury and lead from wastewaters. Likewise, mesoporous silicas with appropriate functionalities were used to adsorb harmful metallic anions and organic pollutants from water.

Micelles and Vesicles

Raoul Zana
Institut Charles Sadron (CNRS-ULP), Strasbourg, France

INTRODUCTION

Surfactant molecules are made up of two moieties *that have antagonistic properties, a polar or electrically charged hydrophilic moiety and a hydrophobic moiety, most often an alkyl chain. In aqueous solution, most surfactants self-assemble and* form *micelles when their concentration* becomes *larger* than *the so-called critical micellization concentration* (CMC). *In micelles (from the Creek mica, which means "grain"), the alkyl chains are in contact and form an oily core that is coated by the polar head groups. The outer layer that contains head groups, counterions (in the case of ionic surfactants), water and the first methylene group of the alkyl chain is called the palisade layer. The* formation *of* micelles *is a cooperative process that is spontaneous and reversible. Micelles* are *thermodynamically stable species that are in chemical equilibrium with free* surfactants.

Some surfactants *self-assemble into closed bilayers called vesicles (or* liposomes *when formed from phospholipids). Vesicles are often spherical but can take other shapes and* can *be unilamellar or multilamellar. In contradistinction to micelles, vesicles may not be thermodynamically stable. Another* important *difference between vesicles and micelles is that vesicles have an inside that encloses* some *of the aqueous phase and an outside. The existence of a critical vesiculation concentration, above which some surfactants would form vesicles. is sometimes mentioned. This is probably incorrect.* At *very low* concentrations, *surfactants always start* forming *micelles that* may *turn into vesicles at higher concentrations. Given in Fig. 1 are* schematic *representations of a* micelle *and a vesicle, both of spherical shape.*

Micelles are important in many uses of surfactants for their capacity to solubilize water-insoluble compounds. Vesicles are model systems for biological cells and can be used for entrapping active compounds in their insides. Besides. vesicles and micelles are used as microreactors for performing chemical reactions and *preparing solid* nanoparticles *of varied shapes.*

Reviewed in *this article are some important properties of micelles and vesicles: formation and stability. size and shape. internal organization. dynamics, and vesicle-to-micelle transition. Only few* of *the most significant papers* in *the immense* literature *dealing with micelles and vesicles are cited due to the lack of space. Also due to lack of space, this article presents no mathematical development.*

FORMATION OF MICELLES AND VESICLES: EXPERIMENTAL ASPECTS

Micelles are obtained by solubilizing a surfactant in water at a concentration $C > \mathrm{CMC}$. *The CMC is the most important property of a surfactant. It is not a single concentration but rather a narrow range of concentrations. Its value slightly depends on the method of determination, reflecting differences in the way each method weighs micelles and free surfactants. The CMC decreases by a factor of 2 for ionic surfactants and 3 for nonionic* surfactants *for each additional* methylene *group in the* surfactant *alkyl* chain.[1,2] *For ionic surfactants, the CMC also decreases upon increasing concentration* C_e *of an added electrolyte having a common ion with the* surfactant, *according to:* $\log \mathrm{CMC} = A - B\log(\mathrm{CMC}_0 + C_e)$. Terms *A and B are two constants, and* CMC_0 *is the* CMC *in the absence of* salt.[1] *The value of B is close to the degree of counterion association to the micelle. Thermodynamic studies showed that the formation of micelles is entropy* driven.[2] *The large positive value of the entropy of* micellization *reflects a change affecting the water molecules surrounding the surfactant alkyl chains when the chains are transferred from the aqueous phase to the micelle core.*

Aqueous vesicles are commonly *observed with phospholipids and with their synthetic analogues, which are two-chain* surfactants *having alkyl chains with 10 or more carbon atoms. Different methods were used to prepare* vesicles.[3] *For instance, dispersions of appropriate sparingly water-soluble surfactants or phospholipids give rise to vesicles upon* sonication. *Vesicles may also be obtained by solubilizing an appropriate amphiphile in an organic solvent, depositing the solution on a glass plate. evaporating the organic solvent; and exposing the resulting film to water. Vesicle-forming surfactants can also be* solubilized *in an aqueous solution of a hydrotrope or of a* micelle-forming surfactant. *Dilution of this solution with water gives rise to vesicles. Sonication, extrusion through Millipore filters. and other methods were used to transform large* multilamellar *vesicles into small unilamellar vesicles. Vesicles prepared by these methods* can *have* long-

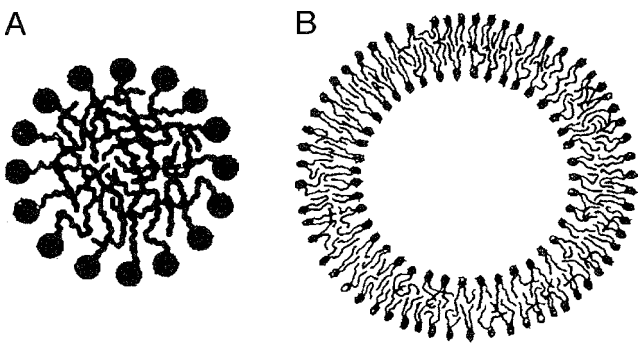

Fig. 1 (A) A micelle (diameter: 5 nm): and (B) a vesicle (diameter: 20–1000 nm. thickness: 4–5 nm) of spherical shape. The alkyl chains were represented in a disordered state reminiscent of the liquid-like structure of the aggregate core. Such a representation is closer to reality than that where the alkyl chains are represented straight and normal to the assembly surface.

term stabilities. Nevertheless, vesicles made of a single surfactant or phospholipid are unstable and revert to liquid crystalline aggregates after a time that can be long. Unilainellar vesicles obtained by mixing aqueous solutions of two surfactants of appropriate structure and of different electrical charge may be different. Such vesicles appear to form spontaneously and reproducibly and can have long-term stabilities.[4]

FORMATION OF MICELLES AND VESICLES: THEORETICAL ASPECTS

The driving force for surfactant self-assembly into micelles or vesicles is the so-called hydrophobic (attractive) interaction between surfactant alkyl chains.[2,5] The origin of this interaction lies in the strong attractive interaction that exists between water molecules. When alkyl chains are immersed into water, some water-molecule–water-molecule contacts are replaced by alkyl-chain–water-molecule contacts. Even though interactions between water molecules and alkyl chains are attractive; they are energetically less favorable than interactions between water molecules. As a result. the system tends to minimize its free energy by eliminating contacts between alkyl chains and water molecules. This is achieved by having the alkyl chains get together. With surfactants, this results in the formation of micelles, where the alkyl chains are bunched together forming the micelle core. The hydrophilic head groups remain at the surface of the core, further reducing alkyl-chain–water-molecule contacts.

The main repulsive interactions involved in micelle formation are the electrostatic interaction between head groups, steric interactions arising from the packing of head groups at the micelle surface and of the alkyl chains in the micelle core, and an interaction associated with residual alkyl-chain–water-molecule contacts at the micelle surface. The balance between attractive and repulsive interactions results in micelles of finite size.

The molecular thermodynamic theory for micelle formation was worked out with increasing sophistication following the pioneering work of Israelachvili, Mitchell, and Ninham.[6] The most comprehensive reports on micelle formation are those of Ruckenstein and Nagarajan[7] and of Blankschtein et al.[8] Many other theoretical approaches were used in recent years to account for the forination of micelles and their properties: thermodynamics of small systems, self-consistent field lattice model, scaled particle theory, Monte Carlo simulations, and molecular dynamics (MD) simulations.[9] The last two approaches are presently much in favor due to the increased calculating capacity of modern computers. A common prediction of all of these theories is that micelles represent a therinodynamically stable state, and that micellar solutions are single-phase systems. Many of the recent results of MD and Monte Carlo simulations are in agreement with experimental results.

The consensus about the existence of thermodynamically stable vesicles remains to be reached. A surfactant monolayer takes a curvature equal or close to its spontaneous curvature. which is determined by the surfactant chemical structure and the interaction between surfactants. Considerations based on the bending energy of a surfactant monolayer led to the conclusion that only flat (zero curvature) bilayers can be thermodynamically stable.[10] The curvatures of the inner and outer layers of a vesicle are finite. Their values are nearly equal in value but opposite in sign. Thus, vesicles (curved bilayers) formed from a single surfactant or phospholipid cannot be thermodynamically stable.[10] The situation may be different for vesicles made from a binary mixture of surfactants. Safran et al.[11] showed that for mixtures of two interacting surfactants forming monolayers with large bending constants. the free energy of the system can be a minimum for vesicles with different concentrations of the two surfactants in the inner and outer monolayers. The spontaneous curvatures of the two layers are then equal but have opposite signs. Systems containing such vesicles would be single-phase systems, like micellar solutions. However, Laughlin[12] pointed out that binary mixtures of surfactants are complex. because they contain up to five components. He concluded that the phase behavior of binary mixtures of water and cationic surfactants, which are made of two oppositely charged surfactant ions, in the absence of other small ions, must be investigated before a conclusion can be reached on the stability of vesicles formed in such mixtures.

SIZE AND SHAPE OF MICELLES AND VESICLES

The technique of transmission electron microcopy at cryogenic temperature (cryo-TEM) allowed for the direct visualization of micelles and vesicles of all shapes described below.[13,14]

At a concentration close to the CMC, the micelles are generally spherical or close to spherical (see Fig. 2). As the concentration is increased. the micelles may remain spheroidal or grow and become oblate (disk-like) or prolate (rod-like). The giant worm-like or thread-like micelles represent an extreme case of growth into elongated micelles. The worm-like micelles can be linear or branched (see Fig. 2). The hemispherical end caps of thread-like micelles have a larger diameter than the cylindrical body,''' a result correctly predicted by theory. Micelles can also be ring-like.[14]

At moderate surfactant concentration. the micelle shape is determined by the value of the surfactant packing parameter $P=v/a_0l$, where v and l are the volume and length of the hydrophobic moiety (alkyl chain), and a_0 is the optimal surface area occupied by one surfactant at the micelle–water interface.[6] It is important to realize that the value of a_0 is determined by the cross-sectional area of the surfactant head group and also by the various interactions at play in micelle formation.[6] Surfactants characterized by values of $P<113$ give rise to spherical1 spheroidal micelles. Surfactants with $1/3<P<1/2$ tend to form elongated micelles. Surfactants with $1/2<P<1$ form disk-like micelles that can be viewed as precursors of surfactant bilayers. Last, surfactants with $P>1$ form reverse micelles. The packing parameter concept is extremely powerful and useful. In particular. it permits one to understand or predict changes of micelle shape induced by changes of experimental conditions. It can also be extended to surfactant mixtures. Besides, the packing parameter is related to the curvature of the surfactant monolayer.[15]

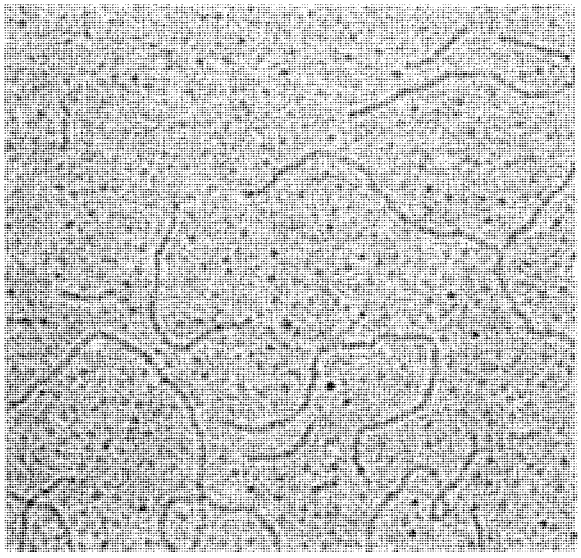

Fig. 2 Cryo-TEM micrograph of a 0.62 wt% solution of the gemini surfactant 12-2-12 that shows spherical micelles (black dots) and thread-like micelles. A branched thread-like micelle can be seen at the right side of the micrograph. Bar=100 nm. Reproduced from Ref. [14] with permission of the American Chemical Society.

The micelle size increases with the carbon number m of the surfactant alkyl chain. For conventional surfactants, the aggregation number of the maximum spherical rnicelle can be estimated from $N_S=4\pi l^3/3v$ using the reported expressions of the length l and volume v of the hydrophobic moiety.[2] The micelle growth with the surfactant concentration is well explained by different models that assume that the free energy of a surfactant in a spherical micelle is higher than in a cylindrical or disk-like micelle.[6–8,16] The free energy difference ΔG_{CS} per surfactant is small, -0.2–0.5 kT per surfactant, as compared to a free energy of micellization of about -15 kT per surfactant with a dodecyl chain. The larger the value of ΔG_{CS}, the steeper the increase of micelle size with increasing surfactant concentration.[6–8] Surfactants with $P>113$ show micelle growth. Ionic surfactants with $P<1/3$ may show moderate micelle growth, because the ionic strength of the solution and. in turn. P increase slightly with the surfactant concentration. The size polydispersity of spherical micelles is small. while that of prolate and oblate micelles can be very large.

Theoretical[16] and experimental[17] studies demonstrated the existence of rapid (10^{-10}–10^{-6} s) and important fluctuations of micelle shape. Substantial shape deformations can take place at a low cost of free energy. For instance. a spherical micelle of diameter 4 nm can be distorted into a prolate rnicelle 4.8 nm long and 3.6 nm wide at a cost of about 1 kT.[16] Surfactants giving rise to vesicles are also those giving rise to disk-like micelles, that is, surfactants with $1/2<P<1$. Such values of P are easily obtained with phospholipids or two-chain surfactants for which l and a_0 are nearly the same as for the corresponding one-chain surfactants, whereas v is two times larger. A disk-like micelle can be thought of as a fragment of a surfactant bilayer having its edge coated by a half of a cylindrical micelle. Disk-like-shaped micelles become rapidly energetically unfavorable as they grow in size and may turn into vesicles (or liposomes when formed from phospholipids) where the edge is eliminated. when some mechanical energy is provided to the system. Vesicles can be large (diameter of several microns) or small (diameter of 20 nm) and unilarnellar or multilamellar. An extreme case of large multilamellar vesicles

Fig. 3 Freeze-fracture TEM of the onion phase in the system tetradecyltrimethylammonium bromide-tetradecyldimethylamineoxide-hexanol, showing large multilamellar vesicles (bar=1 μm). Reproduced from Ref. [18] with permission of Academic Press.

(LMV) is encountered in the so-called onion phase, where each LMV includes tens to hundreds of concentric vesicles and where the LMVs are in contact, as seen in Fig. 3.[18] The onion phase is used in slow-release formulations of active compounds. Vesicles and liposomes are often spherical, particularly those of small size. However, faceted and tubular vesicles were reported.[19]

INTERNAL ORGANIZATION OF MICELLES AND VESICLES

It is now generally accepted that the alkyl chains forming the micellic core are in a quasi-liquid state. Three types of results support this conclusion. First, the viscosity of the core (microviscosity) is only slightly larger than that of alkanes.[20] Second, the order parameter of the alkyl-chain carbon atoms decreases from a finite value for the α-carbon atom (methylene group adjacent to the head group) to a value close to zero for the ω-carbon atom (terminal methyl group) (see Fig. 4). This variation reveals the progressively increasing disorder in alkyl-chain packing as one goes from the micelle surface to its center.[21] Last, extensive chain looping occurs in the core, thereby permitting tight packing of the chains. Any methylene group or terminal methyl group in an alkyl chain has a finite probability to be found at a given distance from the micelle center.[17] In fact, a few terminal methyl groups are present close to or at the micelle surface.

Another important feature of the micellic core is that it is practically devoid of water. Thus, the core of sodium dodecylsulfate micelles contains less than one water molecule per dodecyl chain.[17] Nevertheless, extensive contacts between alkyl chains and water still occur at the micelle surface or in the micelle palisade layer due to three features of micelles. First, surfactant head groups cover only part of the micellic surface. A typical head group covers about 0.25 nm^2, whereas the surface area available per head group at the surface of a spherical micelle may be of about 0.7 nm'. The uncovered parts constitute "fatty patches" that are in contact with water. Second, the surfactants making up a micelle have a radial motion that makes them move out of the micellic and temporarily protrude in the aqueous phase (see next paragraph). Although these surfactants may not leave the micellic, protrusion favors alkyl-chain–water contacts. Third, the penetration of water in the core, even over a relatively small length, results in the wetting of a significant fraction of the methyl and methylene groups making up the core. For instance, water penetration over a length equivalent to one carbon–carbon bond results in the wetting of 20% and 14% of the core of a spherical and a cylindrical micelle, respectively, made with a surfactant with a dodecyl chain.

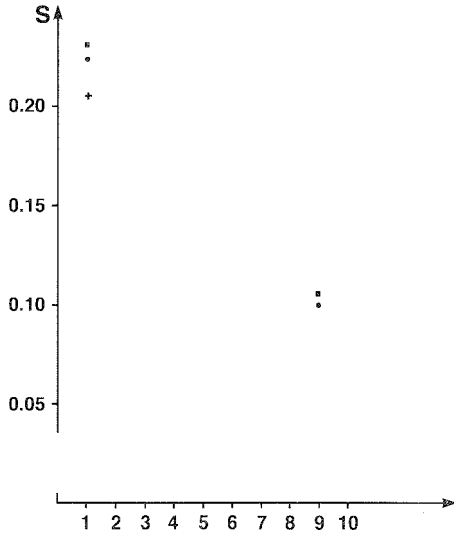

Fig. 4 Variation of the order parameter S with the position of the carbon atom on the alkyl chain of decylammonium chloride for spherical (s) and elongated (s) micelles. Reproduced from Ref. [21] with permission of the American Chemical Society.

Packing is tighter in vesicles than in micelles. It is thus likely that water penetration in vesicles is even less than that in micelles. The viscosity reported by various probes solubilized in vesicles is not significantly larger than in micelles when the measurements are performed at above the transition temperature of the system.[22] Disorder within bilayers and vesicles was evidenced.[23]

DYNAMICS OF MICELLES AND VESICLES

Micelles are not frozen objects. They are in dynamic equilibrium with the free (nonmicellized) surfactant. Surfactants are constantly exchanged between micelles and the intermicellar solution (exchange process), and the residence time of a surfactant in a micelle is finite.[24] Besides, micelles have a finite lifetime.[25] They constantly form and break up via two identified pathways: by a series of stepwise entry/exit of one surfactant A at a time into/from a micelle (Reaction 1) or by a series of fragmentation/coagulation reactions involving aggregates A_i and A_j (Reaction 2).[26]

$$A_i + A \leftrightarrow A_{i+1} \quad (1)$$

$$A_i + A_j \leftrightarrow A_{i+j} \quad (2)$$

The reaction of entry of a surfactant in a micelle is controlled for conventional surfactants with an alkyl chain containing up to 14 carbon atoms.[24,26] This means that the rate of entry is essentially determined by the number of collisions between micelles and free surfactants. The values of the entry rate constant k^+ are all around 10^9 $M^{-1}s^{-1}$, irrespective of the surfactant nature and length of its alkyl chain.[24] On the contrary, the exit rate constant k^- is an exponentially decreasing function of the alkyl chain carbon number m (hydrophobicity), as expected from theoretical considerations,[24] whereas the surfactant residence time $T_R = N/k^-$ increases exponentially with m (N = micelle aggregation number; see Fig. 5). The approximate relationship: $T_R \approx 10^{-9} N/\mathrm{CMC}$ holds for conventional surfactants. The micelle lifetime is relatively long (milliseconds and more) when micelles form and break up via reactions (1) but can become much shorter when reactions (2) dominate the kinetics.

For conventional surfactants with a long alkyl chain ($m > 16$) and dimeric (gemini) surfactants with $m > 8$, the entry of a surfactant in a micelle is slower than for a diffusion-controlled process.[26] The surfactant residence time and the micelle lifetime can become long with respect to the values found for conventional surfactants.[26]

Vesicles also exchange surfactants or phospholipids with the surrounding solution. These exchanges are much slower, probably by several orders of magnitude, than in micellar solutions. essentially because the surfactant or lipids making up vesicles are much more hydrophobic than those giving rise to micelles.[26] Besides, because the number of surfactants making up a vesicle are 10 to 1000 times larger than for a micelle, the lifetime of a vesicle must be extremely long, and vesicles can probably be considered frozen on the laboratory time scale (month to year).

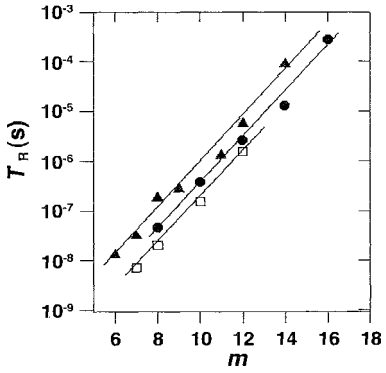

Fig. 5 Residence time T_R of surfactants in micelles. Variation with the carbon number m of the surfactant alkyl chain for sodium alkylsulfates (▲), potassium alkylcarboxylates (○) and alkylpyridinium chlorides (●). Reproduced from Ref. [26].

Many studies investigated the kinetics of the process of vesicle break up upon addition of a micelle-forming surfactant and the reverse process of vesicle formation when a system containing a micelle-forming surfactant is appropriately perturbed.[26–28] In most reports, the kinetics is complex and involves several steps. Also, the rates of the processes are dependent on the system investigated, stretching from fractions of seconds to hours or days.[26–28]

VESICLE-TO-MICELLE AND MICELLE-TO-VESICLE TRANSITIONS

In most instances, the vesicle-to-micelle transition is induced by the addition of a micelle-forming surfactant to a vesicular system.[19,31] The micelle-to-vesicle transition is often induced by mixing two oppositely charged surfactants[27,28] or removing a micelle-forming surfactant or a hydrotrope from a mixed micellar solution of this surfactant and of a vesicle-forming surfactant. The transitions can also be induced by a change of pH, temperature, or ionic strength of a micellar solution or of a vesicular system, or by shearing the system.[29]

Various studies[10,27,28] suggested the existence of structures intermediate between micelles and vesicles. These structures—perforated vesicles, bilayer fragments, giant worm-like micelles, ring-like micelles, and disk-like micelles, depending on the investigated system—were

visualized by cryo-TEM.[13,19,30] Some of these structures are shown in Fig. 6. However, some systems show no intermediate structure.[31] The course of the vesicle-to-micelle and micelle-to-vesicle transition has obviously much to do with the packing parameter of the mixture of the two surfactants and its variation with composition. In a study where the vesicle-to-micelle transition was induced by an increase of the temperature, the vesicles gave rise to giant worm-like micelles.[29] The increase of vesicle size induced by the addition of a micelle-forming surfactant to a vesicular system, at low content of surfactant, was also visualized by cryo-TEM.[19]

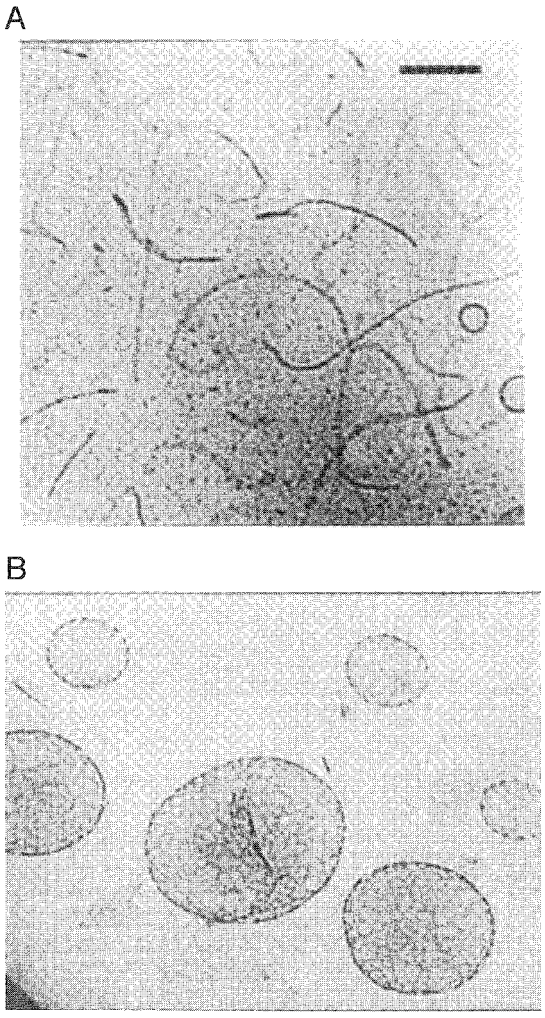

Fig. 6 Cryo-TEM micrographs show the shape of the aggregates in the course of the vesicle-to-micelle transformation in the MGO/CTAB mixture. (A) Coexistence of globular micelles. elongated micellcs that are probably ribbon-like, and vesicles (lipid mole fraction 0.47). (B) Perforated vesicles (lipid mole fraction 0.64). Reproduced from Ref. [30] with permission of the American Chemical Society.

CONCLUSION

Our knowledge of micelles is presently satisfactory thanks to a huge number of experimental studies and increasingly sophisticated methods of investigations. Molecular dynamics and Monte Carlo simulations of the self-association behavior of surfactants into micelles are becoming increasingly accurate. Hopefully, these simulations will become useful tools for predicting micellar properties of new surfactants in the coming years. The situation is still not satisfactory for vesicles on a theoretical level. The problem concerning the thermodynamic stability of vesicles is still unresolved and is the topic of much discussion in the recent literature. However, vesicles continue to be actively investigated, particularly those made from surfactant mixtures. Many of these studies aim at discovering vesicular systems that are nontoxic and have a long stability for future use in drug delivery. The onion phase (see Fig. 3) holds much promise in this respect.

Mineralomimetic Structures

Toschitake Iwamoto
Iwaki Meisei University, Iwaki, Fukushima, Japan

INTRODUCTION

A number of natural minerals have structures comprised of infinite linkages of coordination polyhedra building up multidimensional arrays, as exemplified by chains. networks, and frameworlis in silicate minerals. Clays and zeolites are, respectively, typical two-dimensional (2D) and three-dimensional (3D) materials and give supramolecular systems with organic or inorganic guests, systems that might have played important roles in the generation of well-organized assemblies of prebiotic compounds in the earlier stages of terrestrial evolution. The linkage structure of inorganic coordination polyhedra, mainly that of cyanometallate tetrahedra, mimics the behavior of silicate or other tetrahedral moieties in natural minerals. Countercations of the cyanometallate, mainly octahedral Cd^{2+}, also mimic the behavior of octahedral moieties in minerals. The mineralomimetic crystal engineering strategy, applied to the systems of cadmium cyanide. tetracyanocadmate, polycyanopolycadmate, polycyanopolycuprate(I), secondary ligands other than the primary CN^-, and organic guest and ligand molecules gave a number of self-assembled mineralomimetic crystalline structures under ambient conditions. In comparison with the multidimensional silicate structures. appropriate guest and secondary ligands are necessary to stabilize the whole crystal structures of these mineralomimetic systems by filling the void generated owing to the longer M–CN–M' span length (ca. 5.5 Å), cornpared to Si–O–Si (ca. 3.2 Å). The term mineralomimetic was used as the counterpart of biomimetic. The term rnineralomimetic chemistry was proposed to denote the chemistry of the building-up of mineral-like structures using materials that never give stable minerals in nature. The concept extended to a new aspect of inorganic coordination chemistry developing novel compounds comprised of infinite linkages of coordination polyhedra.[1]

GENERAL CONCEPT

One of the group I4 elements silicon. placed just below C in the conventional periodic table. plays an important role in the lithosphere of the Earth's crust, just as carbon does in the biosphere. The composition of the Earth's crust may be denoted to SiO_2 to the zeroth-order approximation. The relative abundance of O is 6.47 as the exponent normalized to log(abundance of Si) = 6.00; 6.30 of O is formally spent to form SiO_2. Both Si and C share an ability to make multidimensional structures by catenation. but the mode is different (the term catenation is used to denote linking the same moiety repeatedly: not for ''catenane'' formation). Carbon makes –C–C–, –C=C–. and –C≡C– linkages in bio- and organic materials, but Si forms –Si–O–Si– in minerals. In the multidimensional silicate structures, SiO_4 tetrahedra share some portion of O atoms to extend one-dimensional (1D) chains, 2D networks, 3D frameworks. etc. Silica, SiO_2, is formed by the limiting extension of the 3D framework of SiO_4 tetrahedra in the same way as the diamond skeleton results from the succeeding replacement of H atoms of quarternary C_nH_{2n+2} by CH_3 groups. Indeed. the high-temperature-phase cristobalite (H-cristobalite), one of the polymorphs of silica, has a diamondoid structure.

The structure of cadmium cyanide $Cd(CN)_2$ is comparable to those of silica SiO_2 and ice H_2O (=OH_2) with respect to the AB_2 composition, A taking a tetrahedral position linked infinitely by B to form a 3D framework (Table 1). In addition, polycyanopolycadmate $[Cd_x(CN)_y]^{-y+2x}$ resembles polyoxopolysilicates $Si_xO_y^{-2y+4x}$ in its catenation behavior to form multidimensional infinite structures. Hence. silicate and other mineral structures are mimicked by cadmium cyanide and polycyanopolycadmates: in the latter, the tetrahedral Cd can be replaced by such tetrahedral centers as Cu(I) to extend infinite catenation structures with cyanide anions.

The skeletons of the mimicked structures are combined through coordination and covalent bonds. The accommodation of bulky guest species or ligands in the void is essential to stabilize the crystal structures in several cases. The field of mineralomimetics does not include merely copying, imitating, or reproducing natural minerals; it also excludes modifying the structures of natural minerals by using compositional materials identical or similar to those of natural minerals. A number of structures were found to have no counterparts in natural minerals but comprise unprecedented inultidimensional fraineworks made of infinite linkages of coordination polyhedra. The chemistry of coordination polyhedra linkages forms a key part of mineralomimetic chemistry.[1]

Table I Structural similarities among ice, silica. and cadmium cyanide host

Space group	H_2O	SiO_2	$Cd(CN)_2$ host
$Fd\bar{3}m$	I_c	H-cristobalite	$[Cd(CN)_2].C(CH_3)_4$
$P4_12_12$		L-cristobalite	$[Cd(CN)_2].CHCl_2CH_2Cl$
	III. IX	heatite	
$P6_3/mmc$	I_h	H-tridymite	$[Cd(CN)_2]\cdot 0.5(n\text{-}Bu_2O\cdot H_2O)$
$C222_1$, etc.		L-tridymite	
$P6_2(6_4)22$		H-quartz	
$R3_1(3_2)21$		L-quartz	
Pm3m	Clathrate hydrate I[a]	Melanophlogite[b]	
$Fd\bar{3}m$	Clathrate hydrate II[c]		
$Pn\bar{3}m$	VII. VIII	(Cu_2O: cuprite)	Neat $Cd(CN)_2$
$P4_2/mnm$		Stishovite	$[Cd^{(o)}\{Cd(CN)_3(Him)\}_2].G$[d]

[a]General formula: $46H_2O\cdot[6X\cdot 2Y]$.
[b]General formula: $46SiO_2\cdot 8G$.
[c]General formula: $136H_2O\cdot[8X\cdot 16Y]$.
[d]Him = imidazole, G = *p*-xylene.

CADMIUM CYANIDE AND ANALOGOUS HOSTS

Cadmium cyanide has an anticuprite (cuprite: Cu_2O; space group $Pn\bar{3}m$) structure of doubly interpenetrating diamondoid frameworks. in which one framework appears to be the host of another as the guest forming a self-clathrate structure. The formal replacement of the guest framework by appropriate guest (G) molecules affords a clathrate, with a structure that is isomorphous to H-cristobalite (Fig. 1). A group of clathrate compounds was obtained with the chemical formula $[Cd(CN)_2]\cdot G$, which is the simplest formula of the clathrate compounds so far discovered.[1–5]

The thermal phase transition observed for silica was mimicked chemically by appropriately choosing the geometry of the guest molecules. Tetrahedral and pseudotetrahedral guests select the H-cristobalite-like host (space group $Fd\bar{3}m$).[2–4] However. guests that have a molecular shape considerably distorted from tetrahedral, such as $CHCl_2CH_2Cl$, $(CH_3)_2CHBr$, and $(CH_3)_2CHCN$, deform the host to an L-cristobalite-like structure ($P4_12_12$: isomorphous to the low-temperature phase of cristobalite). Aliphatic long-chain guest molecules, such as $\{CH_3\text{-}(CH_2)_3\}_2O$, are included by the H-tridymite-like host ($P6_3/mmc$: high-temperature phase of tridymite) with channel cavities.[1,2]

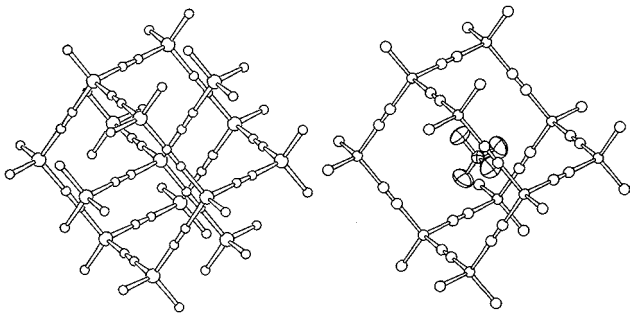

Fig. 1 Doubly interpenetrating diamondoid lattices (self-clathrate) of $Cd(CN)_2$ (left) and the clathrate structure of $[Cd(CN)_2]\cdot C(CH_3)_4$.

Mixed metal cyanide hosts. $[CdHg(CN)_4]$ and $[CdZn(CN)_4]$, are also isomorphous to H-cristobalite, but the formula unit is effectively doubled, e.g., $[CdHg(CN)_4]\cdot 2CCl_4$.[4] When one tetrahedral center is replaced by Cu(I), the host acquires a negative charge that is neutralized by an accompanying cationic guest, such as $N(CH_3)_4^+$, along with a neutral guest as observed for $[N(CH_3)_4].[CdCu(CN)_4].CCl_4$.[4] The assembly of smaller secondary ligands such as $(H_2O)_4$ plays the role of guest in $[Cd_5(CN)_{10}(H_2O)_4].4(cyclo\text{-}C_6H_{11}OH)$.[6] Four of the five Cd^{2+} are five-coordinate with an aqua ligand. four of which form a tetrahedral hydrogen-bonded $(H_2O)_4$ assembly in one of the five cavities per formula. The cyclohexanol guests in the four cavities surrounding the cavity tetrahedrally accommodating $(H_2O)_4$ extend OH groups to the tetramer to form hydrogen bonds. Such spanning of guest molecules between two cavities was also observed for the two H-cristobalite-like host clathrates $[Cd(CN)_2]\cdot 0.5(i\text{-}C_4H_9)_2O$ and $[Cd(CN)_2]\cdot 0.5(i\text{-}C_5H_{11})_2O$,[5] and others.

LINKAGE OF COORDINATION POLYHEDRA

Cadmium(II) and copper(I) are typical central atoms with tetrally coordinated cyanide groups. giving not only a discrete tetracyanometallate anion but also several kinds

of polycyanopolymetallate anions analogous to those observed for natural silicate minerals. Silicate structures are roughly *classified into neso-silicates with a discrete or isolated* SiO_4 *(orthosilicate) units: soro-silicates or coupling silicates with* a *dimeric* Si_2O_7 *(pyrosilicate) or trimeric* Si_3O_{10} *unit: ino-silicates or* chain *silicates extending a* 1D $(SiO_3)_n$ *(metasilicate) chain:* cyclo-silicates *or ring silicates with a ring unit of* $(SiO_3)_n$*; phyllo-silicates or layer silicates extending a* 2D *layer; and tecto-silicates or framework silicates extending a* 3D *framework; ionic charges were neglected. All of these structures were mimicked* in *the* (poly)cyano(poly)cadmate *structures, as shown in Fig.* 2;[7–10] *topologically, the same structures were also seen for* cyanocuprate(I).[11]

A spinel (Al_2MgO_4)-like $K_2[Cd(CN)_4]$ *contains a discrete tetracyanocadmate,* although *spinel is not a silicate.* It *appears there is not a particularly strong interaction between the N-end of* $[Cd(CN)_4]^{2-}$ *and* K^+ [N–K: 2.930(2) Å], *in contrast to the spinel* in *which no isolated* MgO_4 *units* exist.[12]

In the other linking structures, almost always the terminal *N*-ends *of* CN *groups coordinate to other octahedral centers, mainly of* Cd^{2+} (=$Cd^{(o)}$). *The way of* linking to *the* $Cd^{(o)}$ *center is* either *similar to that observed in silicate structures, for example, to* Mg^{2+}, Fe^{2+}, etc., *or different. depending on the components involved with the whole structure.*

Pyrosilicate-like $Cd_2(CN)_7$, *eclipsed and staggered forms, and trimeric* $Cd_3(CN)_{10}$ *moieties are seen as the building blocks of several host structures that were classified into clay-like layers, zeolite-like cages,* and *other* 3D frameworks.[1,3,7,10,13] The *anion of* $[P(C_6H_5)_4]_3[Cd_2(CN)_7]$ *is discrete,* taking *a staggered* form.[14] *A* tetraphenylstibinium *salt* $[Sb(C_6H_5)_4]_2$ $[Cd(CN)_3]_2$ *(there are two* crystallographically *independent chains and cations, respectively, in the unit cell) is* pyroxene($A^{II}B^{II}Si_2O_6$)–mimetic, *but the ino-silicate-like chain is* comprised *of* a *dimeric unit in a staggered form in comparison with the eclipsed form in pyroxenes.*[7,9]

A tetrameric *ring of* $[Cd(CN)_3]_4$, *like the* cyclo-silicate *ring in* tetramellite $Ba_2(Fe,Ti,Mg)_2(OH)_2(Si_4O_{12})$, *is found as the building block in the 319 host* of $[\{Cd^{(o)}(piperazine)\}_2\{Cd(CN)_3\}_4]\cdot 4C_6H_5OH$ *clathrate*[11] *and others. A* beryl($Al_2Be_3Si_6O_{18}$)–mimetic *host* $[Cd^{(o)}(Him)_2\{Cd(CN)_3\}_2]$ (Him = *imidazole) involving the hexameric ring of* $[Cd(CN)_3]_6$ accommodates *m*-xylene *as the guest in its channel cavity, similar to the water molecules of crystallization in beryl."] The trans*-bis *coordination of* Him ligands *to the* $Cd^{(o)}$ *makes it a square planar four-hand linkage builder in place of the tetrahedral Be in beryl. However, if the guest is p*-xylene *in the host of the* same *composition. the host skeleton changes its topology and coordination structure to a* rutile(TiO_2)–mimetic $[Cd^{(o)}\{Cd(CN)_3(Him)\}_2]$.[16] *The Him ligands move to the tetrahedral Cd, which mimics the* three-*coordinate* O^{2-} *in rutile. As exemplified for these structures, the structural variations are complicated and delicate in mineralomimetic structures as well as in natural minerals.*

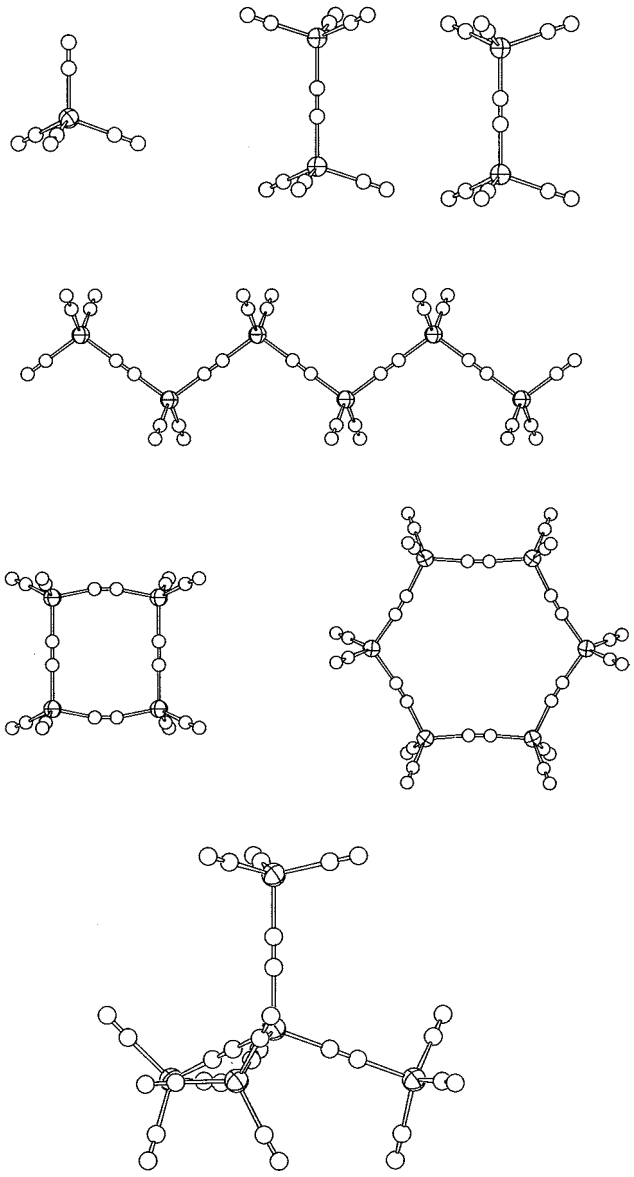

Fig. 2 Silicate–mimetic arrays of $Cd(CN)_4$ and $Cd(CN)_3$ moieties in mineralomimetic structures. From top left to bottom: discrete $Cd(CN)_4$, dimeric $Cd_2(CN)_7$ in a staggered form. dimeric $Cd_2(CN)_7$ in an eclipsed form, $[Cd(CN)_3]_n$ chains, tetrameric $[Cd(CN)_3]_4$ ring, hexameric $[Cd(CN)_3]_6$ ring, and pentameric $[Cd\{Cd(CN)_4\}_4]$ tetrahedron.[7,9]

A number *of clay-* and *zeolite–mimetic structures also show some differences from the natural ones. Layers of the clay–mimetic structures are comprised of the unit of tetrahedral* (T), *octahedral (O), and tetrahedral (T) Cd*

atoms linked successively by CN, Cd–CN–$Cd^{(o)}$–NC–Cd, similar *to the* T–O–T *unit linkage sharing oxide anion in natural clays. However, the* –CN *(or* $-OH_2$, *–OH,* –Cl) *vertices of the tetrahedra are arranged on the surface of the layer instead of the tetrahedra! faces in natural* clays.[7] *Although few natural zeolites involve octahedral coordination centers in their skeletons, the zeolite–mimetic structures are built up of the* T–O–T *units as well as the clay–mimetic* ones.[7,13] To *avoid misunderstanding, it should be noted that in zeolite chemistry,* ''T–O–T'' *is generally used to denote the connection of tetrahedral centers sharing an oxide anion. Some clay–mimetic structures have intralayer cavities. that is, the layer itself generates a void to* accommodate *guest species as a layer zeolite.*

MISCELLANEOUS

The Mofmann-Td-type host (see Hofmann-Type Clathrate) $[Cd(NH_3)_2M'(CN)_4]$ (M'=Cd, Hg) *has a skeleton topologically the* same *as that of cooperite* (PtS), *for which the square planar Pt is mimicked by trans-*$[Cd(NH_3)_2]$ *and the tetrahedral* S *by* $[Cd(CN)_4]$.

The solid acid with apparently a curious cornposition $3HCN \cdot Cd(CN)_2 \cdot 2CuCN \cdot 14H_2O$ *should be* formulated *as* $[H_3(H_2O)_{14}] \cdot [Cd^{(o)}\{Cu_2(CN)_7\}]$ *according to its cubic crystal structure isostructural to pyrite* (FeS_2) *with the same space group* $Pa\bar{3}$.[11] *The dimeric anion* $Cu_2(CN)_7$ *in a staggered form mimics the* S_2 *moiety in pyrite. Three terminal CN groups are linked to three different* $Cd^{(o)}$ *corresponding to Fe in pyrite, respectively. The octahedral coordination of the* $Cd^{(o)}$ *is accomplished by six N-terminals* from *six different* dimeric *anions. Fourteen* H_2O *molecules, three of which should be protonated, extend a 3D hydrogen-bonded framework with a topology the* same *as that of rutile* (TiO_2). *A crown ring of the 12* H_2O *molecules encircles the* –Cu–(CN)–Cu– *axis of the dimeric* $Cu_2(CN)_7$ *to form a rotaxane structure. Six* H_2O molecules *in the dodecameric ring are connected to another kind of six* H_2O *molecules, respectively, which extend the hydrogen bond to three different rings of the dodecamer. The ring mimics* Ti, *and the three-hand* H_2O mimics O *in the rutile structure.*

Finally, an experimental problem should be noted for the discrimination of C *and* N atoms *in x-ray crystallography. The* C *and* N *in ordered structures are clearly discriminated through the processes of structure refinement when the applied space group is appropriate. In some cases, inappropriate space groups are selected by assuming* that *discrimination is possible without any supporting evidence;* the *systematic absences of reflections should be carefully checked. In general, the* CN *group coordinates to a tetrahedral center at* C *and an octahedral center at* N *in the link. The CN* link *between a couple of tetrahedral centers* is *usually disordered. Solid-state NMR of the coordination center nucleus,* e.g., ^{113}Cd,[6] *is* useful *to judge whether the disorder is real or apparent due to the space group applied—a determination which is often ruled by the arrangement of heavy metal coordination centers.*

CONCLUSION

Precise molecular chemistry has developed based on the structures of Avogadro molecules, which are discrete chemical species comprised of definite numbers, as small as H_2 *or as large as DNA, of atoms belonging to distinct elements regardless of electronic charge. Biomimetic chemistry is essentially the chemistry of Avogadro molecule. albeit some with polymeric structure. On the other hand, many inorganic solid materials are substantially* nonstoichiometric *with an infinite range of structures. A relatively simple chemical composition of a species never necessarily means that the species has a simple and unique structure of Avogadro molecules, as exemplified by* C_2H_6O. *The inorganic chemistry of a* non-*Avogadro molecule, paid less attention to in comparison with that of an Avogadro molecule, has yet been less explored as precise structural chemistry.* Mineralomimetic *chemistry is a spike struck artificially into the lithosphere, apparently with a hoary look, in order to reveal another harmony of nature. For more details, refer to a few comprehensive works in the* literature.[1,8–10]

Modulated Structures

Gervais Chapuis
University of Lausanne, Lausanne, Switzerland

INTRODUCTION

The three-dimensional periodic arrangement of atoms or molecules was believed to be one of the most fundamental and indisputable aspects of crystalline architectures. The direct consequences of this periodicity were manifold. Perhaps the most important was that any crystal face could be uniquely characterized, i.e., indexed by three integers, the so-called Miller indices. Prior to the discovery of x-ray diffraction, many generations of mineralogists dedicated a large amount of effort to identify the Miller indices of all possible crystalline faces occurring in nature. Later, the discovery of x-rays was instrumental in providing a clear picture of the three-dimensional arrangements of individual atoms in condensed matter. It was soon discovered that any crystal, placed in an incident x-ray beam, deviates the intensities and redirects them in selected directions covering all the space. Here again, it appeared that each diffracted beam could be uniquely characterized by three integers, the Bragg indices.

At this point, it seems natural to associate each integer index of a crystalline face or a diffracted beam with one dimension of space. In other words, the periodic arrangement of the atoms along the three independent space dimensions explains the property that each face or diffracted intensity can be characterized by three integers.

The paradigm of the three-dimensional (3D) periodic arrangement of atoms was so anchored in the minds of scientists that most ignored some obvious signs pointing to a deviation from this model. Already in the 1930s, Goldschmidt, Palache, and Peacock,[1] following a careful study of more than 100 crystalline samples from different origins, concluded that Calaverite, a mineral of composition $Au_{1-p}Ag_pTe_2$ ($p < 0.15$) did not follow the rule stating that each face could be indexed with three Miller indices. The solution of this troublesome finding had to wait until the late 1980s, when Janner and Dam[2] published their interpretation of the Calaverite crystal form. These authors succeeded in completely reindexing all of the faces, providing the use of four integers to characterize each.

Another interesting phenomenon was discovered in the 1960s by Brouns, Visser, and De Wolff,[3] who studied the room-temperature phase of sodium carbonate. After many efforts, they were unsuccessful in indexing the lines of the powder diagram according to the admitted procedure, i.e., by assigning three integers only. However, they succeeded in completely indexing the diffraction pattern of a single crystal provided the use of four integers. From this period on, other examples of crystal structures requiring more than three indices were discovered, which culminated in 1984 in the discovery of quasicrystals by Shechtman and coworkers.[4] In this material, the full diffraction pattern could only be indexed provided the use of six integers.

In analogy with the rule that we introduced before, can we postulate that (some) crystals are periodic objects in dimensions higher than three? We will show in this article that this is the case and how we can reinterpret a crystal structure in the 3D space in which we live.

DESCRIPTION OF CRYSTALS IN SUPERSPACE

The most direct approach to study any crystalline structure is to place the crystal in an incident x-ray beam and to observe its diffraction pattern following a rotation or any other type of displacement of the sample in the beam. In the introduction, we saw that for a classical crystal, each possible diffracted intensity $I(\boldsymbol{h})$ can be associated with three integers (h_1, h_2, h_3) forming a vector $\mathbf{h} = h_1\mathbf{a_1}^* + h_2\mathbf{a_2}^* + h_3\mathbf{a_3}^*$, a so-called reciprocal vector. The reciprocal basis vectors $\mathbf{a_1}^*$, $\mathbf{a_2}^*$, $\mathbf{a_3}^*$ are linked to the basis vector $\mathbf{a_1}$, $\mathbf{a_2}$, and $\mathbf{a_3}$, forming the unit cell of the periodic structure in three dimensions by the scalar product relation $\mathbf{a_i}\,\mathbf{a_j}^* = \delta_{ij}$, i.e., = 1 if $i = j$ and = 0 if $i \neq j$.

Let us suppose now that the number of integers required to fully index the diffraction pattern is larger than three. We can, of course increase the number of reciprocal basis vectors and form a new vector $\mathbf{H} = \mathbf{h} + h_4\mathbf{q_1} + \ldots$. In this context and without losing generality, we will limit the total number of integer needed to characterize the pattern to four. The vector $\mathbf{q_1}$ becomes $\mathbf{q}$ and is subject to the following restriction $\mathbf{q} = q_1\mathbf{a_1}^* + q_2\mathbf{a_2}^* + q_3\mathbf{a_3}^*$, where at least one of the q_i is irrational. If this condition is not imposed, it would be possible to select another set of bases so that the three-dimensional vector $\mathbf{h}$ could index all the possible reflections. Revealed in Fig. 1 is the way the vector $\mathbf{q}$ and hence $\mathbf{H}$ are reinterpreted in a four-dimensional (4D) space. In this figure, the subscript S refers to

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019158

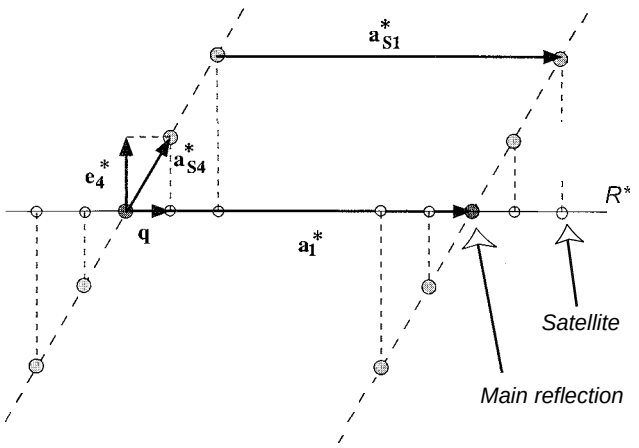

Fig. 1 Four-dimensional extension of the reciprocal space.

the higher dimensional space, i.e., the superspace. The reciprocal vectors $\mathbf{a_{S1}}^*$ to $\mathbf{a_{S3}}^*$ are identical to $\mathbf{a_1}^*$ to $\mathbf{a_3}^*$, respectively. whereas vector $\mathbf{a_{S4}}^*$ includes two parts and is equal to $\mathbf{q} + \mathbf{e_4}^*$. In this 4D example, we classify a reflection as a main reflection if its coefficient h_4 is 0. Otherwise, it is called a satellite reflection. In this model, the observed diffraction pattern (line R^* in Fig. 1) is interpreted as a 3D projection of the superspace.

Now that we learned how to extend the dimension of the reciprocal space, it is legitimate to ask the following: What is the direct space description of a crystal that corresponds to the extension of the reciprocal space? Illustrated in Fig. 2 is the concept of embedding a crystal structure in a space of higher dimension.[''] The basic principle behind this embedding is that the 3D crystal observed in the world in which we live, is a 3D cut out of a higher-dimensional periodic arrangement called superspace. In Fig. 2, a_{S1} and a_{S4} refer to the lattice parameters in superspace. Atoms are characterized by atomic modulation functions that repeat periodically in all dimensions. In this particular 4D case, each atom is represented by a string. In five-or six-dimensional superspace, atoms are represented by surfaces and volumes, respectively. In our figure, the line indicated by R represents the 3D space in which the atoms are located (A, B, and C in this example). In general, this cut is not periodic (AB $\neq$ BC), and in this case. the resulting structure is aperiodic. From Fig. *2*, we can also see that the atoms are displaced along the modulation function relative to an average position (vertical dotted line in the figure). If this is the case, the structure is called modulated. If at least one of the components q_i is irrational, the structure is incommensurately modulated, whereas in the other cases, the structure is commensurately modulated.

With this model in hand, the challenge of the diffraction specialist is to fully characterize the structure, in other words, determine the shape of the modulation curve on the basis of the experimental observations. For classical periodic crystals, the determination of the periodic crystalline structure consists, in a first step, of locating each atomic position in the unit cell, i.e., the unit volume repeated periodically in the three spatial dimensions and determined by the three basis vectors. The diffracted intensities of a crystal structure are related to the atomic positions by the structure factor expression. For aperiodic crystals, the structure factor $F_{\mathbf{H}}$ includes a term describing the modulation and is given by the following relation:

$$F_{\mathrm{H}} = \sum_{\mu} f_{\mathrm{H}}^{\mu} \exp(2\pi i \mathbf{H} \cdot \mathbf{r}^{\mu}) \times \int_0^1 \mathrm{d}t \; p^{\mu}(t) \exp\{2\pi i(\mathbf{H} \cdot \mathbf{u}^{\mu}(t) + h_4 t)\}$$

The summation is over all the μ atoms in the unit cell with atomic scattering factor $f^{\mu}_{\mathbf{H}}$. The modulation $\mathbf{u}^{\mu}$ describes the individual atomic displacement relative to its basic position $\mathbf{r}^{\mu}$. The integration variable t is related to the fourth dimension by the expression $x_4 = \mathbf{q} \cdot \mathrm{r} + t$ (see Fig. *2)*. The first line of this expression corresponds to the structure factor of a conventional crystal (h_4 is equal to zero, and thus $\mathbf{H} = \mathbf{h}$). The second line of the expression is specific to aperiodic structures and contains the information related to the atomic modulation function in superspace. In addition to a displacement parameter, the modulation can also be affected by a variable occupation parameter p^{μ}.

EXAMPLE OF AN INCOMMENSURATELY MODULATED ORGANIC STRUCTURE

In order to illustrate the principles of superspace extension, we will present one example of an organic aperiodic structure that was recently studied. Quininium (*R*)-mandelate, $C_{20}H_{25}N_2O_2^+ . C_8H_7O_3^-$, (Fig. 3) is an organic salt that exhibits a complex x-ray diffraction pattern schematically illustrated in Fig. 4.[6] All the satellites can be uniquely associated to main reflections with the modulation vector q. Without entering into the details of the structure solution, we will describe in this context only some specific stereochemical features of the resulting aperiodic structure determination.

Shown in Fig. 5 is a selection of electron-density maps related to N13 and C10, with the vertical axis representing the x_4 coordinate. We observe that the modulation function is specific for each atom. For N13, the atomic modulation function is continuous along the x_4 axis with extrema lying approximately 1.8 Å apart in the b direction. This deviation indicates that the departure from the average structure is particularly important throughout the crystal structure. The modulation of C10 describes another aspect of the diversity of aperiodic structures. In the crystal, this atom exhibits two stable positions a and b which are best represented in superspace by slightly modulated crenel functions. Thus, the domain of existence of C10a and C10b is colnplementary and mutually exclusive.

Once the refinement of the structure in superspace converged to a satisfactory solution, the nonperiodic structure can be obtained from the appropriate 3D cut. Illustrated in Fig. 6 are some of the features deduced from the structure solution. As an example, the orientation of the quinoline double ring varies continuously in space. This is not the case for the vinyl part that exhibits essentially two different orientations if we neglect the wavy modulation.

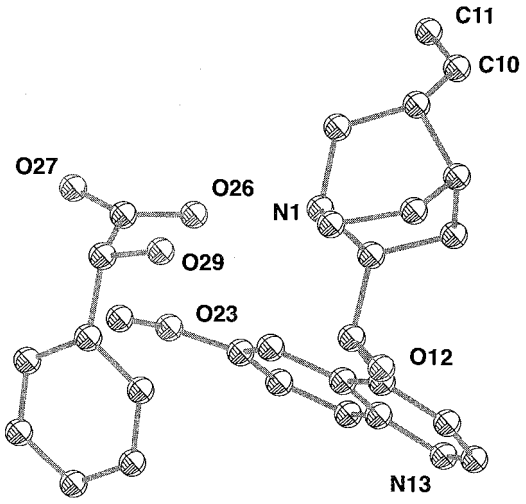

Fig. **3** Quininium (*R*)-mandelate with oxygen atoms (red, indicated with ''O'') and nitrogen atoms (magenta, indicated with ''N''). Mandelic acid is the entity containing 026 and 027. (View *this* art in color at *www.dekker.com.*)

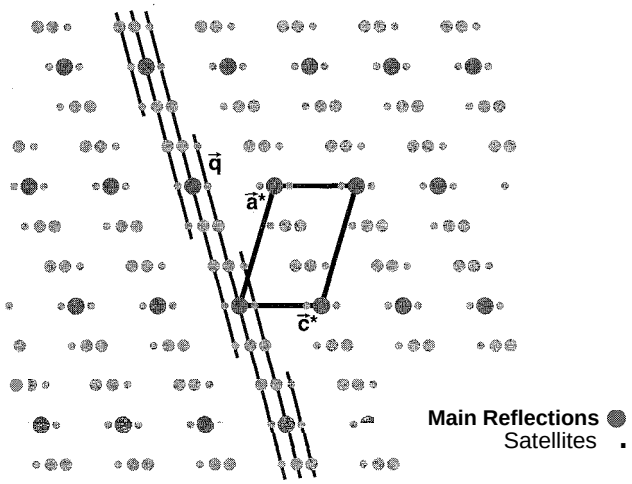

Fig. 4 A reciprocal layer of quininium (R)-mandelate. (*View* this art *in* color at *www.dekker.com.*)

What are the essential features of the refined modulated structure? Most of the effect of the modulation is observed in the H-bond network. The most significant change concerns the alternate intermolecular bonds O29–H···N13 and 029–H..·027. These bonds are mutually exclusive and are equally distributed in space. Obviously, the displacement of the quinoline illustrated above is directly linked to the H-bond formation with N13. The modulation with the shape of a crenel function is associated to a weak H-bond C11–H···O23. The two H atoms bonded to C11 of the vinyl group form alternatively a link to 023. which explains the two conformations observed in Fig. 6.

We should stress at this point that the existence of pairs of possible H–bonds should not be assimilated with any type of disorder. The sharp peaks observed in the diffraction pattern indicate long-range ordering, which means that the distribution in space of one or the other bond satisfies strict rules.

SIMULATION OF MODULATED STRUCTURES

The origin of the modulations is mostly due to competing interactions at the atomic level. The crystal attempts to resolve this frustration by favoring, alternatively. each type of interaction. The periodicity of the alternating interactions is, in general, independent of the 3D periodicity

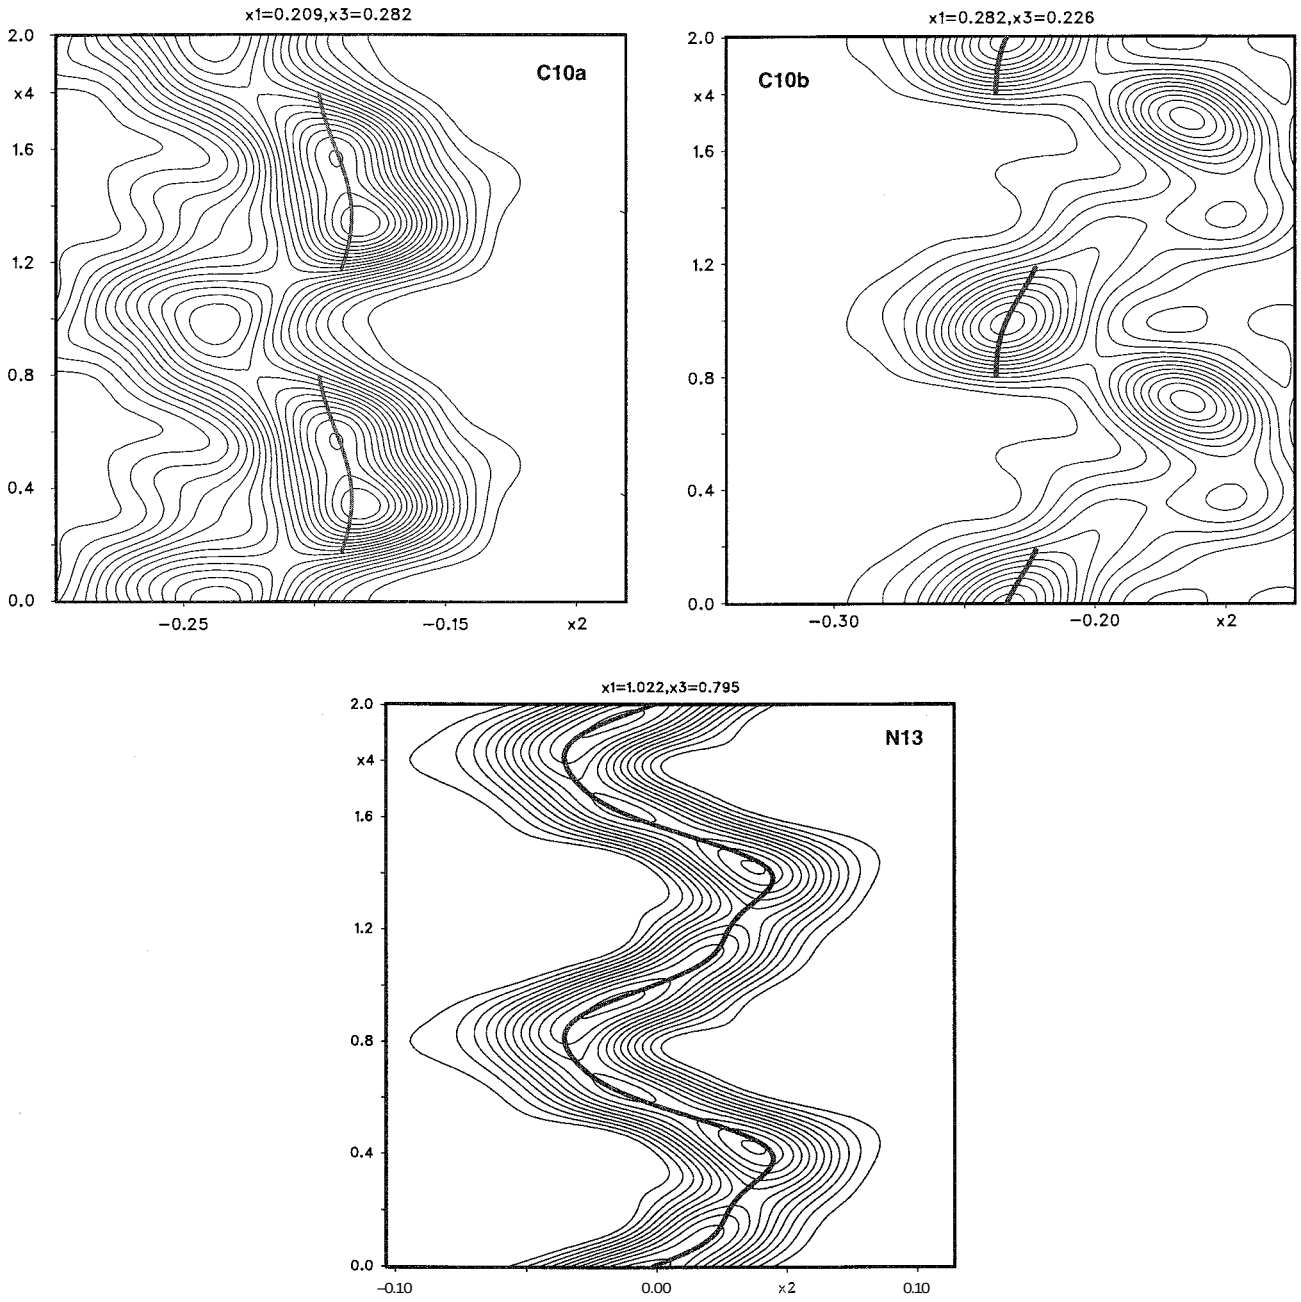

Fig. 5 Electron density of atoms C10 and N13 in the (x_2, x_4) plane. (See Fig. 3). (*View this art in color at www.dekker.com.*)

of the structure and. therefore, is incommensurately modulated. It often varies with pressure or temperature.

In this context, we propose to illustrate the formation of modulated structures by molecular dynamical simulation. As an example, we will consider a molecular crystal structure under various temperature conditions. As nonbonded pair potentials. we apply the Lennard–Jones (LJ) 9–6 potential and the Coulombic potential. Bonded potentials include terms to describe bond stretching. bond angle bending, torsional rotations, and out-of-plane deformations. All potential parameters are taken from a second-generation force field. the consistent force field (CFF91).[7] This force field is commonly used to maintain proper intramolecular geometry coupled with van der Waals and electrostatic interactions between atoms. It was used to successfully predict lattice parameters, root-mean-square (rms) atomic coordinates, and sublimation energies for crystals.

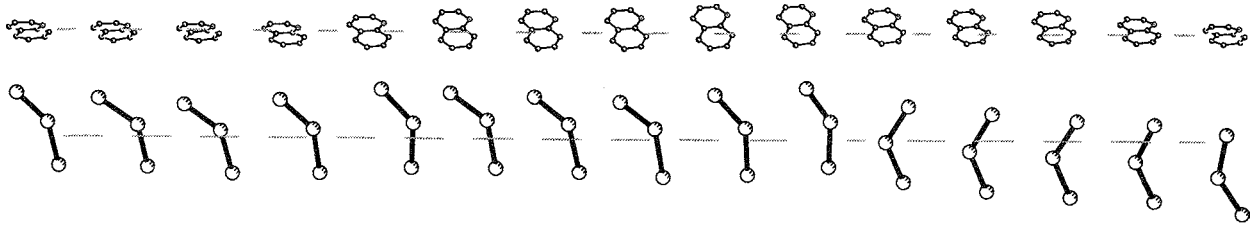

Fig. 6 Sequence ot identical elements of the structure along a particular direction Examples of the orientation variation of the quinoline and the vinyl parts

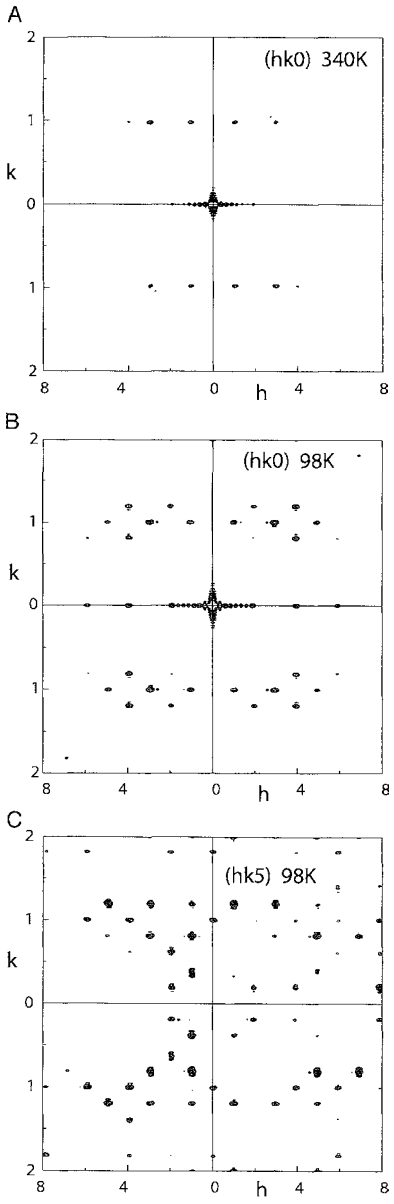

Big. 7 Simulated diffraction patterns of the high-(340 K) and low-temperature phases (98 K) of DCPS resulting from the MD calculations.

The organic compound 4.4'-dichlorodiphenyl sulfone (DCPS) presents an incommensurate structure below 150 K. The structure is periodic above this temperature.[8] The MD simulation starts with an equilibrated system that was first optimized under NVT conditions (constant number of atoms, volume, and temperature) from x-ray data at 90 K. In order to compensate for the imperfections of the CFF and match the MD results with the experimental lattice parameters. a pressure tensor is introduced in the calculation. The evolution of the temperature dependence of the system is obtained by NPT conditions (constant pressure). The results of the simulation are best illustrated by simulating the diffraction pattern of the structures at specific temperatures. Illustrated in Fig. 7 are the phases of DCPS above and below the phase transition. At 340 K, the diffractogram indicates that the structure is periodic. Moreover. it also indicates systematic absences pointing to the presence of specific symmetry characteristics in the crystal. The 98 K diffractograms reveal the presence of satellite reflections, indicating the existence of a modulated structure from which the modulation vector q can be deduced. Note that in this structure, its nonperiodicity requires the use of a single-unit cell containing more than 100.000 atoms, the magnitude of which is only limited by the capacity of the high-performance computer.

Hence, the method of MD simulations is able to reproduce the characteristic modulations that occur in DCPS under specific temperature conditions. The modulation vector obtained by MD exceeds only slightly the experimental value measured by x-ray diffraction. This method was also successfully applied to other organic crystals results,'" reinforcing the results obtained by diffraction and confirming them by an independent method.

CONCLUSION

Modulated crystal structures are by no means a rarity. Since the Calaverite mineral. many other examples of modulated structures and more generally aperiodic crystals were and continue to be discovered. They occur in all types of

crystalline structures, from metals to alloys, from minerals to organic materials, covering the full range of crystalline structures. They often occur in pressure-or temperature-induced phase transitions with variable ranges of stability. As mentioned above, these phases should not be considered as disordered material as was often the case in the past. The discrete nature of their diffractograms, i.e., the presence of sharp peaks is a direct proof of the long-range ordering of the atoms in the crystal. Of course, disorder can occur as well in aperiodic as in periodic structures.

The structural study of aperiodic material is a field that is still evolving. Their detailed study at the atomic level will possibly deliver the origin of the mechanism leading to aperiodicity rather than periodicity. We can also expect to use the structural properties of incoinmensurabilities as a probe to improve our knowledge of the chemical and physical aspects of atomic interactions. In addition, we can also expect to discover and take advantage of some specific properties associated with the aperiodicities of crystalline material. A series of studies on the NMR and NQR properties of incommensurate crystals already revealed some specific characteristics[10] of these systems.

At this point, one may wonder why the studies on modulated structures only recently acquired some momentum. One obvious answer lies in the availability of the tools required to perform these studies. The discovery of the 3D space groups that are fundamental for the symmetry description of crystalline material preceded by a quarter of a century the discovery of x-ray diffraction by crystals. Shortly after, a selected number of crystal structures were described for the first time by W.H. and W.L. Bragg. For aperiodic crystals and, in particular, modulated ones, all the tools and methodologies necessary to study chis new type of materials had to be developed before further progress could be made. The development of the mathematical theory of superspace was instrumental for further success. After more than three decades of development, the availability of good performing tools is just starting to appear and explains the relatively belated development of this speciality.

Molecular Biomimetics

Philip **Ball**
Nature, London, United Kingdom

INTRODUCTION

The idea of nature as engineer is an old one. but only recently have its engineering principles begun to be uncovered at the molecular and supramolecular scales. The cell is now imagined as a production plant in which molecular machinery works in precise orchestration to generate complex products from raw materials. This mechanism is self-assembling, self-repairing, and self-replicating. Meanwhile, advances in microfabrication have made us accustomed to the idea that engineering can be conducted at microscopic scales while employing principles familiar from the macroscopic world.

Reviewed in this article are some of the consequences of this convergence in scale and perspective of biology and engineering. Many of nature's principles and practices at the molecular and nanometer scales can be adapted for developing synthetic chemical and materials systems sharing the kind of superior properties and special functions that natural systems exhibit.

NANOSCALE MECHANISMS

Catalysis

With thousands of enzyme structures now solved and the number growing daily, Emil Fischer's "lock and key" mechanism of enzyme action is embroidered with ever more elegant detail. Fischer's idea. that the enzyme has a cleft at the active site within which its substrate makes a good geometrical fit, is basically sound but in need of refinement in some important ways. At least as important as the considerations of a good geometric fit is the nature of the microenvironment inside the binding cavity. Carboxylic acid groups that will be wholly ineffective at hydrolyzing polysaccharides in aqueous solution are adequate for the job within the active site of lysozyme. because they are not solvated and screened as they are in water. Thus, the active site can provide an effectively different (often hydrophobic) solvating medium that profoundly alters the reactivity of its functional groups relative to their behavior in aqueous solution. In the same way, the internal space of the microporous aluminosilicate zeolites is superacidic—hydroxy groups attached to the silicate framework will protonate alkanes—even while zeolites can be handled safely.

One aim of supramolecular chemistry is to devise molecules that bind substrates according to exacting geometric requirements, through the precise placement of interacting groups. For example, water-soluble cyclodextrins possess hydrophobic cavities reminiscent of enzyme-binding pockets, within which small hydrophobic molecules can be bound strongly. Breslow et al. developed a cyclodextrin-based mimic of the enzyme ribonuclease (which breaks down RNA by catalyzing the selective hydrolysis of a cyclic phosphate) based on a cyclodextrin molecule functionalized with imidazole groups.[1] There is now a broad range of cyclodextrin-based mimics of biomolecules.[2]

Hydrogen bonds often play a role in the binding of substrate to enzyme and are particularly valuable for shape-selective binding because of their directional nature. The use of hydrogen bonding in artificial receptor molecules was studied by Hamilton and coworkers,[3] who reported receptors exquisitely sculpted to bind their targets and stabilize a particular transition state during catalytic transformation (Fig. 1).

Antibodies can provide tailor-made molecular catalysts (although so far lacking enzyme-like rate enhancements) by using transition-state analogues as the antigens.[4] The same kind of sculpting of an active site around a small-molecule template affords catalytic activity via molecular imprinting of polymers.[5]

Self-Assembly

Self-assembly and replication, the paradigms of molecular and cell biology, are being increasingly seen as desirable goals for engineering. The alternative—laborious fabrication of individual structures "by hand"—is still the way that electronic and micromechanical devices are made today. by a sequence of deposition. patterning, etching or mechanical manipulating that becomes harder as the scales shrink and the device areal density increases.

To build a structure as complex as the Golgi apparatus, the chloroplast or the chromosome-charged mitotic

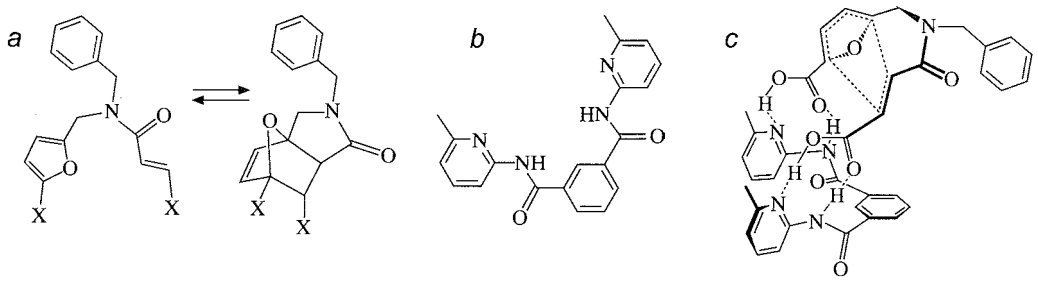

Fig. I The use of hydrogen bonding for enzyme mimicry. The intramolecular Diels–Alder reaction *a* is catalyzed by *b*, which has hydrogen-bonding functionality disposed to stabilize the transition state *c*.

spindle. the cell programs its molecular components with the information needed to bring them together in the right configuration. This is proof of the principle of the kind of "informed chemistry" advocated by Lehn.[6]

Thus. the hydrophilic head group and hydrophobic tail of lipids ensure assembly into the oriented bilayer array of cell membranes. The amphiphilic sheet, bilayer, and vesicle are now familiar mofits in biomimetic materials and structures. Synthetic liposomes are employed as biocompatible, biodegradable drug-delivery vehicles. Amphiphile assemblies may serve as templates: monodisperse nanoparticles are synthesized inside reverse micelles, and inorganic structures and materials such as ceramic tubules[L7] or mesoporous silica[8] are formed around tubular micelles, rather as inorganics are patterned by vesicles in the formation of the exoskeletons of radiolarians and diatoms.

A more sophisticated self-assembly process in nature is the folding of a protein to its native state. The linear polypeptide chain is preprogrammed to adopt and maintain its compact, three-dimensional form. One of the principal programmed motifs of protein folding is the β-sheet. a secondary structural component that was designed into some synthetic molecules.[9] As well as providing a model system for making molecules with well-defined higher-order structures, understanding β-sheet formation might lead to new antibiotics and treatments for diseases in which this process plays a role.

Using noncovalent interactions to guide the assembly of many molecules into organized structures is the major focus of supramolecular chemistry. Hydrogen bonding is used extensively for supramolecular organization; but so are metal-ion coordination chemistry, donor–acceptor interactions, π–π stacking, and other forces that might guide the recognition process. Metal ions, for example. were deployed by Sauvage and coworkers as organizing centers around which ligands are draped in geometries characteristic of the metal's oxidation state, so as to prearrange the organic components for forging into supramolecular topologies such as linked rings (catenanes) or knots.[10] Donor–acceptor interactions furnished a different breed of catenanes and threaded molecular assemblies called rotaxanes.[11]

One self-assembly strategy much used in biology is templating. The idea of using noncovalent supramolecular interactions to assist covalent synthesis is inherent in the formation of proteins on messenger RNA, catalyzed by the ribosome, as well as the formation of mRNA on DNA (transcription) and the replication of DNA. In all these cases, a template molecule helps to bring the components of the product into the right juxtaposition via base pairing. Liu et al. used the same principle — DNA templating — to catalyze the reactions between small molecules.[12] Here the DNA strands provide exquisite recognition groups that plug the reactants together, holding them in close proximity.

More dramatically. biology reveals how templating is the key to chemical replication, which is now achieved in a number of synthetic systems.[13] Templating must be exploited catalytically, requiring eventual separation of the product from the template, so that the bonds holding the two together while assembly takes place must eventually be broken. In the same way, if molecular recognition and self-assembly are the agents of some dynamical process such as ion transport [for example, when ionophores such as valinomycin selectively bind metal (potassium) ions and carry them across a cell membrane (see below)], then the substrate must be able to leave the receptor as well as to bind to it. This need for reversibility is common in biological self-assembly and recognition: it is characteristic of cell-surface signaling, neurotransmission, and the mechanisms of the immune response. High binding affinities favor strong selectivity but at the expense of reversibility. In proteins such as hemoglobin, a conformational change might alter the substrate binding affinity, highlighting the relationship between rigidity and selectivity on the one hand, and flexibility and reversibility on the other.

Energy Conversion

The conversion of photonic to chemical energy is what powers nearly every ecosystem on Earth. because it drives primary production. And yet this ubiquitous process is, at face value. not obviously one that warrants mimicry in solar-energy research. Even commercial solar cells based on polycrystalline silicon exceed the efficiency (at most 8–9%) of the chloroplast. the light-harvesting organelle of plants.

But this does not mean that nature's design for solar cells is poor. The rate of primary *production is generally limited by the availability not of solar energy but of nutrients such as phosphate and iron. Moreover, commercially viable solar energy is not about achieving record-breaking energy-conversion figures but about lowering the unit cost of solar cells. If devices could be produced as cheaply as green leaves, they would have no need of outstanding efficiency. So in asking whether solar-cell technology can usefully learn from nature, the right question is whether there are aspects of photosynthesis that might be gainfully employed to create cheaper devices?*

One *of the key differences between the chloroplast and a silicon solar cell is that the former is modular, and the latter is more or less monolithic. Tasks that are performed by different molecular entities in the chloroplast are subsumed into a single silicon matrix in the artificial devices. In the chloroplast, this division of labor reduces the possibility of recombination of charge carriers: a molecular relay produces quick, long-lived. and long-distance charge separation across the thylakoid* membrane. It is *a trick that was exploited in the nanocrystalline solar cells developed by* Grätzel *and* coworkers,[14] *in which charge generation takes place in ruthenium-based dye molecules, while charge transport is effected by the* titania *nanocrystals on which the dye is bound. The electronics* company *Toshiba is now aiming to commercialize these cells.*

Other systems *may, like the chloroplast. be concerned not with the generation of electricity per se but with the use of solar energy to drive a chemical reaction. Moore, Gust. and their coworkers developed a biomimetic system that derives a kind of artificial metabolism from sunlight (Fig. 2). Photon absorption by a porphyrin-containing molecular triad embedded in a* liposome *membrane stimulates the shuttling of an electron into the interior, accompanied by the simultaneous transmeinbrane movement of a proton. Thus, the pH inside the* liposome *decreases, just as it does within the thylakoid membrane in photosynthesis. The resulting electrochemical potential is used to power the enzyme ATP synthase, incorporated into the liposome* wall.[15]

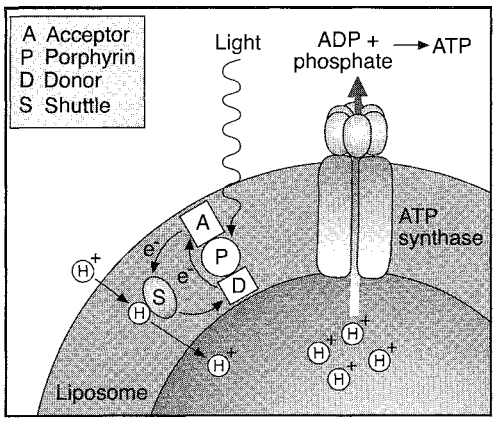

Fig. 2 A biomimetic system for solar-energy conversion. A molecular triad embedded in the bilayer membrane allows photoexcited electrons to be transported across the membrane to acceptor species in the interior. This charge transport is accompanied by the transmembrane flow of hydrogen ions. leading to a decrease in pH inside the compartment. This proton-motive force is then used to drive ATP synthesis by the membrane protein ATP synthase, as it is in photosynthesis.

Light-harvesting in the chloroplast's photosystems is not reliant on absorption by chlorophyll alone. Several accessory photopigments *increase the absorbing area and the wavelength sensitivity while channeling the energy of absorbed photons onto the photosynthetic reaction center down an energy gradient. This concept of an "antenna" system that acts as a funnel for captured energy was mimicked* in *synthetic light-harvesting systems, such as the* dendrimers *prepared by Shortreed et* al.[16] *The arms of these highly branched macromolecules are made of rod-like conjugated groups that absorb visible light.* A *progressive shortening of the arms* in *successive generations of the dendrimer's structure blueshifts their absorption maximum; so that the energy captured by all the light-absorbing groups is funneled into the* dendrimer's *center.*

For storing and transmitting captured photochemical energy, the molecular engineer cannot but be inspired by the elegance of ihe scheme used by photosynthetic bacteria. The light is absorbed by a toroidal protein complex called LH2, *which stores the energy before passing it on to the similarly shaped but larger* LH1 *complex, where it is used to create an electrochemical potential. The* LH2 complex *is a* supramolecular *storage ring in which 18 porphyrin groups are stacked face to face around the* circumference *(Fig.* 3a).[17] *The energy. passing freely between the porphyrin groups, can be tapped off at any point around the ring. This elegant structure inspired the synthesis of porphyrin rings that*

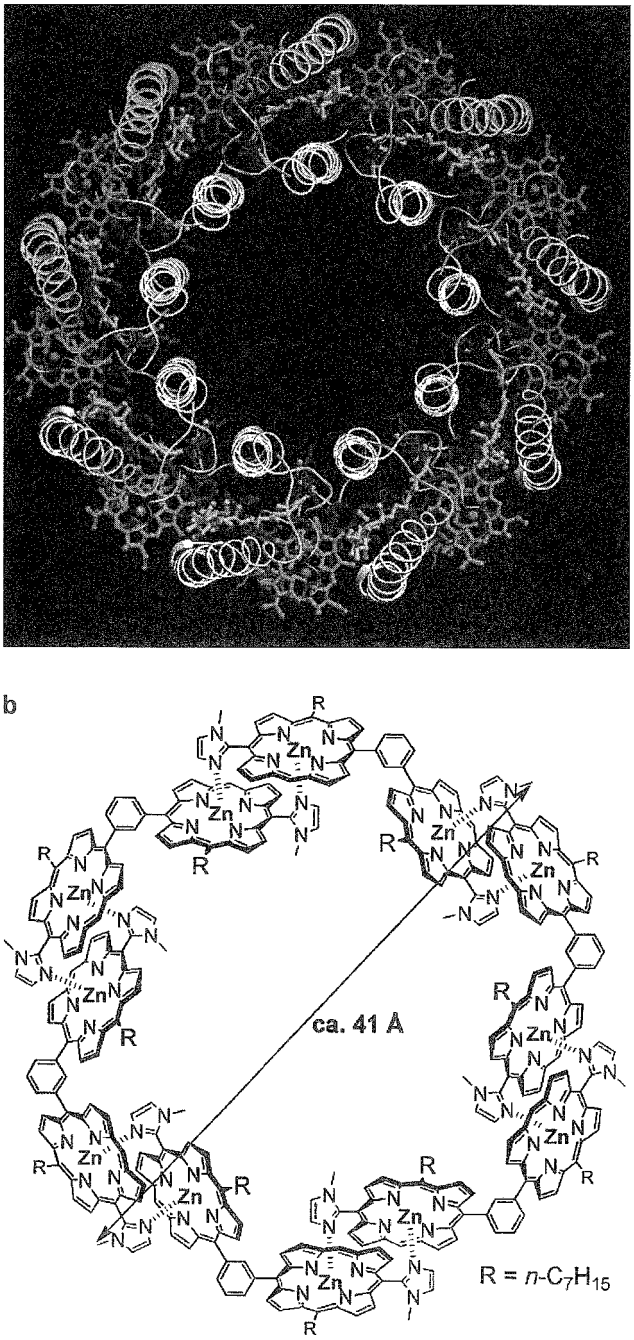

Fig. 3 (a) The light-harvesting LH2 complex of photosynthetic bacteria is a molecular "storage ring" in which absorbed energy is delocalized around a ring of 18 stacked porphyrins. (From Ref. [17].) (b) Such a supramolecular ring structure was mimicked in a hexameric assembly of porphyrin dimers. (From Ref. [19].) (***Virw*** *this art in color at www.dekker.com.*)

might act as antenna arrays or as energy-storage systems. For example, Li et al. made an oligomcric ring of three free-base porphyrins and three zinc porphyrins and saw photoinduced transfer of energy and charge carriers from the former to the latter.[18] Takahashi and Kobuke made a 4 nm ring of 12 zinc porphyrin units from six overlapping dimcr units (Fig. 3b).[19]

Sensing and Transduction

Essential to any sensing device is the process of transduction or signaling. In engineering, this is typically conducted electronically or, increasingly, optically. But it is rare in biology for electrons to represent the charge carriers of electrical signaling, at least in the sense of their being mobile in extended electron states. Electrons are typically passed between molecules in a series of redox reactions. Attempts to develop molecular wires — molecules such as polyacetylene and carbon nanotubes that transport electrons through conjugated systems — are, therefore, still based firmly in the electronics paradigm rather than in the biological.

Electronic signals in nerve cells travel by means of metal-ion transport laterally in and out of the axon. Such transmembrane transport of ions is fundamental to cell biology, and attempts to mimic it artificially laid the foundation of supramolecular chemistry. Early studies in molecular recognition by Lehn in the 1970s explored the use of crown ethers as mimics of cyclic peptide ionophores like valinomycin, which bind cations selectively in their internal cavities. Natural ionophores act as antibiotics by upsetting the ionic balance across bacterial cell walls.

Another way to transport ions is to provide them with a polar channel — in cells, a protein pore embedded in the membrane with a lipophilic outer face and a hydrophilic inner face. Artificial mimics of ion channels include peptide nanotubes — cyclic peptide inolecules designed to stack into cylindrical channels by the suitable placement of hydrogen-bonding groups around their edges (Fig. 4).[20] Thcsc peptides induce transmcmbrane ion transport at rates comparable to those of natural ion-channel proteins, such as gramicidin A, and show considcrablc promise as antibiotics.

Natural ion-channel proteins were used in single-molecule sensors, where the change in transmembrane ion current due to molecules partially blocking the pore provides a signature of the obstructing species. Bayley and coworkers used α-hemolysin as a molecular sensor, its pore neck tailored with a cyclodextrin "collar" to recognize various hydrophobic molecules.[21] Branton and coworkers use the same pore protein for single-molecule DNA sequencing: as each of the four types of

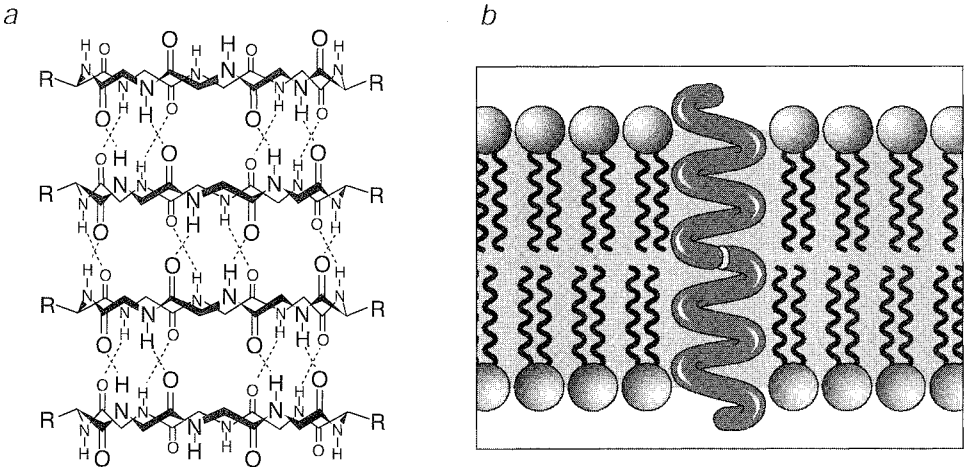

Fig. 4 Biomimetic and natural pore-forming systems for transferring ions across membranes. Tubes assembled from hoop-shaped molecules, such as cyclic peptides (a); mimic tubular ion channels such as the protein gramicidin A (b).

nucleotide is pulled through the pore, it has a distinct effect on the ion current.[22]

In macroscale engineering, transduction is often conducted mechanically. The generation of linear mechanical force and torque is widespread in the cell too: in the rotary motors of bacterial flagella, the rotary head of ATP synthase, and the ratcheting motion of the ribosome along mRNA during protein synthesis, for example. The paradigmatic examples of molecular force generation in biology are the molecular motors myosin, which powers the contraction of muscle tissue, and kinesin and dynein, which drive motion along cytoskeletal microtubules.

Controlled molecular motion was achieved in several synthetic systems,[23] including DNA machines that use a conformational change of the double helix to develop torque, and propeller-like molecules that can be rotated in a specific direction on a molecular axle by a sequence of chemical transformations. The hybridization and dissociation of DNA strands was also used to make DNA motors that extend and contract like pistons in response to DNA "fuel." One such device, unlike many artificial molecular motors, is capable of free running rather than requiring intervention at different points in the duty cycle.[24]

Materials

The extraordinary properties of natural materials, and their mimicry in artificial ones, have been amply advertised.[25] What are the guiding principles that, in determining the properties of natural materials at the nanoscale, are regarded as attractive targets for the materials chemist'?

While optimizing a particular material parameter tends to involve the fine-tuning of a specific feature of the structure, the combination of several desirable properties is typically a matter of controlling structure and organization across several different length scales. That is why natural materials generally display hierarchical structure, as evident in bone, wood, tendon, cartilage, and silk.

Related to the idea of hierarchy is the use of modular structure: building up materials through the assembly of identical smaller units. The stepwise unfolding of the muscle protein titin is due to a kind of modular domain structure and gives it a sawtooth stress–strain curve, very different from a purely elastic filament. Similar force curves were measured for the polymeric filaments that are pulled out from the organic binder between the aragonite plates of nacre as the plates are separated (Fig. 5).[26] This gives the composite a high work of fracture.

Spider capture silk, which can withstand extensions of up to 1000%, shows analogous behavior. The threads dissipate energy strongly as they stretch, minimizing the risk that a captured flying insect will be catapulted free again on the rebound. The capture silk proteins collapse into more or less helical coils that act as "molecular springs" (perhaps entropic). The jumps in the force curve presumably reflect hydrogen-bond breaking as these springs are progressively extended.

Biological materials are, almost by definition, self-assembling—which generally also implies that there are active control systems to provide self-repair, self-reinforcement, and disassembly when needed. Self-assembly has become an objective of much of materials chemistry: for example, in the formation of mesoporous silica and of colloidal crystals with potential uses in photonic tech-

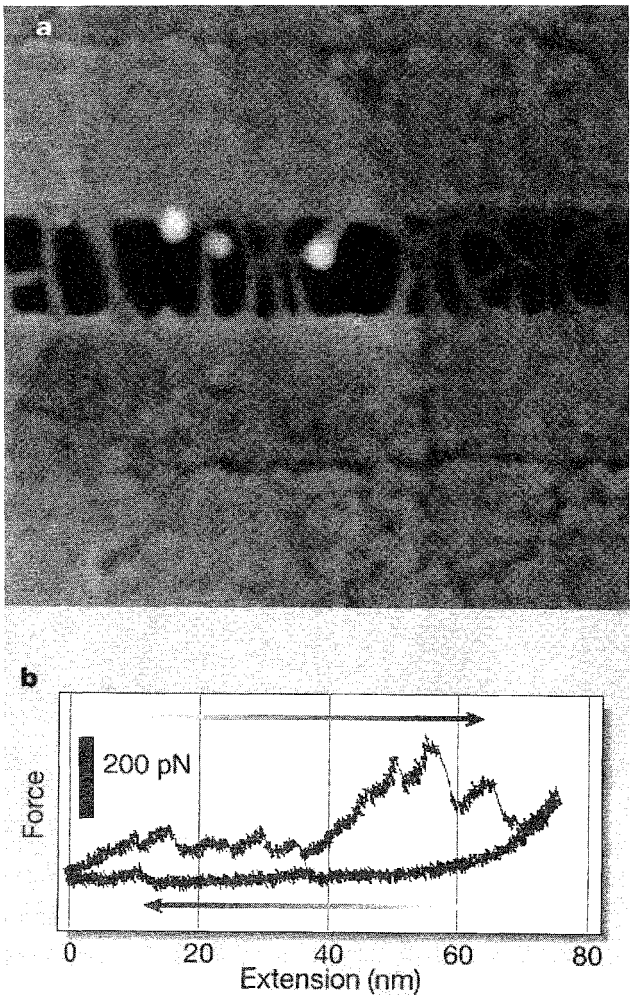

Fig. 5 The proteinaceous filaments that are pulled out of the organic binding layer between separated sheets of aragonite in nacre (a) extend in a stepwise manner, as revealed by force measurements with the atomic force microscope (b). The sawtooth stress–strain curve creates a greater work of fracture (area below the curve) than that for either a short, stiff adhesive strand or a long. smoothly elastic one. (After Ref. [26].) (*View this art in color at www.dekker.com.*)

nology. The sequence-specific ligation of DNA strands was used to create topologically complex self-assembling molecular architectures.[27]

Materials synthesis in biology is often conducted in compartments that delimit the extent of growth as well as provide a microenvironment in which parameters such as supersaturation of a precipitating phase can be delicately controlled by active transport of ions. This is how many biomineralization processes take place—for example, the formation of exquisitely patterned mineral plates in the soft tissues of coccolithophores. Mimesis of this principle is exemplified by the formation of monodisperse iron oxide nanoparticles inside the iron-storage protein ferritin, and the casting of inorganic particles inside the empty protein coats (virions) of viruses.

BIOSYNERGY

While the use of natural systems as guides to design at the molecular scale will surely continue to be exploited in creative ways in the coming years, biomimetic molecular engineering is also starting to employ a somewhat different philosophy in which "learning from nature" becomes a matter of adapting nature's existing machinery for technological ends. There need be no sharp distinction between the natural world and artificial mimics of it; instead, a hybridization of the two might reconfigure the cell's machinery to serve subtly different ends. There is a potential synergy in combining the natural with the artificial to achieve engineering objectives at the molecular scale.

For example, the rotary motion of ATP synthase was commandeered by Montemagno and coworkers to drive a nanoscale metal propeller at a rate of around five revolutions per second.[28] Protein engineering was used to insert a zinc-operated chemical switch into the enzyme to turn it on and off (Fig. 6).

Vogel and coworkers transported microtubules directionally across a surface, propelled by rows or linear channels of surface-bound kinesin.[29] Nanoparticle "cargo" was propelled in this way, and the motion was

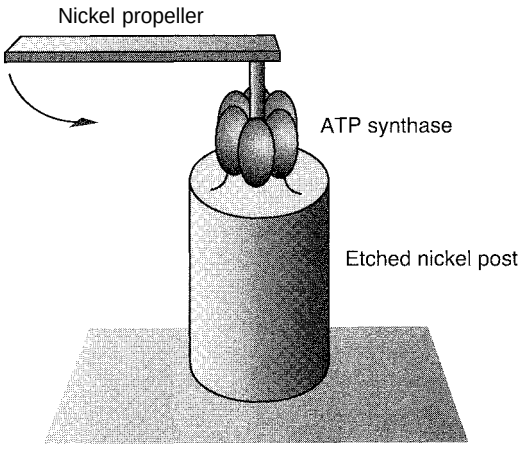

Fig. 6 A molecular-scale propeller representing a hybrid of the synthetic and the natural: the enzyme ATP synthase was attached to a metal post and modified to allow the attachment of a nanoscale "blade" of nickel metal.

switched on and off photochemicaliy using "caged" ATP as the fuel.

Phage transfection was used to transfer DNA into a wholly synthetic polymer vesicle containing the appropriate docking protein in its wall.[30] Modified phages might be used as "nanomachines" for loading genetic material into synthetic polymer nanoparticles used as vectors in gene therapy.

CONCLUSION

Biomimetics has become so popular a buzzword that there is a risk of it becoming its own justification, as if mimicking biology will undoubtedly turn out for the good. Yet nature offers little guidance for designing many technological processes and products, which operate under extreme conditions using materials alien to the living world. This article has illustrated, however, that the benefits accrue when our aim shares more in common with the exigencies of nature. If we wish to conduct chemistry at room temperature in aqueous media or to make organic compounds with complex architectures and precisely defined stereochemistry, nature reveals an astonishing repertoire of useful tricks. The materials engineer who requires a combination of low cost, light weight, and toughness, will probably already be using nature's fabrics in more or less modified forms, such as wood, leather, and paper. And as chemistry's synthetic targets become more sophisticated, embracing many-molecule supramolecular assemblies rather than simple small molecules, they often share features in common with the multi-molecular nanoscale structures of the cell.

A nanotechnology based on a literal downsizing of mechanical engineering. with every nanoscale device fabricated from hard moving parts, fails to acknowledge that there may be better, more inventive ways of engineering at this scale—ways that take advantage of the opportunities that chemistry and intermolecular interactions offer. Traditional engineering is often about trying to eliminate chemistry. At the molecular scale, we shall make life easier by embracing it. On the other hand, the cell's objectives are not necessarily the engineer's. For cellular information processing, accuracy is more important than speed. "Cost" to the cell does not equate with "cost" to manufacturing through a tidy conversion table. The materials of the cell need not be prescriptive. And perhaps most importantly, there is no justification for assuming that nature is optimized for any particular function. Biomimetics, at the nano- or any other scale, cannot afford a rose-tinted view of nature.

Molecular Clefts and Tweezers

M

Michael Harmata
University of Missouri—Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

The phenomenon of molecular recognition has been studied through a number of synthetic hosts of various shapes and sizes—hosts being chosen to exhibit complementarity to various guests on the bases of size, shape, and specific, directional, molecular interactions.[1–3] One class of hosts is the molecular tweezers, defined by Whitlock as receptors in which two, flat. generally aromatic "pincers" or chromophores are linked by a rigid spacer to provide an approximately two-dimensional cleft into which a guest can bind.[4] This guest is generally a flat, aromatic system, but the term "molecular tweezer" was applied to other hosts that can bind other types of guests.

A more general class of receptors is called molecular clefts. These are hosts, that have pockets or indentations in a molecular surface, into which a guest can fit but is not completely encapsulated. They are often, if not always, characterized by convergent functional groups directed toward each other but separated by a spacer. The space between the functional groups provides the cleft into which a guest can bind. Molecular tweezers are examples of molecular clefts. Binding in molecular clefts may be mediated by a number of interactions, including dispersion forces, stacking, hydrogen bonding, and salt bridging, among others.

ACHIRAL MOLECULAR TWEEZERS

Perhaps the most critical factor associated with the design and synthesis of a molecular tweezer is the nature of the spacer separating the two aromatic chromophores that play a key role in guest binding. The molecular tweezers introduced by Whitlock were constructed from caffeine molecules linked by a diyne linker. An example is shown in Fig. 1. This linker provides for a space between the caffeine moieties of about 7 Å, an ideal size for the inclusion of another π system. This compound and related species demonstrated binding in aqueous solution to theophylline derivatives that exceeded that based on simple additivity. Analogues with spacers that consisted of simple aliphatic chains bound the guests with much lower binding constants.

While this seminal work set the stage for further developments in the area, one problem was that the linker, despite its rigidity, still afforded the possibility of conformational isomerism such that the caffeine moieties were free to adopt orientations in which they were not *syn* and did not create a cleft into which binding could occur. The entropic demand associated with producing conformers with a *syn* orientation of binding elements certainly lowered the efficiency of molecular tweezers of this type.

This problem was addressed by Zimmerman and coworkers, who introduced a class of molecular tweezers in which a *syn* orientation between the binding elements was enforced by the nature of the spacer and the linkage between the spacer and the binding elements."' The spacer used by the Zimmerman group was based on dibenz [*c*,*h*]acridine. This was linked at the 2 and 12 positions to various aromatic systems like anthracene and various heterocyclic analogs to produce a class of molecular tweezers represented by Compound 2, shown in Fig. 2. While these species are largely constrained, rotation about the bonds connecting the chromophores to the spacer is possible, but they can readily adopt a conformation in which both chromophores are parallel. as shown. Further. such rotation actually provides for slight changes in the distance between the chromophores, providing the opportunity for finding an optimum fit for a guest through rotation about carbon–carbon bonds. Such tweezers have high affinity for polynitro aromatic species.[6,7] In fact. a stationary phase based on a molecular tweezer in this class was developed for the separation of nitroaromatics.[8]

The binding potentials of molecular tweezers of this class were enhanced by the incorporation of a carboxylic acid functionality within the cavity of the molecular tweezer. Such species were used to bind nucleotide bases with extremely high affinities. Studies as to the origin of the strength and selectivity of the binding were conducted.[9–11]

Another class of rigid molecular tweezers introduced by Klärner and coworkers is represented by Structure **3.** shown in Fig. 3.[12,13] This compound was shown to bind certain secondary ammonium salts. viologen analogues, tropylium ion. and other electron-deficient π systems. Two possible mechanisms for the binding process were

identified, in which a guest enters through the holes on the open sides of the molecule or through the gap between the pincers of the tweezer. Studies involving the effect of temperature and pressure on the binding process were conducted.''] This molecular tweezer was also incorporated into a stationary phase and shown to be effective in separating n-deficient aromatic systems.[15]

Another class of molecular tweezers based on the *trans*,*trans*,*trans*-perhydronapththacene spacer was prepared by Nemoto and coworkers and was shown to bind to x-deficient aromatic guests.[16]

Notwithstanding the good results obtained with rigid molecular tweezers, the synthesis of more flexible systems continues to be of importance, as such systems offer adaptability not found in rigid systems. A recent example comes from the work of Fukazawa, who showed that polyether systems such as 4 in Fig. 4 could bind electron-deficient π systems in solution and in solid state.[17] The distance between the binding chromophores of the molecular tweezer shown containing tetracyanoquinomethane as a guest was 6.54 A. It was postulated. as in studies conducted on derivatives of Kagan's ether (vide infra), that π-stacking and edge–face interactions were important in the binding process.

Warrener and coworkers developed an approach to molecular tweezers that are largely rigid but contain a hinge or hinges to allow limited flexibility, which might prove important in providing a better fit to guest molecules.[18] This approach is a part of the so-called ''Lego'' approach to the construction of rigid and flexible molecular tweezers and clefts.[19]

Recent work by Reed. Boyd. and coworkers led to the development of a series of tweezers, called ''jaws porphyrin'' hosts, that can bind fullerenes.[20]

CHIRAL MOLECULAR TWEEZERS

Among the first molecular tweezers. which were also chiral, were those prepared by the Karmata group. This

class of molecular tweezers was based on the framework provided by Kagan's ether, a C-2 symmetric structure built upon a dibenzobicyclo[3.3.1]octadiene skeleton. Two classes of tweezers thus far were reported, and these are shown in Fig. 5. It was reported that the smallest tweezer *(5)* did not form complexes with various n acids but formed a relatively stable clathrate with ethyl acetate in the solid state.[20] This demonstrated that the depth of the cleft is an important variable in the design of functional molecular tweezers.

In support of this idea. both 6 and 7 showed binding to 1.3.5-trinitrobenzene (TNB). in the solid state and in solution. as evidenced by shifts observed in the proton nuclear magnetic resonance (NMR) spectra of mixtures of

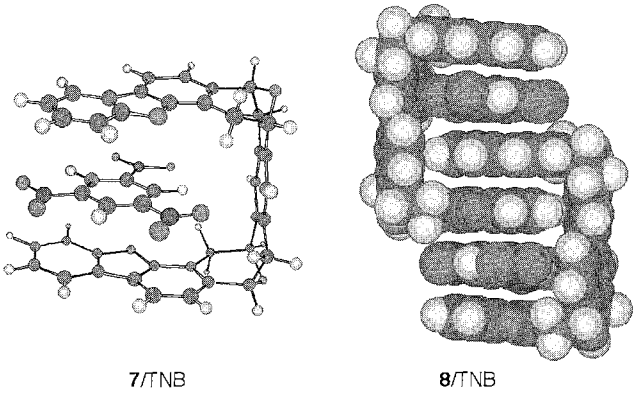

Fig. *6* Crystal structures for the 7/TNB and 8/TNB inclusion complexes. (*View this art in color at www.dekker.com.*)

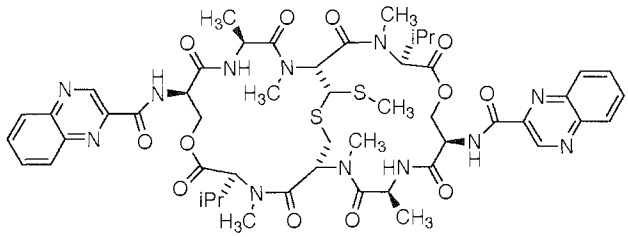
the hosts and TNB.[22,23] Titration experiments indicated that 7 bound TNB more strongly than 6 by more than an order of magnitude. Enantiomer recognition with 7 was examined via variable temperature high-perforiuance liquid chromotography (HPLC) studies using a Whelk-Q 1 chiral HPLC column. The results demonstrated that discrimination of the two enantioiners of **7** was possible; with binding of the two species differing by 0.5 kcal/mol, differences in enthalpy changes being the exclusive basis for the binding differences.

The tweezer **8** was introduced as an analogue of echinomycin (vide infra). As such. the distance between the two binding chromophores is 10.4 Å, large enough to accommodate two π systems. It was shown that in the solid state. two π systems can be bound in the cleft of **8**.[24] Shown in Fig. 6 are crystal structure data for the inclusion complexes of 7 and 8 with TNB. Both n-stacking and edge–face interactions between guest and host are evident from these structures. The 8/TNB complex indicates clearly that two π systems can be accommodated within the cleft of 8.

Other chiral inolecular tweezers are known. including one based on Tröger's base. which is exactly analogous to **5**,[25] as well as several based on a steroidal spacer to which are appended aromatic acids via an ester linkage.[26,27]

NATURAL MOLECULAR TWEEZERS

Nature "beat mankind to the punch" with respect to molecular tweezers. For example, echinomycin (Fig. 7) is



Echinomycin

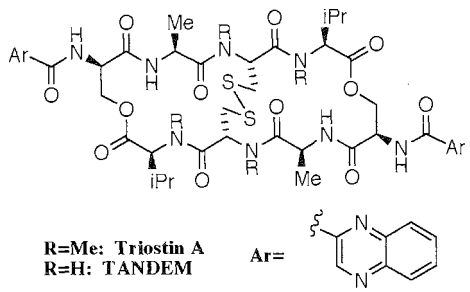


Fig. 7 A selection of natural molecular tueerers

the first representative of a growing class of cyclic depsipeptide antitumor antibiotics that includes the octadepsipeptides triostin A. the synthetic drug TANDEM, UK-63502 and BE-22179, the decadepsipeptides sandramycin, and the luzopeptins (Fig. 7), as well as the decapeptide quinaldopeptin.[28–37] These compounds exhibit a variety of interesting biological activities, including antibacterial, antiviral, and antitumoral.

The solid-state and solution structures of echinomycin and triostin complexes of DNA were studied.[38–40] These indicate that the drugs interact with DNA by "tweezing" two base pairs in GC-rich regions of double-stranded DNA. In the solid state and often in solution with an oligonucleotide target, this results in a twist of the helix to give Hoogsteen base pairing in base pairs flanking the binding site.

Other studies showed that binding affinity and specificity involve the octadepsipeptide and chromophores of echinomycin. One key to affinity and selectivity are hydrogen bonds between the N3 nitrogen and N2 amino of guanines in the CpG step and the NH and CO of the alanines of the octadepsipetide backbone of echinomycin. Replacement of *G* by hypoxanthine (G minus 2-amino) obliterates binding between echinornycin and a normally bound DNA fragment.[41] The synthetic intercalator TANDEM prefers AT regions of DNA, because its alanine CO groups are not available for hydrogen bonding with the 2-amino groups of guanine.[42,43] Further, the bias of echinomycin for the CpG step can be changed by substituting of adenine by 2-aminopurine.[44] The bottom iine is that the spacer of a his-intercalator can be significant in strong and selective DNA binding. Other work suggests that the chromophores of the intercalator are of some significance. Theoretical studies conclude, in particular, that the chromophore interactions with the DNA contribute at least 50% to the binding of the drug and that the electrostatic interactions between the chrornophores and flanking base pairs are important.[45] A balance between repulsive and attractive interactions involving the spacer and chromophores is important to the selectivity observed and, as important, can be changed by appropriate structural modifications.

Solution NMR and footprinting studies of DNA–drug interactions for some other naturally occurring ***Dis***-intercalators led to a grossly similar picture for the event: minor groove binding mediated by hydrogen bonding and van der Waals interactions. with stacking interactions involving dispersion. and electrostatic interactions no doubt being of importance.[46,47] In all cases, two base pairs are "tweezed," but the hydrogen bonding motif varies, as might be expected due to changes in the depsipeptide backbone.

ACHIRAL MOLECULAR CLEFTS

Molecular clefts that bear convergent functionality are of major interest. In systems of this type, a rigid spacer is used to create a scaffold onto which functional groups can be placed. These functional groups are often, but not always, directed toward each other but are held apart by the spacer. Guest binding takes place in the space between the functional groups, and selectivity is determined in part by the size of this aperture.

Many examples of molecular clefts of this type come from the labs of Rebek.[48] Many other structural types are known, including terpyridyl systems introduced by Bell[49] and the "molecular clips" from the group of Nolte.[50]

CHIRAL MOLECULAR CLEFTS

There are a number of examples of chiral molecular clefts. Among the most interesting are those introduced by Wilcox and coworkers, which involve derivatives of Tröger's base.[51,52] Such systems were used as hosts for various guests and as tools for the evaluation of edge–face interactions between π systems. Related molecular clefts are known.[53,54]

NATURAL MOLECULAR CLEFTS

Large biological molecules contain indentations, cavities, and pockets. Essentially all proteins and polynucleotides possessed of even simple tertiary structures have a portion of their structure that forms a gully into which a molecule might fall and bind. The major and minor grooves of DNA come to mind as obvious and important examples. Many enzyme-active sites and receptor-binding sites are essentially molecular clefts.[55] Our attempts tomimic these structural types are responsible for a great dealof the development of bioorganic and molecular cleft chemistry.

CONCLUSION

Design and application of molecular tweezers, particularly those that are chiral and those that can bind multiple π systems within their clefts, are only beginning to be explored. Molecular tweezers and other molecular clefts have the potential to dimerize to produce molecular

capsules; which are currently of great interest. Chiral species with reactive functionality directed toward the inside of the cavity still offer opportunities for creating new catalysts. drug-delivery systems, and perhaps materials for molecular electronics and computing. New directions for molecular recognition and supramolecular chemistry remain to be found or invented in this area, and new breakthroughs are to be expected.

Molecular Logic Gates

Gareth J. Brown
A. Prasanna de Silva
Sheenagh M. Weir
The Queen's University of Belfast, Belfast, Northern Ireland

INTRODUCTION

The forces that drive research in molecular logic gates are identified as neural science and computer technology. The longest established design relies on chemical (usually ionic) inputs and fluorescence outputs. This design also incorporated chemical input–transmittance (or absorbance) output situations. Light and chemical input–fluorescence (or absorbance) output situations involving chemically switched photochromism can also be a valuable design approach. All-optical methods involve electron transfer or two-photon absorption. After decades of discussion and effort; ail-electronic methods are recently making the transition from wires and switches into logic gates. Examples are provided for each design. This article illustrates all of the single-input logic gates and a substantial number of the double-input family.

WHY BOTHER WITH MOLECULAR LOGIC GATES?

None of us are immune to the effects of the modern information technology revolution.[1] Nevertheless; how many of us as chemists helped to start or even drive it? Very few, would be the answer. Chemists were behind the purification of silicon to the exacting levels required for the construction of semiconductor devices, but most of these developments essentially laid in the hands of physicists. mathematicians, and engineers.

There is. however. an arguably more vital and far oider information revolution: the one still functioning in our genes, nerves. and brains.[2] Chemical processes start and drive it. even though the complexities are best examined by biologists. Chemists certainly played their role here. This role is set to grow as the semiconductor revolution runs out of space. After all. molecules gladly go to spaces where semiconductors fear to tread. It therefore falls on chemists to explore the information-handling capabilities of molecules. As far as this article is concerned. information processing is what we are after. That is where molecular logic gates come in.

HOW ARE MOLECULAR LOGIC GATES DESIGNED?

Logic gates are the workhorses of modern information technology. because computation relies on arithmetic and logic units. Arithmetic units can be dissected into simpler logic gate arrays.[1] So, the challenge is to pass on these properties and capabilities to molecules. This challenge has been accepted with increasing frequency since 1993. when we demonstrated that molecular fluorescence signals can be switched under the influence of simple chemical species.[3] Chemical inputs and fluorescence/optical outputs (photoionic schemes) circumvent problems of wiring between molecular and macro worlds. The ease of detecting fluorescence output allows for the operation of such devices at the single-molecule limit.[4] Optical inputs are also useful. High and low signal levels are taken as binary 1 and 0, respectively. whether chemical concentrations or light intensities are under discussion. Of course. the same applies when electric voltages are used as input and output signals. A huge amount of effort was expended to miniaturize existing electronic devices, where the semiconductors were replaced by molecules or at least molecular ensembles. Different logic gates produce different output signal patterns as a small set of input signals are applied. So. let us begin at the beginning, however trivial it may seem at first. For one thing, valuable generalizations emerge early on. For another, the field is young. and consolidation of early material is necessary for progress.

SINGLE-INPUT LOGIC GATES

Shown in Fig 1 are the truth tables of all possible output patterns triggered by a single input These four are now discussed in turn. with the emphasis laid on molecular implementation

PASS 0

Pass 0 is an instance where the output remains switched "off." whatever the input situation. In the electronic case.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012827

	PASS 0	YES	NOT	PASS?
IN	OUT	OUT	OUT	OUT
0	0	0	1	1
1	0	1	0	1

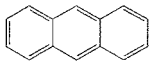
all chis requires is an earthed output unconnected to the input. The same outcome can be arranged by employing common digital electronic components—NOT and AND gates (see below)—as shown in Fig. 1. A molecular implementation with chemical input and fluorescence output would be any molecule without a fluorophore or observation at a wavelength remote from the emission band of a fluorophore. say **1.** If transmittance of light (during an absorption experiment) is employed as output instead of fluorescence. the molecular implementation would require observation at a wavelength near the absorption band maximum of a simple chromophore devoid of receptors. **1** would fit the bill.



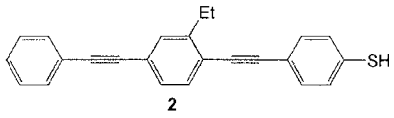
1

PASS 1

Pass 1 would be the opposite extreme. where the output stays switched "on," uncontrolled by the input. Again in the electronic case, a live output unconnected to the input line would achieve this result. Common electronic logic gates—NOT and OR (see below)—can be wired together, as shown in Fig. 1. to give PASS 1 action. A simple fluorophore devoid of receptors would be a molecular implementation. Say that **1** would give a high fluorescence signal if observed within its emission band, while being excited within its absorption band(s), whether or not. say. H^+ was present. If the emphasis is on transmittance rather than fluorescence. the molecular implementation requires observation well away from absorption bands. Better still. one can avoid using a chromophore.

YES

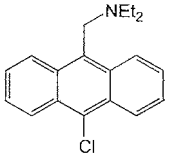
YES requires the output to follow the input. In fact, the electronic case simply corresponds to any point along a wire. Single molecular electronic implementation of a wire[5] was neatly accomplished by planting **2** via its thiol moiety at a grain boundary of a self-assembled monolayer of **3** on a gold surface and then contacting the distal terminus with the tip of a scanning tunnelling microscope.[6] Photoionic implementation can be illustrated by **4**[7] and many other ion sensors (both fluorometric and absorptiometric). We discuss such systems in more depth within a companion article.[8] The choice of **4** is driven by its structural relationship to **1** and by the general utility of its photochemical design. The straightforward observation concerning **4** is that the presence of high levels of H^+ triggers strong fluorescence, whereas there is almost no emission if H^+ concentrations are kept low. All this happens because the fluorophore (9-chloroanthracene. in this case) leads to photoinduced electron transfer (PET) from the amine lone electron pair to the fluorophore. Thus; fluorescence is not an option. The arrival of high enough levels of H^+ blocks the lone electron pair of the amine and lets fluorescence reassert itself. The switching behavior of **4** hinges on the receptor action of the amine toward the H^+ input. Such fluorophore–spacer–receptor systems and relatives often appear in molecular logic implementations, as the following pages will show. A particular feature of these is the switching "on" or "off" of the fluorescence output right across the range of observation wavelengths. Thus, the logic type is robust with respect to variation or fluctuation of observation conditions such as wavelength. Furthermore. fluorescent PET systems are designable with a substantial degree of quantitative predictability.[9]



2

$CH_3(CH_2)_{11}$— SH

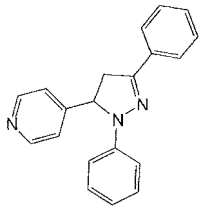
3



4

NOT

NOT logic naturally has the output behaving opposite to the input. Now the electronic case takes on significance, even having its own (and much used) symbol (Fig. 1). Such inversion of a voltage signal received a molecular implementation recently within a single bundle of carbon nanotubes.[10] Avouris' team treats part of this intrinsically p-doped bundle with potassium metal to leave it *n*-doped. This forms the twin hearts of connected. but complementary, field-effect transistors, which produces NOT logic behavior in the same way as currently seen in common semiconductor devices. While this achievement has been quite rightly feted,[11] we must not lose sight of the fact that the full NOT gate occupied an area about 1 μm^2, i.e. about the size of current semiconductor gates. The low-budget photoionic approach is represented by **5**,[12] which is a fluorescent PET fluorophore–spacer–receptor system like 4 but with opposite characteristics. A key difference is that 5 contains a pyridine receptor for H^+ that becomes more reducible when bound, whereas 4 had an amine receptor that becomes less oxidizable upon protonation. So. **5** galvanizes fluorescence-quenching PET from the fluorophore to the pyridine receptor only when H^+ arrives. On the other hand. PET was only seen in 4 when H^+ was absent at the amine receptor.



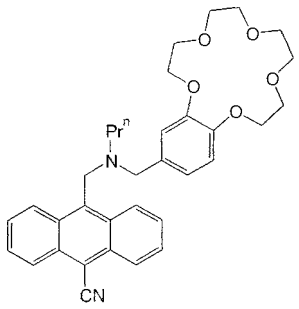
5

DOUBLE INPUT LOGIC GATES

We could work our way systematically through all 16 of the double-input logic gates. except that space restrictions on this article will stop us well short of that objective. Instead. we will consider six types frequently encountered in the computer literature.

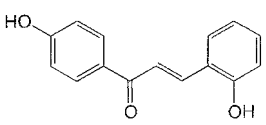
AND

AND is the logic type many people recognize, perhaps because its human analogy embraces those universal values of cooperation and unity. Any one input is powerless to fire the output. But, the output comes alive when both inputs are applied at the same time (Fig. 2). Our 6 is a molecular photoionic implementation and is a fluorophore–$spacer_1$–$receptor_1$–$spacer_2$–receptor: system relying on PET.[3] In fact. each receptor can engage the fluorophore to quench the fluorescence. As in the case of 4, each receptor needs to he blocked by its own target species before the fluorescence can be switched "on." H^+ is the input chosen by the amine group. while Na^+ is selected by the benzo-15-crown-5 ether moiety. Eight and ions can serve as mixed inputs for AND gates. An example by Pina. Balzani, and colleagues is 7, where ultraviolet light allows isomerization of **7** to its *cis*-form.[13] H^+ then cyclizes the latter to a fluorescent product.

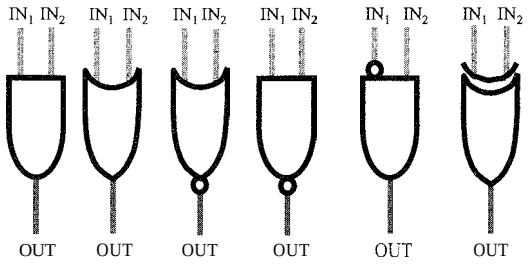


6

All-optical examples of AND logic recentiy became available,[14,15] even though an old claim of this kind in the conference literature seems not to have crossed into the refereed literature.[16] Due to the teams of Wasielewski and Levine. 8 and 9, respectively, achieve their objectives by very different means. Compound 8 shows a tetrachromophore system held together by *m*-substituted benzene rings. The 4-amino-1,8-naphthalimide is initially pumped at 420 nm to cause PET from it to the 1,4:5,8-naphthalenediimide. The other chrornophores become involved only if the naphthalenediimide radical anion is pumped at 480 nm. Now, the extra electron within the napthalenediimide is passed to the 1,8-naphthalimide and then on to the 1,2:4,5-benzenediimide. So. the absorption signature of the benzenediimide radical anion at 720 nm (the output) is only observed if the two femtosecond laser pulses at 420 nm (IN_1) and at 480 nm (IN_2) are applied sequentially (2 ns separation). It is notable. however. that conventional AND gates require simultaneous. and not sequential. application of inputs (a 2 ns delay would matter in devices running near gigaHertz rates). Nevertheless. **8** is a fast gate. because it resets in 25 ns.



Levine noticed that two-photon processes in general could be candidates for two-input AND logic. especially when the output of the process is a detectable fluorescence. This has additional utility. as discussed later. if the

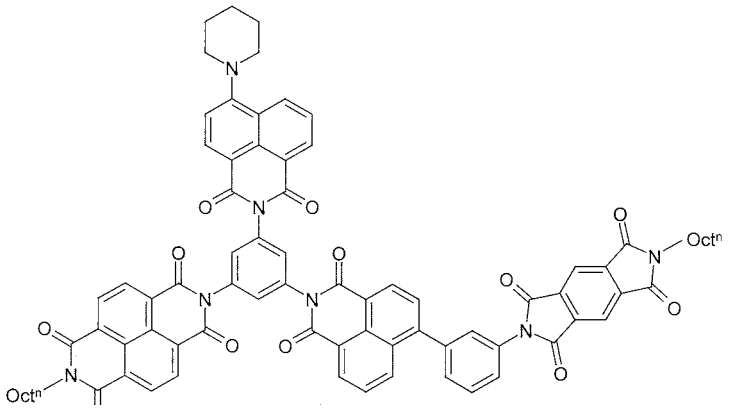


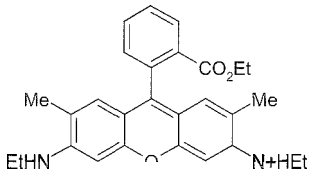
IN_1	IN_2	OUT	OUT	OUT	OUT	OUT	OUT
0	0	0	0	1	1	0	0
0	1	0	1	0	1	0	1
1	0	0	1	0	1	1	1
1	1	1	1	0	0	0	0

Fig. 2 Truth tables and physical electronic representations of six of the 16 double-input logic gates: *AND, OR. NOR. NAND,* INHIBIT. and XOR. (*View this art in color at www.dekker.com.*)

fluorescence is from an upper-level excited state. A fundamental photochemical generalization—the Vavilov–Kasha rule—stands in the way of this requirement, though thankfully it makes a few exceptions.[17] The common laser dye **9** is a suitable example. where a relatively low-intensity laser beam at 532 nm (IN,) would allow one-photon absorption to the lowest excited state. Another laser beam of similar intensity (and color) (IN_2) is then directed onto the sample such that the combined intensity enables two-photon absorption that populates the next higher excited state. This obviously requires judicious choice of the beam intensities. Now. a weak but detectable fluorescence is seen at 430 nm. AND and all 15 other two-input logic gates are recently described by Zhang et al., with bacteriorhodopsin as the active medium; two laser beams (blue and yellow) as inputs, and a chosen transmittance as the output.[18] Another laser beam is required for biasing purposes. The rich photochemical cycle of bacteriorhodopsin is the source of this versatility.

Conventional semiconductor logic gates, such as AND, are produced by wired arrays of simpler switches, such as diodes or (in newer systems) transistors. Molecular electronic implementations can therefore do the same with a good chance for success. Heath, Stoddart, and colleagues use a monolayer of **10** sandwiched between metal and metal oxide layers and outer metallic contacts to produce diode behavior,[19] several of which are known.[20,21]





9

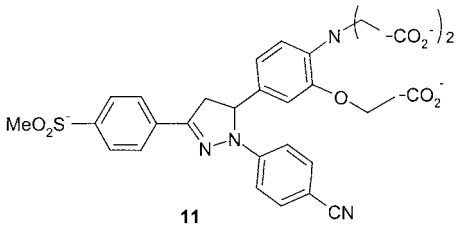
These diodes can now be wired conventionally to give logic behavior. AND logic arises when a power supply leads via a resistor to the output unless diverted through two diodes, each of which would conduct only if the inputs applied to their distal end are zero. If both inputs are high, both diodes cease to conduct, and the output takes on the voltage of the power supply.

OR

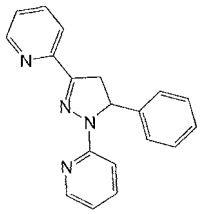
OR logic gates (Fig. 2) also receive a molecular electronic implementation in Ref. [19], with a conventional wiring of diodes. OR logic happens when two diodes lead to the output. Each of the diodes conducts only if the inputs applied to their distal ends are high. If both inputs are zero, the output takes on zero, the value of earth to which it is also connected via a resistor. Our **11** shows the photoionic approach to OR logic. Ca^{2+} and Mg^{2+} inputs are sufficiently unselective to produce essentially identical extents of switching "on." Scheme **11** shows a fluorophore–spacer–receptor PET system, where the aromatic amino acid receptor acts as an electron donor toward the excited diarylpyrazoline fluorophore. resulting in negligible emission. Ca^{2+} or Mg^{2+} binding blocks the electron-rich sites of the receptor and cuts off PET. It is notable that a single-receptor system is sufficient in this case to achieve a two-input logic gate.

NOR

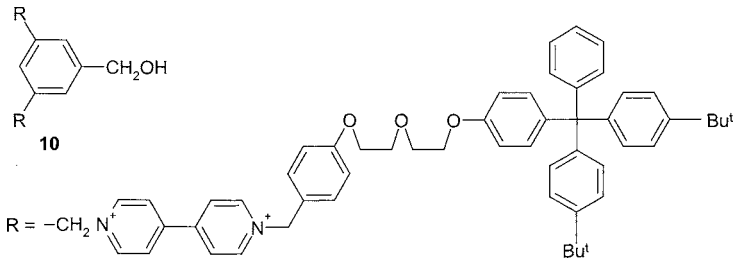
Though NOR logic (Fig. 2) is as legitimate as any of the other 15 double-input logic gates. common computer literature represents it as a particular integration of NOT and OR gater (as its name also suggests). Such physical integration requires additional wiring that throws more obstacles toward molecular implementation. This challenge can be mitigated by remembering that even OR gates (already implemented at the molecular scale) are commonly physical integrations of wires, resistors, and diodes (or transistors), as mentioned in the previous paragraph. Furthermore, a functional integration of NOT and OR logic operations would be sufficient to achieve the same objective. In a fluorescent photoionic context, we can argue as follows. NOT logic represents the switching "off" of fluorescence when an ionic species arrives. Two-input OR logic represents unselective switching "on" of fluorescence when either of two ionic species arrive. So, NOR logic corresponds to the switching "off" of fluorescence when either of two ionic species arrive. Our **12**[22] fits the bill if the two ionic species are H^+ and Hg^{2+}. H^+ kills the fluorescence of this internal charge transfer (ICT) fluorophore, a 1,3-di(2′-pyridyl) pyrazoline, by launching a transfer of electronic excitation into vibrational quanta of N ··H–O bonds. The latter are formed when H_3O^+ docks into the bay region with its three nitrogen lone electron pairs. Hg^{2+} quenches the fluorescence of 12 in a different, but equally efficient, way. Hg^{2+} binds to the 2.2': 6'. 6" - terpyridyl look-alike, and the excited state of the complex takes on a ligand-to-metal charge transfer (LMCT) character verging on a PET process.



11

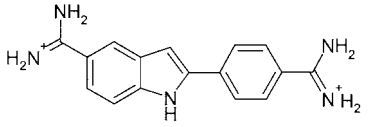


12



NAND

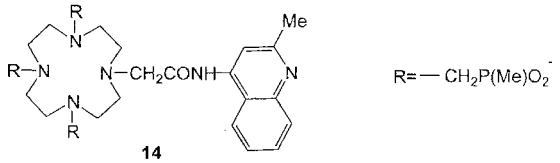
NAND logic (Fig. 2) can be discussed in much the same way as NOR logic was considered in the previous paragraph. While several molecular NAND gates exist,[23–25] we highlight Akkaya and Baytekin's **13**[25] here. because the entire experiment requires no new syntheses. Because 13 is a well-known fluorescent reagent in DNA research, it even binds to a single mononucleotide pair, such as the one involving adenine and thymine bases. In fact, it is likely that **13** stabilizes the Watson–Crick base pair via two amidine–phosphate interactions as well as some degree of aromatic π–π stacking. Nevertheless. the experiment requires substantial dilution of water with dimethylsulfoxide in order to be successful. Then, a significant drop in the intensity of the fluorescence spectrum is seen at 455 nm. No such drop is found if the mononucleotides are applied singly. Several other delights await readers of Ref. [25].



13

INHIBIT

INHIBIT logic is another type that can be viewed as an integration of NOT and AND operations. though in a different connectivity than seen with NAND logic. The NOT operation is only applied to IN_2 (Fig. *2)*. So, IN_2 is really a disabling input that kills the output, irrespective of the state of IN_1. Though three-input INHIBIT logic is known,[22] a two-input case comes from the work of Gunnlaugsson and colleagues that is based on the Tb^{3+} complex of **14**.[26] O_2 is the disabling input IN_2, which quenches the delayed, line-like emission. The role of IN_1 is taken by H^+, which tunes the absorption spectrum into the range of the excitation wavelength. Once excited. strong emission arises only if O_2 is barred.

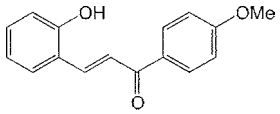


14

R= — $CH_2P(Me)O_2^-$

XOR

XOR logic (Fig. *2)* received a higher than normal amount of attention. because it is an essential part of semiconductor numeracy. Arithmetic units within computers are composed of XOR and AND gates running in parallel. Though an earlier example of a fluorescent molecular XOR gate driven by chemical inputs is available,[27] we put the spotlight on a recent fluorescent case driven by optical inputs.[28] Compound 15 shows a close structural and functional analogue of 7. One novel twist introduced by Pina, Balzani. and colleagues is that $[Co(CN)_6]^{3-}$ costars alongside 15. While **15** rapidly leads to a fluorescent cyclized product under the influence of light and H'. $[Co(CN)_6]^{3-}$ slowly hydrolyzes and ties up H^+ in the form of HCN. So when suitably high photon numbers are absorbed. the fluorescent cyclized product is turned back to 15 in the alkalinized solution. The second novel twist is the design of an experiment with two light flashes such that either flash alone produces a large amount of fluorescent product, whereas the flashes together lead to the alkalinized solution where the amount of the fluorescent product is very low. The latter situation of low fluorescence almost corresponds to the preirradiative condition. i.e., XOR logic applies. Ref. [28] contains more information.

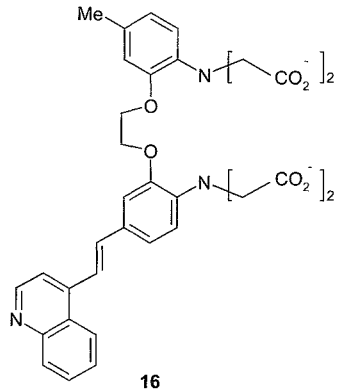


15

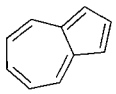
Our photoionic approach to XOR logic uses Ca^{2+} and H^+ inputs applied to **16**,[29] while transinittance is monitored at a wavelength close to the ion-free absorption band maximum. The chromophore within 16 is of the ICT type and has the two ion receptors attached at the opposite ends. The excited-state dipole arising from the cha ge transfer will suffer opposite energetic influences when each ion arrives. The monitored transmittance rises in each case, because the absorption band moves away from the monitoring wavelength. These two ionic influences virtually cancel each other when simultaneously applied. So. the monitored transmittance falls again to the original ion-free level. This XOR gate can be run in parallel with an optically and ionically compatible AND gate to produce a numerate molecular system for the first time outside of our brains.[29] Such a half-adder can "comprehend" the decimal numbers 0, 1, 2 but no higher.

Compound 9. discussed above with respect to AND logic, also contains an XOR logic gate within.[15] Whereas the fluorescence output at 430 nm from the second excited state produced AND logic from two *532* nm inputs, the emission output at 571 nm from the lowest excited state corresponds to XOR logic. The latter is naturally zero when both inputs are absent. Provision of a relatively low-intensity laser beam at *532* nm leads to strong fluorescence at 571 nm. A combination of input beams gives sufficient intensity to kick-start two-photon absorption to populate the second excited state at the expense of the lowest. So. the 571 nm emission is less than might have been expected (on the basis of one-photon

processes, exclusively). Overall, this means that **9** on its own can serve as a half-adder.



16



17

The results from Ref. [15] continue. The 571 nm emission of **9**, or the output from the XOR gate component, can be used to feed a second half-adder **17**, with a lowest excited state that is suitably lower than that of **9**. Electronic energy transfer (EET) is the link. The additional input (IN_3) required to run **17** is a third relatively low-intensity laser beam at 694 nm. As seen with **9**, Compound **17**'s lowest and higher excited state emissions at 746 and 375 nm, respectively, produce XOR and AND logic, respectively. Together, **9** and **17** constitute a full-adder if the outputs of the AND gate parts of **9** and **17** at 430 and 375 nm are put through a final OR gate. The authors suggest that this can be done with a one-photon broadband absorber, though guaranteeing a uniformly high signal in the "on" state may not be easy. Nevertheless, the numerical "comprehension" of this system does not meet a glass ceiling at decimal 2. Amazingly, all this is achieved with two compounds that are available from virtually any chemical supply house.

The numerical operations highlighted in the previous paragraphs underline the fact that several molecular logic systems now available involve the integration of gates as components. Of course, it must not be forgotten that even a two-input AND logic gate of the electronic variety, which can be emulated by a single molecular gate of the photoionic kind, consists of several wires, transistors, and resistors joined in an array. Some of these molecular logic systems involve integration of functions rather than physical components, e.g., **12**. Others involve a degree of physical component integration, as in the case of the parallel operation of **16** and its partner AND gate or in the case of the serial operations of **9** and **17**. Furthermore, **9** and **17** involve functional integrations within. So, molecular logic arrays containing parallel and serial links between components are growing. Dabestani's team[30] as well as Raymo and Giordani[31–33] recently consolidated this growth with some excellent examples.

CONCLUSION

After being in the realm of science fiction for a considerable time, molecular logic gates are now among us for real. Virtually all of the simpler logic types now have molecular implementations. Chemical, optical, and electrical interfaces proved successful for communication across the billion-fold size difference between molecules and ourselves. When we appreciate that these successes arrived in less than a decade, it is clear that the future will be fun.

INTRODUCTION

The evolution of computational chemistry, facilitated by the development of ever more powerful computers in conjunction with more efficient computational methods, has increasingly contributed to a better understanding of structural and thermodynamical features of chemical systems.[1] In this context, computational studies of supramolecular systems became increasingly popular in order to interpret processes of molecular recognition and supramolecular organization.[''']

Typically, supramolecular systems incorporate noncovalent interactions, such as hydrogen bonding, electrostatic. van der Waals, and donor–acceptor interactions — all of which are amenable to simulation. Thus, even though normal characterization by physical methods may lead to supramolecular systems that are chemically well defined, coinputational studies often provide the means with which to obtain additional complementary structural and electronic information about the system. This, in turn, can help rationalize experimental data and lead to predictions concerning the outcomes of future experiments.

Generally, molecular modeling studies provide deeper insights into conformational and recognition properties and enable questions concerning preorganization. complementarity, and binding selectivity to be addressed. In addition to the countless calculations of individual molecules in the gas phase, increasingly. the influence of solvent and environinental effects on the precise structure and dynamics of molecular systems has been considered.

MOLECULAR MODELING — THE MAIN TECHNIQUES

Several computational methods are routinely employed for the study of molecular systems.[1 3–5] However, due to limitations of space, it is not possible here to discuss each of these in detail. Rather, a brief overview is presented of the common techniques employed in computational studies, with some important features of each type highlighted. Reviews covering the use of computational methods, in particular, supramolecular applications, have appeared. These include studies concerned with sulfur-containing host–guest systems,[6] cyclodextrins[7] (in each case using methods that range from molecular mechanics to ab initio quantum mechanics), macrocycles,[8,9] calixarenes[10] and anion-binding receptors[''' (all mainly molecular mechanics), cyclophanes[12] (Monte Carlo methods). and siinulations of the complexation dynamics and phase-transfer behavior of synthetic ionophores[13] (molecular dynamics).

Molecular Mechanics (MM)

Molecular mechanics or force field methods are empirical procedures widely used for studying molecular structure — particularly of medium-sized molecules, although the technique was also employed for larger systems; including supramolecular host–guest design. One important advantage of this method is its high calculation speed.

A force field is a set of energy functions that describes the potential energy surface of the investigated system. It includes functions for bond lengths and angles. torsion angles. out-of-plane coordinates, van der Waals interactions, and electrostatic interactions. Typically, parameterization based on a large amount of experiinental data is required for the development of a reliable force field. Although different force fields frequently involve different potentials. reflecting differences in their calibration procedures, they, nevertheless. usually give rise to similar calculated geometries. Allinger's MM2 and MM3 force fields. AMBER, GHARMM, and MMFF, are examples of widely used force fields, although a number of others also exist.''' It needs to be noted that the calculated energies

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012817

from MM have no direct physical meaning but are useful in a relative sense.

MM calculations involving metal-containing species are usually not as straightforward as those for organic species,[14] especially when transition metals are involved. Special care needs to be exercised when considering the relative energies of such species, as these can be force field dependent.[15–17] Where possible, in such cases, it is prudent to interpret any result in the context of appropriate experimental data for the system.

Quantum Mechanics (QM)

An objective of quantum mechanical methods is to describe the positions of all electrons and nuclei that occur in a molecular system.[1] Using these methods, the calculation of molecular geometries. electron density distributions, and some other molecular properties is possible. with electrons and nuclei treated explicitly. The starting point and basis of quantum mechanics is the Schrodinger equation, which can be solved using the Hartree–Fock formalism. Quantum mechanical methods include ab initio and semiempirical procedures. Ab initio methods range from the simplest Hartree–Fock, self-consistent field inethod to methods that include some treatment of the effects of electron correlation, such as those based on Moller–Plesset perturbation theory, without ignoring or approximating any of the integrals or terms in the Hamiltonian operator.

Semiempirical methods. for example, MNDO. AM1. and PM3. are simplifications of ab initio molecular orbital theory and employ empirically determined parameters; in essence, they only differ in the approximations being made. These methods involve adjustable parameters associated with molecular properties that are calibrated against experimental data. The chief advantage of semiempirical calculations over ab initio calculations is that they are several orders of magnitude faster. Thus, calculations for systems of up to c. 200 atoms are currently possible. whereby with ab initio methods, the limit is a moderately sized molecule (about 50 atoms at the time of writing), if rational results are to be obtained. Frequently, semieinpirical methods have proved to be the computational procedures of choice for studying relatively large molecules.

Density Functional Theory (DFT)

Density functional theory is now an established alternative to conventional ab initio methods. It is well documented that with DFT calculations. geometries, bonding energies. and spectral characteristics of a wide range of molecular systems can accurately be predicted. The advantage of DFT over ab initio calculations is that calculations for systems of up to c. 100 atoms are possible. The DFT approach is based upon a strategy of modeling electron correlation via general functionals of the electron density instead of a wave function. There are now many different functionals. each containing a functional for exchange and a functional for correlation. Currently, the B3LYP hybrid functional is commonly used for inolecular calculations.

Hybrid Methods (QM/MM)

An interesting approach used for the treatment of particular systems has been to employ a combination of MM and QM methods. In such a case. the information about molecular structure and therinodynarnic properties obtained by MM. and on the electronic behavior. bond breaking. and bond formation resulting from QM, can be brought together. Hybrid methods have been employed to investigate chemical processes in large molecular systems and in condensed phases. For example. in such a study. a solute molecule is treated quantum mechanically. while the solvent molecules are approximated by a force field procedure. It is noted that hybrid methods of the present type have the potential advantage of being able to describe the role of the electrons as a natural part of the overall simulation.

Molecular Dynamics (MD)

Molecular dynamics simulations emerged as an important tool for the study of motion in inolecular systems. During a MD simulation. the classical Newtonian equations of motion for interacting atoms are solved interactively. The force on an atom is given by the negative gradient of the potential. which is derived from the same force field employed in MM calculations. The solution of the differential equations gives the position of each atom at each time step over a total time interval limited by the computational speed of the computer. the force field, and the size of the molecular system. Trajectories can be used to investigate time-dependent phenomena, as in conformational transitions, and thermodynamic averages. Further. use of the method gives a high probability that a given conformational search will be complete. Because MD is capable of overcoming the energy barriers between different conformations, it is possible to locate local minima. provided the simulation time and temperature protocol are appropriate.

The application of MD to liquids or solvent–solute systems allows for the computation of properties such as diffusion coefficients or radial distribution functions for use in statistical mechanical treatments.

Monte Carlo (MC) Methods

Monte Carlo simulations are inherently of a statistical nature and provide an alternative to MD. They involve the generation of a sequence of molecular configurations showing a Boltzmann distribution in the potential energies of the selected configurations. The calculation starts with an optimized structure, and new Cartesian coordinates are assigned randomly. The resulting conformation is then minimized using MM, and this procedure is repeated. The minimized conformation obtained is compared with the previously generated one and only saved if it is unique. This method can be employed to treat most molecules. however, for larger, highly flexible species, the conformational space may be too large for convergence to occur. Ab initio MD simulations (Carr Parinello, CPMD), which are based on Newtonian dynamics and where the interaction potential is handled quantum mechanically,[18] tend to be important for the treatment of large systems.

MC simulations (as for MD simulations) are often more difficult than running single-molecule calculations. The input must specify not only the molecular structure but also the temperature, pressure, density, boundary conditions, time steps, and more.

Conformational Analysis

Molecules are not rigid, with the atoms in a molecule moving continuously. The conformational space of a

system can be calculated using QM or MM methods. However, because QM calculations are so time consuming, they are normally not employed for conformational analysis of large and flexible molecules. In such cases, MM, MD, and MC methods or a systematic search of conformational space may be more appropriate tools for undertaking conformational analysis. In the latter case. torsion angles are systematically varied in order to generate all possible configurations. The number of generated structures depends on the chosen step size and the number of rotatable bonds *n* (with the number increasing with the nth power).

COMMERCIAL PACKAGES

Most of the computational techniques so far discussed are available as commercial software packages. which differ in cost, functionality. efficiency, ease of use, and automation. Some widely used computational chemistry software packages and their Internet addresses are listed in Table 1.

COMPARISON OF SELECTED METHODS

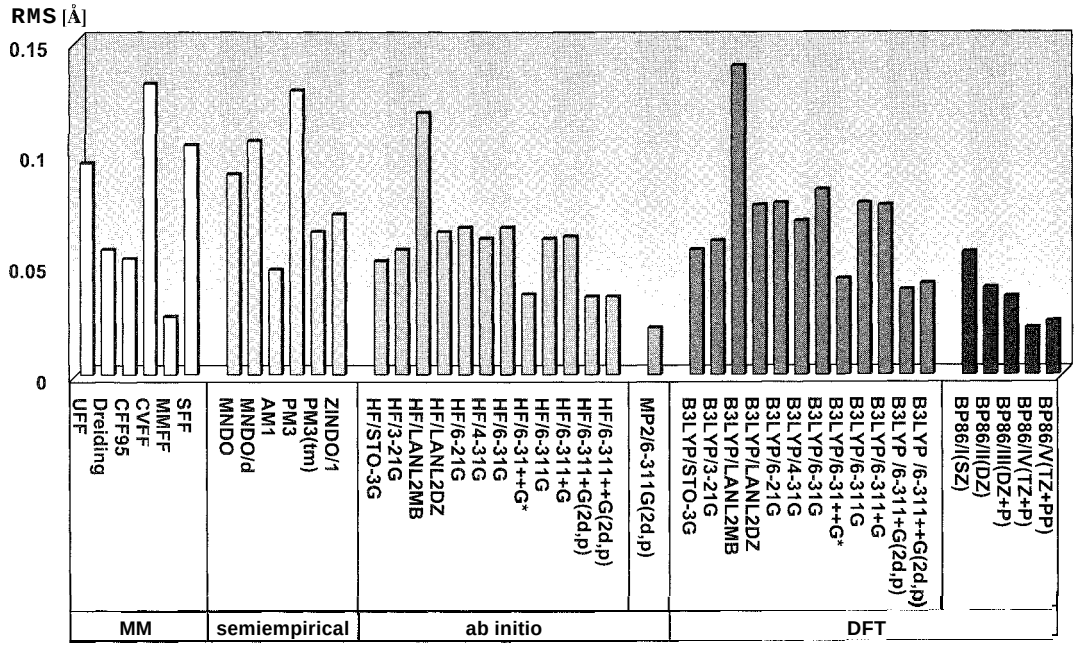
The relative quality of structure calculations by different computational techniques was assessed using the small macrocycle 1,4,7-trithiacyclononane 9S3 (Fig. 1a.b)—a ligand showing a complexation preference for soft transition and post-transition metal ions.[6] Given in Fig. 2 is a compilation of the deviations (represented by the respective RMS values) of the calculated structures from the corresponding crystal structure.[19] It is clearly shown that the force field MMFF, the ab initio method MP2 [basic set 6-311G(2d,p)], and the DFT method BP86 [basic set GGA-IV(TZ+P)] lead to comparable results in this case.

A conformational analysis using the MM or MD techniques allowed the identification of 11 conformers with small energy differences separating them (Fig. lc). For the structure calculation of the corresponding Ag(I) and Hg(II) complexes[iG1] with 9S3. only the DFT method using the BP functional yielded satisfactory results.

FURTHER CONSIDERATIONS

Each of the methods discussed has its strengths and weaknesses (Table 2), and one needs to be careful when selecting the calculation method in order to ensure the validity of the results. Indeed. it seems as important to know the limitations of a method as it is to know its capabiiities. Further, it is also important to be aware of the theoretical basis underlying the procedure as well as the nature and role of the type of paramete ization used.

A common problem in many calculations revolves around obtaining adequate sampling of the possible configurations accessible to a molecular system under investigation. Similarly. there are often difficulties associated with correctly evaluating the potential energies of these configurations. For a given system, there usually needs to be a compromise between the chosen level of



$$RMS\,[\text{Å}] = \sqrt{\sum \frac{(x_a - x_b)^2 + (y_a - y_b)^2 + (z_a - z_b)^2}{N}}$$

N is the number of atoms over which the *Root Mean Square* is measured;
x, y and *z* are the Cartesian coordinates of the calculated and the X-ray structures.

computation employed and the available computer resources. In practice, such a consideration may effectively limit the size of a molecular system that can be investigated by a given technique, if the results are to be meaningful.

While X-ray diffraction studies of supramolecular systems yield solid-state structures directly, they are frequently of additional utility by providing the "starting" structures for computer simulations. In this context, it is noted that the relevance of solid-state structural data to solution behavior is often not straightforward, because the statistical presence of conformers and of various host–guest species (and their associated time-dependent dynamic processes) may then come into play. As already mentioned, these features are amenable for investigation

Table 2 Comparison of methods

Method	*Advantage*	*Disadvantage*
MM	Modeling of giant molecules (proteins, segments of DNA)	Many chemical properties not defined (electronic excited states)
QM—semiempirical	Good for predicting molecular geometry and energetics, predicting vibrational modes and transition structures (but does so less reliably than ab initio methods)	Poor results for van der Waals and dispersion intermolecular forces (lack of diffuse basic functions)
QM—ab initio	Very good qualitive results	Expensive (computer CPU time, memory and disk space)
DFT	Less computationally intensive than ab initio (similar accuracy), optimal accuracy versus CPU time	Some classes of problems not yet explored

by computational means, even though the situation in solution is usually different from that in the gas phase and in the solid state. For example. MD or MC simulations may be employed to provide statistical representations of the solvent shell around a solute. Such studies met with various degrees of success: in many cases, they were successful in providing insight into explicit solvation behavior, as well as in yielding a microscopic view of host–guest complexes and their solvation. However, the inclusion of solvation (either implicitly or explicitly) increases the computational expense, and this, in turn. may limit the level of sophistication of the solvation model that can be employed.

SOME CASE STUDIES

Examples of molecular modeling studies that exemplify the use of individual calculation types will now be discussed in order to further illustrate the manifold applications of such calculations.

An MD Study

Although variable temperature line-broadening NMR investigations are frequently employed to obtain conformational and dynamic information for supramolecular systems, for a number of reasons. such measurements are not always possible. As an alternative, dynamic processes of this type can sometimes be investigated using computational techniques. An example is given by an investigation of the maleonitrile-dithiacrown ether **mn-S_2O_{n+1}** (n=1–4) (Fig. 3) ligands and their interaction with Pt(II).[20] Simulations using molecular dynamics of processes involving the **mn-S_2O_{n+1}** (n=1–3) ligands and their Pt(II) complexes were performed at different temperatures. and these investigations were also coupled to search calculations. Different ground-state conformations for the ligands and their Pt(II) complexes were obtained, where the exodentate orientation of the *S* atoms proved to be preferred. Sulfur inversion was observed at *500* K for [**$PtCl_2$(mn-$15S_2O_3$)**] and at 373 K for [**$PtCl_2$(mn-$18S_2O_4$)**]. The localization of the transition state proved difficult, because simultaneous changes of more than one dihedral angle were involved in the search. The semiempirical (PM3) energy barriers were found to be about *5* kcal/mol (21 kJ/mol). These calculated low barriers are in accordance with the high flexibility of the ring systems and with the experimental results.

An MC Simulation Study

In order to obtain insight into the conformational influences affecting the stronger Ca^{2+} selectivity of *p-t*-butylcalix[4]arene-ethyleneoxydiphenylphosphine oxide **1** relative to *p-t*-butylcalix[4]arene-methyleneoxydiphenylphosphine oxide 2 (Fig. 3), MC conformational searches in conjunction with Merck Molecular Force Field calculations were performed.[21] From these studies, it appears that the selectivity of **1** toward Ca^{2+} lies in the adoption of a unique eight-fold coordinate complex that involves close interaction of all four phenoxy and four phosphine oxide oxygen atoms with the Ca^{2+} ion. In contrast, for 2, the closeness of the phenoxy oxygen atoms and the phosphine oxide oxygen atoms appears to allow a number of metal ions to form stable eight-coordinate complexes.

Computational Studies of Host–Guest Complexation in Solution

The behavior of a hexaprotonated aminocryptand **3** (Fig. 3) toward 1:1 halide inclusion in aqueous solution was investigated using MD simulations. Structural aspects,

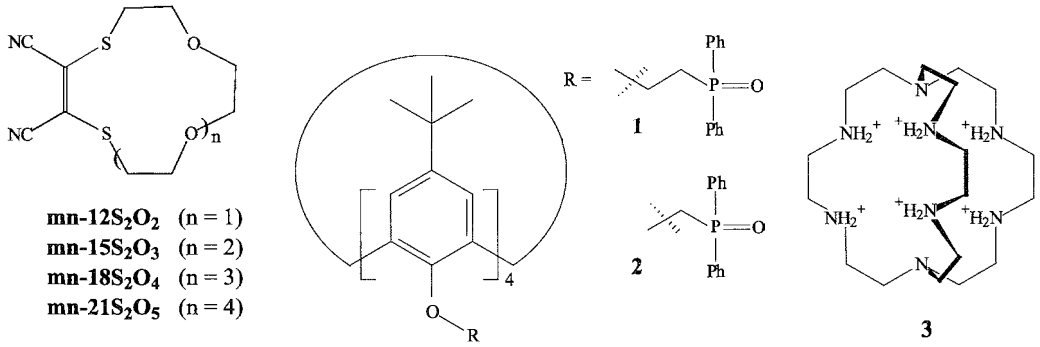

Fig. *3* The host compounds discussed in the text.

hydration properties, and status of external halide counterions were probed in order to gain microscopic insight into the host–guest complexes and their environments.[22] This represented the first reported study of spontaneous ion binding by a polycyclic ligand.

The nature of the 1:1 inclusion complexes of **3** with the fluoride or chloride ion in water were described and compared with the X-ray structure of the relevant compound. Furthermore, simulations involving the uncomplexed ligand and both anions led to the experimentally observed F^- over Cl^- binding selectivity. which was reproduced quantitatively by free-energy perturbation (FEP) calculations.[23] The latter provide a thermodynamic measure of the relative interaction and binding free energies in solution, these are, of course. of particular interest in supramolecular chemistry, where molecular association is of paramount importance.

FUTURE PROSPECTS

Molecular modeling is an essential tool in supramolecular chemistry. A significant number of computational studies of macrocyclic compounds continue to be directed toward understanding molecular structural features in the gas and liquid phases. These include the geometry. charge distribution, lipophilicity pattern. energetics of host–guest binding, as well as an assessment of the structure and dynamics of individual host–guest complexes. Such data are often useful for explaining observed molecular recognition behavior. for predicting the structure of a flexible receptor in solution, for assessing the binding and extraction properties of a given ionophore, as well as for understanding the self-assembling properties of monomer units. The computational tools used are typically both quantum mechanical and force field based.

With the further development of hardware and improvements in theory and algorithms, molecular modeling will undoubtedly be employed increasingly as a useful tool for solving problems in supramolecular chemistry in a rapid and effective way. Clearly. it will increasingly aid in the interpretation of experimental results as well as allow for the prediction of an extended range of supramolecular properties and behavior.

What is the prognosis for the future of computational chemistry? Computing hardware is nowadays stellar. Even commonplace computers are capable of handling calculations of systems containing thousands of particles and simulation times in the range of nanoseconds on a single processor. As the power of modern computers continues to grow. it is only a matter of time before computational techniques are used more routinely for problems of interest to supramolecular chemists. Calculations that are more accurate and able to handle a wider range of compounds will be possible.

Molecular Squares, Boxes, and Cubes

Peter H. Dinolfo
Shih-Sheng Sun
Joseph T. Hupp
Northwestern University, Evanston, Illinois, U.S.A.

INTRODUCTION

Molecular squares, boxes, and cubes featuring transition-metal corners are the focus of tremendous activity in contemporary synthetic coordination chemistry. Their design and study comprise a promising subfield of inorganic and organometallic supramolecular chemistry. The interest in these objects is partly aesthetic: they are beautiful high-symmetry assemblies. The interest is also functional: the assemblies contain cavities that are capable, in principle, of encapsulating, and then sensing, processing, or transporting useful molecules or atomic ions—in other words, all the functions associated with organic host–guest chemistry.

Why coordination chemistry? And why discrete molecules? Actually. metal-free squares and boxes exist, albeit, without the ubiquity of the metal-containing systems. Notable examples include the various viologen-derived cyclophanes or boxes of Stoddart and coworkers,[1]—clear antecedents of many molecular squares. What metal ions offer are a readily accessible range of angles for ligand-metal-ligand subunits (including right angles, which is difficult to achieve with carbon chemistry), structural predictability based on well-known metal-ion coordination motifs (linear. octahedral. square planar, etc.), a range of charges, a range of ligand-binding capacities, and, perhaps most importantly, a propensity to engage in highly efficient directed assembly. Metals, of course, can also usefully expand the range of redox, photophysical, and catalytic properties displayed by supramolecular assemblies. In principle, squares and other structures can be assembled not only as discrete molecules, but also as porous two- and three-dimensional arrays or coordination polymers. While the array strategy clearly works[2], a common complication is the formation of interpenetrating grids that eliminate most of the void volume associated with isolated cavities. Preassembly of discrete squares and related structures avoids the problem; indeed, to date there are no examples of extended catenation. the molecular equivalent of grid interpenetration.

An important idea suggested by the chemistry of coordination polymers is higher-order assembly of squares and other structures into large void-volume, high-porosity molecular materials. This can be done surprisingly easily using van der Waals interactions (which, of course, are large for large molecules), although more elaborate and controllable strategies are emerging. In any case, the notion of porous molecular materials and the stacking of cavities to make uniformly sized channels is one that is receiving increasing attention as supramolecular coordination chemistry evolves from a mainly synthetic effort toward one that also strongly focuses on function.

Finally, the connection to nanotechnology cannot be overlooked. The cavity sizes of existing molecular squares, boxes, and cubes extend from about 0.4–5 nm, as measured along the cavity edges. These, of course, are the right dimensions to couple to other nanoscale objects or simply to function as building blocks for periodically nanostructured thin films or other materials. In these contexts, descriptions of functional suparamolecular assemblies as nanoreactors, nanofactories, nanogates, nanotemplates, and so on, are appropriate.

MOLECULAR SQUARES

Some Early Examples

The first metal-containing molecular squares appeared in 1983.[3] They featured $M(CO)_4$ (M=Cr, W, or Mo) corners and $P(OCH_2)_3P$ ligand edges, **1** (Fig. 1). While these compounds are potentially capable of behaving as hosts for small molecular guests, interest in squares as receptors or hosts really did not take hold until 1990 when an ethylenediamine Pd(II) square featuring 4,4′-bipyridyl edges, **2**, was shown to function as a hydrophobic host for organic guests in water as solvent.[4,5] Aqueous solubility was engendered by the square's 8+ charge and by the use of nitrate as a counterion. Nuclear magnetic resonance (NMR) titrations revealed association constants on the order of 10^2 for planar, electron-rich aromatic species. while aliphatic compounds showed little propensity to associate. The difference was attributed to the ability of the electron-rich, aromatic guests to form charge-transfer complexes with the bridging bipyridine ligands of the molecular square. Extension of the chemistry to Pt(II) was

DOI: 10.1081/E-ESMC 120012772

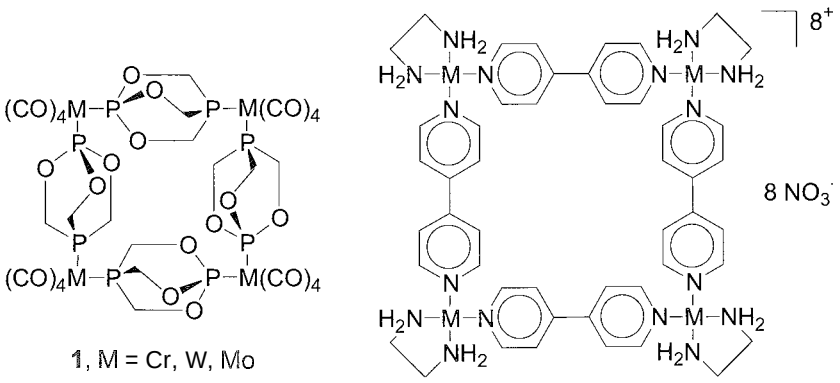

Fig. 1 Two of the earliest examples of tetrametallic molecular squares

followed by the observation that for longer edges. closely related square and triangle structures can coexist in dynamic equilibrium. The equilibrium is concentration-dependent, with entropy favoring triangles, because they assemble from fewer components.[6] A related transformation, observed with a Pd(II) square and a pair of dimeric Pd(II) loops in D_2O as solvent. is formation of two copies of a nonsquare catenated assembly.[7] The driving force for catenation is primarily the enhancement of dispersion interactions accompanying van der Waals contact of pairs of ligands.[8] Formation of the catenated species should occur most readily in solvents that offer comparatively little stabilization via dispersion interactions.

Another early approach, since generalized to more than 70 different squares, triangles, prisms, rectangles, and dodecahedra, also relies upon Pd(II) and Pt(II) as corners but with chelating diphosphine ligands in place of ethylenediamine to provide solubility and enforce subsequent ***cis*** coordination.[9] The combination of corner units with difunctional imine edges leads to octa-cationic squares. The variety of ligand edges used ranges from porphyrins, luminescent perylene diimides,[10] and redox-active ferrocene derivatives,[9] to chiral linkers, such as phosphine-functionalized binaphthols.[9] With chiral squares, one could easily envision applications such as enantioselective catalysis, separation, or sensing. Indeed, several examples of moderately enantioselective sensing with a chiral-ligand-containing square were reported."[1] Elaboration of squares via functionalization of the phosphine ligands is also possible. In one instance. squares featuring pendent crown ethers were prepared.[9]

What about neutral squares? By using acetylides or phenylides as edges. and forming metal(II)-carbon linkages, squares lacking net charges can be formed.[12] Other routes to neutral squares are described below.

Assembly Principles

Why has the square motif proven so popular in supramolecular coordination chemistry? First. with the right set of ancillary ligands. octahedral and square planar coordination geometries provide pairs of ligation sites oriented at 90° with respect to each other. Second, square formation is typically accomplished with high efficiency, usually in a one-pot reaction. The one-pot forination process is often termed ''self assembly,'' although a more accurate term might be "directed assembly." which is the combination of ***cis*** coordination sites and edge-ligand rigidity. providing the necessary initial directions or instructions.

There is more to the process. however. In nearly every case. the square represents a thermodynamic rather than kinetic product. The reasons are several. The open ligation sites that characterize dimeric. trimeric, and noncyclic oligomeric species are temporarily filled by weakly coordinated solvent molecules; this, in turn. tends to keep these intermediates in solution. In addition. coordinate–covalent bonds tend to be labile, at least at elevated temperatures. Mistakes in the assembly process can be corrected, and assembly can continue until formation of the desired square molecule is complete (Fig. 2).[13] If the completed tetrametallic cycles are less soluble than open oligomers (often the case), precipitation of the cycles can pull the reaction toward completion. Also favoring reaction completion (i.e., high yields) is the enthalpy released upon replacement of a weak metal–solvent bond with a somewhat stronger metal–ligand (edge) bond. For several reasons, therefore, the choice of solvent is important in square synthesis.

Ignoring occasional complications due to triangle formation, the directed assembly approach works well with rigid difunctional ligands. What about flexible

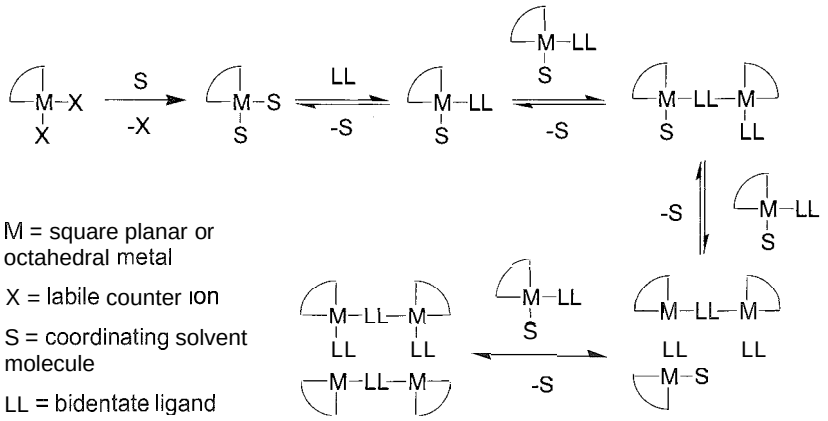

Fig. *2* Proposed mechanism of molecular square formation

ligands? If the ligands are long. the standard assembly approach tends to yield cyclic dimers instead of squares. consistent with simple entropy considerations. While no examples were reported, presumably, in some cases, templating methods could be used to generate flexible-walled squares.

Other Structural Motifs

Squares can also be obtained by linearly coordinating bent (right-angle-containing) difunctional ligands. A metal ion then occupies the center of each edge, and the bent ligands comprise the corners. One example is trans coordination of Pt(II) by 5,10-pyridyl-porphyrins, **3** (Fig. 3).[14] Notably, construction of the square in this way configures the four porphyrin ligands in a coplanar fashion. The alternative assembly featuring linear ligand edges (5,15-pyridyl porphyrin species) and cis-coordinated metal ions as corners configures alternating pairs of porphyrins in a nominally cofacial arrangement. **4**.[9] The two motifs obviously suggest different applications and different ways of assembling multisquare structures.

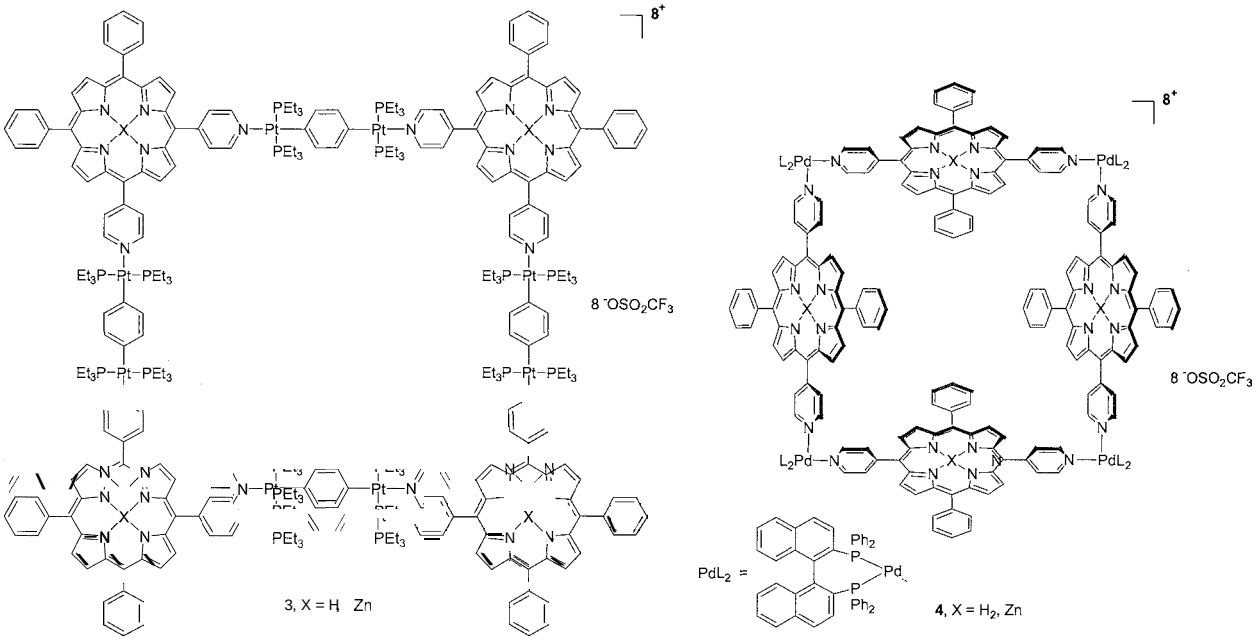

Fig. 3 Two examples of porphyrinic molecular squares. In 3. the cis orientation of pyridyl groups, combined with the *trans* binding of the Pt metal units, leads to a coplanar orientation for the four porphyrins. The *trans* configuration of dipyridyl porphyrins in 4 leads to a nominally cofacial arrangement of opposing pairs of porphyrins. For the particular example shown, however, steric demands force the porphyrins to fold in to yield an almost flat structure.

Another alternative square motif is based on carboxylate coordination of triply and quadruply bonded dimetallic corner units.[15] The coordination geometry requires the metal–metal bond axis to be oriented normal to the plane of the square or, in some cases, triangle. An interesting consequence is that monodentate ligand coordination sites at the ends of the dimetallic units can often be accessed, permitting squares to be linked ''vertically'' in extended structures. Examples of squares based on Mo_2^{4+}, Ir_2^{4+}, and Rh_2^{4+} were reported. In solution, several show multistep metal redox reactivity that is reversible on an electrochemical time scale. Unfortunately, on a longer time scale. the ease of oxidation together with further chemical reactions renders some of the squares structurally unstable in air or in oxygen-containing solutions.

A third alternative simply uses ferrocenes as walls in cyclophane-like structures.[16] The ferrocenyl units typically are linked via flexible hydrocarbon chains appended to cyclopentadiene ligands. In other words, covalent carbon–carbon bonds rather than coordinate–covalent metal–nitrogen, –carbon, –oxygen, or –phosphorous bonds are used.

Porous Molecular Solids

Remarkably, almost all molecular squares crystallize as one-dimensional channel-containing materials, with square cavities defining the channel width. For smaller squares, microcrystallinity typically persists when the squares are cast as thin films. For larger squares, such as porphyrin squares, thin films are more typically amorphous. Films of both kinds, however, can display good microporosity. Obviously, facilitating porosity for neutral squares is the absence of potentially channel-blocking counterions. Many charged squares, however, also feature open channels with counterions positioned above and below metal corners rather than within cavities. (An interesting idea yet to be examined is that the cavity fields generated by the spatially separated charges may engender catalytic activity in a fashion reminiscent of many reactions in zeolites.)

An important characteristic of molecular materials based on squares is their ability to withstand solvent removal without cavity collapse or loss of porosity. The stability reflects the strength of coordinate–covalent bonds. These bonds are often four to 10 times stronger than typical hydrogen bonds.

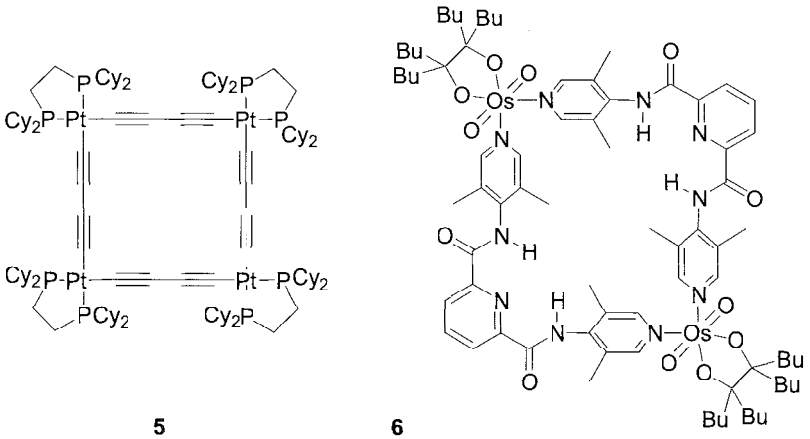
Explored in most detail with respect to porosity were molecular materials based on neutral tetrarhenium squares {$[Re(CO)_3Cl(\mu\text{-diimine})]_4$ species) as described further below. One step beyond strictly molecular materials are ones composed of covalently or coordinatively linked square units. Interesting examples here are the dimetallic-cornered squares mentioned above, although their behavior as porous materials has yet to be explored. Another approach involves liquid–liquid interface polymerization. Acid-chloride functionalized linkers (short alkane chains) in one phase react with hydroxyl-functionalized porphyrin squares in another phase to generate high-porosity thin-film polymers.[17] Film growth is self-limiting (a few microns), and the density of pinhole defects that fully penetrate the films is low. A third approach uses phosphonate-functionalized porphyrin squares and makes use of the enormous affinity of Zr(IV) for phosphonates. Layer-by-layer porous film assembly can be done on glass, conductive glass, or ceramic platforms. The approach provides exceptional control over film thickness and yields films with channels strongly preferentially oriented in the direction normal to the platform.[18]

Functional Squares

Thin films of tetrarhenium squares {$[Re(CO)_3Cl(\mu\text{-diimine})]_4$ species} can function as molecular sieves, in the form of coatings on macroporous membrane supports or as overlayers on electrode surfaces. Sieving can be followed by spectrally observing the passage of dye molecules, via the coated membrane, from a reservoir solution to a receiving solution or by monitoring the electrochemical cunent produced by passage of a redox-active probe molecule through a porous square coating.[19] Sharp size cutoffs for probe molecules are observed, with the cutoffs corresponding to the sizes of cavities for isolated squares. Quantitative studies with films as thin as 20 nm show that molecular flux scales inversely with film thickness. demonstrating that rates of transport in these cases are limited by film-based diffusion rather than solution-to-film partitioning. For small- and medium-sized squares, known to form microcrystalline films, the observed molecular transport rates exceed by 20- to 50-fold rates of transport through related amorphous metallopolymers featuring similar size cutoffs. These observations point to the importance of the one-dimensional channels created by alignment of squares and their cavities. Films of larger squares featuring metalloporphyrin walls are amenable to cavity functionalization via axial ligation of porphyrin-embedded metal ions. Extensions of this kind readily permit size cutoffs for film sieving to be rationally altered. In principle, chemical selectivity could also be engendered in this way.

Facilitated transport of sodium tosylate across a chloroform solution separating two aqueous phases was demonstrated. The carrier was a Pt(II)-bipyridine square featuring calixarene receptors as corner appendages.[9]

Advantage was taken of the luminescence of small- and medium-sized rhenium squares to accomplish chemical sensing: anions in solution[20] and volatile aromatic



5 6

Fig. 4 Two examples of molecular squares designed for enhanced host–guest binding interactions. Structure 5 is able to bind Ag^+ ions between adjacent alkyne ligands via a n–tweezer effect. The corner receptor groups in 6 allow for enhanced binding of various amides through hydrogen-bonding contacts.

compounds in the vapor phase.[21] Quartz crystal microgravimetry and modulated visible-light diffraction schemes were also used to report on selective uptake of analytes by porous molecular square films.[22] By expanding the number of potential host sites available, porous thin films of squares offer sensitivity advantages over simple monolayers of host compounds. Nevertheless, squares are usually of limited effectiveness in sensing schemes. Few, if any, candidate guest molecules (analytes) are square shaped, ruling out efficient sensing based on shape complementarity, and simple squares lack the requisite functionalities to bind analytes in a highly cheinically selective fashion. (The examples described above depend on comparatively weak and nonspecific electrostatic, donor/acceptor, and dispersion interactions.)

Interesting exceptions are Pt-acetylide-based squares such as 5, that bind Ag^+ strongly based on specific interactions with pairs of ethynyl groups (Fig. 4).[9,23] Another involves a square featuring OsO_4 units as two diagonal comers and pyridine-2,6-dicarboxamides as the other corners (6). This assembly selectively binds appropriately sized amides via multiple hydrogen-bonding interactions.[24]

A potentially more general solution is to decorate the interiors of large molecular squares with receptor ligands, for example. by anchoring them to metal ions embedded in porphyrins (Fig. 5). More than 100 cavity-modified squares were described. Nevertheless, only a handful were exploited for selective chemical sensing (e.g., iodine sensing with tethered thiols, alkali metal ion sensing with cavity-confined crown ethers, and zinc ion sensing with a cavity-confined polyamine ligand).[25]

Encapsulation of metalloporphprin-based epoxidation catalysts by a porphyrin square was described.[26] By largely preventing the catalysts from destructively encountering other catalyst molecules, the square substantially extends catalyst lifetimes. At the same time, it creates a spatially restricted reaction environment that translates into substrate size selectivity in the epoxidation reaction. In one case, a dipyridylporphyrin catalyst was encapsulated within a Zn(II)-containing square. leaving two of the four porphyrinic zinc sites available for further ligation. By binding sterically demanding ligands to these sites, the substrate size selectivity was shown to be tunable. The degree of selectivity engendered in this way, however, is limited, because the putative cavity-modifying ligands are apparently sometimes bound to the square exterior.

MOLECULAR BOXES AND CUBES

In contrast to the vast assortment of molecular squares now in existence, relatively few examples of molecular boxes or cubes were synthesized, unless one views squares having tall edges (for example, porphyrinic squares) as open-ended flexible boxes. As defined here; molecular boxes are right-angle-containing complexes, where the metal coordination units are arranged in three dimensions. instead of two.

A ruthenium-based molecular cube was described.[27] Comprising its corners are $\{([9]aneS_3)Ru\}^{2+}$ ([9]aneS$_3$ = 1,4,7-trithionane) units, Iinked by 4,4′-bipyridine edges. The assembly was obtained by reaction of stoichometric amounts of $\{([9]aneS_3)Ru\}^{2+}$ and 4.4'-bpy (8:12) in a noncoordinating solvent for 4 weeks. Key to the cube synthesis is the sulfurcontaining macrocycle. By occupying three coordination sites in a facial fashion, it

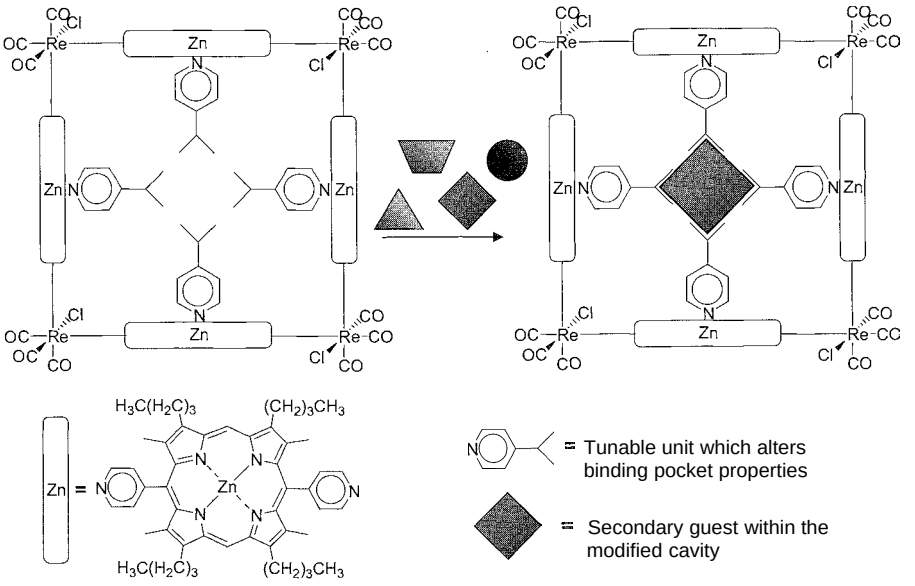


Fig. 5 Porphyrin square functionalization for selective guest binding. (*View* this *art* in color *at www.dekker.com.*)

leaves open three additional sites (also facially arranged) for ligation of the cube's rigid edges. A crystal structure of a cube fragment. $\{([9]aneS_3)(4,4'\text{-bpy})_3Ru\}^{2+}$, clearly illustrates the anticipated mutually perpendicular arrangement of the three *bpy* ligands. Although an x-ray crystal structure of the cube was not reported. ^{1}H-NMR of the sample reveals two sets of 4,4′-bpy resonances. consistent with the formation of the highly symmetrical product.

Two types of molecular boxes featuring (ethylenediamine)Pd(II) corners and polypyridyl linkers were described.[28,29] One uses roughly rectangular tetrapyridyl ligands as walls for an open-ended cube. (7) Multiple isomers were obtained. and one is shown in Fig. 6. By carrying out the synthesis in the presence of an appropriate guest molecule, the isomer distribution can be

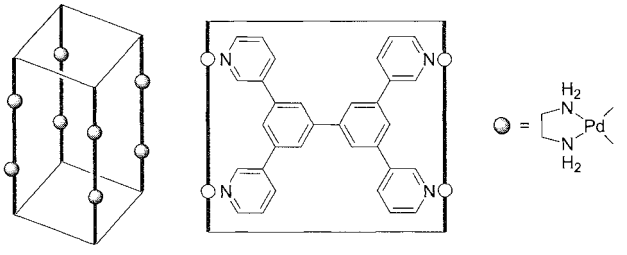

Fig. 6 One of three isomeric boxes that can be obtained from the combination of 3.3′,5,5′-tetrakis(3-pyridyl)biphenyl and (en)Pd$(NO_2)_2$

controlled; as can an equilibrium between competing prisin and cube assemblies. The second type comprises a family of elongated boxes. The wails here consist of 3,5-linked terpyridine, tetrapyridine. and pentapyridine ligands with 6, 8, or 10 (en)Pd(II) units serving as connectors along the box seams. Remarkably. box formation is efficiently templated by rod-like guest molecules. In the absence of templates. either no supramolecular complex formation is seen, or a range of complexes (trimers, tetramers. and pentamers) are present. presumably in dynamic equilibrium. These observations clearly point toward the idea of employing dynamic combinatorial libraries to generate optimal supramolecular inorganic hosts for specific molecular guests. In addition to x-ray crystallography and solution-phase NMR spectroscopy. cold-spray ionization mass spectroscopy was shown to be useful for identifying reaction products. including thermodynamically unstable products in these initial synthesis studies.

A series of mixed-metal molecular cubes, based on the coordination chemistry of Prussian blue and other polymeric cyanometalates, was described. The cubes feature Rh and either Co or Mo on alternating corners, with edges consisting of bridging CN groups.[30] The cubes are formed by the binary combination of molecular squares, subsequent to removal of axially bound chloride ligands. The intermediate molecular squares species are formed by the reaction of $[Cp^*M(CN)_3]^-$ (*Cp** = pentamethyl cyclopentadienyl, *M* = Rh, Co) with either $\{[(R)MCl_2]_2\}$ (*R* = Cp*, $C_{10}H_{14}$; *M* = Rh, Ru) or $(\eta^6\text{–}C_6H_3Me_3)Mo(CO)_3$. The *Cp** ligands serve to block three of the six octahedral

sites, thereby precluding polymer formation. Recently, however, the controlled formation of a double cube (one shared corner) was described.[31]

An interesting property of cyanide-bridged molecular cubes is their ability to bind alkali metals (especially K^+ and Cs^+) selectively within the cube interior.[30] Crystallographic analysis of a Rh–Mo molecular cube indicates bond formation between the cationic guest and the cube's CN edges. When K^+ is encapsulated, the ion is distributed over two equivalent positions, both slightly displaced from the cube center. Encapsulated cesium ions, on the other hand, occupy a central position. The locational differences reflect differences in ionic radii: 2.02 and 1.78 Å for Cs^+ and K^+, respectively, with coordination numbers of 12 for each. The structural differences translate into a nearly 4000-fold preference for uptake of Cs^+ versus K^+ from salt solutions, where the difference was evaluated competitively via ^{133}Cs-NMR measurements.

CONCLUSION

Inorganic supramolecular chemistry yielded an enormous number of discrete assemblies having square or box-like structures and ranging in size from several angstroms to several nanometers. Many of these compounds feature accessible, well-defined voids, rendering them useful, or at least viable, for several applications, including ones involving host–guest chemistry, mesoporous materials, or catalysis. Substantial possibilities for expansion upon applications in selective chemical catalysis, in particular, appear to exist. Applications yet to be fully realized include transport functions in which assemblies serve as artificial pores for natural or biomimetic membranes, as electron or energy transfer for solar energy conversion, and service as components of molecular electronic devices. Also yet to be exploited is the use of channels for templated growth of polymeric or other materials. If the square or cube templates were retained after polymer growth: new classes of nanocomposites, potentially having exceptional or even unique materials properties, might be obtained. Obviously, further advances in molecular and higher-order assembly chemistry will facilitate these developments and likely stimulate others.

Molecular Switches

Ruud G. E. Coumans
Alan E. Rowan
University of Nijmegen, Nijmegen, The Netherlands

INTRODUCTION

In nature. control and regulation of enzymes in biological pathways are of fundamental importance.[1] The switching "on" and "off" of processes is principally carried out by the binding of ions or molecules, which. in turn. influences the conformation of the enzyme and its activity and materials properties. These types of enzymes can therefore be viewed as nanosized switches, e.g., their activities can be turned on or off under the influence of external chemical or physical stimuli. These so-called "allosteric" interactions[2] play a key role in life and inspired many chemists to mimic these systems using simpler building blocks.'" The innovative designs and creative thinking of numerous scientists led to artificial molecular switches that do not serve only a role as biomimetic models but are of interest in their own right and. in some cases: are on the verge of being used in device applications.[4] Moreover. with the arrival of nanotechnology, there is even more interest in the design, synthesis, and characterization of artificial molecular machine~.[~This interest can contribute greatly to the bottom-up approach in nanoscience. Molecular switches comprise an interesting class of artificial molecular machines and can be defined as molecules that can be switched between two or more different states. In this article, several examples of such switches will be presented; ranging from relatively simple molecular switches to more complex (macromolecular) switches based on DNA. It is impossible to give a thorough overview of all the molecular switches described in the literature. Consequently, we chose to highlight only a few exciting examples.

A SIMPLE PHOTOREDOX MOLECULAR SWITCH

A simple but illustrative example of a molecular switch is shown in Fig. 1a and was developed by Lehn and coworkers.[6] It consists of a quinone/hydroquinone moiety covalently attached to a luminescent Ru$(bpy)^{2+}$ core (bpy = 2,2′-bipyridine).

The luminescence of the excited metal complex **1** is quenched by the lower-energy quinone moiety. Once the quinone is electrochemically reduced to hydroquinone, the luminescence is restored. because the hydroquinone is unable to quench the luminescence of the excited metal complex. In turn, the hydroquinone can be switched back by oxidation to the quinone, and quenching of the luminescence is restored. The electrochemical interconversion of both species was shown to be fully reversible, and both the oxidized and reduced forms are isolable and stable. In the simplest form, this system can be regarded as a bistable (on/off) electrophotoswitch.

SWITCHES BASED ON PHOTOCHEMICAL *CIS–TRANS* ISOMERIZATION

An important example of a molecular switch in nature is the *cis–tmns* isomerization of retinal in the retina.'" This isomerization is the primary event in the process of vision, in which, through a cascade of enzymatic reactions, the light signal is eventually converted to generate a nerve signal. A considerable part of the molecular switches described in the literature rely on the photoinduced *cis–trans* isomerization of olefinic bonds and azobenzenes. One example of the use of azobenzenes as switches is in the switching of the alignment mode of a nematic liquid-crystalline (LC) phase.[7] The switching is achieved by attaching functionalized azobenzenes to quartz surfaces. These surfaces were then used to construct nematic LC cells. Irradiation of the azobenzenes with visible light results in a *trans* configuration of the azobenzenes and an alignment of the LC molecules perpendicular to the surface. Irradiation with UV light results in *trans–cis* isomerization of the azobenzenes, and concomittantly, the LC molecules are aligned parallel to the surface. An elegant example of a molecular system based on *cis–trans* isomerization was reported by Inoue and coworkers, who used the photochemical *cis–tmns*

isomerization to switch a catalyst on and off (Fig. 1b) and chemically fixate CO_2.[8] It is known that under the influence of methoxyaluminum tetraphenylporphyrin 2, carbon dioxide and an epoxide can be coupled and converted to a five-membered cyclic carbonate. However, coordination of a nitrogen-containing base to the aluminum center is necessary to achieve high catalytic activity. By using 3′,5′-di-*tert*-butyl-2-stilbazole as the base in this system. the catalyst could be switched on and off by irradiation at an appropriate wavelength. Upon irradiation with UV light, the stilbazole exists predominantly in its ***cis*** form; and the catalyst exhibits high activity. By irradiation of the system with visible light, the stilbazole moiety isomerizes to its *trans* form, blocking the coordination of the nitrogen to the metal center due to unfavorable steric interaction between the tert-butyl groups and the porphyrin, and the catalyst loses its activity and is in its off slate.

MOLECULAR SWITCHES BASED ON DIARYLETHENES

Diarylethenes emerged recently as versatile building blocks for several types of molecular switches. The switching mechanism of these compounds is based on a photocyclization with UV light of the colorless, open form **3,** resulting in a colored, conjugated species 4. This

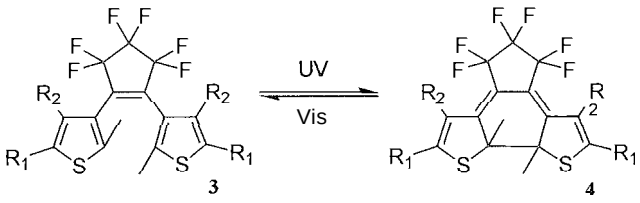

Fig. 2 Switching of diarylethenes with light

process can be reversed by a visible-light-induced cycloreversion (Fig. 2). The diarylethenes based on the perfluoro-cyclopentenebisthien-3-yl framework were found to be ideal due to their excellent thermal and chemical stabilities (Fig. 2).

Irie and coworkers utilized this aryl framework in a wide variety of molecular switches, ranging from photoelectrochemical switches to liquid-crystalline switches.[9] One outstanding example is the reversible switching of surface morphology in single crystals of **5** (R_1 = Ph, R_2 = Me)[10,11] (Fig. 3).

It was shown that the surface morphology of these crystals can be altered by irradiation at an appropriate wavelength. Upon irradiation with UV light, the colorless crystals turned blue, and 1 nm steps appeared on the surface. Upon irradiation with visible light, the crystals decolored. and a flat surface was obtained. It was shown that these crystal are structurally resistant. because the crystal integrity remained intact through thousands of irradiation cycles. The surface morphological changes are related to the molecular structural changes of **5,** which are regularly packed in the single crystal. These small atomic molecular changes are amplified by the crystal packing. This exciting result demonstrates the potential for this as a photodriven nanometer-size actuator.

MORE COMPLEX SWITCHES: OVERCROWDED ALKENES AND UNIDIRECTIONAL ROTORS

The group of Feringa developed the concept of overcrowded alkenes as potential molecular switches.[12] These alkenes adopt a helical conformation due to steric interactions between the bulky groups attached at either end of the double bond. This approach was used in several examples of molecular switches. Compound 6 exists as two equal enantiomers. This racemic mixture can be enriched in P or *M* enantiomers, by irradiation at 313 nm with either left or right circular polarized light (*l*- or *r*-CPL) (Fig. 4a).[13] This chiral bias can be removed by irradiation with linear polarized light (LPL), which results in a racemic mixture. Doping of 4′-(pentyloxy)-4-biphenylcarbonitril with 20 wt% of racemic 6 resulted in a stable nematic liquid-crystalline phase. If a thin film of this LC material was irradiated at 313 nm, with *l*-CPL for 90 min, a chiral cholesteric LC phase was obtained. Irradiation of the nematic phase with *r*-CPL resulted again in the formation of a cholesteric phase but now with the opposite screw sense. Both cholesteric phases could be switched back to the nonchiral nematic phase by irradiation with LPL at 313 nm (Fig. 4b), because then racemization of the dopant occurs. It is now possible to

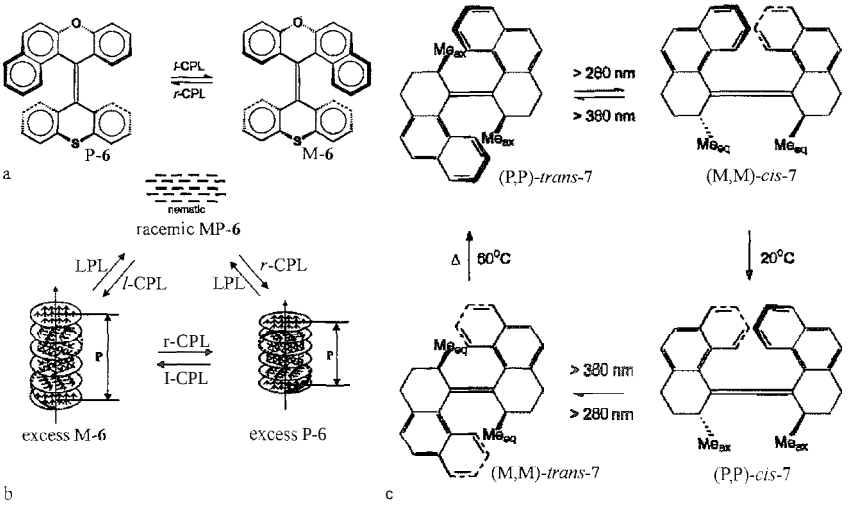

Fig. 4 (a) Photochemical switching between P-6 and M-6. (b) Photochemical switching between three different LC phases. (c) Light-driven molecular rotor. Reprinted with permission from Ref. [12]. Copyright 2000 by American Chemical Society.

switch between three different LC phases by irradiation with LPL or CPL.

Another application of the overcrowded alkene framework is in a light-driven unidirectional molecular rotor, also described by Feringa and coworkers.[14] It was demonstrated that at $-55°C$, compound (*P*,*P*)-*trans*-7, with two helical substituents attached to the olefinic bond, could be converted to a mixture of (*P*,*P*)-*trans*-7 and (*M*,*M*)-*cis*-7 in a 5:95 ratio by irradiation at $\lambda > 280$ nm. The process can be reversed by irradiation at $\lambda > 380$ nm. Helix inversion of the less-stable (*M*,*M*)-*cis*-7 to (*P*,*P*)-*cis*-7 occurred irreversibly at 20°C. Irradiation of (*P*,*P*)-cis-7 at $\lambda > 280$ nm resulted in a mixture of (*P*,*P*)-*cis*-7 and (*M*,*M*)-*trans*-7 in a 10:90 ratio: which also can be reversed by irradiation at $\lambda > 380$ nm. Helical (*M*,*M*)-*trans*-7 could be thermally inversed back to (*P*,*P*)-*trans*-7 (Fig. 4c) at 60°C. By using circular dichroism (CD) spectroscopy. the unidirectionality of the rotor was established. Every step of the rotary motion could be identified spectroscopically. and full cycles of the rotary motion can be followed at 217 nm. The unidirectionality of this rotor arises from the thermal interconversion of the less-stable forms. with equatorial Me substituents. to the more stable forms, with axial Me substituents. Compound 7 can rotate a full 360° unidirectional rotation in two photochemical steps and two thermal steps. This unique rotor can be regarded as an optical switch with four distinct states. Switching between these states depends on the wavelength of the light and the temperature used. A chemically driven unidirectional rotor was described by Kelly and coworkers (Fig. 5).[15,16] The operating mechanism of this rotor consists of several stepwise chemical modifications on triptycyl[4]helicene 8. Reaction of **8** with carbamoylchloride resulted in isocyanate 9. which rotates to give urethane 10. This relatively high-energy conformation rotates further to give **11.** Cleavage of the urethane bond results in Compound 12, completing a 120" rotation. To achieve a full 360° rotation, each of the blades of the triptycene needs to be functionalized with amino groups and by repeated reaction, rotation. and cleavage. a chemically driven rotor can be obtained.

MOLECULAR SWITCHES BASED ON ROTAXANES AND CATENANES

Rotaxanes are systems in which one or more macrocyclic molecules encircle a linear molecule that is terminated at both ends with bulky substituents, preventing the macrocycles from sliding off the thread. With the expansion of the field of supramolecular chemistry, several interesting rotaxanes systems were assembled, making use of different kinds of ternplating effects, e.g., noncovalent interactions and metal coordination.[17] Members of the Stoddart group were the first to demonstrate that rotaxanes can be switched between two different states. chemically (acid/base controlled) or electrochemically. One example is benzocrown ether/bipyridinium [2]-rotaxane 13 that can be switched chemically and electrochemically (Fig. 6).[18] It consists of a π-electron-accepting tetracationic cyclophane as the macrocycle that encircles a dumbbeli-shaped component that contains two diffe ent π-donating sites, a benzidine. and a biphenol unit. The cyclophane unit can bind to the benzidine and the biphenol unit on the

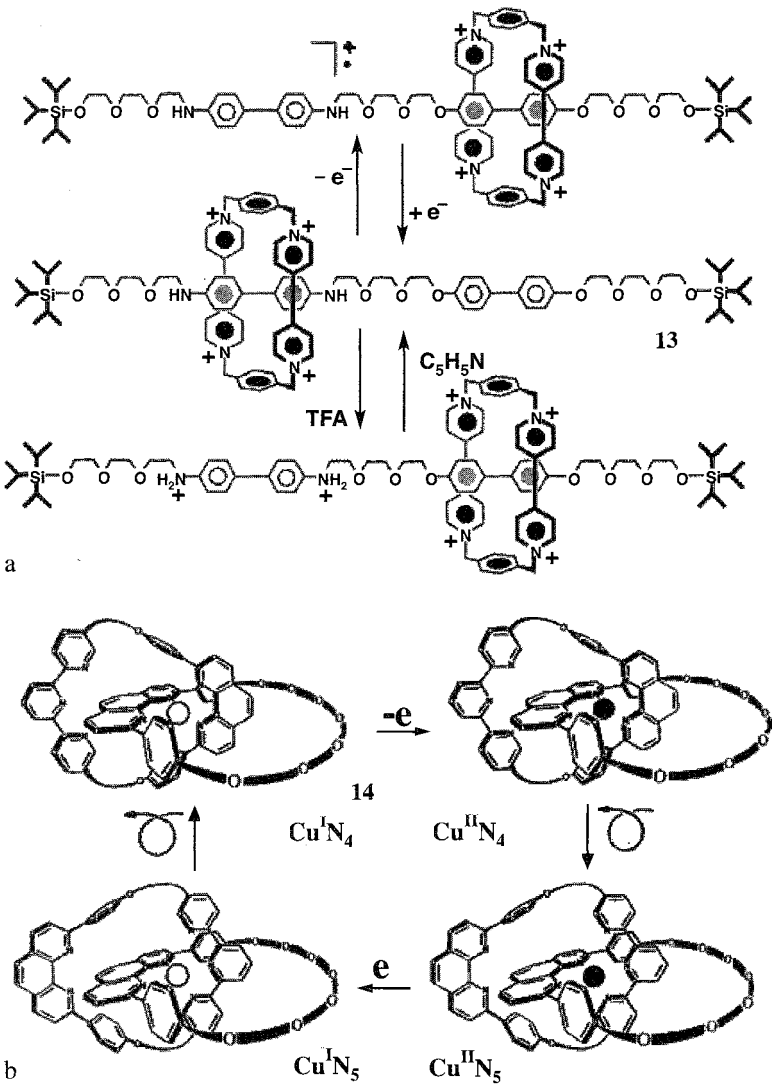

Fig. 6 (a) Electrochemical and chemical switching in a molecular shuttle. Reprinted with permission from Ref. [17]. Copyright 1998 by American Chemical Society. (b) Electrochemical switching in a [2]-catenane. Reprinted with permission from Ref. [22]. Copyright 1997 by American Chemical Society.

dumbbell because of attractive $\pi-\pi$ interactions and [CH—O] hydrogen bonds between the α-bipyridinium hydrogen atoms and the poiyether oxygen atoms.

At room temperature, the cyclophane was shown to shuttle between the benzidine and the biphenol unit. At 229 K, an equilibrium was established in which 84% of the cyclophane encircles the benzidine unit, because the cyclophane has a higher binding affinity for the benzidine group than for the biphenol group. Upon protonation of the nitrogen atoms of the benzidine group, the cyclophane shuttles away from the protonated benzidine groups, due to electrostatic repulsion of the protonated nitrogens and the tetracationic cyclophane. Only binding to the biphenoi unit is observed. The addition of base resulted in re-establishment of the aforementioned equilibrium. The same results can be obtained by electrochemical oxidation of the benzidine unit to its radical cation. Again because of electrostatic repulsion, the cyclophane reside5 at the biphenol unit. Electrochemical reduction regenerates the neutral dumbbell. and preferentially, binding to the benzidine group is observed. More recent derivatives, e.g., a bistable pseudorotaxane incorporating a tetrathiafulvalene (TTF) unit and a naphtalene unit in the dumbbell part. were incorporated in material devices.[19,20]

Catenanes are molecules similar to rotaxanes in that they consist of interlocked components. Instead of using linear molecules that are encircled by macrocyclic compounds, circular molecules can also be used, resulting in

interlocked macrocycles. The group of Sauvage developed a template-directed strategy based on metal coordination for the synthesis of switchable electrochemical catenanes.[21] An example is the switchable copper–catenate 14, i.e., a copper complex with an organic [2]catenane backbone (Fig. 6).[22] The organic [2]catenane backbone consists of one macrocycle containing a bidentate phenantroline unit interlocked with another macrocycle that contains a bidentate phenantroline and a terdentate terpyridine unit. The switching mechanism depends on the preferred coordination number accompanying the mono- or divalency of copper. Monovalent copper prefers to be 4-coordinate, while divalent copper prefers to be 5-coordinate. In the red-brown catenate 14, a tetrahedral coordination geometry is obtained by the coordination of the two bidentate phenanthroline units to the monovalent Cu center. Oxidation to the divalent species leads to a metastable complex that rearranges to the give the stable, deep green 5-coordinate copper(II) complex, coordinated by one bidentate phenantroline unit and one terdentate terpyridine unit. Reduction of this 5-coordinate species results in a metastable complex that rearranges back to catenate 14. The first step in the cycle can also be initiated by photochemical oxidation with p-nitrobenzylbromide. Unfortunately, the reduction step could not be initiated with light, because the 5-coordinated species is not photosensitive.

MACROMOLECULAR SWITCHES

Switches based on polymer arrays are of great general interest, because polymers often already exhibit interesting application-directed macroscopic properties. These properties could, in principle, be switched on or off, if switchable polymers could be utilized. One interesting example of such an approach is based on the chiroptical switching of polyisocyanates. Polyisocyanates are helical macromolecules in which an enantiomeric excess of a certain helical conformation (*P* or *M*) can be obtained by incorporating small amounts of chiral isocyanates during the polymerization of achiral isocyanate monomers. This so-called "sergeants and soldiers" effect, which is basically an amplification of chirality, was first reported by Green and coworkers.[23] And, this principle was used by the group of Zentel in the preparation of chiral photoswitchable polyisocyanates **15** (Fig. 7a).

The incorporation of chiral azobenzenes, containing two chiral centers, in the backbone of a polyisocyanate

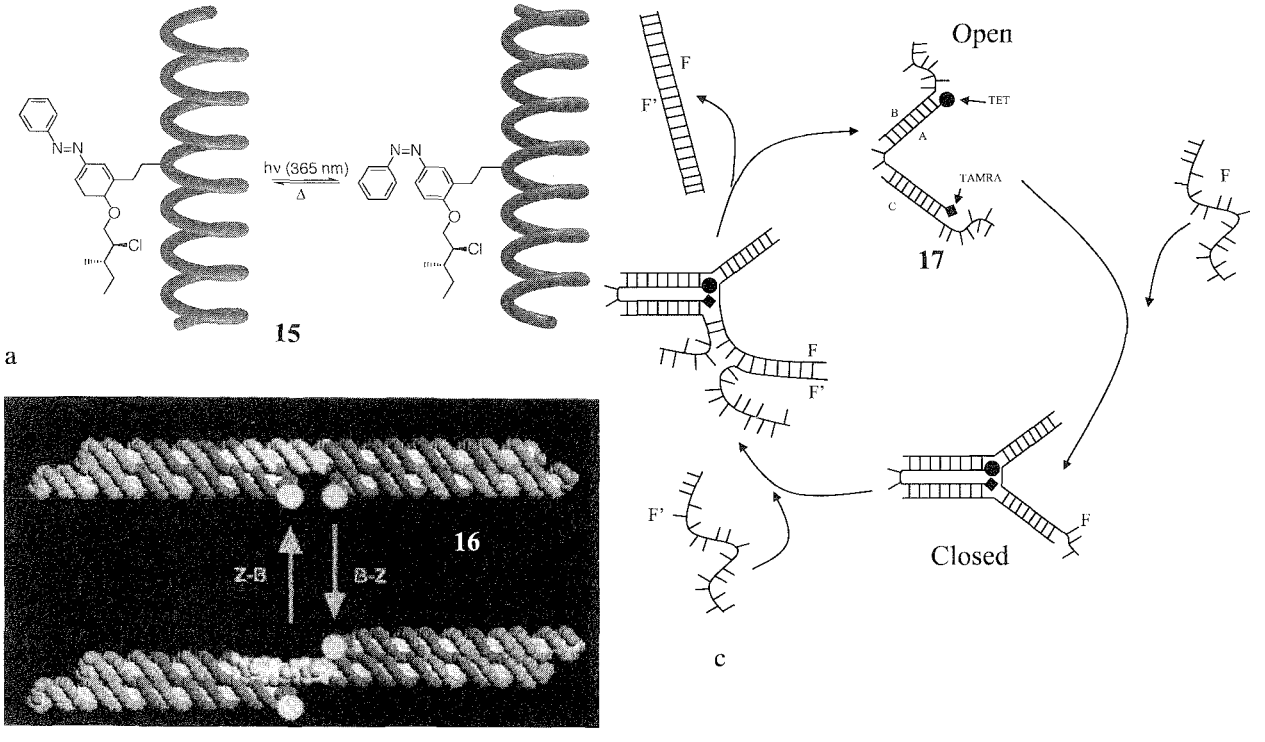

Fig. 7 (a) Chiral photoswitchable polyisocyanates. (b) DNA-based switch by Seeman. Reprinted with permission from Ref. [28]. Copyright 1999 by Macmillan Magazines Limited. (c) DNA-based switch by Yurke.

resulted in amplification of chirality, and a preference in the polyisocyanates for an *M*-helix was observed.[24] Irradiation of the azobenzene moieties at 365 nm resulted in a *trans–cis* isomerization of the azobenzene with a concomitant isomerization. The helical twist sense of the macromolecules was inversed, and a preference for the P-helical conformation was obtained. Further studies revealed that an increase of chiral azobenzenes in the polymer backbone resulted in an even higher stereoselectivity.[25] The incorporation of other azobenzenes, with only one chiral center, resulted in a change in the occupation of helical segments within one polymer but left the preferred helical twist sense of the overall polymer unchanged.[26]

Not only have synthetic polymers been used as a scaffold for macromolecular switches, but also nature's polymers, e.g., polypeptides and DNA, have also been used as a basis for macromolecular switches. Seeman et al. pioneered the use of DNA as a building block for a variety of topological objects, e.g., cubes and truncated octahedron and DNA arrays.[27] Because the DNA used is flexible; they developed the use of the DNA double-crossover (DX) system. This DX-DNA is much stiffer than normal DNA and was shown to be an ideal building block for a DNA-based molecular switch.[28] Switch **16** consists of two DX molecules connected to each other by 4.5 turns of DNA. At the free ends of the DX molecules, two dye molecules (a donor and an acceptor) are attached (Fig. 7b). The actual switching of the DNA-based switch relies on the B–Z transition of DNA, which can be regulated by adjusting the solution conditions favoring either B or Z forms of DNA. Under conditions that favor right-handed B-DNA, the two dye molecules are on the same side of the central helix. If conditions are used that favor left-handed Z-DNA, the dye molecules lie on opposite sides of the central helix. The fluorescence resonance energy transfer between the two dye molecules was monitored, and by observing the donor and acceptor energy transfers it could be shown that upon switching between conditions that favor B- or Z-DNA, energy transfer between the dyes was less in Z-DNA than in *B*-DNA. This can be explained by the fact that in Z-form DNA, the dyes are further apart, and electron transfer is less efficient.

An alternative DNA-based molecular switch **17**, developed by Yurke and coworkers.[29] consists of three strands of DNA (A, B, and *C*), and it has the form of a pair of tweezers. As shown in Fig. 7c, the DNA-based switch can be switched between an open form and a closed form. Adding an additional DNA strand **F** results in a hybridization of *F* with the dangling ends of strands B and *C*. This results in a closed form, with a dangling end of *F*. Addition of DNA strand **F'** results in the hybridization with **F**, and the duplex DNA strand *FF'* is removed from the tweezers. This again creates the open form of the tweezers. The whole process can be followed by monitoring the fluorescence intensity between the two dyes (a donor and an acceptor) at both ends of the A strand. Addition of *F* to the tweezers leads to a decrease of fluorescence intensity, because the dyes come in close proximity to each other, and fluorescence is quenched. Addition of *F'* leads to an increase in fluorescence intensity, corresponding to the open form. The process can be cycled by alternating additions of **F** and **F'**. Not only is this switch based on DNA, but also the ''fuel'' to operate it is made of DNA.

CONCLUSION

Throughout millions of years, nature developed subtle protein architectures that can alter conformation upon some forms of stimuli. It is amazing how only a limited amount of building blocks available for the biosynthesis of these architectures can lead to such a diverse range of switches. Using nature as an inspiration, physicists, biologists, and chemists are only now constructing a wide variety of synthetic switches with possible applications in the areas of microelectronics and materials sciences. With availability of a much wider range of building blocks and increasing insight into how to design, synthesize, and implement synthetic molecular switches, scientists are on the way to more closely mimicking the elegant switches found in nature. It has yet to be seen if they can rival the natural switches or perhaps even out-perform them. Toward this goal, there are already several exciting examples of the incorporation of switches in device applications,[''''the next step in the development of nanomachines.

Molecular Wires

Franco Scandola
Università degli Stodi di Ferrara, Ferrara, Italy

INTRODUCTION

The origin of molecular electronics can be traced back to 1974, when Aviram and Ratner[1] suggested that a single molecule could perform as a current rectifier. The paradigm of molecular electronics[2–6] is that typical functions of electronic devices can be emulated by individual molecules or by suitable assemblies thereof (supramolecular systems). The ultimate objective of this research field is the construction of electronic circuits (and computers) from molecules, in a bottom-up approach.

The simplest component of an electrical circuit is a wire, and the design of molecular wires has received a great deal of attention. In a broad sense. this term can be used to designate any molecular" structme able to mediate the transfer of electrons between appropriate electron donor and acceptor sites (electrodes, photoactive, and redox-active molecular components). In practice. different "conduction" mechanisms may apply, depending on the molecular structure of the wire and on the type of experimental setup used (see below). Molecular wires were studied in a variety of experimental conditions, depending on the nature of the donor and acceptor terminals the wire is connected to. and on the method used to detect the electron flow. Available methods can be broadly divided into the following (Fig. 1): photoinduced eiectron transfer in donor-wire-acceptor systems (dyads), fast electrochemistry of adsorbed wire-electroactive group asseinblies, and conductance $[I(V)]$ measurements on metal-wire-metal junctions.

PHOTOINDUCED ELECTRON TRANSFER

Some examples of donor–acceptor dyads for studies of photoinduced electron transfer across molecular bridges are shown in Fig. 2.[10–12] These systems are usually studied by exciting the chromophore (left component in Fig. 2) with appropriate light pulses and by observing electron transfer to the acceptor (right component in Fig. 2) by means of time-resolved spectroscopy. The time resolution of such techniques is generally limited by the light pulse duration. extending now into the ultrafast (femtosecond) regime.

In many of the systems investigated (e.g., in those of Fig. 2a–c), the energy levels of the bridge are far apart from those of the donor and acceptor sites (Fig. 3a. middle). Therefore, the electron tunnels in a single coherent step from donor to acceptor, without being localized at any time on the bridge (Fig. 3a. top). These processes are described by standard nonadiabatic electron transfer theory,[13–18] where the transfer probability is proportional to the square of the donor–acceptor electronic coupling. The role of the connecting bridge is actually that of a mediator of donor–acceptor electronic coupling. The phenomenon is conveniently described in terins of superexchange,[19–22] whereby "virtual" bridge states (i.e., high-energy excited states of electron transfer character involving the bridge) mix into the initial and final wave functions. as represented schematically in Fig. 3a (bottom) (where a donor-to-bridge state is shown. and possible bridge-to-acceptor states are omitted for clarity). According to this mechanism. the electron transfer probability k_{ET} decreases exponentially with donor–acceptor distance r_{DA} (Eq. 1).

$$k_{ET} = k(0)\exp(-\beta r_{DA}) \quad (1)$$

Thus, in the superexchange regime, the bridges behave differently from macroscopic ohmic conductors. In such cases, the term "molecular wire" can only be used in a broad sense. to emphasize the fact that bridges play an important role in eiectron transfer processes. Different bridges give different β attenuation factors. and measurements of photoinduced electron transfer rates as a function of bridge length can be used to characterize the "conducting" properties of the bridge. For modular bridges. made of a sequence of individual weakly coupled units (e.g., like those shown in Fig. 2a–c), the value of β depends on the following: 1) the energy of the virtual states localized on each module: and 2) the magnitude of the coupling between adjacent modules. As a consequence of 1 (above). fully saturated bridges usually give high β values (e.g., $\beta = 1.0 \pm 0.2$ Å^{-1} for the bridges in Fig. 2a–b),[10] while

"This restricts the Geld to discrete molecular systems. Thus. some very interesting work carried out with more extended wires, such as carbon nanotubes (Refs. [7,8]) and one-dimensional semiconductors (Ref. [9]), will not be dealt with in this entry.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120017790

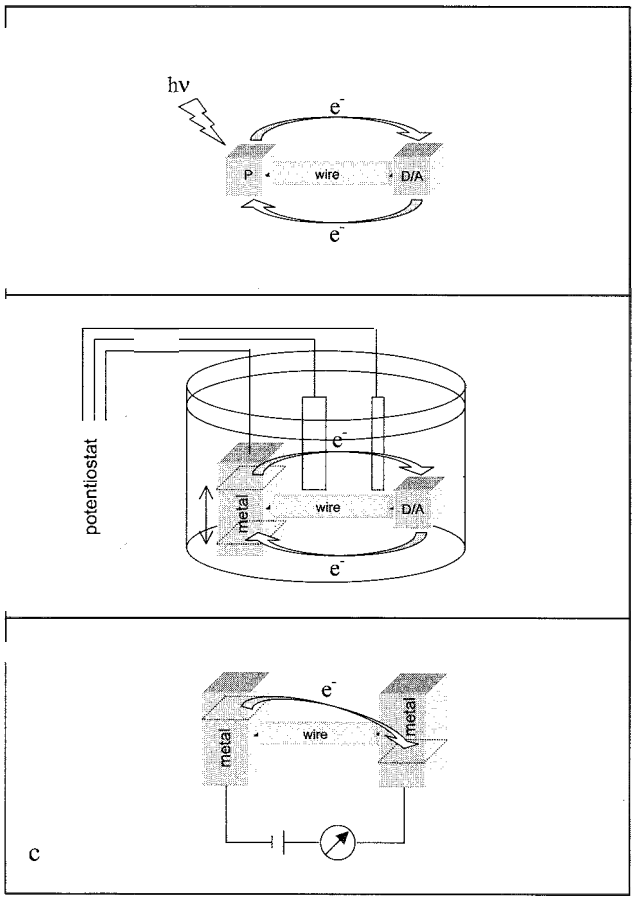

Fig. 1 Schematic representation of three types of experiment used to study electron transfer across molecular wires.

bridges with unsaturated units are characterized by lower values (e.g., $\beta = 0.5$ Å^{-1} for the bridge in Fig. 2c).[11] As an example of the effect of 2 (above), photoinduced electron transfer in the dyad of Fig. 2c is slowed by a factor of 50, simply by introducing alkyl substituents (R = hexyl instead of H) in the central ring. This is a consequence of the increased torsion angle and decreased electronic coupling between adjacent phenyl rings.[11]

A different situation may be encountered when the molecular wire connecting the donor and acceptor molecular components is a highly delocalized organic bridge. In such a case, the wire levels may become energetically accessible (Fig. 3b, middle). The bridge-localized states are no longer "virtual" (Fig. 3b, bottom), and the electron transfer proceeds via real injection of electrons into the wire (Fig. 3b, top). In such cases, the term "molecular wire" applies in a more strict sense, and the bridge is expected to approach the behavior of a conventional ohmic conductor, with a simple inverse dependence of the electron transfer rate on distance. An example of such a situation is represented by the dyad of Fig. 2d, based on a poly-p-phenylenevinilene bridge.[12] In fact, an interesting switch in mechanism was observed when the length of this type of bridge was changed systematically, by increasing the number of phenylenevinylene units from 0 to 4. For short bridges (0 and 1 repeating units), the distance dependence expected for superexchange ($\beta = 0.57$ Å^{-1}) was obtained. But then, an abrupt change in mechanism occurred, and the systems containing 2, 3, and 4 repeating units exhibited higher electron transfer rates and a true molecular wire behavior (apparent $\beta = 0.04$ Å^{-1}). This was explained by the decrease in energy of the LUMO of the bridge with increasing length of the conjugated system: beyond a critical bridge length, the LUMO bridge becomes thermally accessible from the donor level, and the mechanism switches from superexchange to molecular wire.[12]

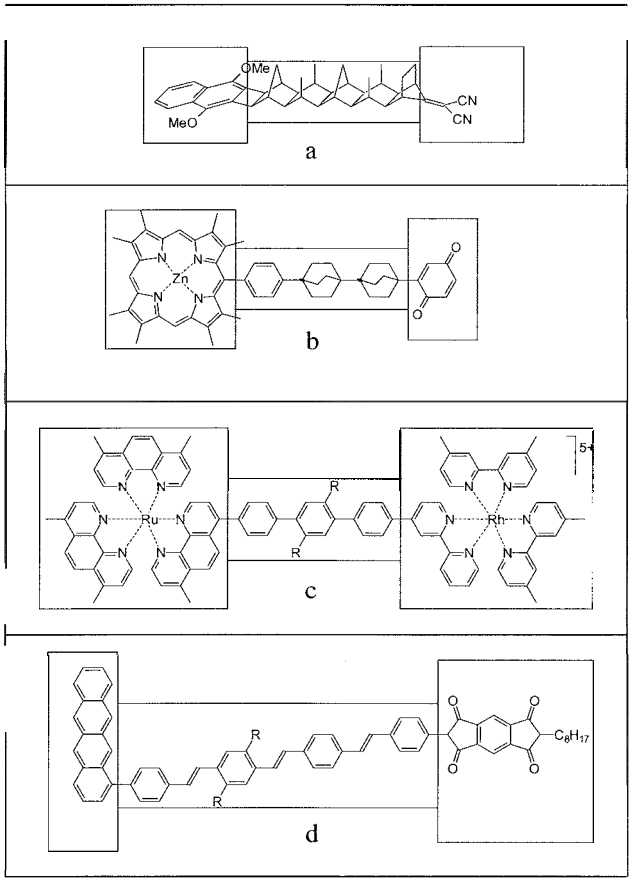

Fig. 2 Examples of covalently linked donor-acceptor systems (dyads) used for the study of photoinduced electron transfer across organic spacers. Boxes are drawn to identify the photoexcitable chromophore (left), the bridge (center), and the acceptor unit (right).

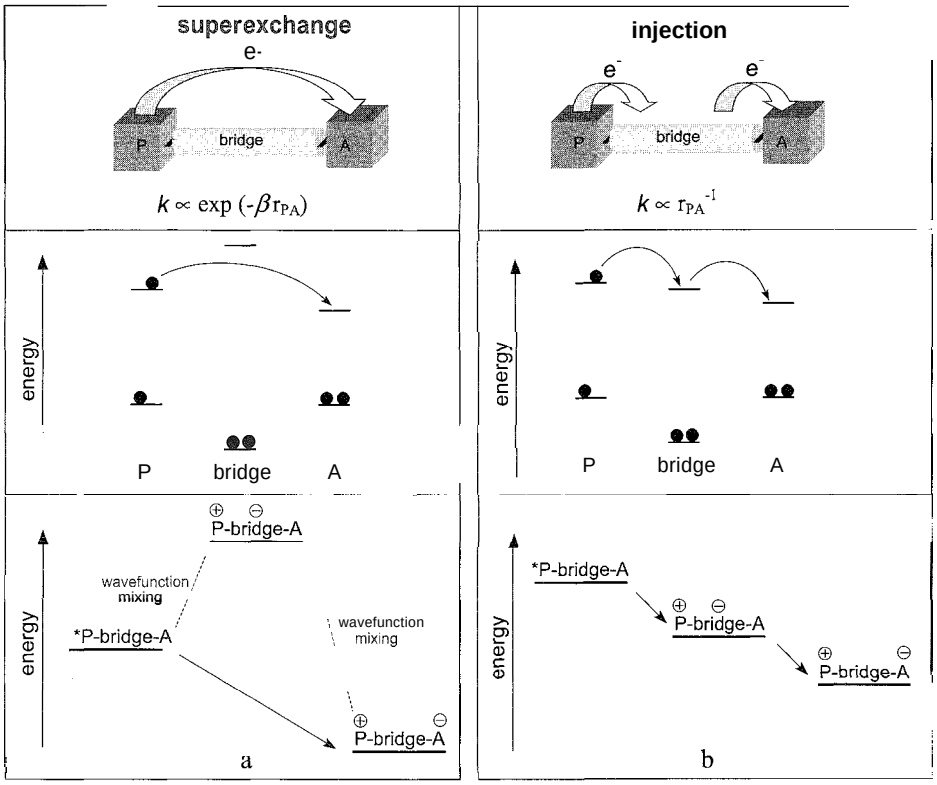

Fig. **3** Schematic representation of two limiting mechanisms for photoinduced electron transfer across a bridge: superexchange (a) and electron injection (b).

ELECTROCHEMISTRY IN SELF-ASSEMBLED MONOLAYERS

One-dimensional organic molecules with head groups suitable for metal binding (e.g., –SH, pyridyl) form self-assembled monolayers (SAMs) at metal surfaces (e.g., Au. Ag. Hg. Pt). Particularly well-characterized stable SAMs are those formed by alkanethiols.[23] Several interesting studies were carried out with SAM-forming molecules that comprise a binding group. an organic spacer, and an electroactive group (Fig. 1b). In such systems. various types of electrochemical techniques (e.g., fast-scan cyclic voltammetry,[24] AC voltammetry,[25] coulostatic T-jump methods,[26,27] and potential step chronoamperometry,[28]) can be used to measure heterogeneous electron transfer rates between the electrode and the electroactive group. Pure SAMs of the electroactive species or mixed SAMs. where the electroactive species is diluted in a monolayer of inactive molecules, can be studied by such techniques. The time scales of the electron transfer processes that can be observed depend on the technique, with rates as fast as 10^7 s^{-1} being presently accessible.

Representative examples of such types of measurement involve thiol-based SAMs on gold, with ferrocene as the electroactive group, and hydrocarbons of varying degrees of conjugation (alkanes[25] phenylethynyl,[25] and phenylenevinylene oligomers,[27]) as spacers. The length of the spacer can be systematically changed by varying the number of modular units (Fig. 4). With the alkane and phenylethynyl spacers, the experimental rates were found to fall off exponentially with distance, as required for an electron tunneling mechanism (Eq. 1). The damping factor is much higher for the saturated systems (β = 0.9 $Å^{-1}$ for the alkane spacers) than for the unsaturated ones (β = 0.36 $Å^{-1}$ for the phenylethynyl spacers),[25] again in agreement with the predictions of a superexchange mechanism. For the systems involving phenylenevinylene oligomers as spacers, electron transfer is so fast that the rates are not limited by eiectronic coupling (adiabatic limit) for bridges up to 28 Å long.[27] Interestingly, the β values obtained by these electrochemical techniques are similar to those obtained from photoinduced electron transfer in dyads with similar types of spacers.

METAL-MOLECULE-METAL JUNCTIONS

Toward the objective of molecular electronics. i.e.. to use molecules as components of electronic circuits, a

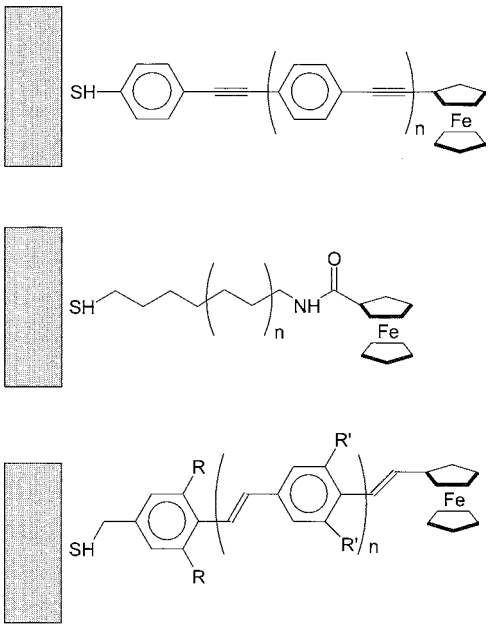

Fig. 4 Examples of molecules used for studies on electroactive SAM.

key step is the possibility to effectively wire molecules to solid (metal or semiconductor) contacts, so as to measure, e.g., their electrical conductivity. In recent years, this is becoming a feasible goal, thanks to the progress made in nanotechnology and scanning microscopy techniques. Several ingenious techniques are currently being applied to this problem. They include, among others, the following: probing conjugated molecules inserted into an isolating SAM by scanning tunneling miscroscopy (STM);[29] binding dithiolated molecules within a break junction;[30] using nanopores to build metal-SAM-metal junctions;[31,32] touching molecules in an isolating matrix with a conducting atomic force microscope (AFM);[33] contacting two SAMs together using a mercury drop electrode;[34,35] and attaching gold nanoparticles to dithiolated molecules inserted into a SAM and probing with STM[36] or conducting atomic force microscopy (AFM).[37]

Among such techniques, the last seems to be particularly reliable in terms of generating reproducibile single-molecule contacts. In a recent example,[37] molecules of 1.8-octanedithiol were inserted into an octanethiol SAM on Au(111). The thiol groups at the surface of the monolayer were derivatized with gold nanoparticles (less than 2 nm in diameter). A gold-coated conducting AFM tip was used to locate and contact individual particles bonded to the monolayer (Fig. 5). Current-voltage [$I(V)$] measurements made on a large number of nanoparticles (> 4000) produced only five distinct types of curves. These curves correspond to integer multiples of a fundamental one, that is thus assigned as the $I(V)$ characteristics of a single-molecule contact. The resistance of a single octanedithiol molecule, measured in this way, is 900 ± 50 MR. On the other hand, the resistance of the molecules of the octanethiol layer (which are probed via nonbonded contacts) are at least four orders of magnitude larger and much less reproducible.[37]

An experimentally simple, but versatile, approach is that based on M-SAM(1)SAM(2)-Hg junctions (M = Ag, Au).[34,35] These junctions are formed by depositing a first SAM on a solid metal surface (e.g., Ag, Au), a second SAM on a hanging drop of Hg, and then by bringing into contact the two monolayers (Fig. 6). This junction takes advantage of the smooth, compliant, defect-free nature of the Hg surface to minimize the effects of irregularities of the solid surface and the potential for shosting. A variety of experiments can be performed with such a simple experimental setup, by systematically changing the length of the SAM-forming molecules, their chemical natures, the natures of the chemical groups that consitute the interface between the two SAMs, or by inserting appropriate chemical species at this interface (Fig. 6). When the length of the molecules in the Au-supported SAMs are varied systematically, the $I(V)$ curves show exponential decreases in current density with distance, with potential-independent β values that depend on the chemical nature of the molecules. Again. the β values for saturated SAMs (0.87 $Å^{-1}$ for alkanethiols) are larger than those for unsaturated ones (0.61 $Å^{-1}$ for oligophenylene thiols),[35] in agreement with the trends found by studying photoinduced electron transfer in molecular dyads and electrochemical processes in SAMs with electroactive groups.

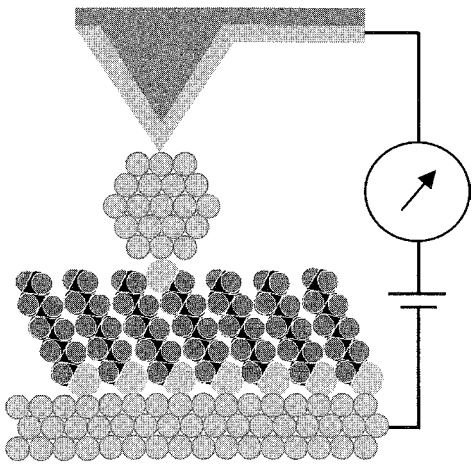

Fig. **5** Schematic representation of the AFM experiment described in Ref. 37.

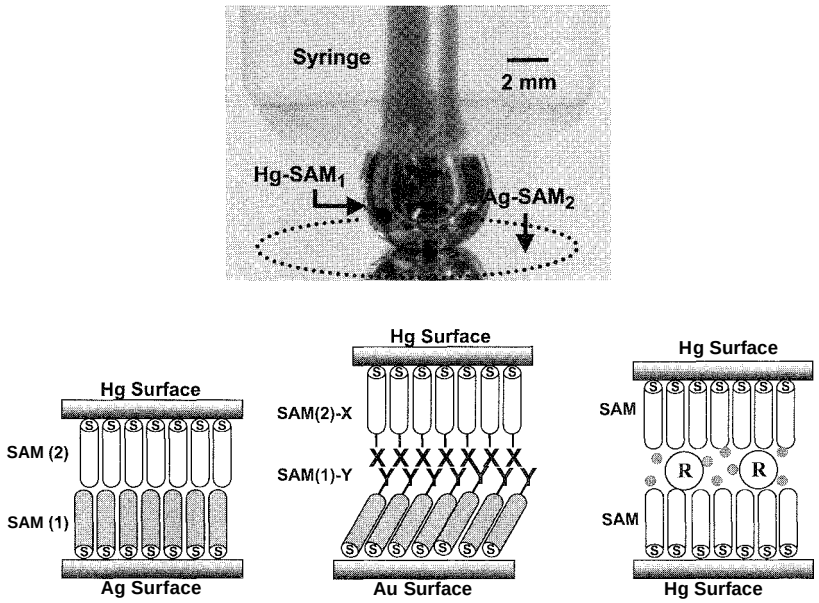

Fig. 6 Schematic representation of double-SAM junctions between a metal surface and a mercury drop (adapted from Ref. 35)

CONCLUSION

The techniques employed to characterize the behavior of molecular wires are so varied that extreme care should be used in comparing data between different experiments, especially absolute values of electron transfer rates, resistance, etc. Nevertheless, some general features can be noticed. In particular. in most of the experiments, the rate of electron transfer is found to decrease exponentially with the length of the wire, consistent with a coherent electron tunneling process. The interesting point is that the damping factor of this exponential decrease, β, is appreciably constant for a given type of bridge, regardless of the type of experiment from which it is derived. Thus, β emerges from these studies as a characteristic property of the bridge, suitable to describe its electron-transmitting (''conducting'') ability in a variety of experimental contexts.

The study of electron transport through molecules (especially at the single-molecule level) is a forefront scientific field that deserves considerable experimental and theoretical efforts. However, the fact that a variety of methods for wiring molecules and studying their electrical characteristics is now available should be regarded as an exciting breakthrough on the way to the ambitious goals of molecular electronics. Indeed, a number of interesting functions, reminiscent of those of conventional electronic devices, were recently observed by studying metal-molecule-metal junctions (e.g., rectification,[38] negative differential resistance,[31,32] conductance switching,[29] electromechanical amplification,[39] and field-effect transistor behavior.[''''])

Molecular-Level Machines

Vincenzo Balzani
Alberto Credi
Università di Bologna, Bologna, Italy

INTRODUCTION

The concept of "machine," which is so familiar in our macroscopic world, can be extended to the molecular level."] A molecular-level machine can be defined as an assembly of a discrete number of molecular components (i.e., a supramolecular system) designed to perform mechanical-like movements under the control of appropriate energy inputs. Molecules have nanometer dimensions and are the smallest entities exhibiting well-defined structures and shapes. Therefore, molecular-level machines represent the ultimate limit of miniaturization of the mechanical-machine concept.

In order to generate motion, a molecular-level machine requires an energy source. Therefore; spontaneous molecular movements caused by thermal energy; including the demonstration of the rotation of a single molecule on a surface,[2] have nothing to do with the concept of a molecular-level machine.

NATURE'S MOLECULAR MACHINES

Living organisms represent the synergistic integration of functionally diverse molecular machines.[3] The molecular machines produced by nature are extremely complicated assemblies of proteins with structures at the atomic and molecular levels that are not yet determined. In most cases, biological machines use chemical energy produced by ATP or proton gradients to perform their fucntions. How these biological fuels ultimately cause mechanical motions is still largely unknown.

In the last few years, however, the outstanding development of single molecule manipulation and observation, particularly by fluorescence spectroscopy, has thrown some light on the operational mechanism of several biological machines. For example, it was shown[4–6] that ATP synthase. the enzyme that manufactures adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate (Pi) is powered by a rotary motor fueled by a proton gradient (Fig. 1). The asymmetric membrane-spanning F_0 portion of the enzyme contains a proton channel. and the soluble F_1 portion contains three catalytic sites that cooperate in the synthetic reactions. The catalytic region is made up of nine protein subunits with the stoichiometry $3\alpha{:}3\beta{:}1\gamma{:}1\varepsilon$. approximating to a flattened sphere. 10 nm across and 8 nm high. The flow of protons through F_0 generates a torque that is transmitted to F_1 by an asymmetric shaft, the coiled-coil y-subunit. This subunit acts as a rotating "cam" within F_1, sequentially releasing ATPs from the three active sites. The F_0F_1-ATP synthase is reversible, i.e.. the full enzyme can synthesize or hydrolyze ATP; F_1 in isolation, however, can only hydrolyze it. The spinning of F_1-ATPase, i.e., the rotary motor nature of this enzyme. was directly observed[7] during ATP hydrolysis by attaching a fluorescent actin filament to the γ subunit as a marker.

Enzymes such as myosin. kinesin, dynein, and their relatives are linear rnotors that convert the energy of ATP hydrolysis into mechanical work along polymer substrates: myosin along actin filaments in muscle and other cells, and kinesin and dynein along microtubules.[3] Motion derives from a mechanochemical cycle during which the motor protein binds to successive sites along the substrate in such a way as to move forward on the average. For myosin II (skeletal muscle myosin). the working stroke was observed[8,9] by optical methods. but the motor mechanism is still unknown. Several other biological processes are based on motions. For example, RNA polymerase moves along DNA while carrying out transcriptions, acting as a molecular motor. The force and velocity of single molecules of RNA polymerase were measured."] The folding and unfolding of proteins is also subjected to intensive investigations.

ARTIFICIAL MOLECULAR-LEVEL MACHINES

The idea of constructing artificial molecular-level machines is recent. This topic was first discussed by R. P. Feynman,[10] Nobel Laureate in Physics. in his famous address. "*There is plenty of room at the bottom*," to the American Physical Society in 1959. His idea was that of constructing nanoscale machines "atom by atom." a concept later expanded with fascinating perspectives but almost no practical progress, by K. E. Drexler.[11,12] With the advent of supramolecular chemistry."] it became

DOI: 10.1081/E-ESMC 120012829

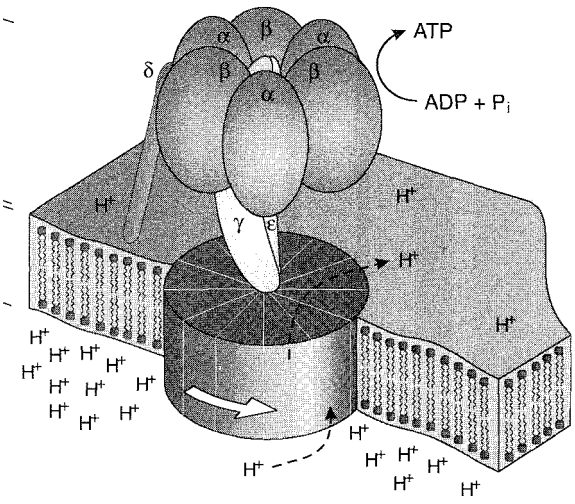

Fig. 1 Structure of F_0F_1-ATP synthase. (*View* this *art in color at www.dekker.com.*)

clear that molecules are by far more convenient building blocks than atoms for constructing molecular-level devices,[13–15] and in recent years, research on molecular-level machines has grown vigorously.[1,16–21]

Molecular-level machines operate through chemical reactions that cause electronic and nuclear rearrangements. Like macroscopic machines, they are characterized by the kind of cnergy input supplied to make them work, the kind of movement performed by their components, the way in which their operation can be controlled and monitored, the possibility to repeat the operation at will, the time scale needed to complete a cycle of operation, and the function performed.

The Energy Problem

The problem of the cnergy supply to make artificial molecular machines work is of greatest importance.[22] The most obvious way to supply energy to a chemical system is through an exergonic chemical reaction. In his address to the American Physical Society, R. P. Feynman observed the following:[10]

> An internal combustion engine of molecular size is impossible. Other chemical reactions, liberating energy when cold, can be used instead.

This is exactly what happens in our body, where the chemical energy supplied by food is used in a long series of slightly cxergonic reactions to power the biological machines that sustain life.

If an artificial molecular-level machine has to work by inputs of chemical energy, it will need the addition of fresh reactants (''fuel'') at any step of its working cycle, with the concomitant formation of waste products. Accumulation of waste products, however, will compromise the operation of the machine unless they are removed from the system, as happens in our body as well as in macroscopic internal combustion engines. The need to remove waste products introduces noticcable limitations in the design and construction of artificial molecular-level machines based on ''chemical fuel'' inputs.

Chemists have long known that photochemical and electrochemical energy inputs can cause endergonic and reversible reactions. In recent years, the outstanding progress made in supramolecular photochemistry[23] and electrochemistry[24] has thus led to design and construction of molecular machines powered by light or electrical energy that work without formation of waste products. In the case of photoexcitation, the commonly used endergonic and reversible reactions are isomerization and redox processes. In the case of electrochemical cnergy inputs, the induced endergonic and reversible reactions are, of course, heterogeneous electron transfer processes. Photochemical and electrochemical techniques offer further advantages, because lasers provide the opportunity to work in very small spaces and in very short time domains, and electrodes represent one of the best ways to interface molecular-level systems with the macroscopic world.

Needless to say, the operation of a molecular machine is accompanied by partial conversion of free energy into heat, regardless of the chemical, photochemical, and electrochemical natures of the energy input.

Other Features

The motions performed by the component parts may imply rotations around covalent bonds or the making and breaking of intercomponent noncovalent bonds. In order to control and monitor the machine operation, the motions of the component parts should cause readable changes in some properties of the system; any kind of chemical or physical technique can be useful, particularly the various types of spectroscopies. Because a machine has to work by repeating cycles, an important requirement is that any chemical reaction involved in the operation has to be reversible. The time scale needed to perform a cycle can range from less than picoseconds to hours, depending on the nature of the molecular components and the types of rearrangements involved. Finally, the functions that can be performed by exploiting the movements of the component part in artificial molecular-level machines are varied and, to a large extent, still unpredictable. In this regard, it should be pointed out that the mechanical movements taking place in molecular-level machines, and the related changes in the spectroscopic and electrochemical properties, usually obey binary logic and can thus be taken as a basis for

information processing at the molecular level. Artificial molecular machines capable of performing logic operations have already been reported.[25]

In the following. we illustrate a few examples of molecular-level machines powered by chemical. electrochemical, or light energy.

MOLECULAR MACHINES **POWERED** BY **CHEMICAL FUELS**

Chemical energy inputs are used[1,16–22] to induce rotary motions in specially designed molecules, to control threading/dethreading processes in pseudorotaxanes. to govern ring shuttling in rotaxanes, and to cause ring motions in catenanes. Two among the most significant examples are illustrated below.

Unidirectional Rotation

The unidirectional rotation illustrated in Fig. 2 from structure 1a to 1b is an important step toward the realization of a chemically powered molecular motor.[26,27] Compounds 1a and 1b are two of three low-energy rotamers about the axle connecting the triptycene and helicene components. Rotamer 1a is activated by reaction with phosgene to give isocyanate 2. Isocyanate 2 is chemically armed to react with the OH group in the hydroxypropyl tether attached to helicene. but, in the rotational ground state 2, the isocyanate and the OH group are too far apart to interact. However, at those instants when a clockwise rotation of the triptycene (not possible with a comparable counterclockwise rotation) brings the isocyanate and the OH group sufficiently close to react (see 3), urethane formation can then result (4). This irreversibly traps the triptycene in a relatively high-energy conformation around the triptycene/helicene axle. Ambient thermal energy then drives the exoergonic, but very slow, unidirectional rotation from 4 to 5. Finally, 5 is cleaved to 1b, thereby completing the chemically driven rotation of 1a to 1b. After this proof of principles, much work still has to be done to obtain a system that can undergo a full, continuous, and fast rotation.

A pH-Controllable Molecular Shuttle

Rotaxanes are made of dumbbell-shaped and ring components that exhibit some kind of interaction originating from complementary chemical properties. In rotaxanes containing two different recognition sites in the dumbbell-shaped component, it is possible to switch the position of the ring between the two stations by using an external stimulus. A system that behaves as a chemically controllable molecular shuttle[28] is shown in Fig. 3. It is made of a dibenzo[24]crown-8 (DB24C8) macrocycle and a dumbbell-shaped component containing a dialkylammonium center and a 4,4′-bipyridinium unit. An anthracene moiety is used as a stopper, because its absorption, luminescence: and redox properties are useful to monitor the state of the system. Because the hydrogen bonding interaction between the DB24C8 macrocycle and the ammonium center is much stronger than the charge–transfer interaction of the macrocycle with the bipyridinium unit, the rotaxane exists as only one of two possible translational isomers. Deprotonation of the ammonium center, however, causes 100% displacement of the macrocycle to the bipyridiniuin unit; reprotonation directs the macrocycle back onto the ammonium center (Fig. 3).

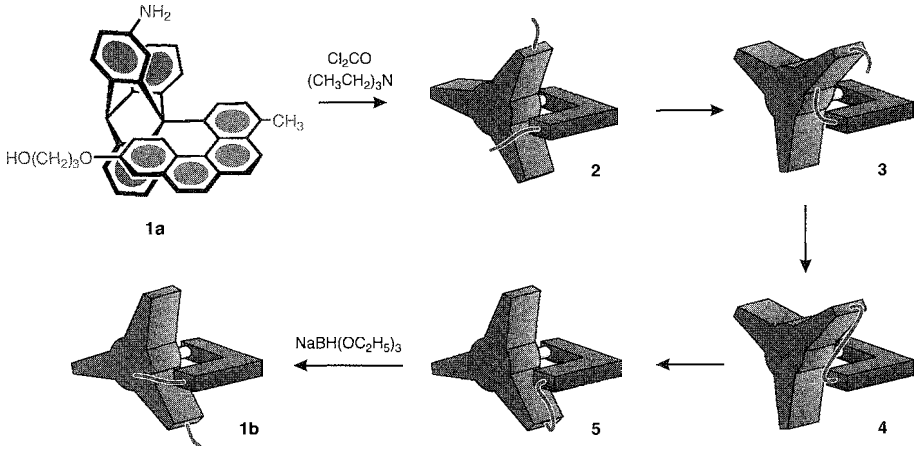

Fig. **2** Sequence of events involved in the chemically powered unidirectional rotation of a compound made of triptycene and helicene components. (*View this art in color at www.dekker.com.*)

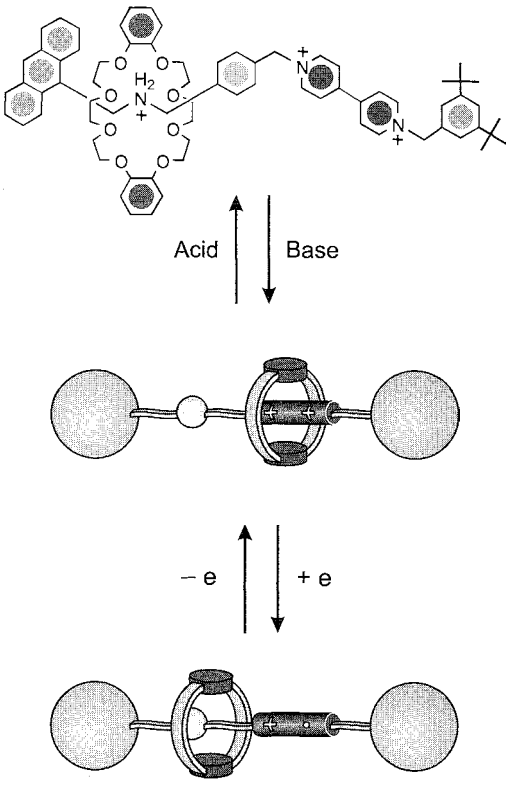

Fig. **3** A chemically controllable molecular shuttle: the macrocyclic ring can be switched between the two stations of the dumbbell-shaped component by base/acid inputs. Additionally, in the deprotonated rotaxane, the ring can be displaced from the bipyridinium station through reduction of such unit. (*View this art in* color *at www.dekker.com.*)

Such a switching process was investigated by ^{1}H-NMR spectroscopy and by electrochemical and photophysical measurements. The full chemical reversibility of the energy-supplying acid/base reactions guarantees the reversibility of the mechanical movement, in spite of the formation of waste products. Notice that this system could be useful for information processing,[29] because it exhibits a binary logic behavior. It should also be noted that in the deprotonated rotaxane. it is possible to displace the crown ring from the bipyridinium station by destroying the charge–transfer interaction through reduction of the bipyridinium station (Fig. 3) or oxidation of the crown ring. Therefore, in this system. mechanical movements can be induced by two different types of stimuli (acid/base and electron/hole).

MOLECULAR MACHINES POWERED BY ELECTROCHEMICAL ENERGY

Electrochemical energy inputs are used[1,16–22,23] to control threading and dethreading in pseudorotaxanes, ring shuttling in rotaxanes, and ring motions in catenanes. An example of the last type of motion is illustrated below.

Controllable Ring Motions in Catenanes

In a catenane, structural changes caused by circumrotation of one ring with respect to the other can be clearly evidenced when one of the two rings contains two nonequivalent units. In the catenane shown in Fig. 4, the electron-acceptor tetracationic cyclophane is symmetric, whereas the other ring contains two different electron-donor units, namely, a tetrathiafulvalene (TTF) unit and a 1.5-dioxynaphthalene (DON) unit.[30] In a catenane structure, the electron donor located inside the cavity of the electron-acceptor ring experiences the effect of two electron-acceptor units, whereas the alongside electron donor experiences the effect of only one electron acceptor. Therefore; the better electron donor (i.e., TTF) enters the acceptor ring and the other (i.e., DON) remains alongside. On electrochemical oxidation, the first observed process concerns TTF, which thus loses its electron donating properties. Fusthermore, an electrostatic repulsion arises between TTF^+ and the tetracationic macrocycle. These effects cause circumrotation of one ring to yield the translational isomer with the DON moiety positioned inside the acceptor. Upon reduction of TTF^+, the initial configuration is restored. However, this may happen without the occurrence of a full rotation. because it is equally probable that the reset caused by reduction of TTF^+ occurs by a reverse rotation compared to that which occurred in the forward switching caused by TTF oxidation. In order to obtain a full rotation, i.e., a molecular-level rotary motor, the direction of each switching movement should be controllable. This goal can likely be reached by introducing appropriate functions in one of the two macrocycles.[22] When this goal is reached, it will be possible to convert alternate electrical potential energy into a molecular-level mechanical rotation.

MOLECULAR MACHINES POWERED BY LIGHT ENERGY

Light is the most appealing energy source with which to make molecular-level machines work.[22] A variety of such machines using light as a partial or exclusive energy source were described.[1,15–23,31] They include tweezers. controllable doors and boxes. piston–cylinder systems, ring motions; rotary motors, and linear motors. A rotacatenane was also designed that should be able to couple a linear and a rotary motion upon a photosensitized electron-transfer reaction.[32]

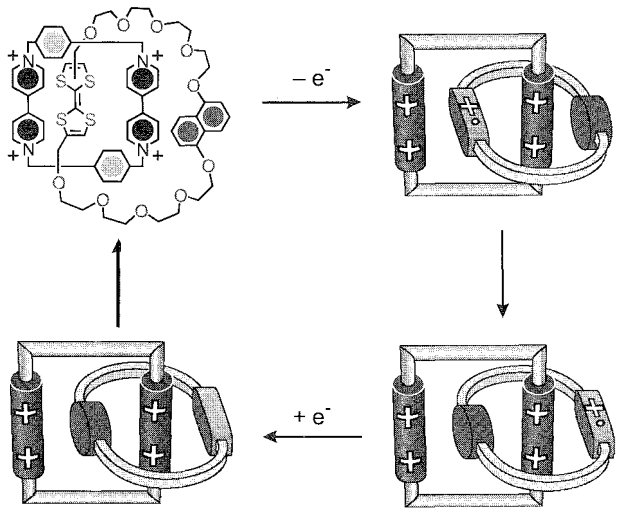

Fig. 4 Electrochemically controlled movements of the ring components upon one-electron oxidation/reduction of a TTF unit in a catenane containing a nonsymmetric ring. *(View this art in color at www.dekkcr.com.)*

A Light-Driven Molecular Rotary Motor

Photochemical *trans-cis* isomerization around a carbon–carbon double bond is a well-known reversible reaction.[123] Exploitation of this photochemical reaction in a suitably designed compound that contains two chiral elements has led to a photoinduced unidirectional rotary

In the methyl-substituted phenanthrylidcne 6, shown in Fig. 5, each one of the two helical subunits linked by a double bond can adopt a right-handed (P) or a lest-handed (M) helicity. As a result, a total of four stereoisomers are possible for this compound. The cis-trans photoisomerization reactions are reversible and occur upon irradiation at appropriate wavelengths. By contrast, the inversions of helicities, while maintaining a *cis* or a truns conliguration, occur irreversibly under the influence of thermal energy. Upon irradiation ($\geq$280 nm, 218 K) of a solution of (*P*,*P*)-*trans*-**6**, a mixture of (*P*,*P*)-*trans*-**6** and (*M*,*M*)-*cis*-**6** is obtained in a ratio of 5:95. By warming the solution to 293 K, (*M*,*M*)-*cis*-**6** interconverts irreversibly to (*P*,*P*)-*cis*-**6**. Subsequent irradiation ($\geq$280 nm) of the solution produces a mixture of (*P*,*P*)-*cis*-**6** and (*M*,*M*)-*trans*-**6** in a ratio of 10:90. Upon increasing the temperature further (333 K), (*M*,*M*)-*trans*-**6** interconverts irreversibly to the original isomer (*P*,*P*)-*trans*-**6**. Thus, a sequence of light- and temperaturc-induced isomcrizations can bc exploited to move this molecular rotor in one direction only (Fig. 5). When (*P*,*P*)-*trans*-**6** is irradiated ($\geq$280 nm) at a high temperature (293 K), a clockwise 360° rotation occurs spontaneously. The overall process can be followed by monitoring the change in the intensity of the absorption band at 217 nm in the circular dichroism trace. The unidirectional motion in this system is dictated by the stereogenic centers associated with the two methyl substituents. As a result of a trans ›*cis* isomerization, the axial methyl substituents of (*P*,*P*)-*trans*-**6** are forced to adopt a less favorable equatorial orientation in (*M*,*M*)-*cis*-6. However, the strain associated with the equatorial methyl susbstituents is released upon thermal interconversion of (*M*,*M*)-*cis*-**6** in the more stable isomer (*P*,*P*)-cis-6. The subsequent cis-–)trans isomerization forces the methyl groups to adopt, once again, equatorial orientations in the isomer (*M*,*M*)-*trans*-**6**. Finally, the thermal interconversion of (*M*,*M*)-*trans*-**6** into the original isomer (*P*,*P*)-*trans*-**6** is accompanied by a change from equatorial to the more stable axial orientations for the methyl substituents (Fig. 5). Morc recently, this molecular motor was redesigned to improve its performance, and it was shown that unidirectional rotation can be controlled by a single stereogenic center.[''']

A Photocontrollable Molecular Shuttle

In order to achieve photoinduced ring switching in rotaxanes containing two different recognition sites in the dumbbell-shaped component, the designed compound 7^{6+} shown in Fig. 6 was synthesized.[''''] This rotaxane is made of macrocycle **R** and a dumbbell component that contains the following: 1) a photoactive Ru(II) polypyridine complex (**P**) as a stopper; 2) a 4,4′-bipyridinium unit ($\mathbf{A_1}$) and a 3,3′-dimethyl-4,4′-bipyridinium unit ($\mathbf{A_2}$) as electron accepting stations; 3) a p-terphenyl-type ring system as a rigid spacer (**S**); and 4) a tetraarylmethane group as the second stopper (**T**). The stable translational isomer is the one in which the **R** component encircles the better electron-acceptor $\mathbf{A_1}$ unit. In order to obtain the

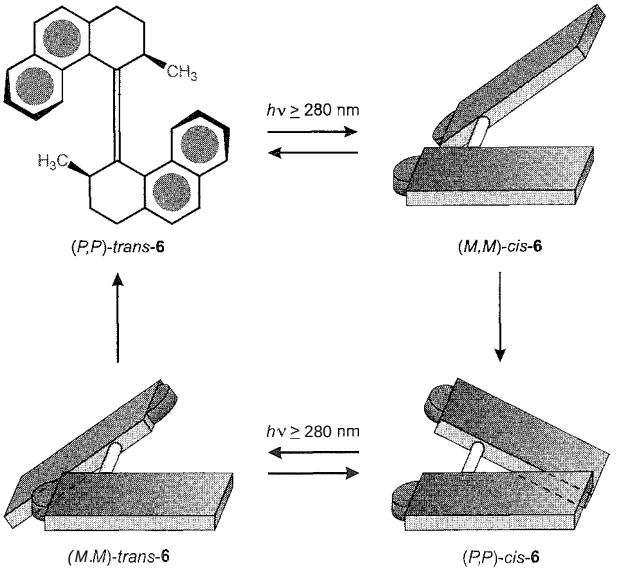

Fig. 5 The light-fueled rotary motor 6 undergoes unidirectional rotation in *n*-hexane at 333 K upon irradiation at appropriate wavelengths. (View *this art in color at www.dekker.com.*)

photoinduced abacus-like movement of macrocycle $\mathbb{R}$ between the A_1 and A_2 stations. two strategies were devised: one is fully based on processes involving the rotaxane components (intramolecular mechanism), while the other requires the help of external reactants (sacrificial mechanism).

The intramolecular mechanism, which implies the conversion of light energy into mechanical energy without generating waste products,[34] is based on the four operations illustrated in Fig. 6.

1. *Destabilization of the stable translational isomer:* Light excitation of $\mathbb{P}$ (Step I) is followed by the transfer of an electron to the A_1 station (Step 2), which is encircled by ring $\mathbb{R}$; such a photoinduced electron-transfer process, which competes with the intrinsic excited-state decay (Step 3), deactivates the A_1 station.
2. *Ring displacement*: The ring movement from A_1^- to A_2 (Step 4) has to compete with the back electron-transfer process from A_1 (still encircled by $\mathbb{R}$) to the oxidized photoactive unit $\mathbb{P}^+$ (Step 5).
3. *Electronic reset*: The back electron-transfer process from the free reduced station A_1 to $\mathbb{P}^+$ (Step 6) restores the electron-acceptor power to the A_1 station.
4. *Nuclear reset:* As a consequence of the electronic reset. back movement of the ring from A_2 to A_1 occurs (Step 7).

It is worthwhile noticing that in a system which behaves according to the intramolecular mechanism shown in Fig. 6. each light input causes the occussence of a forward and back ring movement (i.e., a full cycle) without generation of any waste product. In some way, it can be considered a four-stroke cyclic linear motor powered by light. For another example of photocontrollable molecular shuttle, see Ref. [35].

CONCLUSION

In the last few years. several examples of inolecular-level machines have been designed and constructed.[1,16–22] It should be noted. however, that the described systems work in solution, i.e, incoherently. For most applications, they need to be interfaced in some way with the macroscopic world by ordering them, so that they can behave coherently either in parallel or in series. Research on this topic is developing at a growing rate.[19,21]

The extension of the concept of a device to the molecular level is of interest not only for the development of nanotechnology but also for the growth of basic research. Looking at supramolecular chemistry from the viewpoint of functions with references to devices of the macroscopic world is an interesting exercise that introduces novel concepts into chemistry as a scientific discipline.

Naked Anion Effect

Dario Landini
Angelamaria Maia
Università degli Studi di Milano, Milano, Italy

INTRODUCTION

The fundamental role that the interactions with the solvent as well as with the counterion play in determining the rate of anion-promoted reactions is well known. This class of reactions is of primary importance in organic and industrial chemistry. The effect of the medium can be quantified by comparing the reactivity in the condensed phase with that in the gas phase. where in the absence of any solvation, the "intrinsic" reactivity of the "naked" anion is observed. The goals of this entry are to briefly summarize the research on anion activators and activation. The scope of the article is necessarily limited and readers are urged to use the citations for more information.

NAKED ANION CONDITIONS

The anion reactivity (nucleophilicity and basicity) in solution can differ greatly according to the strength of the interaction with the surrounding molecules, the stronger the bond with the molecules of the solvent shell. the higher the Gibbs energy of activation and the lower the reaction rate. A typical example is represented by the S_N2 ion–molecule reaction (Eq. 1). where when going from a hydrogen-bond donor (HBD) solvent (water) that specifically solvates the anion through hydrogen bonds to a dipolar aprotic non-HBD solvent (DMF), where interactions are minimized, and then to the gas phase. the chloride anion reactivity increases by 5 and 15 powers of 10, respectively.[1,2] Comparison of the activation energy of this reaction in the gas phase (12.5 kJ mol ') with that in water (104.5 kJ mol^{-1}) indicates that the reaction rates in solution are mainly determined by the amount of energy necessary to destroy the solvation shell of the nucleophile in the activation process and: to a lesser extent. by the intrinsic properties of the reactants:[1]

$$Cl^- + CH_3Br \longrightarrow Br^- + CH_3Cl \qquad (1)$$

The association of the anion with the corresponding cation is another important factor in determining anionic reactivity. In general, the ion-paired anion is found to be less reactive than the corresponding free nonassociated ion.[3] According to Coulomb's law, the energy of interaction between cation and anion depends on the nature of the ionophores, decreasing on increasing the dielectric constant of the solvent. Depending on the ability of the medium to separate charges, the ionic species in solution range from scarcely solvated ion-pair aggregates to solvated free ions (Eq. 2):[4]

$$\underset{\text{Aggregate ion pairs}}{[(M^+Y^-)_n]_{solv}} \rightleftharpoons \underset{\text{Contact ion pairs}}{n(M^+Y^-)_{solv}} \rightleftharpoons \underset{\text{Solvent–separated ion pairs}}{n(M^+//Y^-)_{solv}} \rightleftharpoons \underset{\text{Free ions}}{n(M^+)_{solv} + n(Y^-)_{solv}} \qquad (2)$$

The interaction with the cation noticeably affects the reactivity of the anion in media of low dielectric constant. Thus. on switching from the large tetra *n*-butylammonium to the small lithium cation, the reactivity sequence of the corresponding halides in the nucleophilic substitution of *n*-butyl 4-bromobenzenesulfonate in the weakly dissociating acetone is completely reversed (Eq. 3).[5] Whereas the order obtained with bulky quaternary onium salts ($Cl^- > Br^- > I^-$) corresponds to that of free, nonassociated halides in dipolar non-HBD solvents (e.g., acetone). the sequence of the lithium halides ($Cl^- < Br^- < I^-$), typical of protic solvents, is mainly due to the increasing deactivation of the anion in the ion pair on increasing the cation charge density:[5]

$$nC_4H_9OBs + M^+Hal^- \xrightarrow{\text{Acetone}} nC_4H_9Hal + M^+OBs^-$$
$$M^+ = Bu_4N^+, Li^+; \quad Hal^- = Cl^-, Br^-, I^-; \quad Bs = 4BrC_6H_4SO_2 \qquad (3)$$

Main Anion-Activating Systems

The highest values of anion reactivity are obtained in the condensed phase. when the anions are less solvated and associated with the cation. Both of these conditions can be realized at the same time by using bulky quaternary onium salts; electron pair donor (EPD) solvents of high Lewis

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012707

basicity (specific cation solvators); or cation complexing agents. such as polyether ligands (cyclic and open-chain).

The EPD solvents of high Lewis basicity include the most common dipolar non-HBD solvents (e.g., DMSO. acetonitrile, DMF, acetone, HMPA, etc.) and some open-chain polyethers (oligoethylene glycol dialkyl ethers **1** (''glymes''). They specifically solvate the cation but weakly interact with the anion and, for this reason, are found to enhance nucleophilicity and basicity of anion-promoted reactions in comparison with the reactivity realized in protic HBD media.[1,2]

Cyclic and open-chain polyethers (polyethylene glycols. crown ethers, cryptands, polypodands, such as **1–10**) are known for their unique abilities to specifically bind inorganic salts. giving rise to stable inclusion complexes. In the complexation process. such ligands coordinate, through ion–dipole interactions, a relatively small metal ion M^{n+} and transform it into a large. more lipophilic cationic species. This allows the solubilization, even in weakly polar nonaqueous media, of a number of metal salts. as $(M^{n+} \subset \text{Lig})\ nY^-$ ion pair, and their transfer from an aqueous to an immiscible organic phase. As a consequence. anion-promoted reactions can be performed in the presence of these ligands under homogeneous and heterogeneous conditions.[1,6–17] Whereas in the first case the ligand is used in stoichiometric quantity. only catalytic amounts of it are required in two-phase systems, such as solid–liquid (SL) or liquid–liquid (LL) phase-transfer catalysis (PTC).[1,6–17] In these complexes, the anion is remarkably activated due to the reduced interaction with the bulky complexed cation and the small stabilization by the weakly polar medium.

POLYETHER LIGANDS AND QUATERNARY ONIUM SALTS AS ANION ACTIVATORS

Liotta and coworkers were among the first to utilize 18-crown-6, ***3*** for solubilizing inorganic salts in polar and nonpolar aprotic solvents.[18] In particular, they studied the relative nucleophilicities in a typical S_N2 reaction (Eq. 4) of a series of potassium salts dissolved in acetonitrile by 18-crown-6, **3**. The sequence ($N_3^- > MeCO_2^- > CN^- > F^- > Cl^- \geq Br^- > I^- > SCN^-$) and the narrow nucleophilicity range found, different from those in polar protic media; were attributed to a much weaker solvation of the anion in acetonitrile that does not modify anionic intrinsic reactivity. Because this behavior is typical of the gas phase. the authors claimed the complexes formed by crown ethers with potassium salts in acetonitrile as sources of "naked" anions:[18]

$$C_6H_5CH_2OTs + [K^+ \subset \mathbf{3}]Y^- \xrightarrow{\text{Acetonitrile}} C_6H_5CH_2Y + [K^+ \subset \mathbf{3}]OTs^-$$
$$Y = N_3, MeCO_2, CN, F, Cl, Br, I, SCN \quad (4)$$

In a systematic kinetic study,[19] Thomassen and coworkers compared the effect of the addition of cyclic and acyclic polyethers on the rate of alkylation of potassiuin phenoxide with bromobutane in dioxane, a solvent of low cation-solvating power and low dielectric constant (ε=2.2, at 25°C) (Eq. 5):

$$n\text{BuBr} + \text{PhOK} \xrightarrow{\text{Dioxane}} \text{PhBu}n + \text{KBr} \quad (5)$$

As reported in Table 1, the addition of one molar equivalent of DCH18C6. ***5,*** produced a reaction rate increase of 8700-fold , while a reactivity enhancement of only 11 times resulted from the addition of the same amount of tetraethylene glycol dimethyl ether, **1**.

Table 1 Effect of the addition of polyether ligands on the alkylation rate of potassium phenoxide with n-butyl bromide in dioxane at 25°C[a]

Additive	[Additive]/[phenoxide]	k_{rel}
None	0	1
Tetraglyme **1**	0.054	1.5
	0.62	7.1
	1	11
DCH18C6 **5**	0.054	280
	1	8700
	1.53	11,200
	2.06	11,700

[a]From Ref. [19]

In addition, especially in the case of crown ethers, the rate constant depends strongly on the ligand–potassium phenoxide molar ratio, reaching a maximum value for the complete salt complexation, e.g., DCH18C6 **5**/PhOK=2.06. Under these conditions, the rate increased 11,700-fold, an enhancement similar to that observed by using tetraglyme **1** as a pure solvent. Because kinetic evidence showed that in dioxane the **5**/PhOK complex reacts as a single ion pair, these data clearly indicate that crown ethers are much better metal-cation-solvating ligands than acyclic polyethers with a comparable number of oxygen atoms, producing highly reactive solvent-separated ion pairs. Interestingly, the reactivity of these ion pairs approaches that of bulky tetrabutylammoniurn phenoxide ion pairs in the same solvent and is only 10 times lower than that of free ions in DMF and DMSO.[19] In line with these data. Hirao and coworkers reported[i''''] that the alkylation rate of sodium phenoxide with bromobutane in dioxane was strongly accelerated (about 100 times) by the addition of 5.4 molar equivalents of DB18C6, 4. A comparable rate increase was only obtained in the presence of the same amount of polyethylene glycol dimethyl ethers **1** of molecular weight $\geq 10^4$. Analogue results (Table 2) were obtained upon addition of DCH18C6. ***5,*** in the alkylation rate of diethyl sodium n-butylmalonate with bromobutane in both THF and benzene[12''] (Eq. 6):

$$n\text{BuBr} + n\text{BuC}(CO_2Et)_2^-Na \longrightarrow (n\text{Bu})_2C(CO_2Et)_2 + \text{NaBr} \quad (6)$$

Table 2 Effect of the addition of DCH18C6 5 on the alkylation rate of diethyl sodium *n*-butylmalonate with *n*-butyl bromide in various reaction media at 25°C[a]

"From Ref. [21]

Also. in this case, a rate plateau is reached when the sodium enolate is totally complexed by the ligand (≈4 molar equivalents of 5). Under these conditions, the crown-ether-separated ion pair is only 3.8 in THF and 2.3 times in benzene less reactive than the kinetically active species in DMF. Once again. these results highlight the remarkable ability of crown ethers to specifically solvate cations activating counterions.

A systematic study was performed by our group on the anion activation realized by complexes of different polyether ligands 2c, 5. 10 with alkali salts and the corresponding tributylhexadecylphosphonium salts in the low polar chlorobenzene (Eq. 7).[13,22] As reported in Table 3, the anion reactivity increases when going from the open-chain polypodand 2c to the cyclic crown ether **5** to the bicyclic cryptand 10 in parallel with the increasing cation–anion separation induced by the ligand. The nucleophilicity scale found with cryptates of 10. the same as for quaternary salts, is slightly modified with the complexes of crown ether 5. In addition, with the latter ligand. the reactivity spans a narrow range, particularly for halide ions (Cl:Br:I=1.3:1.4:1). Such behavior is mainly due to the different topologies of these ligands:

$$n\mathrm{C_8H_{17}OMs} + \mathrm{Q^+Y^-} \longrightarrow n\mathrm{C_8H_{17}Y} + \mathrm{Q^+OMs^-}$$

$$\mathrm{Q} = \mathrm{C_{16}H_{33}P^+Bu_3}\ \ \mathrm{Octyl_4N^+}\ \ (\mathrm{M^-}\ \mathrm{C}\ \mathrm{lig})$$

$$\mathrm{M^+} = \mathrm{K^+}.\mathrm{Li^-}\ \ \mathrm{lig} = \text{polypodand 2c DCH18C6 5}$$

$$[2\,2\,2\ \mathrm{C_{10}}]\mathbf{10} \qquad (7)$$

Cryptates, where the metal cation is completely included in the cavity of the tridimensional ligand, give rise to "solvent-separated" ion pairs particularly reactive in low-polarity media. Conversely, in the crown ether complexes, the ligand does not induce a large cation–anion separation, and the complexed anion is still accessible for interaction with the anion in a "crown-separated" ion pair. As a consequence, by increasing the charge density of the cation or the anion, the ion pair becomes progressively more intimate and. hence, less reactive. This is confirmed by the trend obtained with the complexes of the lithium halides (Table 3).[13]

In this case. in fact, the nucleophilicity sequence is reversed on switching from the complexes of crown ether **5** to the corresponding cryptates. Interestingly. the same trend of crown ether **5** is found with the corresponding complexes of cyclophosphazenic polypodand **2c**. As shown in Table 3. cyclophosphazenic polypodands like **2c** have a reactivity only slightly lower (three to four times) than that of the corresponding crown ethers and, hence, can be considered a valid alternative to the more sophisticated cyclic ligands.

Crown ether/cryptand effects were also revealed by Buncel et al. in the oximate-promoted 1,2-elimination from β-phenylmercaptoethyl *p*-nitrophenolate in tetraglpme (Eq. 8).[23] The addition of cryptand [2.2.2], 9, in fact. greatly enhanced (654 times) the oximate reactivity in comparison with the potassium oximate ion-paired, whereas the effect was much lower with crown ether DCH18C6, **5** (only 11 times): (see equation below)

The use of lipophilic crown ethers and cryptands in catalytic instead of stoichiometric amounts (LL-PFC or SL-PTC) revealed considerable improvement for synthetic applications due to the relatively high cost of these cyclic ligands in comparison with the cheaper quaternary onium salts and the open-chain analogues.[6–13]

Under LL-PTC conditions. the anions associated with bulky lipophilic cations (quaternary onium salts, macrocyclic and macrobicyclic polyethers, etc.) are extracted into the organic medium specifically solvated by a limited number (1–11 moles per mol of Q^+Y^-) of water molecules. Furthermore. two additional molecules of water are found to accompany the cyclic polyethers 5, 10, as both free and complexed ligands.[13] This hydration sphere, characteristic of each anion, always reduces, more or less remarkably. anionic reactivity. As shown in Table 4, when changing from LL-PTC to anhydrous homogeneous

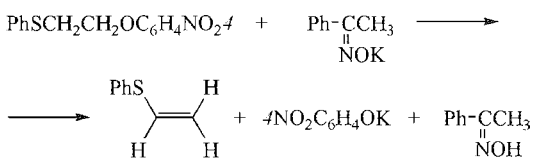

Table *3* Anionic reactivity of complexes $(M^+ \subset Lig)Y^-$ ($M^+ = K^+$, Li^+; Y = N_3, Cl^-, Br^-, I^-, SCN^-, Lig = **2c**, **5**, **10**) and quaternary phosphonium salts $C_{16}H_{33}P^+Bu_3Y^-$ in the S_N2 reaction with *n*-octylmethanesulfonate in chlorobenzene, at 60°C[a]

[c]$M^+ = Li^+$.

conditions, the nucleophilicity of a representative series of tetraoctylammonium saits increases: particularly in the case of anions with high charge density and more hydration (Eq. 7).[22,24] It is worth noting that the reactivity of the homogeneous anhydrous phase can be reproduced under LL-PTC conditions by using concentrated aqueous alkaline solutions (50% aq NaOH, 60% aq KOH). These solutions. where the water activity tends to zero, are found to be efficient systems for having anions largely or even completely "nonhydrated" in the organic phase (Table 4).[22,24]

Once again. crown ethers behave differently from quaternary salts and cryptates. With the complexed crown ethers. removal of the hydration sphere of the anion in going from two-phase to anhydrous conditions is balanced by a larger cation–anion interaction in the ion pair. thus resulting in a small variation of anionic reactivity. This is another proof that, unlike cryptates, complexed crown ethers can hardly be considered as a source of "naked anions."[24]

In low-polarity media, specific interaction with protic species (water) dramatically affects the reactivity (nucleophilicity or basicity) of anions with high charge density (OH . F . oxanions. carbanions, etc.). Basicity of OH in the Hofmann elimination reaction of $(hexyl)_4N^+OH^- \cdot nH_2O$ (Eq. 9), carried out in a chlorobenzene–water two-phase system, increases 50.000 times by reducing the hydration number *n* of the anion from 11 to 3. The enhancement is extrapolated to be more than nine powers of 10 for the hypothetical anhydrous hydroxide.[22,24] This indicates that the largely dehydrated hydroxide. extracted in a low-polarity solvent (chlorobenzene) from concentrated alkaline soluiions. is an extremely powerful base. Results account for the dramatic effect produced by an increase of base on the rate of reactions promoted by alkali hydroxides under LL-PTC conditions, such as carbanion formation and alkylation. alkene isomerization, H/D exchanges in carbon acids. and acid–base equilibria:

$$hexyl_4N^+OH^- \xrightarrow{\text{PhCl-aq NaOH}} hexyl_3N + \text{hex-1-ene} \qquad (9)$$

In a recent kinetic study. we investigated the ability of macrocyclic polyethers to activate enolates in the alkylation of deoxybenzoin with butyl derivatives *n*BuY (*Y*=Br, I, OMes) catalyzed by crown ether 5 or cryptand **10** under EL- and SL-PTC conditions with strong bases (NaOH, KOH) (Eq. 10).[25] The enolate reactivity increases; up to 40 times. on going from crown ether **5** to cryptand **10** in line with the better anion activation realized by the latter. The regioselectivity of the reaction (O/C ratio) is also reinarkably affected by the ligand.

Table 4 Effect of the anion hydration *n* of $octyl_4N^+Y^- nH_2O$ on the second-older rate constant of reaction (5) under LL-PTC and anhydrous homogeneous (PhCl) conditions, at 35°C

With crown ether **5**, the preferential association of the complexed cation with oxygen favors the alkylation of the less-electronegative center, the carbon, and hence, only the C-alkylation product is obtained. Conversely, cryptand **10**, which realizes a better cation–anion separation, leads to an increase in the nucleophilicity of the enolate 0-center. resulting in a greater quantity of *O*-alkylated product and, hence, lower regioselectivity:[25]

$$\mathrm{PhCH_2COPh} + n\mathrm{BuY} \xrightarrow[\text{PhCl-conc MOH (or solid)}]{\text{catalyst (5 or 10)}} \mathrm{PhCHBuCOPh} + \mathrm{PhCH{=}COBuPh} \quad (10)$$

GENERATION AND ACTIVATION OF ANIONS FOR SYNTHETIC APPLICATIONS

Since the appearance of Pedersen's work on the discovery of crown ethers in late 1967,[26] the special ability of polyether ligands, in particular crown ethers, to activate anionic reagents in homogeneous and heterogeneous systems was exploited in a huge number of applications on both laboratory and industrial scale (many of them were already reviewed).[6–17] Some recent examples among the most relevant ones are presented and discussed here.

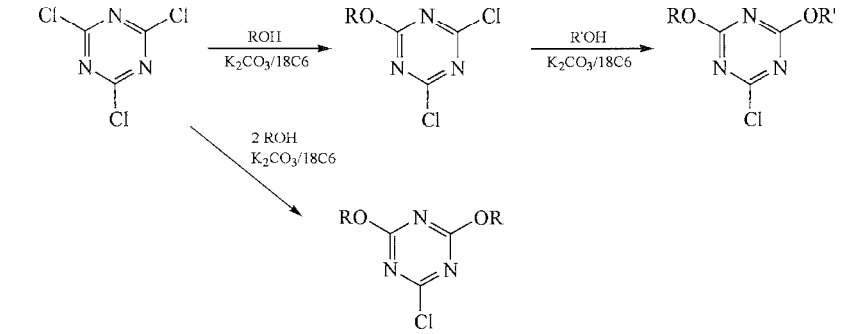
The K_2CO_3/18C6, **3,** system is widely used for in situ generating oxa- and azanions, and promoting their reactions under homogeneous and heterogeneous condition~.[~It'wa]s the base of choice in the synthesis of an important class of dendrimers, i.e., poly(benzyl ether) dendrimers, 17. via an elegant "convergent-growth" methodology[27] (Scheme 1).

The procedure, based on the 3,5-dihydroxybenzyl alcohol **11** as the monomer unit, involves a repetitive two-step process: reaction of **11** with benzyl bromide 12 in the presence of K_2CO_3/18C6, **3,** gives the next generation of alcohol **13,** that is converted to the corresponding bromide 14. Repetition of the two-step process affords successive generations up to the sixth-generation dendron **15**. The synthesis of final poly(benzyl ether) dendrimers, e.g., 17, involves the Williamson coupling of bromide **15** with a polyfunctional phenolic core, in this case, 1,1,1-*tris*(4′-hydroxyphenyl) ethane **16,** once again promoted by K_2CO_3/18C6, 3. In this procedure, the Williamson reaction is the key step of the overall process. In particular, the appropriate power of the base is the crucial factor for the reaction outcome. Solid potassium carbonate, activated by even catalytic amounts of 18C6 in dry acetone, fulfills this requirement.[27] The K_2CO_3/18C6 couple is widely used in the synthesis of other dendrimer structures bearing traditional and chiral[28] segments, and in the preparation of linear-dendric copolymers and dendronized linear polymers.[27]

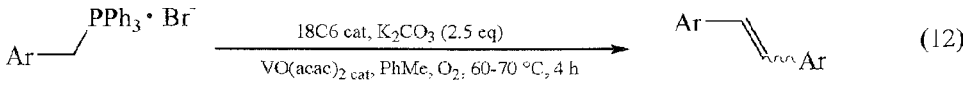
Similarly, K_2CO_3/18C6 was the base of choice for selectively performing mono- and dialkoxylation of cyanuryl chloride, affording the corresponding 2-alkoxy-4,6-dichloro- and 2,4-dialkoxy-6-chloro-1,3,5-triazines, valuable intermediates for the organic synthesis[i''' (Eq. 11).

Recently,[30] anhydrous K_2CO_3 in the presence of catalytic quantities of 3 in toluene was used as the base for the in situ generation of ylides from the corresponding phosphonium salts. This reaction is the first step of an one-pot eco-safer protocol for the preparation of olefins directly from phosphonium salts under oxygen atmosphere in the presence of $VO(acac)_2$ as the oxidation catalyst (Eq. 12).

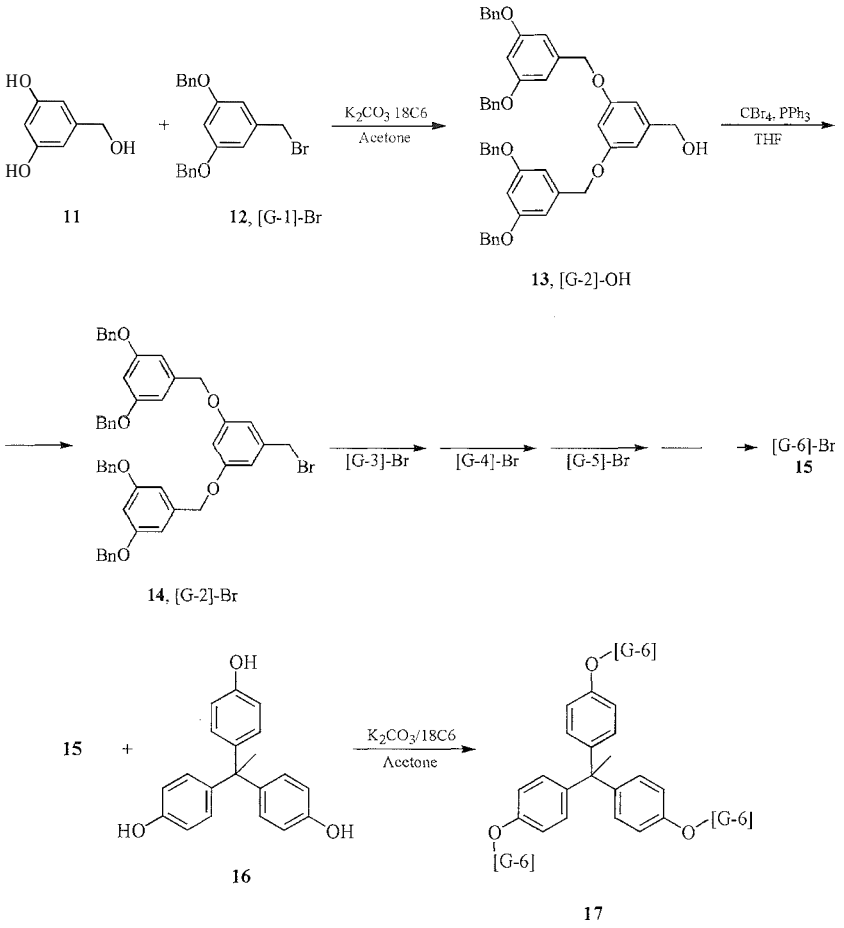
The efficient activation of poor nucleophilic acetate by crown ethers was exploited for introducing this versatile group in organic valuable molecules. For example, Nakata and coworkers developed an efficient method for the



(11)



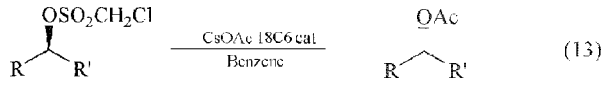
(12)



Scheme 1 Synthesis of poly(benzyl) ether dendrimers.

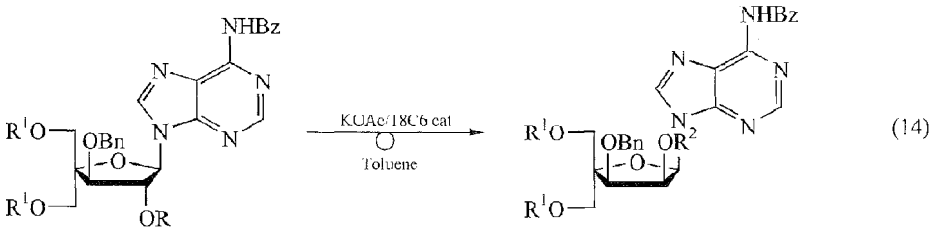
inversion of secondary alcohols by reaction of the corresponding chloromethanesulfonates with cesium acetate. activated by 18C6 in benzene (Eq. 13).

The reaction smoothly proceeds, affording the inverted *sec*-alkyl acetates in excellent yields, via a clean S_N2 reaction.[31] Recently. a similar protocol, i.e., KOAc/18C6/toluene. was applied by Wengel et al.[32] in interconverting C2′-epimeric nucleosides. key intermediates for the preparation of α-L-*ribo*-configured nucleic acids (Eq. 14).



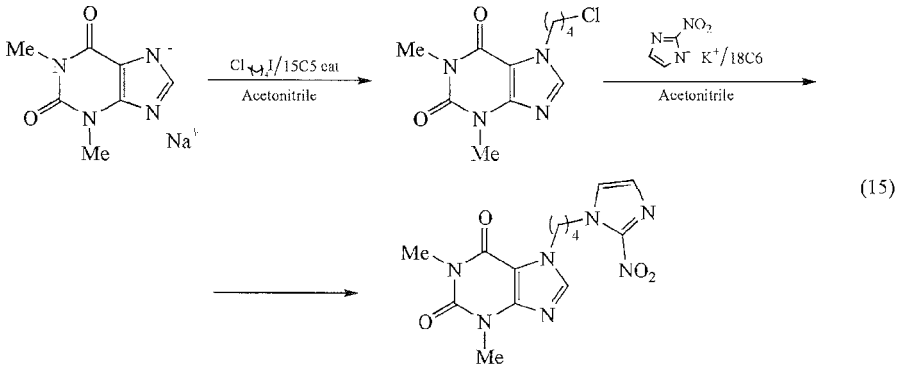
(13)

The N-alkylation of "naked" nitranions of 2-nitroimidazole and theophylline, generated from their alkaline salts in the presence of 18C6 or 15C5. was usefully applied to the synthesis of nitroimidazolylbutyltheophylline 18.



(14)

R^1 = Bz or Ms; R = Tf; R^2 = Ac



(15)

18

which is a probe to identify. locate. and quantify hypoxia in sections from solid tumors[33] (Eq. 15).

We found that K_2CO_3/DCH18C6 is an effective basic system for the in situ generation and reaction of activated trifluoroacetoamidide with 2-bromo carboxylic esters, affording the corresponding *N*-(trifluoroacetyl)-α-amino esters, valuable precursors of natural and unnatural a-amino acids[33] (Eq. 16). The reactivity of nitroanion activated by crown ether 5 was found to be comparable to that obtained by using bulky onium salts as anion activators:[34]

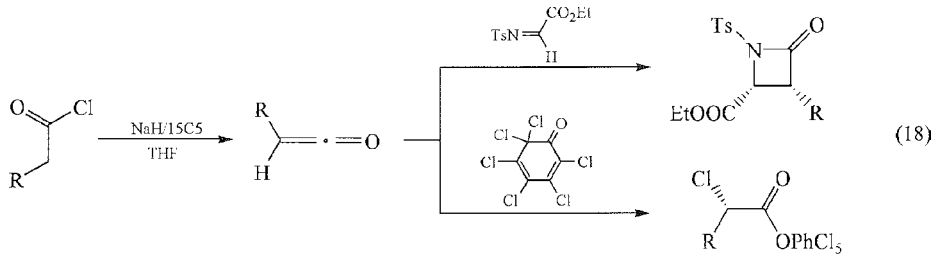
$$CF_3CONH_2 + RCH(Br)CO_2R^1 \xrightarrow[\text{Acetonitrile}]{K_2CO_3 \text{ solid/DCH18C6}} R(CF_3CONH)CHCO_2R^1 \quad (16)$$

The N-anions. generated in situ from aryl and hetero-arylamines and NaH/DCH18C6 5 in toluene. smoothly reacted with 4-chloronitrobenzene to give the corresponding diarylamines, the protocol being a possible alternative for the synthesis of diarylamines[35] (Eq. 17). Interestingly. kinetic data showed that the reactivity of (DCH18C6 ⊃ Na^+)$ArNH^-$ species in toluene is more than two orders of magnitude lower than that of $ArNH^-Na^+$ in DMSO in the absence of crown ether. The UV/Vis evidence indicates that such a behavior is mainly due to the different reacting species in these two media: mostly free ions in dipolar DMSO and ion pairs in the low-polarity toluene:[35]

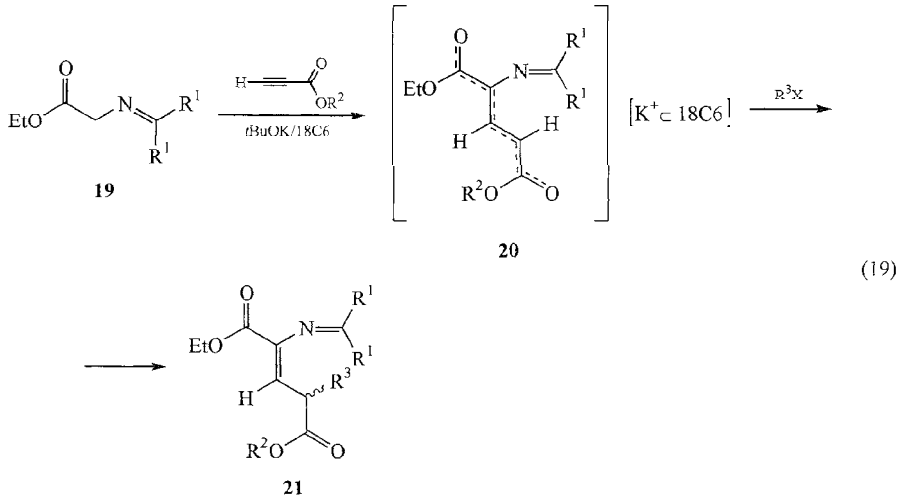
$$4NO_2C_6H_4Cl + ArNH_2 \xrightarrow[\text{Toluene}]{\text{NaH/DCH18C6}} 4NO_2C_6H_4NHAr \quad (17)$$

Leckta et al. recently described an efficient procedure for the in situ generation of reactive monosubstituted ketenes through dehydrochlorination of acid chlorides promoted by NaH/15C5 in THF. This new methodology was applied to a cost-effective, catalytic asymmetric synthesis of β-lactams and α-chloroesters, pharmaceutically useful classes of compounds[36] (Eq. 18).

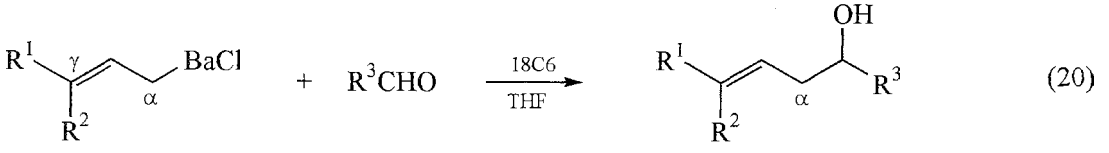
The last step of an efficient protocol for the one-pot synthesis of biologically important (*Z*)-γ-substituted-α, β-didehydroglutamates 21 starting from *N*-alkylidene-glycinates 19, involves the C-alkylation of intermediate alkaline dienolates 20 in THF. However, capture of 20 with an excess of electrophiles. such as MeI, failed even in the presence of DMPU as an anion activator. The generation of "naked" enolates by using 18C6 allowed for a smooth and efficient reaction[37] (Eq. 19).



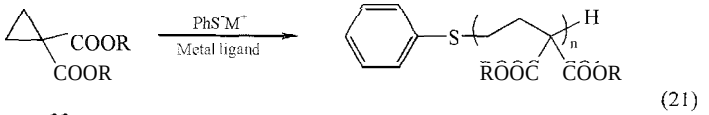
(18)



(19)



(20)



22

(21)

$M^+ = Na^+, K^+, [K^+ \subset 18C6], [K^+ \subset (2.2.2)]$

Similar results were obtained only in the presence of bulky Schwesinger's base.[37]

Yamamoto and coworkers reported that the complexation of allylic barium reagents with crown ethers, in particular 18C6. substantially improved the reactivity toward electrophiles. e.g., aldehydes, and α-regioselectivity of these organoalkyl derivatives in THF[38] (Eq. 20). By contrast. only a negligible effect of acyclic polyethers on the reaction was observed.[38]

The ability of polyether ligands to activate alkoxyde anions was checked in the etherification of primary alcohols with alkyl bromides, by using solid potassium hydroxide as a base. Results showed that the efficiency of the open-chain PEG2000 dimethylether 1 is similar to that of cryptand 9 and DCH18C5.[39]

In anionic ring-opening polymerization of cyclopropane-1,1-dicarboxylates 22 using sodium and potassium thiophenolates as initiators, the nature of the cation was found to play an important role in the rate and selectivity of the polymerization. In particular, reaction rate increased in the order $Na^+ < K^+ < [K^+ \subset DCH18C6] < [K^+ \subset (2.2.2)]$, relative rates being ≈1, 2. 6, and 15, respectively (Eq. 21).[40] According to the authors. these results suggest that the anionic polymerization involves ceveral kinds of propagating species in equilibrium with each other (aggregates, contact ion pairs. solvent-separated ion pairs, and free ions), the relative contribution of each depending on the nature of the counterion. As expected. the complexation of the potassium ion bicyclic polyether ligands, in particular, cryptands, gives rise to highly reactive "naked" carbanions.[40]

CONCLUSION

Lipophilic polyether ligands, like crown ethers, cryptands, polypodands. and quaternary onium salts. proved to be efficient activators of anions ("naked anions") in low-polarity media. In these solvents. they give rise to ion pairs particularly reactive due to the low stabilization by the solvent and the low interaction with the bulky cation. The reactivity of these ion pairs is even higher than that

observed in dipolar aprotic media, where mostly free ions are present. It *mainly depends on the ability of the ligand to induce cation–anion separation. increasing in the following order: open-chain < cyclic < bicyclic polyether. The use of these complexing agents in catalytic amounts (LL-PTC or* SL-PTC) *revealed considerable improvement for synthetic applications due to the high cost of these cyclic polyethers, especially cryptands. in comparison with the open-chain analogues and quaternary* onium *salts. The LL-PTC conditions with concentrated aqueous alkaline solutions allow the transfer into the organic phase of the anions largely or completely* nonhydrated, *so obtaining the same reactivity of the anhydrous homogeneous phase. This is particularly useful for high-charge-density anions* (OH^-, F^-, *oxanions, carbanions, etc.). with reactivities that are* dramatically *reduced by the specific interaction with a limited number of water molecules. Anion activation realized by lipophilic polyether ligands and quaternary* onium *salts in anhydrous low-polarity media is probably the highest obtainable in solution. approaching that of the gas phase.*

The application examples, here discussed, clearly indicate that anion activation remarkably improves *several synthetic procedures and is often essential for the outcome of certain reactions. From a practical point of view. the criteria for selecting an anion-activating system (quaternary* onium *salts.* PEGs, *crown ethers, cryptands, etc.), especially in* industrial *applications, include considerations dealing with efficiency. stability. availability. recycling. and cost. Quaternary* onium *salts and crown ethers appear to be the best compromise; indeed, they fulfill many of* these *requirements. The high cost and the scarse availability of lipophilic cryptands are strong limitations to the use of these very active anion activators. The cheap PEG* dimethyl *ethers can be the ligands of choice when a limited anion activation is required.*

Nanocasting Strategies and Porous Materials

Sebastian Polarz
Ruhr-University Bochum, Bochum, Germany

INTRODUCTION

Recent efforts of scientists worldwide concentrate on structuring all sorts of matter on a nanoscale. This structuring process is the key to nanotechnology. One fascinating class of nanornaterials are those with pores of the order of just several nanometers in width, possessing a mutual correlation *to each other (order), so-called ordered nanoporous materials. Therefore, methods to obtain control over pore size, pore shape. pore correlation,* and *ultimately pore surface are highly desired. A process enabling this superior level of* materials *design is the so-called* nanocasting *technique.* Nanocasting *is related to a method known to all of us in the macroscopic world transferred into the nanoscale dimensions, namely. the molding technique as used for the production of church bells.*

Organic template structures derived by self-assembly processes of amphiphiles *are imprinted into cross-linked networks. mostly of the inorganic type. The* template *morphology determines the structure and morphology of the entire pore system. Furthermore, detailed investigation of the pore structure allows inferences to be dl-awn about the template, and therefore. about the* self-assembly *process.*

Many applications of nanoporous materials relate to more than pure size-sieving effects. One interesting field is the use of nanopores *as nanoreactors.*

THE PRINCIPLES AND RULES OF NANOCASTING

Template⟶Materials Relationship

One goal of nanoscience *in* general *and in the field of* nanoporous *materials''' in particular is to achieve control over the architecture of matter on the nanoscale* (1–*100* nm). *Because porous materials are divided into the subgroups* microporous *(voids* smaller *than 2 nm).* mesoporous (voids *between 2–50 nm). and macroporous (voids larger than 50 nm), it becomes obvious that these materials are raw* models *for nanostructured matter. Three criteria can be formulated to* evaluate *the ultimate goals in the synthesis of* porous *materials:*

Criterium I: *Control over pore size.*
Criterium II: Control *over pore shape.*
- Criterium *IIH: Control over pore-surface* functions.

If one *considers how* to *fulfill these three criteria: it seemed to be beneficial if* it *was possible to apply a* bell-*casting process on the* nanoscale *(Fig. la).*

At first. a suitable template *structure needs to be provided, as demonstrated in Fig.* 1b. *This template can range from molecules* (i, ii) *to* assemblies *of molecules* (ii–iv, *v) to colloidal* particles *(v) or even to* assemblies *of colloidal particles* (vi). *The template* is *then surrounded by liquid (or dissolved) network precursors that are subsequently cross-linked. After* removal *of the template (depending* on *the network materials and template. this is done by calcination. liquid–liquid extraction.* ion-exchange, *or etching), a void is left over with a structure that is fully determined by the template. Normally. when single molecules are used as templates. microporous materials are derived. Famous examples for this case are zeolites or* moleculary imprinted polymers.[1] *Colloidal crystals as templates lead to* macroporous solids *with photonic properties. However. for this article. templates made from* self-assembling *molecules are of special importance. These* molecules. *so-called amphiphiles, contain one hydrophilic and one hydrophobic part. as* shown *in Fig.* 1b(ii). *In aqueous systems.* these *chemically different molecular parts tend to microphase separate, and depending on concentration. self-assembly to* micelles *(iii) or* lyotropic liquid crystals *(iv) occurs (see Fig.* 1). *Typically. these* templates *lead to* mesoporous *structures.*

Boundaries sf Nanocasting

It was indicated *in the previous* section *that the promise of nanocasting is* that the template morphology *will* fully *determine* the *structure of the porous system. However. certain conditions have to be fulfilled* in *the template–network combinations in order to make the* nano-*casting process work.*

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019195

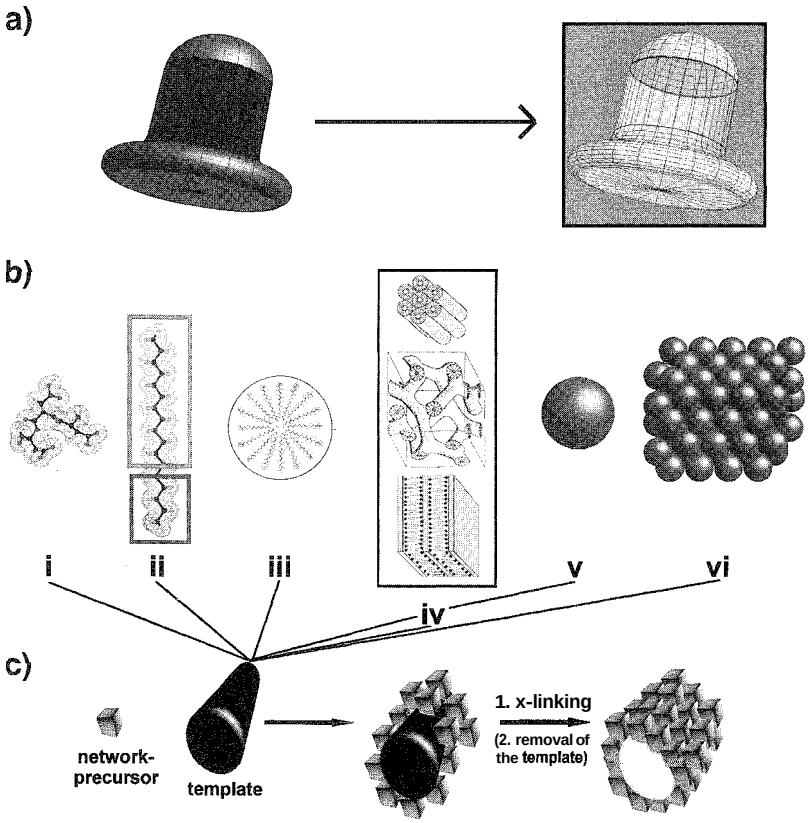

Fig. 1 It is shown how ideas from the ancient bell-casting technique (a) are transferred to obtain nanoporous materials (b–c). This process, accordingly named nanocasting, uses nanoseale template structures (b) ranging from molecules (i) to colloidal crystals (vi). This template structure is imprinted into a solid hybrid material (c). Finally, after removal of the template, one ideally achieves a pore resembling the template. (*View this art in color at www.dekker.com.*)

The template structure needs to be compatible and dispersion-stable in the solvcnt–network precursor system throughout the entire nanocasting process and during the solidification of the network phase (via polycondensation or cross-linking, for instance). Macrophase separation has to be avoided at all times. Therefore, repulsive forces between the template and the network precursors must be avoided. However, in cases where the forces between these components are strongly attractive as, for instance, between a positively charged template and negatively charged network species, cooperative effects are likely to occur, which restrict the direct relation between the template morphology and the pore. A typical example for this case is the preparation of the well known MCM-41[2] material, where cylindrical pores resembling a hexagonal liquid crystal are obtained, although the concentration of the cationic surfactant CTAB is even lower than the CMC (critical micelle concentration). It can be concluded that providing weak attractive interactions between the template and the network source is the key for the nanocasting method. Hydrogen-bonding interactions are ideally suited for this purpose.

Simple considerations make it obvious that the porous materials created arc characterized by high surface area and, therefore, also high surface energy. The porous materials are only metastable in comparison to the corresponding bulk state due to this vast interface energy. 'A high degree of cross-linking as observed for most silica materials demands such a high activation energy for restructuring processes that the pore structure is stable practically infinitely. Additionally, it should be noted that the pore walls represent a confined situation. If amorphous phases or entropically restricted phases are thermodynamically significantly less stable than the bulk or crystalline counterparts, nanocasting is restricted. Two examples should elucidate this point. Crystallization processes often occur for porous transition-metal-oxide materials, and it is hard to maintain the full integrity of the pore structure at higher temperatures. Many attempts were also made to produce ordered mesoporous polymer materials via nanocasting procedures.[3] The high flexibility and the entropically unfavorable situation of limiting the polymer conformation inside the thin walls make it practically impossible to nanocast polymers with

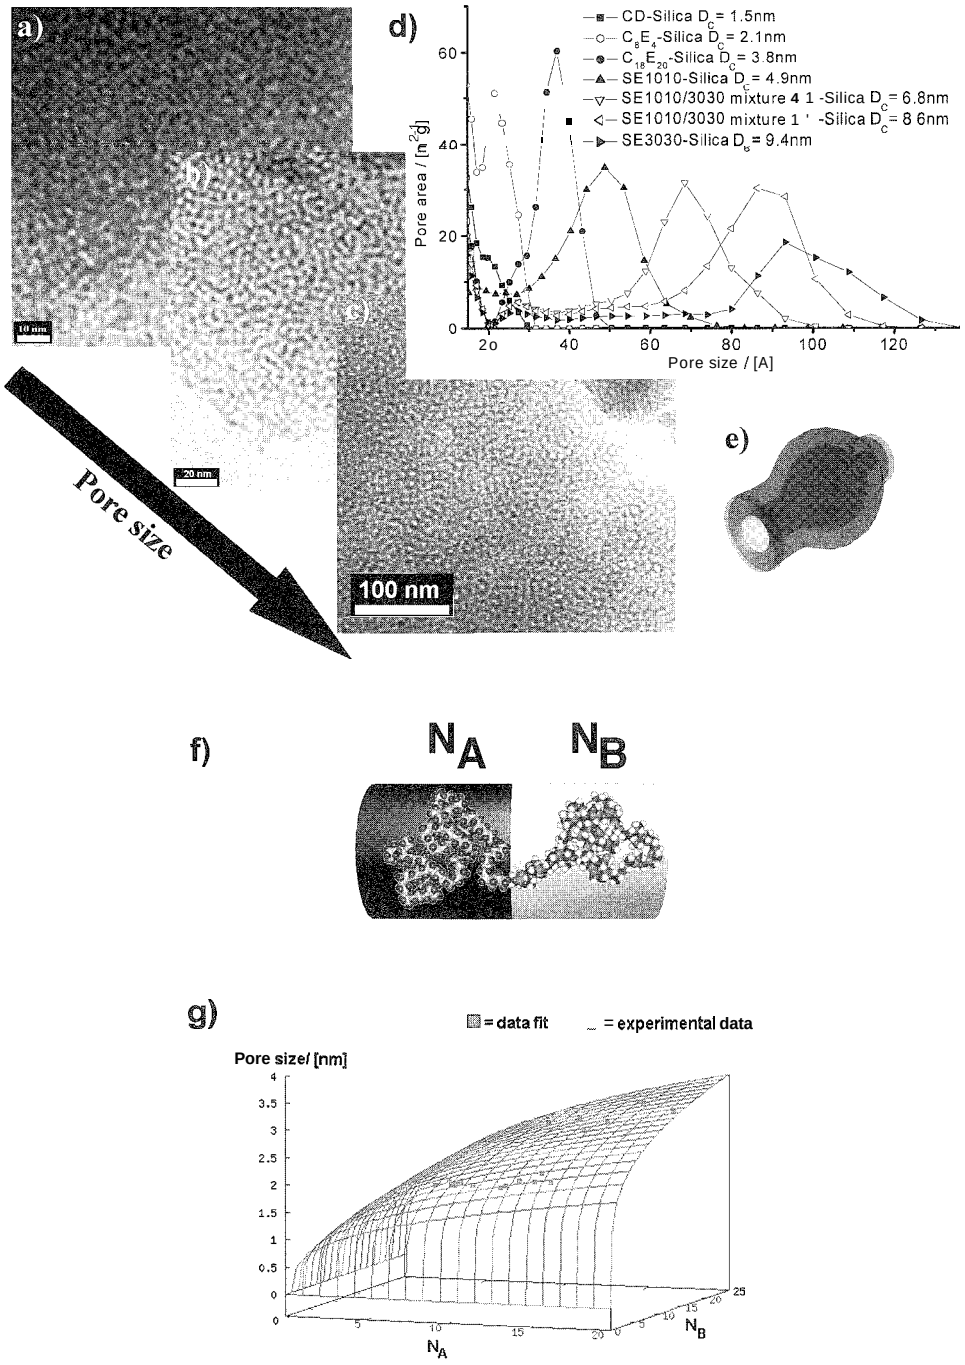

Fig. 2 (a–c) Transmission electron microscopy (TEM) images of mesoporous materials obtained via nanocasting of self-assernbled structures of amphiphiles of different sizes. The smallest type of templates CDs (cyclodextrins will be mentioned later) lead to the smallest pores of 1.5 nm in diameter, as also determined by N_2-sorption experiments and correlating pore-size distributions (d). Block copolymer systems such as SE (polystyrene–polyethlylencoxide) lead to larger pores of the order of 5–10 nm. A model for the obtained pores is given in (e). The amphiphilic molecules can be described by the number of monomeric units in each of the amphiphile chains (f). The hydrophobic block is characterized by N_A, and the hydrophilic block is characterized by N_B. (g) This part shows how the pore sizes correlate to N_A and N_B for Brij [alkyl-poly(ethylene oxide)] surfactants. (*View* ***this*** *art in color at* www.dekker.com.)

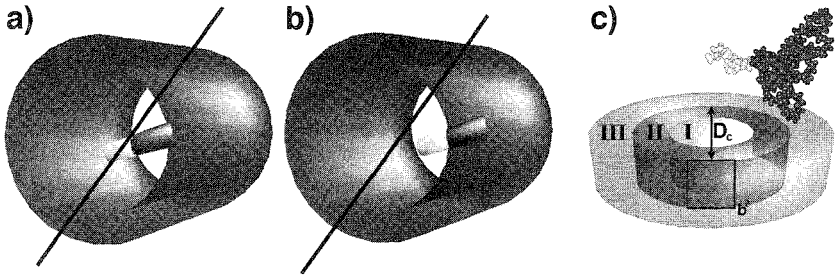

Fig. 3 The three possible scenarios of how the amphiphilic molecule (yellow–blue units) create a pore. (a) The "one-phase" scenario, where both blocks, hydrophilic and hydrophobic (yellow), contribute with full length to the pore. The classical view (b) expects a microphase separation, whcrc the hydrophobic core would determine the pore size, while the hydrophilic shell would be dissolved in the aqueous network-precursor medium. (c) The "three-phase" scenario proved to represent thc results most accurately."[7] (View this *art* in color *at* www.rlekker.com.)

amphiphilic templatc structures. Only when the templates are much bigger, which results in thicker walls, can successful nanocasting be achieved. For instance, inverted polymer opals exist.[4]

DESIGNER MATERIALS VIA NANOCASTING

It will be demonstrated in this section how the Criteria I–III mentioned in the first section of this article, desirable for porous nanostructures can be controlled via nanocasting. Therefore, it is not unrealistic to state that nanocasting materials are "designer materials."

Gaining Control over Pore Size

Within thc philosophy of nanocasting, it is straightforward to expect that the size of the template will directly influence the size of the pores. As larger amphiphilic molecules will lead to larger self-assembled structures (lyotropic phases with respectively larger periodicities), a correlation should be shown as well.

Howcvcr, at first it is important to know if, in principle, larger pore sizes are possiblc, as it is known, for instance, for zeolithes (with crystalline alumosilicate walls) that there is a natural limitation. Navrotsky et al. were able to show that there is, in principle, no limitation for accessible pore sizes in amorphous silica materials.[5] They demonstrated that the amorphous silica in materials like MCM-41 is only marginally less stable than the most stable form of SiO_2, crystallinc quartz. This means that suitable experimental pathways have to bc found to reach a certain pore size. Then, the materials are stable. One of these pathways, and maybe the best one, is nanocasting.

A series of experiments with different-sized templates proves that this assumption is correct (see Fig. 2). Larger amphiphiles lead to larger templates and, thus, to larger pores.

However, more details would be desirable. It is possible to express the architecture of an amphiphilic moleculc by the number of units in the molecular chain. For instance, N_A would denote the number of CH_2 atoms, and N_B would denote the number of ethylene oxidc units in so-called Brij surfactants (see Fig. 2f). It is then possible to relate the sizc of the pores to the molecular architecture of the templatc molecules for a row of compositions (see Fig. 2g). Interestingly, the pore size depends on the size of both blocks. Classically (Fig. 3b), a microphase separation of the hydrophilic parts and hydrophobic parts into separate domains is expected. In this case, the pore-size dependence on both molecular parts is impossible. A "one-phase" scenario as depicted in Fig. 3a can also be excluded due to many reasons, which will not be further discussed here.[6]

It seems in Fig. 2g that all the experimental points are lying on a master surface, which is a first indication that there might be a physical law describing the correlation between the pore size and the molecular architecture of the amphiphile. However, because neither the one-phase nor the two-phase model was appropriate to describe the data (as shown elsewhere),"[7] a new model was needed. It seems that in addition to the hydrophobic core (bright yellow), a certain fraction of the hydrophilic poly(ethylene oxide) (PEO) chain contributes to thc size of the mesopore D_c (areas I and II in Fig. 3c). Only the remaining fraction of PEO is imbedded in the pore wall. By considering the total volume given by the number of units in the amphiphile chain and the stabilization of thc interface I + II/III, it was finally possible to derive an equation that relates the mesopore size D_c to the molecular composition of the amphiphile expressed as $N_{A/B}$ (see Eq. 1):

$$D_C = \frac{c}{N_A^{0.16} N_B^{0.40}} \{K_I [N_A]_I + K_{II}([N_B]_{II} - [0.26N_A + 0.24N_B]_{III})\}$$

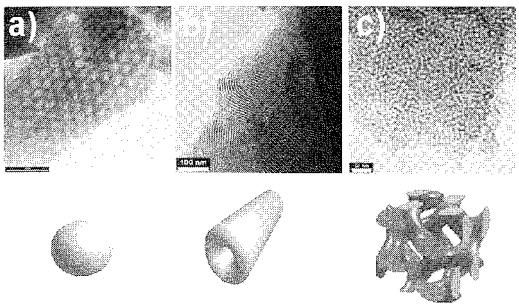

Fig. 4 Three alternative pore shapes are shown schematically and in TEM images for spherical pores (a); cylindrical pores (b), and bicontinuous, "worm-type" pores (c). (View this *art* in color *at www.dekker.com.*)

The constants $K_{I/II}$ contain molecular parameters, and a more detailed description of the derivation of this equation is given in Ref. [6]. Surprisingly, pore sizes can be adjusted by applying mixtures of chemically similar but different-sized amphiphilic molecules, as shown in Fig. 2d. This is a key result, because it is now possible to obtain every pore size between two borders determined by the "parent templates." Nevertheless, it is worth mentioning alternative ways to influence and control pore size. It was already demonstrated that a possible way would be to select an amphiphilic molecule with a suitable molecular composition in order to obtain the desired pore size. However, it is practically impossible to get all of these amphiphiles, or at least it is tedious to synthesize them. The dependence of the pore size on the length of ammonia-based surfactants was demonstrated by the first works of Beck, Vartuli, Kresge, et al.[2]

Two additional routes to change pore size are as follows:

- Swelling of the lyotropic phase by adding selective solvents.[7]
- Changes in reaction parameters like temperature or electrolyte concentration.[8]

It can be concluded that nanocasting allows for control over pore size.

Gaining Control over Pore Shape

The analogy between nanocasting and bell-casting can be further used to influence the shape of the pore. Spherical templates (micelles) lead to spherical pores, cylindrical templates to cylindrical pores, and bicontinuously interwoven templates to bicontinuous and highly curved pore systems. This is shown in Fig. 4.

Therefore, nanocasting allows for control of the pore shape.

Gaining Control Over the Pore-Wall Surface

The ultimate goal in materials design would be achieved if in addition to size and shape the properties of the pore surfaces could be chosen by demand. Thus, one needs to overcome the limitation of SiO_2 as the network material. Either the silica is modified with organic groups or other network compositions are treated with nanocasting.

Organic modification of the pores without affecting pore size and shape was realized recently. Here, silica-network precursors with bridging organic ligands $(OEt)_3Si–R–Si(OR)_3$ are used for the preparation of ordered mesoporous materials. The organic groups practically cover the pore walls, as can be seen in Ref. [9]. Neither pore shape nor pore size are altered due to the use of the modified precursors. Furthermore, nanocasting (as, for instance, creating pores of different sizes) is fully applicable (see Fig. 5). It also brings the benefits of preparing monolithic materials.

This tool allows coverage of the walls of the pores with functional groups R, and thus control of the properties of the pore walls.''' For instance, the pore wall can be adjusted to show $Si–CH_2–Si$, $Si–CH_2CH_2–Si$, $Si–CH{=}CH–Si$, $Si–C_6H_4–Si$ motifs, and many more. Crystallinity in the otherwise amorphous walls was also achieved.[10]

Many experiments were designed to obtain ordered mesoporous materials with completely different compositions of the network no longer correlated to silica. Also here, nanocasting is beneficial. Due to their high relevance in many areas of catalysis and their variable redox- and magnetic properties. much work was devoted to the creation of stable ordered mesoporous transition-metal oxides. In the meantime, many compositions with Ti, Zr, V, Ta, Mo, W, Mn, and Y, as the central element were introduced."[11]

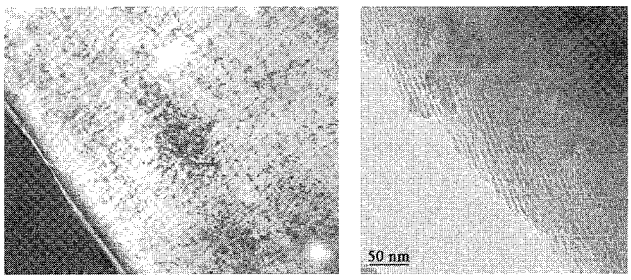

Fig. 5 Ordered mesoporous materials with double bonds (C=C) covering the pore walls obtained via nanocasting a Pluronic liquid crystal. The high degree of ordered nanostructure is shown by polarization optical microscopy (left) and TEM (right). (*View* this art in color *at* www.dekker.com.)

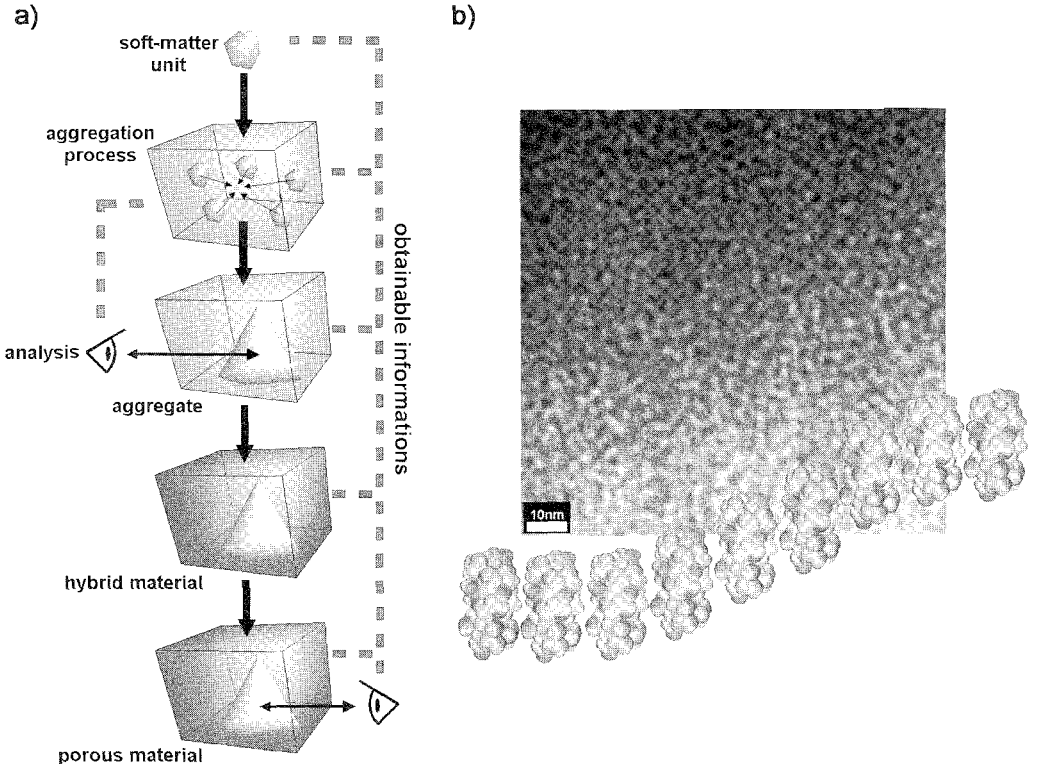

Fig. 6 (a) Shown is how the nanocasting principle may be applied as a new technique to investigate soft-matter aggregation in water. Instead of investigating the soft-mattcr aggregate directly, those aggregated are as templates cast into a solid silica mold, and the porc structure is finally investigated. Under nanocasting conditions. it is possiblc to relate the pore to the shape and size of the template. (b) Shown is how this concept was successfully applied to elucidate the aggregation behavior of cyclodextrin molecules in water.[12] Worm-type pores as presented in the TEM image allowed for the conclusion that cyclodextrin molecules self-assemble to aggregates. where the exterior hydrophilic domain shields the interior hydrophobic domain (see schematic). (View *this* art in color *at www.dekker.com.*)

NANOCASTING AS AN ANALYTICAL TECHNIQUE

So far, nanocasting was presented as a method to produce innovative and state-of-the-art materials. It would bc interesting to explorc if it is possible to invert this idea, namely to discover something about the self-assembly of a sort-matter unit by investigating the nanocast pore structure. The idea behind this concept is shown in Fig. 6a. Here, soft-matter aggregates are interpreted as templates for the nanocasting process. Accordingly, the size and shape of the pore is determined by the template. Instead of investigating the soft-matter structure in water directly, the pore structure can be used to yield information about the guest template aggregates. The analytical processing of a solid, porous material is easier to achieve than for the correlating dispersed aggregate. The electron contrast between void space and porc wall is very high, which increases the contrast for any scattering technique. The porous silica is stable against most conditions, such as ultrahigh vacuum uscd in electron microscopy, excluding solvents The pores are fixed in position and, therefore, do not represent a time average The last point is somewhat problematic, because dynamic information is lost It is, for instance, not possible to determine the weight of the aggregate via nanocasting

Some examples should elucidate the use of nanocasting as an analytical technique

Nanocasting and the Conformation of Amphiphiles

The reader might have been wondering about the origin of the following term in Eq. 1:[6]

$$\frac{1}{N_A^{0.16} N_B^{0.40}}$$

This relation stems Pi-om the description of amphiphiles in polymer physics, as follows:

$$b^2 = b_0^2 N_A^{\alpha} N_B^{\beta} \qquad (2)$$

and describes how the interface area per amphiphile scales with the molecular composition. The exponents α=0. 16 and β=0.40 are the outcomes of the experiments described in the section "Gaining Control over Pore Size" and in Ref. [6]. However, if one realizes that the volume of the molecular chain X in general scales with $V \propto L \cdot b^2 \propto N_X^1$, it is possible to conclude that the length l of the hydrophobic chain A scales as $L \propto N_A^{0.86}$. In comparison to this, the hydrophobic chain in a micellar system (diluted situation) scales with $L \propto N_A$ (stretched conformation),"" while chains in a polymer melt scale with $L \propto N_A^{0.66}$ (coiled chain).[14]

In conclusion, nanocasting gives detailed information about the formation and structure of molecules in lyotropic liquid crystals. without having investigated organic matter. Just the fine details of the pore structure reveal these secrets: It seems that a classical two-phase separation model is not fully applicable to lyotropic liquid crystals (high-concentration situation). but it seems that a fraction of the hydrophilic block belongs to the micellar core. Furthermore. it was seen that the chain conformation is an intermediate between stretched (micelles) and coiled (polymer melt).

Nanocasting end the Aggregation of Cyclodextrins

Cyclodextrins (CDs) are cyclic oligosaccharides, and it is known that they possess a hydrophilic shell and a hydrophobic core. Despite their high technical potential and academic importance, little is known about the structure of cyclodextrins in water.[12] Both opinions of aggregated modes and nonaggregated states were discussed in the literature. Nanocasting aqueous CD solutions were used to approach this problem (Fig. 6b). Interestingly, no disordered materials were found. Instead. the experiment revealed materials with a well-defined pore size and a worm-type structure. The size of the pores inatched the size of a single-CD molecule, and the order of the materials was highly dependent on the hydrophilic–hydrophobic difference of outer and inner CD moieties. It was, therefore. reasonable to argue that cyclodextrins self-assemble to worm-type aggregates in water.[12]

Nanocasting end Polyoxometalates

As pointed out before, it can be hard to investigate supramolecular species in solution. This is true for a particula inorganic system, the so-called giant polyoxometalates prepared by Müller et al.[15] Although these fascinating compounds are fully characterized, it was an open question as to if these large clusters can be dissolved and if crystallization is a driving force for their formation. In other words, it was questioned if these giants exist only in the solid state or also in solution. Again. nanocasting was able to shed some light onto this problem. Aqueous solutions of giant polyoxometalates were nanocasted into a solid silica material. and in both cases studied, the spherical keplerate and the disk-like giant wheels were found to be dispersed in the material.[16] Therefore. it was clear that giant polyoxoinetalates exist in solution. and new materials were prepared.

Nanocasting and Swelling of Lyotropic Phases

Another interesting phenomenon is observed via nanocasting when trimethylbenzene (TMB) is added to the lyotropic phase of a Pluronic block copolymer for the preparation of SBA-15[17] to increase the pore size by swelling. At a certain ratio. mesocellular foams are obtained. as Stucky et al. pointed out.[17] The ideal hexagonal structure of SBA-15 is maintained only for relatively low concentrations of TMB. When the oil-to-polymer ratio is 0.2–0.3. the silica walls begin to buckle, forming nodes accompanied by an increase in pore size. If the amount of oil is increased further, the nodes undergo a transition to spherical pores ($d \approx 20$ nm), the so-called mesocellular foam. The explanation for this phase transition lies in the reaction of the iyotropic phase due to a change in the surfactant parameter by adding a hydrophobic solvent. The TMB Is located in the hydrophilic PPO regions of the amphiphilic assemblies. which changes the packing pararneter of ihe surfactant and finally leads to the transition of micelles to microemulsions.[7]

NANOCHEMICAL APPLICATIONS OF NANOCASTING MATERIALS

As nanocasting allows us to obtain porous materials with desired pore sizes and shapes. these materials are ideal candidates to act as nanoreactors[18] or to study host–guest relationships. However, the latter is a topic in its own right and is not mentioned here in further detail.

But. the analogy given previously that nanocasting is a bell-casting technique on the nanometer scale is not absolutely correct. Because for bell-casting, the first hollow replica is filled again to get the desired material in its desired shape. Therefore. it would be tempting to be able to use mesopores as a cast for new materials. showing the structure of the original organic liquid crystal.

Many scientists successfully realized this goal. The pore system can be infiltrated with precursors for metals. semiconductors. or polymers. and afterwards, a suitable reaction is carried out. and the empty pore space is

transformed into a metal, for instance. It was shown that the pore determines the shape and size of the new nanoparticle.[19] A lot of work was done in the field of polymerization in ordered mesoporous hosts.[20] Just one example among many should be mentioned.[21] Kageyama et al. connected a titanocence catalyst covalently to the pore walls of MCM-41. When the polymerization of ethylene is performed, the poly(ethylene) chain is hindered to bend backwards. so it has to grow along the channel axes. This results in the situation that hexagonally aligned polymer fibers leave the MCM-41 "crystals." Finally. bundles of several polymer fibers with diameters 30–50 nm form. The obtained molecular weight is extremely high (M_n=62,000,000).

As described earlier. the other important subfield of nanochemistry in ordered mesoporous materials is the creation of nanoparticles. Due to the high interface energy, once-nucleated nanosized crystals tend to grow by Ostwald ripening. This growth can be restricted by performing the crystallization inside the pore system of a mesoporous host. Often, caused by quantum size effects, interesting composite materials are created. Therefore, much of the work was devoted to the preparation of semiconductor nanoparticles via this route. Examples are gallium nitride, cadmium selenide. cadmium sulfide. silicon, titanium dioxide, germanium, gallium arsenide, zinc sulfide, and indium phosphide.[1,22] Ordered mesoporous silica materials, especially of the MCM-41 type, were also used as matrices for the preparation of metal colloids. In this way, for example, metal nanowires were produced with Pd, Pt, or Ag.[23,24]

A different, interesting topic is one where the whole pore system is transformed into carbon. This interesting area of producing ordered porous carbon materials was reviewed elsewhere.[25,26]

CONCLUSION

Reviewed in this article was the so-called nanocasting process. which is the three-dimensional transformation of self-assembled organic structures (templates) into hollow inorganic replicas. This process allows for significant control over the morphological features of the resulting porous materials. Most importantly. pore size can be controlled via mixed-template routes. Furthermore. the pore size was rationalized as a dependence on the molecular compositions of the template. Additionally, pore shape can be tuned by selecting different-shaped templates. Nanocasting still holds when network precursors other than those leading to pure SiO_2 are used. Organically modified materials or other porous inorganic oxides can be achieved. Furthermore, nanocasting allows for the production of porous materials of different macroscopic appearance as monoliths or thin films.

This high level of materials design enables researchers to go one step further. to use the cavities (pores) of well-defined sizes, shapes. and surface functionalities to perform chemistry under confined conditions.

Neutron Diffraction

Chick C. Wilson
University of Glasgow, Glasgow, United Kingdom;
Central Laboratory of the Research Councils (CLRC) Rutherford Appleton Laboratory, Oxon, United Kingdom

INTRODUCTION

The general characteristics of neutron diffraction as applied to studies of condensed matter are summarized, along with their means of production in steady-state reactor and pulsed spallation sources. Techniques for single-crystal neutron diffraction are discussed, and the application of these techniques in the study of molecular systems is summarized. A short review of applications in the field of molecular crystals is given. A more detailed account of this area was recently published.[1]

NEUTRON SCATTERING

Neutrons are, in many ways, unique probes of condensed matter. In many cases, the information available from neutron scattering is not only conveniently measured using the technique but is also the only method with which to obtain the information. In contrast to other techniques such as x-ray or electron diffraction. neutrons are scattered by the nucleus, rather than by the electrons in an atom. As a consequence, the scattering power, given by the scattering length, b, does not vary monotonically with Z (Fig. 1). This means that neighboring elements in the periodic table generally have substantially different scattering cross sections, offering a direct method of distinguishing neighboring elements. The dependence of the scattering on the nucleus also allows isotopes of the same element to have substantially different scattering lengths for neutrons, thus allowing the technique of isotopic substitution to be used to yield structural and dynamical details. In the area of organic and biological molecular structures, the most relevant isotopic substitution is that of ^{2}H (deuterium, scattering length 6.67 fm) for ^{1}H (hydrogen, scattering length -3.74 fm). The use of contrast variation, where the scattering density of different parts of a molecule or of an H_2O–D_2O mixture is altered. is powerful and has been key to many successful applications of neutron scattering in chemistry and biology.

In addition, with neutrons it is easier to sense light atoms, such as hydrogen. in the presence of heavier ones. For example. in the presence of relatively light carbon atoms, a hydrogen contributes around 0.32 of the measured neutron scattering intensity (proportional to b_2) for a carbon atom. The equivalent ratio for x-rays is less than 0.03, meaning that hydrogen atoms are determined around 12 times more accurately with neutrons than x-rays in the presence of carbon atoms. This factor increases as the atomic number of the "heavy" atom increases.

The lack of a fall-off in scattering power as a function of scattering angle also gives us the ability to study structures to very high resolution with neutron diffraction.

Among the other properties of the neutron that make it a successful probe of structure is the fact that neutrons interact weakly with matter and are therefore nondestructive, even to complex or delicate materials. Similarly, neutrons allow probing of the interior of materials, not merely the surface layers as probed by x-rays, electron microscopy, or optical methods. Neutrons also have a magnetic moment, allowing magnetic structure (the distribution of magnetic motnents within a material) and magnetic dynamics (how these moments interact with each other) to be studied in a way not possible with other forms of radiation.

There are also some drawbacks, however, largely due to sample size and data collection time requirements. With the relatively low flux of neutron sources and the weak scattering of most materials, usually crystals of several mm' are required to allow for the collection of a good data set in a reasonable data collection time. The limit is usually regarded as being around 1 mm^3, but there are significant efforts being made by source and instrument designers to allow this to be reduced further, as we shall see below. Assuming an appropriate sample is available, the choice between neutron and x-ray diffraction in the study of molecular systems is often clear cut. If there are one or more hydrogen atoms in the structure, of which location is critical to a complete understanding of the system, its configuration, and its interactions, then neutron diffraction should be the method of choice. In general; hydrogen atoms can be treated on an equal basis with the other atoms in a neutron diffraction experiment. More subtly, if some or all of the hydrogen atoms can be exchanged for deuterium, the use of contrast variation methods renders neutron diffraction still more powerful.

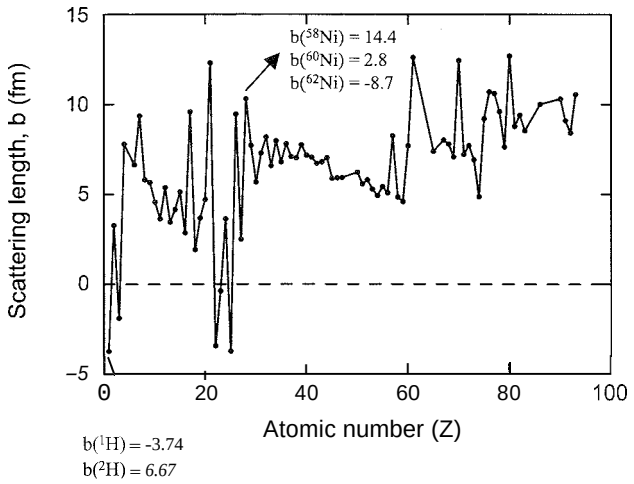

Fig. I Neutron scattering lengths vary randomly as a function of atomic number. In addition, isotopes of the same element can have substantially different scattering lengths, two representative examples. H and Ni, being shown here.

Neutron Sources

The characteristics of the two types of neutron sources (nuclear reactors and accelerator-driven spallation sources) used for condensed matter research are very different. A reactor is a steady-state source, in which neutron production is continuous. The neutrons produced are slowed (moderated) for use in neutron scattering experiments. Typically these neutrons are then passed through a monochromator. or filter. to select a wavelength, or wavelength range, to be used in the experiment. The 58 MW high flux reactor at the ILL. Grenoble, France. operational since 1973, is the highest flux research reactor in the world dedicated to neutron scattering and the study of condensed matter. Details can be found on the Web page http://www.ilI.fr/.

In a spallation source. the neutron production is normally pulsed, and all neutrons are effectively produced at the same time, when the proton beam hits the target. This leads to a tight pulse that must be retained for use of the white-beam time-of-flight technique, essential at such a source. The high-energy neutrons are thus slowed to thermal energies by using small hydrogenous moderators that retain the pulse structure. The use of pulsed spallation sources for neutron scattering science was largely established in the past two decades or so. The highest flux pulsed neutron source is currently the 160 kW ISIS facility at Rutherford Appleton Laboratory in the U.K. Details can be found on the Web page http://www.isis.rl.ac.uk/.

Future Neutron Sources

For practical technological reason, it is difficult to achieve substantially higher flux at a reactor-based steady-state source. The inherent limits of reactor technology mean that a factor of five in flux is the most one could realistically hope to achieve, though there is a vigorous program of instrument optimization and upgrading to ensure optimal use of the available flux. For pulsed sources, the situation is different. The ISIS will remain the brightest pulsed neutron source for several more years. and its capacity is likely to double in the next few years. as a second target station is constructed to host a further suite of neutron scattering instruments. There are currently in construction 1–2 MW pulsed sources in the U.S. and Japan. These will be six to 12 times more powerful than ISIS. Looking forward. the proposed European Spallation Source would provide a 5–10 MW pulsed neutron source, 30–60 times the power of ISIS. which would combine the time-averaged flux of the best reactor source (produced at 1/10th of the power consumption) with the benefits of the pulsed structure from a spallation source—a true next-generation source.

SINGLE-CRYSTAL NEUTRON DIFFRACTION

In order to meet the needs of scientists working on modern aspects of structural molecular science, such as supramolecular chemistry, the instrumentation used for neutron diffraction determinations has developed enormously over the last few years. This was an essential advance, because neutron diffraction is intrinsically a flux-limited technique, due to the relatively low neutron fluxes available from even the most advanced sources. For the structural determination of a sample under a set of variable conditions, experiment times of a few hours per determination are becoming the norm. This also allows for the screening of larger numbers of different materials. further increasing the power of the technique in this area.

On a steady-state neutron source, traditional four-circle diffractometer techniques[2] are normally used for single-crystal diffraction, with a monochromatic beam and a single detector. Rotations of the crystal (and detector) are used to allow measurement of each reflection sequentially. For each Bragg reflection, it is necessary to set up a scan in order for the reflection intensity to be recorded. In such cases, all reflections are observed with the same neutron wavelength. eliminating the need for wavelength-dependent corrections. The constant wavelength nature of the data collection and the steady state of the source also remove the need for correcting data for the incident flux profile and lead to more straightforward error analysis. It is possible to increase the region of reciprocal space accessed in a single measurement by using an area detector, but when this is combined with a monochromatic incident beam, it is still necessary to scan the crystal or the detector to observe the diffracted intensity. Alternatively. an area detector can be combined with a polychromatic

beam and used for Laue or quasi-Laue diffraction, with a stationary crystal and detector. The time-averaged flux at current high-flux steady-state sources is substantially higher than at present-day pulsed sources, allowing better counting statistics to be obtained at the same time, and allowing the study of smaller crystals or larger unit cells. particularly in the Laue diffraction technique.

All of these factors tend to lead to more accurate structure factors, better internal agreement, and ultimately to lower crystallographic *R* factors and somewhat more precise atomic parameters, hence: the best accuracy for neutron single-crystal structure determination. Constant wavelength single-crystal diffraction is the method of choice if ultimate precision is required in an individual structure determination. The high-flux reactor sources are currently favored for larger unit cells or smaller crystals.

The time-of-flight Laue diffraction technique used at pulsed sources samples a large three-dimensional volume of reciprocal space in a single measurement with a stationary crystal and detector. This is due to the combination of the wavelength sorting inherent in the time-of-flight (TOF) technique with large area position-sensitive detectors (PSDs).

For structural studies, there are advantages to collecting the structure factor data on an instrument with a PSD on a pulsed source. Many Bragg reflections are collected simultaneously in the detector, allowing for the accurate determination of crystal cell and orientation from a single data frame (collected in one fixed crystal/detector geometry). The nature of the Laue method also allows greater possibilities for the rapid collection of data sets by removing the need to measure each reflection individually. This flexibility, long appreciated in synchrotron Eaue methods for studying protein structures,[3] recently became recognized as a great strength of TOF neutron Eaue diffraction methods.'" For some applications, a single frame may be the only data required. The high flux of useful epithermal neutrons from the undermoderated beams thus enables collection of data to potentially high sinθ/λlues. which can allow more precise parameters to be obtained. thus enabling subtle structural features to be examined.

The TOF single-crystal diffraction method is ideal for surveying reciprocal space. rapidly determining large numbers of reflections, and following structural changes using a subset of reflections. It also provides accuracy and precision in standard structural refinements, while not matching the ultimate performance of a constant wavelength instrument in this area. It is worth noting in this context that large electronic area detectors can lead to systematic deviations caused by fluctuations of detector response and can also be more difficult to shield; hence it is more difficult to obtain low background levels.

The Future Potential of Laue and TOF Laue Diffraction

The relative lack of flux of neutron sources compared with x-ray sources means that in spite of the large amount of high-quality work achieved to date, the full potential of the unique ability of neutrons to look at structure and dynamics in different ways has not as yet been fully exploited. The solution to this in terms of instrumentation is to collect large amounts of data as efficiently as possible — hence. using larger detector arrays.

The quasi-Laue diffractometer LADI at the ILL[5] exploits newly developed neutron image plate detectors wrapped around a cylinder surrounding the sample to give more than 2π solid angle coverage (Fig. 2). In order to reduce the problems of accidental reflection overlap, and more importantly to prevent the accumulation of a large background in the Laue pattern from the hydrogenous samples of interest to the supramolecular chemist. LADI operates with a relatively narrow wavelength range of around 1 Å (typically $3.2 < \lambda < 4.2$ Å). hence. the term "quasi-Laue." This instrument has already demonstrated

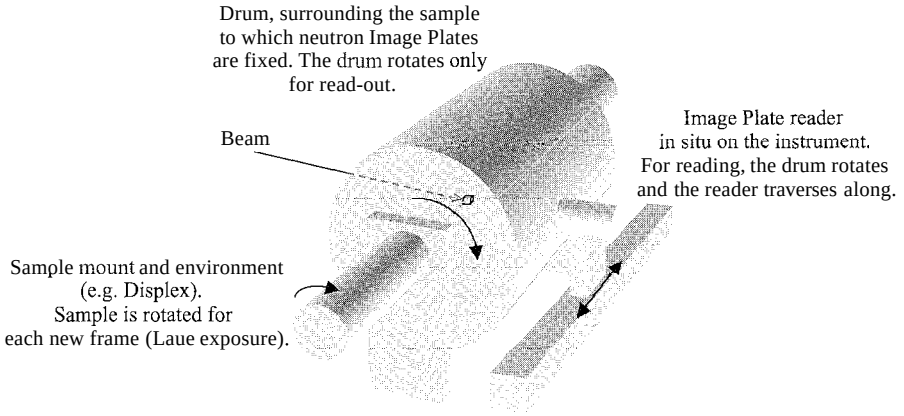

Fig. 2 The LADI diffractometer at ILL. with its large cylindrical image plate detector.

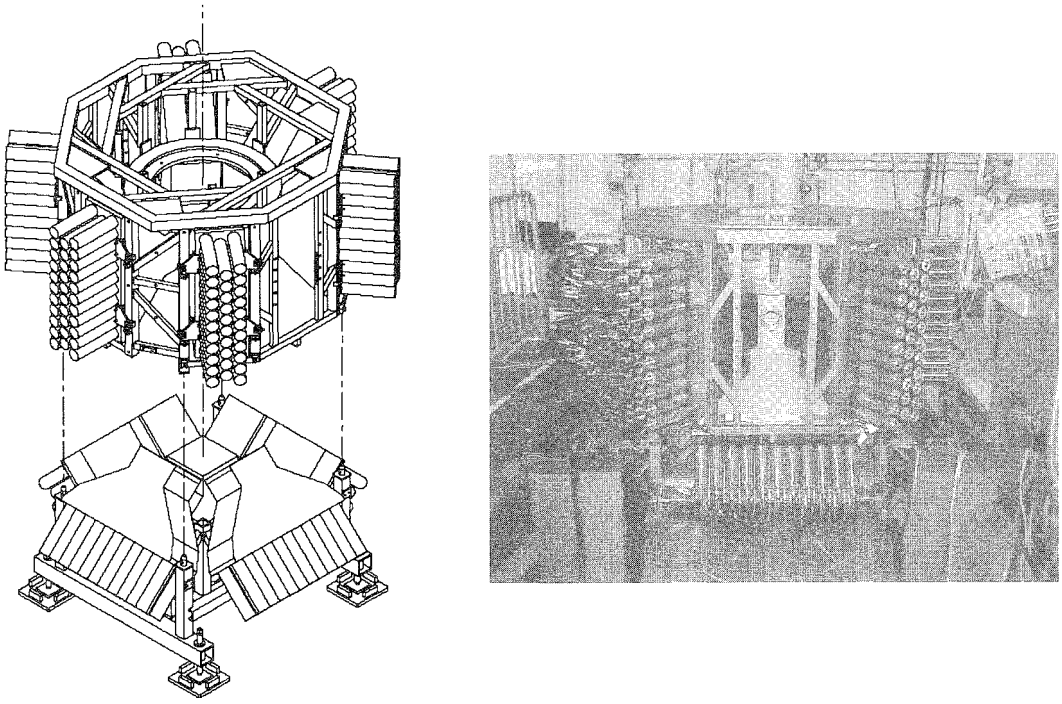

Fig. 3 The newly upgraded SXD at ISIS provides an instrument with 11 area PSDs arranged around a sphere surrounding the sample and over 50% solid angle coverage. Shown here arc an exploded view of the detector array (left) and a view of the detector assembly prior to installation (right).

its potential to revolutionize neutron protein crystallography with dramatically reduced data collection times.[6,7] In addition to these exciting applications in biological crystallography. the LADI concept has obvious applications in the study of smaller molecular systems, including supramolecular chemistry. The thermal LADI instrument VTVALDT, also at the ILL, promises to expand capability in this area.

There is also a tremendous opportunity for the exploitation of neutron TOF diffraction using single-crystal samples. As we have seen, the combination of polychromatic incident neutron beam and large area detector coverage results in a simultaneous measurement of a three-dimensional portion of reciprocal space. If the detector coverage is sufficiently great, a complete collection of the unique portion of reciprocal space is possible to good resolution with a minimal number of crystal orientations. An upgrade recently undertaken to the single-crystal diffractometer SXD at ISIS begins to realize this potential. This upgraded instrument has detectors covering over 50% of the solid angle, with a total of 11 PSDs placed on a sphere centered on the sample (Fig. 3), and thus offers fast collection of Bragg intensities.

These new instruments will benefit all areas of structural science, including chemical crystallography, drug structure, phase transitions, magnetism, and structural disorder, and will be of particular relevance to supramolecular chemists wishing to build up systematic patterns of structural information from a range of samples.

POWDER NEUTRON DIFFRACTION

Modern high-resolution powder diffraction, particularly with neutrons, is a powerful method for structure determination and refinement. particularly for inorganic materials and systems. for which it is very difficult to obtain single crystals. The information in a powder pattern, overlapped as it is, is increasingly being used to allow the refinement of detailed structural parameters, particularly using the method of Rietveld refinement.[8,9] Increasingly more complex structures have been examined and successfully refined using the method, and the iinproved resolution of modern day diffractometers can be combined with Rietveld refinement to further expand these horizons.[10]

There are limits, of course. and particularly relevant here is the fact that powder diffraction is not ideal for studying molecular systems. This is due to several factors. Molecular structures frequently have large, low symmetry unit cells. which leads to much peak overlap in the powder pattern. The structures under study also frequently

contain many atoms and are flexible, leading to many parameters in a refinement. and to difficulty in obtaining stability, even in geometrically constrained refinements. These factors are true for both x-ray and neutron powder diffraction. There is an additional technical problem in measuring neutron powder diffraction from a hydrogen-containing material. due to the large incoherent scattering cross section of ^{1}H, which leads to very high background levels. This problem can be minimized by deuterating the material under study, but this is often chemically unfeasible and expensive. There is, in general. no need to deuterate an organic structure for study by single-crystal neutron diffraction. The advent of very high count-rate neutron powder diffractometers may give new opportunities for neutron powder diffraction to make an impact in the study of molecular systems and become of more relevance to the supramolecular chemist, but for now, single-crystal neutron diffraction is clearly the method of choice.

NEUTRON CRYSTALLOGRAPHY OF MOLECULAR MATERIALS

Neutron diffraction played a major role in developing an understanding of how structure affects the properties of crystalline materials, in areas of relevance in much of modern structural chemistry.[11] Areas accessible to single-crystal and powder neutron diffraction include organic materials, pharmaceuticals, small biological macromolecules, zeolites, polymer electrolytes, battery materials, catalysts. superconductors, time-resolved and in situ studies, and chemical magnetism.[12] Neutron diffraction experiments are often carried out under extreme conditions of sample environment. such as high and low temperature, under controlled atmospheres, high pressure, and in chemical reaction cells. The combination of x-rays and neutrons is powerful in many studies. including the characterization of host–guest interactions in, for example, zeolites. and in determination of charge distributions in crystal structures.

Specifically in molecular systems, neutron diffraction is essential for obtaining the most definitive answers to structural problems. The technique is especially powerful in providing accurate positional and thermal parameters of all atoms. It is unparalleled in its ability to locate hydrogen atoms and refine their positions and thermal parameters. Hydrogen atoms (e.g., hydride ligands) can be located in organometallic complexes[13–20] far more reliably than by any other method (Fig. 4). Much of the structural work on hydrogen-bonded systems (e.g., amino acids, nucleic acid components, carbohydrates. cyclodextrins) used neutron diffraction.[21–32] In addition, determination of the hydrogen anisotropic displacement parameters in short **O**...O hydrogen bonds allows, for example, the deduction of the shape of the potential well in which the atom sits.[33–36] Neutron single-crystal diffraction has an important role in defining the patterns of "weak" intermolecular interactions in complex molecular and supramolecular structures, as these often crucially involve hydrogen atoms.[37–39] This leads directly to a strong impact in the expanding area of supramolecular chemistry and crystal engineering. (Fig. 5)[1,11] Neutron diffraction also gives complementary information to x-ray diffraction for charge density studies.[40–45] In joint x-ray/neutron studies, the neutron parameters fix the nuclear positions, and with the x-ray data. the electron density involved in bonding and nonbonding interactions is determined.

Neutron diffraction also has a prominent role in the determination of thermal parameters, in particular, their interpretation and analysis and the implications of this for interatomic potentials. The accuracy of single-crystal neutron diffraction studies of molecular structure, along with the complete description of positional and vibrational parameters of all atoms in a structure, has led to many examples of its use in this area. These applications include the accurate determination of thermal parameters for

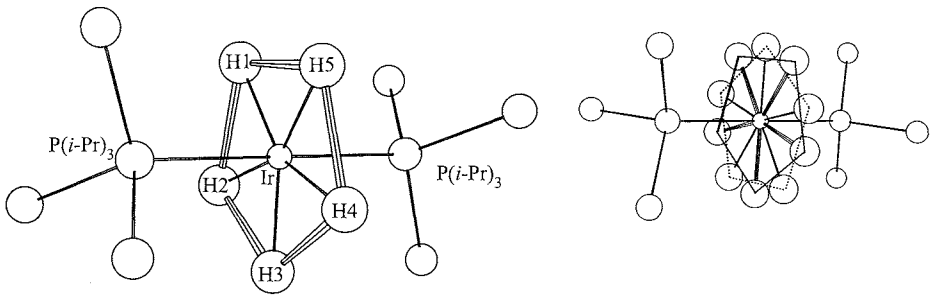

Fig. 4 Determination of the disposition of the terminal hydride ligands in $H_5Ir[P(i\text{-}Pr)_3]_2$ by single-crystal neutron diffraction shows these to adopt an equatorial pentagonal arrangement (left).[20] Disorder in the structure means that there are actually two superimposed pentagons (right), each comprising half-occupancy hydrogen sites.

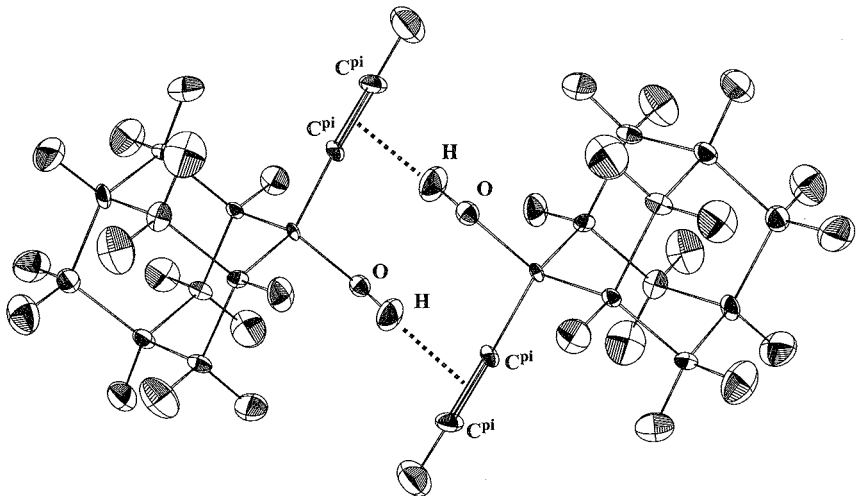

Fig. 5 The dimeric synthon in 2-ethynyl-adamantan-2-01, formed via O–H···π interactions between symmetry-related copies of one of the two molecules in the asymmetric unit.[38] The neutron study allows the full directionality of the O–H···π interaction forming this synthon to be determined.

hydrogen atoms,[46] allowing the comparison between x-ray and neutron diffraction determinations,[47] allowing for understanding of the effect of thermal vibrations on apparent molecular geometry,[48] allowing for the study of the effect of temperature on structure.[49] and in many other areas. Accurate single-crystal neutron diffraction is also well suited to the study of disorder and is particularly important where there are disordered hydrogen atoms present in a structure.[50,51]

Neutron diffraction is an important, complementary structural tool for the supramolecular chemist. The facilities available are developing in directions that are well suited to applications in this area. and the technique can have an increasing impact.

CONCLUSION

Modern neutron diffraction is becoming an increasingly relevant tool for supramolecular chemistry. Allied to its natural advantages for the determination of hydrogen atom parameters, and thus for the fuller description of many nonbonded interactions, improvements in sources and instrumentation for neutron diffraction are now enabling these advantages to be realized in a wider range of systems.

Nomenclature in Crystal Engineering

Ashwini Nangia
University of Hyderabad, Hyderabad, India

INTRODUCTION

The definition of the term "csystal engineering" evolved since its inception over three decades ago. Gerhard Schmidt (1971) used this term in the context of engineering crystal structures having intermolecular contact geometry appropriate for photodimerization in the solid state."' He noted that the introduction of a dichlorophenyl group in unsaturated molecules steers crystallization into a unit cell with a shortest axis of ca. 4 Å, a distance optimal for photoreaction of alkenes. Gautam Desiraju (1989) widened the meaning of crystal engineering as "the understanding of intermolecular interactions in the context of crystal packing and in the utilisation of such understanding in the design of new solids with desired physical and chemical properties.''[2] In 1996, Kenneth Seddon stated that the subject "now hovers on the edge of maturity, a scientific discipline establishing its own unique identity, developing a distinctive profile, and with a promising future ahead."'" Rapid developments in supramolecular chemistry in the 1990s and the realization that a crystal is a supermolecule par excellence. led to the idea that crystal engineering is the synthesis of supramolecular structures in the solid state.[4,5] Today, crystal engineering is an interdisciplinary subject dealing with the self-assembly of molecular crystals. metal–organic architectures, nanostructures, and coordination polymers using hydrogen bonding, electrostatic, and van der Waals interactions. and metal coordination bonding. It brings together chemists of different specialization (synthetic. physical, computational. theoretical, analytical) to work in collaboration with crystallographers and physicists for the design of organic, inorganic, and hybrid systems. In order that such a diverse group of scientists interact and communicate effectively, the meaning of commonly used terms must be uniformly understood and accepted by all. This justifies the need for the present article. I now present a glossary of terms in crystal engineering.

GLOSSARY

Cambridge Structural Database (CSD)

A storehouse of over 290,000 organic, organometall~c. and coordination polymer crystal structures (April 2003 update) maintained and distributed by the Cambridge Crystallographic Data Centre (CCDC). The reason for archiving crystal structures is that while a structure may have been determined for one reason (e.g., to confirm the stereochemistry), it may provide valuable data on intermolecular interactions and close packing to a crystal engineer at a subsequent date. The CSD is now routinely employed as an empirical database for supramolecular retrosynthesis—to use what is known to predict what is unknown.

Cone Correction

The D–H···A hydrogen bond has a preference for linearity ($\theta=180°$). The N versus θ histogram of O–H . ·O hydrogen bonds shows a peak at $\theta=160$–$170°$. The departure from linearity for strong H-bonds is actually an artefact, because the solid angle covered by an angular interval $\Delta\theta$ is smaller for linear than for bent geometry. If this bias is corrected by plotting Nlsin θ versus 8. the histogram has a sharp maximum at 170–180° indicating hydrogen bond linearity. Cone correction is an obligatory step in the statistical analysis of hydrogen bond data.

Cooperativity

Hydrogen bonds possess the important property of cooperativity (synergy). The energy of an array of n hydrogen bonds is greater than the sum of isolated hydrogen bonds, $(O–H\cdot\cdot O–H\cdot\cdot O–H\cdot\cdot)_n > n \times (O–H\cdot\cdot O)$. Cooperativity in effect represents the difference between calculating energies using atom-pair potentials and many-atom potentials. This nonadditive property tapers off at about $n=5,6$ and arises because the ability of donor and acceptor groups to form hydrogen bonds is enhanced by the polarization of hydrogen and lone-pair electron densities in a collective ensemble. Hydrogen bond arrays may have resonance-assisted H-bonding (RAHB) in P-diketones, π-bond cooperativity in carboxylic acids and amides, σ-bond cooperativity in carbohydrate crystal structures, and polarization-enhanced H-bonding in homodromic, antidromic, and heterodromic arrays of alcohols/phenols.

Crystal Structure

A crystal is a solid having a regularly repeating internal arrangement of atoms. Crystal structure is the mutual arrangement of atoms. molecules, or ions packed together on a lattice to form a crystal.[6] In the context of this volume, crystals are ordered supramolecular systems, and crystallization is an impressive display of supramolecular self-assembly in a periodic arrangement.

Crystal Structure Prediction

This is an ab initio prediction of the crystal structure from computation and theory given the molecular structure. The CCDC conducted blind tests in 1999 and 2001 to assess the progress in this challenging goal that lies at the heart of crystal engineering. Given our present understanding of molecular conformations and intermolecular interactions in crystals and despite the progress in accurately computing atom–atom potentials. a general solution to this problem is impossible to very difficult at the moment. but conditional success is likely in the foreseeable future.

Disordered Structure

A crystal structure in which ions or molecules pack in alternate ways in different unit cells is a disordered structure. Such disorder may be revealed by the presence of diffuse scattering, either as halos or streaks. around intense reflections. Guest molecules in crystals tend to be disordered. at times in a liquid-like state. Disorder is of two types. Static disorder occurs when a molecule is located in different orientations/conformations in syrnmetry-related positions in the unit cell. When molecules are fluxional at the same position in the crystal. the disorder is dynamic (e.g., perchlorate anion. *tert*-butyl group). Dynamic disorder can be dampened or frozen at low temperature. whereas static disorder persists even if x-ray data is collected at cryogenic conditions.

Graph Set

This is a geometrical description of hydrogen-bond patterns to encode complicated networks as combinations of four simple patterns: chains (*C*), rings (R). intramolecular H-bonds (*S*), and other finite motifs (D). The number of atoms (n) is the degree of the pattern. Specification of a pattern is augmented by the number of hydrogen bond donors (d) and acceptors (a). e.g., $G_d^a(n)$. Basic graph sets are of the lowest degree, and complex graph sets describe patterns of higher degree. Unitary or first-level graph set N_1 is a list of all motifs (one type of H-bond) in the structure, binary or second-level N_2 describes patterns of two H-bonds. and N_3 describes patterns of three H-bonds. The same hydrogen bond array may be analyzed in more than one graph set notations. e.g., α-glycine has $C_2^2(6)$, $C_2^2(10)$. and $R_4^4(16)$ graph set patterns depending on the complexity with which the structure is analyzed. Graph sets are useful in identifying different hydrogen-bond patterns in polymorphs.

Helix

A helix is characterized by a helical axis. a screw sense (i.e., chirality). and pitch (rate of axially linear to angular movement). Ideally, the axis is a straight line. and the two kinds of tnotion are circular and linear at a constant distance r from the axis, producing a cylindrical (constant radius), palindromic (constant pitch) helix. A helix may be right-handed (designated *P*) or left-handed (*M*) according to whether the rotation is clockwise or anticlockwise when the helix is considered to wind from the viewer's eye toward a point distant from the viewer.

Herringbone Motif and π···π Interactions

Recognition between phenyl groups is mediated by numerous interactions that have two extreme geometries: edge-to-face herringbone T-motif (dipole–quadrupole interaction, energy 1–2 kcailmol). and parallel-stacked arrangement of phenyl rings with face-to-face interaction between π-electron clouds (quadrupole–quadrupole interaction, energy 1 kcal/mol). Possible variations in these geometries are the vertex-to-face approach, and the presence of offset or slight inclination between π-stacked rings.

Host–Guest Compound

The inclusion of small guest molecules in the open framework of a host molecule constitutes a host–guest compound. They are of two major types: cavitands. or molecular host compounds with intramolecular cavities—the cavity is an intrinsic property of the molecule and exists in solution and in the solid state. e.g., calixarenes. cyclodextrins: clathrands are hosts with extramolecular cavities that result from the aggregation of two or more molecules—lattice inclusion hosts exist only in the crystalline or solid state, e.g., hydroquinone and urea. The corresponding host–guest adducts are referred to as cavitates and clathrates. Tuning the pore sire and shape and controlling the hydrophobic/hydrophilic nature of a host cavity are major endeavors in crystal engineering. The distinction between a host–guest adduct H•G and a binary molecular complex A•B is that in H•G, there are either no specific H···H and G···G interactions. or H···H interactions along with weak H···G association stabilize

the structure; in A•B there are A···B interactions, or A···B is comparable in strength to A···A aggregation. When the guest molecule is the solvent of crystallization, the structure inay also be referred to as solvate or pseudopolymorph. The overlap of meaning for these terms makes the classification of multicomponent crystals difficult. For example, the 1:1 sulfathiazole•acetonitrile adduct is a clathrate, while 1:1 sulfathiazole•*N*-formylpiperidine is a cocrystal.[7] The difference between a cocrystal and a molecular complex was never outlined clearly. Borderline cases can be difficult to classify with the above terminologies, because they are somewhat subjective.

Hydrogen Bond

A hydrogen bond D–H···A is formed when the electronegativity of donor *D* relative to *H* in the D–H covalent bond is such as to withdraw electrons and leave the proton partially unshielded so that it can interact with the lone-pair or polarizable π electrons on the acceptor A. Hydrogen bonds are of three types: strong or conventional H-bonds (O–H···O, O–H···N, N–H···O) with energy of 4–15 kcal/mol, weak or unconventional H-bonds (C–H···O, C–H···N, O–H···π) with energy of 2–4 kcal/mol, and very strong or ionic H-bonds ($O–H\cdots O^-$, $O^+–H\cdots O$) with partial covalent character and energy of 15–40 kcal/mol. The total energy of the hydrogen bond may be partitioned into electrostatic, charge transfer, polarization. dispersion, and electron repulsion with the major contribution varying, depending on whether the H-bond is strong (mostly electrostatic), weak (electrostatic); and very strong (mostly covalent). The strongest hydrogen bond is comparable in strength to the weakest covalent bond.

Hydrogen Bond Rules

Formulated by Margaret Etter, these rules correlate functional groups in neutral organic molecules with hydrogen-bond patterns in crystals. 1) All good proton donors and acceptors are used in H-bonding. 2) Six-membered-ring intramolecular H-bonds form in preference to intermolecular PI-bonds. 3) The best proton donors and acceptors remaining after intramolecular hydrogen-bond formation will form intermolecular H-bonds to one another. There is a ranking of hydrogen-bond donors and acceptors in a crystal; and pairing takes place in an hierarchical fashion. These rules inay be exploited in the design of cocrystals.

Interpenetration

Open or porous networks minimize the empty space between them (nature abhors a vacuum). Interdigitation, interpenetration. interweaving, or catenation of two or more networks can occur to fill the empty space in crystals. Intercalation or inclusion of guest molecules (solvent, ligand) is another route to close packing. Self-penetrating nets have two types of topology: parallel interpenetration of corrugated layers leading to a two-dimensional network (generally) and inclined interpenetration of laminated nets resulting in a three-dimensional structure. Thus, interpenetration topology is a way to increase the dimensionality of the structure. The number (n) of independent interweaving networks defines n-fold interpenetration. e.g., trimesic acid is fourfold inclined interpenetrated, and its 2:3 adduct with 4,4′-bipyridine has a threefold parallel interpenetrated network.

isomorphism and Isostructurality

Isomorphism is similarity of crystal shape, unit-cell dimensions. and structure between substances of similar chemical composition. Ideally, the substances are so closely similar that they can generally form a continuous series of solid solutions. The degree of similarity between crystals can be calculated using Kálmán's parameters: the unit cell similarity index, Π. and isostructurality index $I_i(n)$:

$$\Pi = \left|\frac{a+b+c}{a'+b'+c'}\right| - 1$$

where a. b, *c* and a', b', c' are the orthogonalized lattice parameters of related crystals.

$$\mathrm{I_i(n)} = \left[1 \quad \left(\frac{\sum \Delta R_i^2}{n}\right)^{1/2}\right] \times 100$$

where n is the number of distance differences (ΔR_i) between the absolute coordinates of identical nonhydrogen atoms within the same section of the asymmetric units of related structures. For an isostructural pair of crystals, Π must be close to 0, and $I_i(n)$ should approach 100%. These parameters were derived in the context of steroid crystals but are now used for all classes of molecules.

Isotropic and Anisotropic Interactions

Intermolecular interactions in organic solids are of two types: short- to medium-range isotropic or van der Waals interactions; long-range anisotropic interactions and hydrogen bonds. Dispersive forces are attractive, their magnitudes are proportional to the sizes of the molecules, and they vary as r^{-6} (r=interatomic distance). Exchange repulsion (varies as r^{-12}) balances the attractive forces to define the arrangement of molecules in the crystal based on the close-packing principle of Mitaigorodskii. Anisotropic interactions define directional preferences in the

mutual recognition of molecules during crystallization. They are electrostatic in nature and operate at long range (fall off as r^{-1}). These include ionic interactions ($K^+ \cdots O$), strong and weak hydrogen bonds (O–H···O, C–H···O), and interactions between heteroatoms (halogen . .halogen). The crystal structure of a molecule is the free-energy minimum resulting from the optimization of attractive and repulsive intermolecular interactions with varying strengths, directional preferences, and distance-dependence properties.

Molecular Network

A supramolecular structure, theoretically composed of an infinite number of molecules (tectons) capable of mutual recognition; is termed a molecular network. Complicated structures that contain repeating arrays of molecules joined by strong and directional metal–ligand or hydrogen bonds can be reduced to simple topological networks of multiple connecting nodes (molecules) and the rods that connect them (intermolecular interactions). The network representation facilitates analysis and design of crystal structures, e.g., a three-dimensional diamondoid network from tetrahedral molecules, and a two-dimensional honeycomb network of trigonal molecules.

Neutron Normalization

The D–H distance in a typical organic molecule (D=O, N. C) is systeinatically underestimated by x-ray diffraction, because the one-electron of H is polarized toward the heavy atom to which it is bonded and also because of the librational motion of the D–H bond, even at low temperature. Because x-ray crystallography relies upon electron density to locate atoms. the D–H bond is artificially shortened by up to 0.2 Å. The accurate location of a proton is paramount in hydrogen-bond studies. This error is corrected by lengthening the D–H bond vector to the standard distance determined by neutron diffraction. The H···A distance is slightly shorter in normalized geometry. and the angle is lower. Neutron scattering depends upon the atomic nuclei and not the electron density to locate atoms. and so the coordinates of both H and D are determined with near-equal precision (±0.002 Å, ±0.2°). The precision of locating an H-atom with a cryogenic x-ray diffractometer is 10 times lower (k0.02 Å).

Polymorphism

A solid crystalline phase of a coinpound resulting from the possibility of at least two different arrangements of the molecules of that compound in the solid state. Polymorphs are like supramolecular isomers in the spontaneous organization from molecule → nucleus → crystal. Polymorphism is the antithesis of crystal engineering. Yet. this phenomenon is of fundamental and commercial importance, because polymorphs have different physical and chemical properties. About 10% of compounds are estimated to be polymorphic, though the percentage could be higher for pigments, dyes, explosives. and pharmaceuticals. When polymorphs occur, kinetic factors are deemed to be important during crystallization. Some related terms are concomitant polymorphs (crystals from the same flask under identical crystal growth and solvent conditions), conformational polymorphs (different conformations of the same molecule in different crystals), conformational isomorphs (multiple conformations of the same molecule in the same crystal), configurational polymorphs (different configurations of the same molecule, e.g., Z, E, in different crystals), and pseudopolymorphs (crystals formed by the same substance crystallized with different amounts or types of solvent molecules).

Porous Solids

Organic zeolite analogues are commonly referred to as porous solids. These materials promise a new range of applications. e.g., in pharmaceutical manufacture and in molecular sieves, sensors. and devices. They are crystalline or amorphous materials that permit the reversible passage of molecules through holes on their surface. Porous solids are classified according to pore diameter: nanoporous or microporous (<15 Å), mesoporous (15–500 A) and macroporous (>500 Å). The natural and synthetic inorganic zeolites with uniform pore sizes of 10–20 Å are the classical examples of microporous materials with widespread use in industry.

Site Occupancy Factor (SOF)

The SOF is the partial occupancy of a given site by a particular atom. It is most frequently used to describe disorder in a portion of a molecule or for describing nonstoichiometric situations. e.g., in solid solution.

Structure Solution and Refinement

The intensity data from 1000–100,000 reflections (depending on molecular size) collected on x-ray diffractometers is solved by direct methods or by Patterson function to "guess" approximate phases. This gives the outline of the molecule with bond lengths to ±0.1 Å precision. The structure is refined by the least squares method

to minimize the difference between experimental and calculated electron density maps. The optimized model of coordinates and thermal parameters is converted to display the molecular structure (bond distances, angles, torsions) with hydrogen-bonding interactions. The structure solution and refinement process is complete when the agreement between calculated and observed data is as good as possible. For a good structure determination; the estimated standard deviation or standard uncertainty, or errors in bond lengths and angles, should be t0.002 Å and $\pm 0.2^{\circ}$. respectively, and the residual R factor should be <5%. Structure solution and refinement are almost automated now with programs like SHELX.

Supramolecular Chemistry

This is the chemistry of molecular assemblies. intermolecular bonds, noncovalent interactions, and hydrogen bonds. The original meaning of "supramolecular" is "beyond the molecule."[8] '"Supramolecular" currently has three different meanings: intermolecular interactions. coordination chemistry, and a strategy for the controlled organization of multiple components. Supramolecular chemistry is a philosophy and strategy for the controlled grand assembly of complex matter.[9]

Supramolecular Chiron

This is a suprainolecular synthon involving recognition between chiral molecules and leading to enantio- or diastereopure architectures. The term, suggested by Hanessian. may also be used to designate the minimum hydrogen bond ensemble leading to chiral or polar crystals of racemic molecules.

Supramolecular Isomerism

The existence of more than one type of network superstructure for the same molecular building block represents supramolecular isomerism. Therefore, it is related to structural isomerism at the molecular level. Supramolecular isomerism is the existence of different architectures (i.e., architectural isomerism) or superstructures. Polymorphism is a type of supramolecular isomerism but not vice versa. Supramolecular isomerism can be classified as structural (the same components result in different network superstructures). conformational (different conformations of a flexible molecule generate different. but often related. network architectures). catenane (the different manner and degrees in which networks interpenetrate or interweave), and optical (chirai networks that crystallize in enantiomorphous space groups. or the spontaneous resolution of chiral solids).

Supramolecular Synthon

Structural units within supermolecules (crystals) that can be formed and/or assembled by known or conceivable synthetic operations involving intermolecular interactions. most often hydrogen bonds, are supramolecular synthons. The goal of crystal engineering is to design robust synthons that can be exchanged from one structure to another and then incorporate recurring synthons in retrosynthesis to anticipate (predict) the one-, two-, or three-dimensional structure of novel target architectures. Desiraju suggested that this exercise may be referred to as crystal synthesis in analogy with target molecule synthesis. However. because hydrogen bonds are an order of magnitude weaker than covalent bonds. the robustness of a synthon is reliably derived from statistical trends, i.e., the probability of occurrence of a particular structural motif in the CSD. The prediction of crystal packing through such an empirical-cum-chemical intuition approach was reasonably successful. This is distinct from crystal structure prediction, i.e., to know the unit cell and space group of a given molecule without any experimental data. Synthon interchange is the exchange of one functional group with another (e.g., halogen; ethynyl, hydroxy) to generate topologically identical structures.

Synthon Interference and Structural Insulation

Crystal structures are a result of a subtle balance of forces between various intermolecular interactions with different distance-dependence and directional properties. When the geometrical requirements of two interactions can be met in isolated regions of the crystal. the two interactions are said to be structurally insulated. If the geometric demands of two interactions come into conflict, optimization of one interaction changes the normal pattern of the other, and this phenomenon is termed as interaction interference. The challenge in crystal engineering is that it is difficult to anticipate when a particular chemical modification will conserve the synthon and when the structure will be disturbed.

Tecton

(Greek word τεκτων for builder) Molecules with sticky surfaces with interactions that are dominated by specific attractive forces that induce the assembly of aggregates with controlled geometries are tectons. Wuest suggested

molecular tectonics as the art and science of supramolecular construction using tectonic subunits.

Twinned Crystal

This is a composite crystal built from two or more crystal specimens that grow together in a specific manner. so that there is at least one plane and a direction perpendicular to it that are related in the same manner to the crystallographic axes of both parts of the twin.

CONCLUSION

Today, crystal engineering covers a wide palette spanning organic, inorganic, and organometallic structures in the solid-state; crystal growth and morphology; pharmacophore mapping and drug design; and materials science and nanoscience.[10,11] The importance of this subject is increasing and its scope diversifying, as it lies at the intersection of engineering-down and synthesis-up technologies. The present article gives working definitions of some terms that were selected based on the personal experience of this author, who entered crystal engineering from an organic synthesis background. Exact definitions are all but impossible in chemistry, and working definitions should not be taken too literally. For example. the accepted definition of organometailic chemistry as "the chemistry of cornpounds with metal-to-carbon bond" rules out the coinmon industrial compound, Wilkinson's catalyst, $RhCl(PPh_3)_3$. I conclude my glossary on this sobering note.

INTRODUCTION

There has been a growing interest in fundamental and scientific research in the area of molecule-based nonlinear optical (NLO) inaterials with large second- and third-order nonlinearities. The research was primarily motivated by applications of optical and electro–optical devices based on these materials in the telecommunications and optical data-processing industries.'" In particular, second-order NLO inaterials offer many attractions, such as large nonresonant ultrafast response times, low dielectric constants, and intrinsic architectural tailorability.[2] The noncentrosymmetric organization of chromophores is an essential requirement for efficient bulk second-order nonlinear optical materials. Thus. the controlled construction of supramolecular assemblies has become a popular method in the design and synthesis of NLO materials. A variety of methods such as electric field poling,[3–6] Langmuir–Blodgett assembly.'".'' and crystal engineering'''''] were employed to prepare second-order NLO materials. In the last decade. the layer-by-layer molecular self-assembly approach was tremendously active in the development of new NLO materials.'''' In this article, we discuss the concept of optical nonlinearity and the strategies for design and synthesis of nonlinear optical chromophores and supramolecular structures.

THE CONCEPT OF OPTICAL NONLINEARITY

When the electric field of electromagnetic radiation interacts with a material, it induces a dipole moment in the material. The dipole moment induced per unit volume is called "polarization." At low electric fields, the inacroscopic polarization or polarization of the bulk medium. P. is linearly related to the field by the proportionality constant, $\chi^{(1)}$, known as the linear electric susceptibility. At high fields, typically those associated with lasers. contribution of the nonlinear (second- and higher-order) terms becomes significant.[15] Higher-order susceptibilities $\chi^{(n)}$ $(n>1)$ are inherently inuch smaller than $\chi^{(1)}$, and progresrively become smaller as n increases. The polarization component along the i^{th} axis can. therefore, be generally represented as follows:

$$P_i = \chi_{ij}^{(1)} E_j + \chi_{ijk}^{(2)} E_j E_k + \chi_{ijkl}^{(3)} E_j E_k E_l + \ldots \quad (1)$$

Because the electric field and the polarization are vectors. the n^{th}-order macroscopic electric susceptibility ($\chi^{(n)}$) that relates the components of the polarization to the applied field; is an $(n + 1)$-order tensor. The microscopic polarization in molecules is defined by the induced dipole moment pi, which depends on the molecular polarizability, α, and hyperpolarizabilities, β, γ, etc., as follows:

$$\rho_i = \alpha_{ij} E_j + \beta_{ijk} E_j E_k + \gamma_{ijkl} E_j E_k E_l + \ldots \quad (2)$$

In Eqs. 1 and 2. the indices i, *j*. *k*. and I refer to the coordinate system of the bulk material and molecule. respectively. Illustrated in Fig. 1 are the linear and nonlinear polarizations with respect to electric field. The Fourier decomposition of this nonlinear polarization comprising components of zero frequency, the fundamental frequency, the second-harmonic frequency, the third-harmonic frequency. etc.. is shown in Fig. 2. The effects up to the second order. which are easily observed experimentally, are called the optical rectification. $P(0)$; linear electro–optic effect $P(\omega)$; second-harmonic generation $P(2\omega)$, and third-harmonic generation $P(3\omega)$.

Second-Harmonic Generation (SHG)

The phenomenon of frequency doubling or second-harmonic generation can be visualized as follows. If the applied electric field is of frequency ω, it can be represented as $\sin\omega t$. and the quadratic terms are seen to have a 2ω dependence.

$$E \propto \sin \omega t$$

$$E^2 \propto \sin^2 \omega t \left(= \frac{1}{2}(1 - \cos 2\omega t) \right)$$

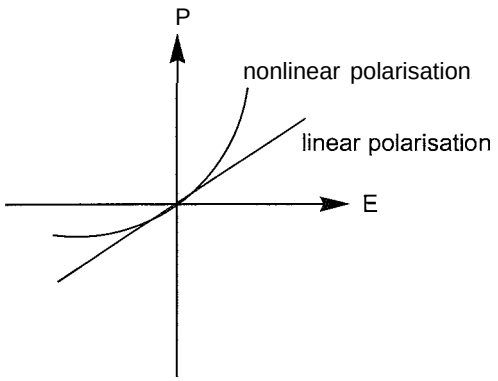

Fig. 1 Linear and nonlinear polarization versus electric field.

There is an important symmetry constraint for observing second-harmonic generation or other quadratic (in general any even order) *NLO* effects. The quadratic and other even-order effects are possible only in noncentrosymmetric systems. In a gaseous or liquid state where random fluctuations create a center of symmetry, one needs an alignment of molecules using an external field to break the center of inversion and observe second-order effects. However, in the case of third-order nonlinearities. there is no such symmetry constraint. Thus, in this article, we deal exclusively with second-order nonlinear optical properties of organic materials because of the important role of supramolecular chemistry in designing noncentrosymmetric systems.

SECOND-ORDER NONLINEAR OPTICAL MATERIALS

Most of the materials developed initially for *NLO* applications were based on inorganic systems. Ferroelectric materials lacking a center of symmetry were prime candidates. With inorganic materials, the optical and acoustic phonons as well as the electronic polarization contribute to the *NLO* effects. The NLO effects in inorganics can be interpreted only at a bulk level; extension of the atomic or ionic polarizabilities to the bulk *NLO* properties is complicated. There is growing interest in developing π-conjugated organic molecules for *NLO* applications.

The molecular structures of some well-known systems are presented in Fig. 3. It was established that push–pull organic molecules have very high values of β_{ijk} (Eq. 2) and when they crystallize in a non-centrosymmetric space group, they possess large nonlinear susceptibility. The nonlinearity in these systems is dominated by electronic polarization effects. In the solid state, these organic compounds form molecular crystals in which the molecules interact through weak intermolecular forces and retain their individual identity to a high degree.

The quadratic *NLO* active molecules are mostly based on donor–acceptor substituted aromatics; benzene, stilbenes, diaryl acetylenes, diacetylenes, and biaryls are commonly used frameworks. In addition to the above materials, many more organic and organometallic compounds were examined by the powder SHG method, or their molecular hyperpolarizabilities were measured using EFISHG/HRS techniques, or both.[16–19]

STRATEGIES TO OBTAIN NONCENTROSYMMETRIC STRUCTURES FOR QUADRATIC NLO APPLICATIONS

In the previous section, we already noted that a noncentrosymmetric structure is essential for a material to show second-order NLO properties. Amorphous and glassy solids are, in general. centrosymmetric. A majority of crystalline organic materials are also centrosymmetric. A variety of techniques were attempted to induce a noncentric lattice formation. Thin films can be prepared as noncentrosymmetric structures, using special techniques. Some of the popular strategies developed to induce noncentrosymmetry in bulk structures are as follows: inclusion of chirality in the molecule: utilization of crystal engineering techniques that exploit weak intermolecular forces; electric field poling of thin films or polymer films in which the mclecules of interest are bound physically or chemically: preparing *X*, *Z*, or alternate-type Langmuir–Blodgett (LB) films; and layer-by-layer molecular self-assembly for generating intrinsically noncentric super lattices. These methods are discussed in some detail below.

Crystal Engineering

Inclusion of chirality

The utility of chirality for the fabrication of NLO organic materials was recognized very early in the case of amino acids and sugars.[1] Molecular chirality guarantees the crystallization of a pure enantiomer in one of the 21 noncentrosymmetric space groups. Achiral molecules generally crystallize in a centric lattice, though some important exceptions are known, e.g., urea ($P42_1m$), benzil (P32), *m*-nitroaniline. mNA ($Pbc2_1$), MNA (Cc), POM ($P2_12_12_1$), and 3-acetamido-4-dimethylaminonitrobenzene, DAN ($P2_1$). On the other hand, a pure enantiomer must crystallize in an enantiomorphous space group, and there are plenty of examples of such systems. Some well-known cases are MAP ($P2_1$), NPP ($P2_1$), and PNP ($P2_1$) and TCNQ-based push–pull quinonoid molecule, DMPDQ (Fig. 4).[24] Though a mixture of equal quantities of a pair of enantiomers, i.e., a racemate, usually crystallizes in centrosymmetric space groups. some cases of crystallization in enantiomorphous space groups are also known. We note that the optical activity of a molecule only guarantees a noncentric lattice structure, but does not guarantee usefulness as a material for SHG. This is because the polarizable part of the molecules may still be aligned almost antiparallel, resulting in near cancellation of the NLO response of the molecules that are so aligned. It is important to have the NLO chromophores turned away from an antiparallel alignment to generate good SHG capability. In spite of this. the utilization of optical activity appears to be one of the most successful techniques for the generation of noncentric crystal structures, especially when used in conjunction with one of the following techniques. From Fig. 4, the effect of inclusion of

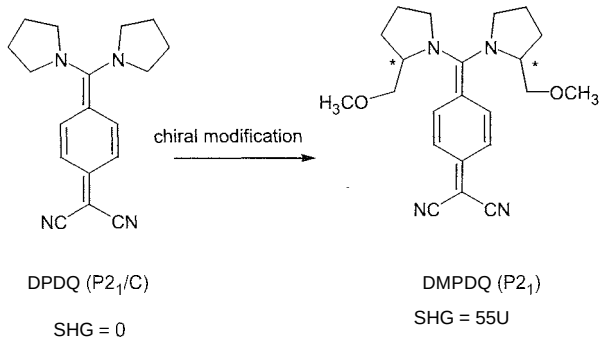

Fig. 4 Chirality-induced noncentrosprnmetry and nonlinearity

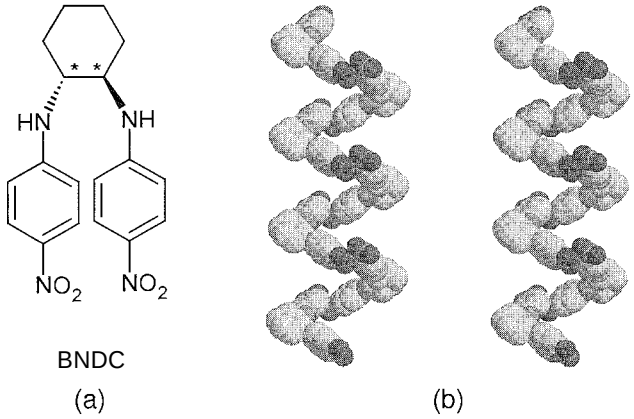

Fig. 5 (a) Molecular structure of BNDC and (b) helical superstructures of BNDC formed during crystallization. Reprinted with permission from Ref. [28]. Copyright (2001) Wiley-VCH. (*View this art* in color *at www.dekker.com.*)

chirality in a molecule on its crystal space group and bulk NLO property is clearly seen.[20]

Intermolecular H-bonding

Hydrogen bonding is a well-known crystal engineering tool used to obtain desired crystal packing.[21] In the field of NLO. it was also used to get optimized noncentric structures in the organic crystals. The hydrogen bond bridges two atoms that have high electronegativities (such as O, N), and this can strongly influence the crystal structure and the spectroscopic properties of the molecules. Some examples of NEO systems where H-bonding has been crucial are, *o*-nitroaniline and its derivative, MAP, and urea. Urea is an extreme case of a hydrogen-bonded network.[1] The urea molecule that has eight atoins is involved in eight hydrogen bonds (four to each carbonyl and one each from each of the hydrogens). In urea, the hydrogen bonding played a crucial role in evolving a noncentric crystal structure.[10] Even though W-bonding affects the crystal structure in many significant ways. it is known to have a negligible effect on the molecular hyperpolarizabilities. Some theoretical investigations[11] do, however, indicate that in special cases molecular βs are influenced mildly by H-bonding. The weak interactions between iodo and nitro groups that form supramolecular synthons were also exploited for designing materials for SHG.[22]

Recently, Radhakrishnan et al. reported the formation of a perfectly polar lattice in the crystal of (4-dimethylaminopyridyl) *bis*(acetylacetonato) zinc (II) (ZNDA).[23] This is one of the best examples of molecular assemblies that aligned noncentrosymmetrically in the lattice and is useful as a prototype for engineering polar supramolecular assemblies for NLO applications. In another article: they also reported[i2''] the formation of helical superstructures (Fig. 5b) from a simple crystallization of the C_2-symmetric and chiral *N,N′-bis*(4-nitrophenyl)-(1R-2R)-diaminocyclohexane (BNDC. Fig. 5a), which showed strong second-harmonic generation comparable to that of a well-known NLO compound, WPP. This study suggests that the control of supramolecular organization by molecular structure and symmetry can be a useful strategy in induction and enhancement of solid-state SHC in molecular materials.[25]

Poling of Doped Polymer Films

Polymer films with exceptionally large second-order nonlinearities can be produced by the corona poling (Fig. 6) process.[26] An efficient NLO chrornophore molecule is either doped in a host polymer matrix or covalently linked as pendant groups on a polyrner backbone. The polymer is then cast as a film. usually by spin-coating techniques. Subsequently, the film is subjected to a strong external dc electric field and heated to the glass transition temperatures of the polymer. At this point, the chromophores are aligned parallel by the field and locked into position when the film is cooled to room temperature with the external field on.

The poling thus leads to the alignment of doped molecules in the polymer films according to the Boltzmann distribution law. The oriented molecular dipoles produce a polarization. $P=N\mu\langle\cos\theta\rangle$, where N is the number density of the molecules, μ, the ground state dipole moment, and 0, the angle between the dipole and the direction of the poling field. This method can

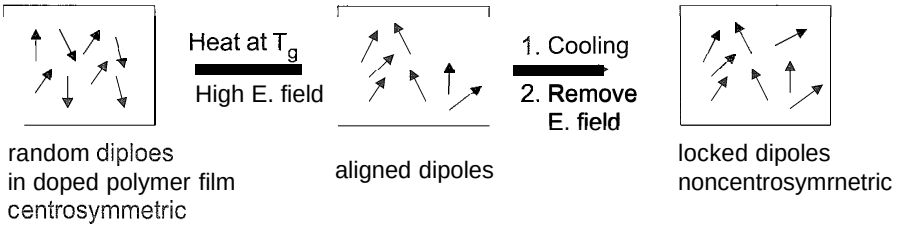

Fig. 6 Orientation of chromophoric dipoles under high electric field using corona poling in doped polymer films

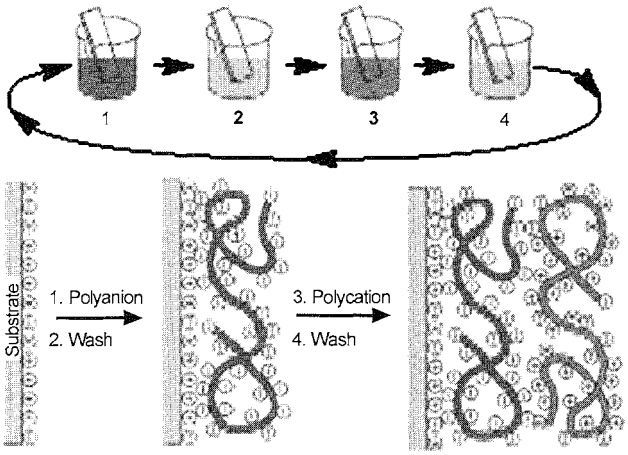

Fig. 7 Procedure for electrostatic layer-by-layer assembly. Reprinted with permission from Oliveira et al. (Ref. [29]). (View this art *in* color *at www.dekker.com.*)

also be used for functionalized and cross-linkable polymer matrices. The resulting polymeric material is of high optical quality and suitable for wave-guided electro–optic devicec. The main problem associated with the poled polymer is the metastability of the system. After the external field is removed, the poled orientation of the chromophores slowly gets randomized over a period of time, and hence, the noncentrosymmetry geneiated is lost This destroys the quadratic NLO capability Post-poling treatments such as cross-linking have to be undertaken to arrest the depoling process

Langmuir–Blodgett (LB) Films

Another approach to the construction of efficient thin-film-based SHG materials has been to incorporate NLO chromophores into acentric X- or Z-type LB films.[1] This approach offers far greater net chromophore alignment than is possible in a poling field (where the net alignment is statistical). LB films are built up from amphiphilic molecules: i.e., molecules having a hydrophilic part and a hydrophobic part. The preparation of the LB film consists of the following steps. The amphiphilic molecule is first dissolved in a solvent immiscible with water, and the solution is spread onto the clean water surface in a Langmuir trough. The solvent is left to evaporate. leaving the molecules spread on the water surface. The Langmuir trough is equipped with a mobile barrier to compress the film laterally. The film is gradually compressed to a surface pressure just below its collapse pressure. Because of their long aliphatic chains: the molecules cannot

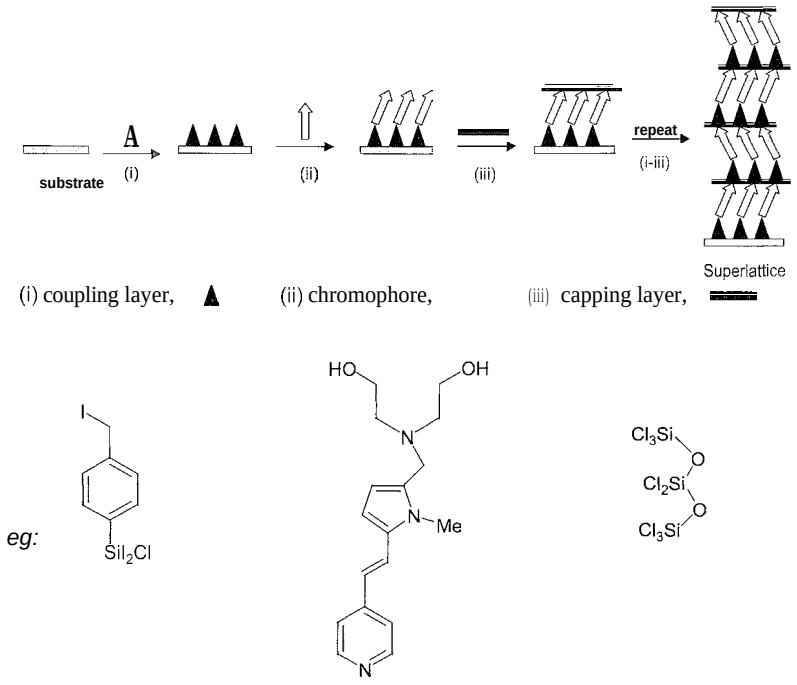

Fig. 8 Assembly of chromophoric super lattices by an iterative sequence of (i) covalent chemisorption of (*p*-iodomethyl)-phenyl-diiodochlorosilane onto hydrophobic substrates to form a "coupling" layer, (ii) spin-coating of a methanol solution of chromophore precursor followed by vacuum oven treatment, and (iii) reaction of the quaternized-chrornophore-based monolayer with octachlotrisiloxan. Reprinted with permission from Ref. [31b]. Copyright (2003) American Chemical Society. (*View this art in color at www.dekker.com.*)

dissolve in water. and due to their hydrophilic group, they cannot leave the water surface. Hence, they form a compact. monomolecular, and in many instances. stable film at the water–air interface. When a hydrophilic substrate previously immersed is slowly raised through the monolayer, deposition takes place with the hpdrophilic group attached to the substrate and the hydrophobic part sticking out. Subsequent dipping creates a head-to-head or tail-to-tail assangement of the amphiphiles deposited as multilayers on the substrate. By the above method, one prepares an EB film that is basically centrosymmetric (called Y-type). Such films are not suitable for optical second-harmonic generation. The X- and Z-type films with a head-to-tail arrangement and. hence, a noncentric bulk arrangement can be prepared with relatively low-polarity hydrophilic groups or with special functionalization of the hydrophobic chain ends.

Another approach is to prepare alternate layered films of the type A–B–A–B–A–B, wherein one of the molecules A or *B* is the active NLO chromophore and the other is just a binding spacer unit.

Layer-by-layer (LBL) Molecular Assembly

Orientation of nonlinear optical active dyes in electrostatically self-assembled polymer films containing cyclodextrins was studied.[27] The concept of molecular recognition of organic chromophores by coordinating polymers was another novel approach in the construction of nonlinear optical supramolecular assemblies.[28]

Electrostatic layer-by-layer (LBL) self-assembly techniques based on oppositely charged poipelectrolytes can be useful to create stable noncentrosymmetric order in thin films. Using this interesting technique. thermodynamically stable noncentrosymmetric multilayer films can be prepared without any need for poling. Tripathy et al. reported the fabrication stable multilayer films of epoxy-based side chain azo polymers for second-order nonlinear optics.[29] The second-order NLO coefficients of the five-bilayer LBL films of these polymers were found to be comparable to those of spin-coated poled films. A schematic view of the procedure to fabricate polyelectrolyte-based LBL films is shown in Fig. 7.

Since 1990, self-assembly techniques involving covalent linkages and layer-by-layer fabrication were reported to yield robust noncentric super lattices highly suited for applications such as SHG and electro–optic effects.[30–33] Spontaneous and sequential adsorption of appropriately derivatized adsorbates onto substrates in a self-limiting fashion can yield thin films with uniform polar orders in individual layers. This represents an attractive approach to the construction of intrinsically acentric chromophoric super lattices. Li et al.[30] reported synthetic routes to the first SHG-active multilayer structures using an attractive covalent siloxane self-assembly approach, highly regular and highly nonlinear [$\chi^{(2)} \sim 200$ pm/v at $\omega = 1064$ nm] self-assembled stilbazolium multilayers were constructed in a regular, layer-by-layer fashion. Recently. the synthesis of super lattices of pyrrole-based diethanolamino methyl functionalized derivatives was reported and is described in Fig. 8.[31] The key feature to self-assembled multilayers is that the microstructural acentricity is maintained, and thus. they show the quadratic dependence of the SHG response on the number of assembled layers. These multilayers have good structural reproducibility and are suitable for efficient NLO properties as was reported for the second-order nonlinear optical susceptibility [$\chi^{(2)} \sim 150$ pm/v at w = 1064 nm] for the chromophore in Fig. 8.

CONCLUSION

In this article. we discussed the basic concept of nonlinearity and fabrication of noncentrosymmetric structures using well-known strategies like crystal engineering, corona poling, LB films, and molecular assembly of acentric structures. The role of supramolecular chemistry in developing efficient NLO materials is clearly delineated. Though physical methods like poling and LB techniques are successful strategies for creating noncentrosyrnmetric materials for NEO. the design of molecular chromophores with specific groups and functionalities for creating noncentrosyminetric materials through crystal engineering is still a fascinating subject to chemists and material scientists. Molecular assembly via synthesis is also a well-accepted strategy for fabricating covalent. robust, noncentrosymmetric structures for electro–optics and many other controlled structures for applications like light-emitting diodes. sensors and photovoltaics, etc. In the forthcoming years. the approaches of creating layer-by-layer molecular assemblies synthetically or by ionic adsorption may lead to other approaches and provide new methodologies for materials chemistry.

Nuclear Magnetic Resonance Spectroscopy

Arvin Moser
Christian Detellier
University of Ottawa, Ottawa, Ontario, Canada

INTRODUCTION

The 1952 Physics Nobel prizewinners Bloch and Purcell independently carried out the first nuclear magnetic resonance (NMR) experiments during the 1940s.[1,2] In the following decades, NMR spawned several major breakthroughs. During the 1960s, NMR sensitivity was strongly improved with the use of short, intense, radio frequency pulses. which led to the development of Fourier transform NMR. In the 1970s, two-dimensional (2D) NMR emerged as a revolutionary technique. Ernst, 1991 Chemistry Nobel prizewinner, played a key role in these developments."' In the same years, one could start exploring the NMR spectroscopy of a large amount of nuclei in the Periodic Table. all those possessing a nonzero spin quantum number. NMR was becoming multinuclear,[4] while the field of kinetics in NMR was expanding through the analysis of different patterns of line shapes.[5,6] Consequently, in addition to providing a powerful structural characterization tool. NMR spectroscopy was becoming invaluable in providing access to dynamic information. leading to essential mechanistic interpretations.

In the 1970s, a major medical breakthrough came with magnetic resonance imaging (MRI), a technique relying on the water content of the sample to provide detailed images without invasion.[7] This technique can be applied to a large variety of soft, amorphous, inorganic. or organic supramolecularly organized materials. For example. it can be applied to the human body to provide detailed images without invasive surgery or harmful radiation exposure to the patient.

In parallel, more sophisticated materials were used in the design of the magnets, allowing access to continuously higher magnetic fields. Fields of 21.6 T are becoming available in 2003. compared to 0.7 T available in the first commercial spectrometer proposed by Varian in 1953.

The development in the 1960s–1970s of magic angle spinning NMR (MAS NMR),[8] following the construction of probes capable of containing high-speed rotors for solid samples. allowed for the recording of high-resolution, liquid-like spectra for solid samples. Nowadays, a large variety of nuclei are routinely studied, for structural, dynamic, and mechanistic information. The availability of Fourier transform techniques, high magnetic fields. powerful signal processing and magic angle spinning techniques, led to the development of this extremely versatile spectroscopy, finding applications in a broad range of disciplines, from chemistry to biology. from biochemistry to earth sciences, and from materials sciences to medicine.

Because NMR is capable of distinguishing minute changes in the geometric and stereoisomeric properties of a structure and is also capable of obtaining qualitative as well as quantitative information, which includes information on dynamic processes of chemical exchange within the molecule or with other molecules, it is an essential, invaluable, technique for the study of aggregation phenomena, of self-assemblies, and of supramolecular structures. both in solution and in the solid state.

BRIEF OVERVIEW OF THE TECHNIQUE

The observation of a signal in NMR spectroscopy necessitates a nucleus with a nonzero spin quantum number, that is. a nucleus with either an odd mass number or an even mass number and an odd atomic number. The resulting nuclear spin produces a magnetic moment. When the nucleus is placed inside a static magnetic field, B_0, the magnetic moment of the nucleus interacts with the external field, the Zeeman interaction, yielding different energy levels for the nucleus.

When a specific radio frequency pulse is applied to the nucleus in the field B_0, the magnetic moment precessing about B_0 at a frequency called the Larmor frequency, is perturbed. That is, energy is transferred to the spin system via the radio frequency pulse. and the state of the system changes: transitions between the allowed magnetic energy levels are induced. The system subsequently relaxes and emits a signal or free induction decay (FID) as a function of time that is recorded. The FPD is converted to frequency domain data using a Fourier transformation.

The Larmor (ω_0) frequency of precession is denoted by the equation $\omega_0 = |\gamma/(2\pi)|B_0$, where γ is the gyromagnetic

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012819

ratio and is specific to the nucleus being studied. The effective field (B_{eff}) received by the nucleus under study depends on the density and on the spatial distribution of the electronic clouds in its close proximity ($B_{eff} = B_0 - \sigma B_0$, where σ is a screening constant). This is the origin of the chemical shift. The value of B_{eff} received by the nucleus under study will also depend on the presence in its close proximity of other nuclei with magnetic moments, resulting generally in splittings of the signal. This is the origin of the coupling constants.

The acquisition of the signal in the time domain allowed for the development of spectra recorded in two dimensions. indicating, generally more clearly than in one dimension. the various relations existing between nuclei, such as, among others, coupling and exchange.

In addition to signal intensities, to chemical shifts, and to coupling constants, the relaxation times, T_1 and T_2, are essential characteristics of a nuclear spin system. The T_1 is the longitudinal or spin-lattice relaxation time. It is related to the relaxation of M_z, the magnetic moment component in the B_0 direction. the z direction. The relaxation process occurs as a result of the nucleus transferring the absorbed energy to its surrounding. The T_2 is the transverse or spin–spin relaxation time. It involves the mutual exchange of spins between two precessing nuclei that are in close proximity. That is, the energy transfer occurs from one nucleus to the other and results in line broadening. As such, the T_2 (excluding the effects of B_0 inhomogeneity and of chemical exchange) is inversely proportional to the line width at half intensity of the corresponding peak.

These brief considerations demonstrate the extreme sensitivity of the NMR parameters to the electronic environment of the nucleus being examined. Minute modifications of the electronic densities and distribution can result in large effects on the spectrum. This is particularly true for quadrupolar nuclei. whose signals' linewidths can vary by several orders of magnitude depending upon the nature of their closest neighbors. The reader is referred to monographs and textbooks for complete description and development of the theory of NMR spectroscopy and of its parameters and techniques. Just two examples are suggested[9,10] among a number of other excellent books and recent reviews, giving an overview of current solid-state NMR methods.[8,11]

NMR PROBES OF SUPRAMOLECULAR STRUCTURES

The aim of research in supramolecular chemistry is to interpret, rationalize. and design new chemical systems beyond the covalent bond, developing complex supramolecular architectures with specific new properties in, for example, molecular recognition, catalysis, separations, sensors, and, perhaps, ultimately, in the simulation of living, self-replicating systems.

Supramolecular systems result from organized molecular associations: aggregations. and assemblies. Any agglomeration of molecules constitutes a supramolecular system. because, at the minimum, weak dispersion forces are present, organizing the distribution of the molecular components among themselves: a liquid solvent is structured and is a supramolecular host system for the solute, and a crystal is a supramolecular assembly. The forces responsible for the supramolecular organization, ranging from H-bonding and ion–dipole to induced dipole–induced dipole, are then responsible for the directionality of the assemblies. such as in multiple H-bonds[12] or in π-stacking.[13,14]

In that context. NMR spectroscopy provides essential tools for the characterization of supramolecular organizations. The chemical shifts are sensitive to the nucleus' electronic environment: ^{1}H, ^{13}C, or ^{15}N chemical shifts, for example, are affected by H-bonding involving their molecule. and the magnitude of the ^{1}H chemical shift is indicative of the strength of the H-bond. Also, ^{1}H chemical shifts are strongly dependent upon anisotropic shielding effects, which can provide information on relative molecular orientations involving aromatic rings, for example.[15,16] Metal ion chemical shifts (^{23}Na, for example) can vary considerably with the molecular nature of the first coordination sphere of the cation.[17] With the demonstration that scalar couplings across the hydrogen bond are observable for Watson–Crick base pairs in ^{15}N-labeled RNA, Dingley and Grzesiek gave. for the first time, direct evidence of H-bonding, which. otherwise. must come from a variety of indirect observations.[18]

The relaxation times. T_1 and T_2, among other factors, depend upon the size of the supramolecular entity, and, consequently, can constitute an invaluable tool for the characterization of its size, giving information about the number of assembling units.[19,20]

Nuclear Overhauser enhancement (NOE) experiments, both in one-dimensional (1D) and 2D domains; can give information on the proximity of noncovalently bonded nuclei, and, consequently, to spatial relationships between molecules in an assembly.[21]

In addition to thermodynamic measurements. NMR spectroscopy provides an invaluable tool for kinetics and mechanistic measurements, giving access to a time range from the picosecond to years.[6] The dynamic NMR studies of supramolecular complexes were recently reviewed.[22]

This short review, which cannot be exhaustive, will give examples of applications of these NMR tools to structural determinations and mechanistic elucidations of supramolecular systems.

STRUCTURES AND MECHANISMS OF SUPRAMOLECULAR ASSEMBLIES

Large Network Assemblies

In recent years, the number of noncovalent synthesis of sophisticated systems has strongly increased. One example is the report by the group of Reinhoudt of the spontaneous and reversible assembly of similar to 20kDa synthetic hydrogen-bonded assemblies via the formation of 144 cooperative hydrogen bonds. In connection with other techniques, ^{1}H-NMR spectroscopy clearly showed the formation of the "eight-floor" assembly, named so because eight singlets between 12 and 15 ppm are observed fo the N–^{1}H signals of the 5,5-diethylbarbituric acid building blocks. Moreover, the N–^{1}H signals for the outside floors are significantly different from the signals of the other floors.[23] Another example is the assembly of calix[4]hydroquinones in nanotube bundles. In this case, the ^{1}H-NMR large chemical shifts of the phenolic protons are indicative of the presence of short H-bonds.[24] Hydrogen-bonded supramolecular complexes were prepared by self-assembly of a proton donor (diacid) and an acceptor (bipyridyl ethylene) through the formation of intermolecular hydrogen bonds.[25] An upfield shift of the ^{13}C-CP/MAS NMR (where CP stands for cross-polarization) carbonyl carbon resulted from the forination of intermolecular hydrogen bonds. The natural abundance of ^{15}N-CP/MAS NMR chemical shifts was in agreement with the formation of hydrogen-bonded molecular complexes.[25]

In the context of large assemblies resulting from multiple hydrogen bonds. one cannot resist mentioning an example from the mineral world. Kaolinite is a remarkable, dissymmetric. 1:1 layered aluminosilicate composed of repeating layers of a tetrahedral silicate sheet sharing oxygens with an octahedral aluminate sheet in an extended 2D network. The surface silicate sheet is coinprised of hexagonal-(SiO-)$_6$ macrorings, and the surface aluminate sheet is covered with aluminol groups. The layers are held together by van der Waals attractive forces. electrostatic interactions, and a large network of hydrogen bonds between the aluminol groups of a layer and the silicate sheet of another layer. A chemistry of intercalation and of interlamellar grafting could be developed in the interlayer spaces of reduced diinensionality, by the rupture of the H-bonds network.[26,27] The 2D confinement of poly(ethylene glycols) (PEG) was achieved in kaolinite.[28] The interlayer structure and dynamics of the intercalated PEGs could be probed by ^{13}C-CP/MAS NMR. Dipolar dephasing experiments were particularly useful in showing that the polymer chains in the kaolinite interlamellar spaces are more constrained and less mobile than in the bulk form (Fig. 1).

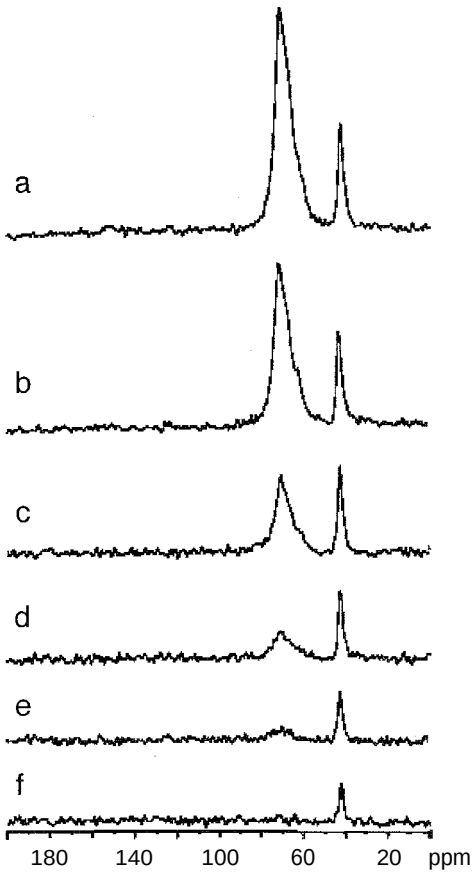

Fig. I Solid-state ^{13}C-CP/MAS NMR spectra of a kaolinite-polyethyleneglycol intercalate: (a) no dipolar dephasing: (b–f) with dipolar dephasing. (From Ref. [28]. Reproduced with permission from the American Chemical Society.)

A series of 1D and 2D NMR experiments performed on nanocomposites of hectorite, a smectite clay mineral. showed new opportunities for studying large assemblies of layered minerals with polymeric materials.[29] In particular. rotational-echo double-resonance (REDOR) experiments afforded ^{1}H–^{29}Si distances with precision, and a mobility gradient of intercalated polyethyleneoxide (PEO) segments was demonstrated in ^{1}H–^{29}Si wideline separation (WISE) experiments.[29]

Nucleotide Aggregation

The structure of the most celebrated supramolecular structure was published more than 50 years ago, in the April 2, 1953, issue of *Nature*, when Watson and Crick proposed "a structure for Deoxyribose Nucleic Acid," the current paradigm for the structure of life.[30] While the ability of the guanine moiety to form tetrameric. planar assemblies. called "G-quartets," was recognized for a while,[31,32] it is more recently that G-quartets were shown

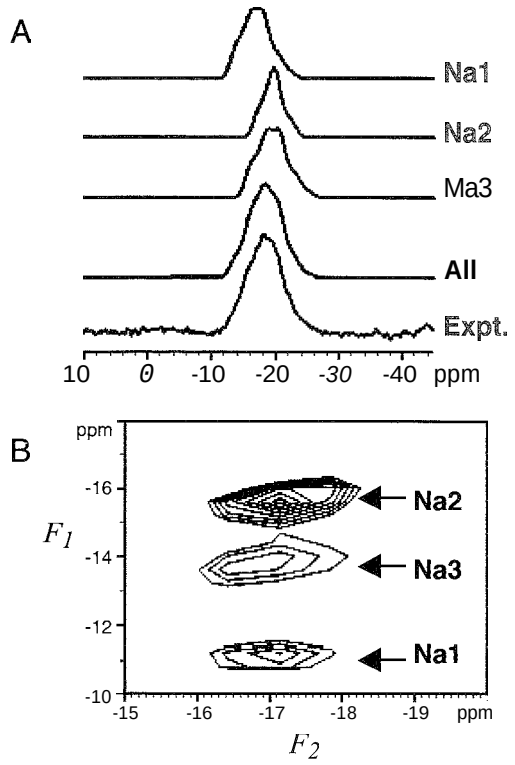

Fig. 2 (A) Experimental and simulated 1D ^{23}Na-MAS spectra and (B) 2D ^{23}Na-MQMAS spectrum of a G-quadruplex channel. (Frorn Ref. [40]. Reproduced with permission from the American Chemical Society.)

to form from various C-rich DNA or RNA sequences.[33] The G-quartets further aggregate in the presence of various monovalent cations.[33]

The NMR provided invaluable information on the structures of a variety of assemblies of 6-quartets. In the presence of $Na^+$and K^+. an octameric structure of 5'-CMP is formed in water.[34–38] The analysis of the non-Lorentzian line shapes of the ^{23}Na-NMR signals afforded a measurement of the correlation time of the reorienting. rigid, supramolecular entity, confirming the size of the aggregate. in complement to the ^{1}H- and ^{31}P-NMR structural data.[19,37,38]

Among the numerous recent studies on various G-quartet structures, two examples will be given, one in a nonpolar organic solvent and one in the solid state. A lipophilic derivative of deoxyguanosine, soluble in chlorinated solvents, can transfer alkali metal salts from the aqueous to the organic phase. An in-depth NMW study, including 1D and a variety of 2D experiments, elucidated the solution structure of the K^+ octameric assembly, demonstrating that a well-defined structure, resulting from the stacking of two tetramers sandwiching a potassium cation, is obtained in $CDCl_3$ solution. The glycosidic bonds have a *syn* conformation in one tetramer and an all-*anti* conformation in the other.[39]

Another illustration of how powerful structural NMR tools can be is found in the ^{23}Na multiple quantum MAS (MQMAS) NMR study of a G-quadruplex channel. A guanine nucleoside derivative forms tetramers, G-quartets. which. in the presence of monovalent cations, assemble to result in a G-quadruplex channel consisting of the stacking of four 6-quartets, coordinating in the channel four cations: in this case, three Na^+ and one Cs^+.[40] While the 1D ^{23}Na-MAS NMR spectrum exhibits only a broad, unresolved signal; the 2D MQMAS spectrum gives a clear and neat separation for the three crystallographically distinct Na^+sites (Fig. 2).

Polymer Associations

Supramolecular polymers, made of polymeric chains associated by noncovalent interactions such as H-bonding, are expected to display new types of properties, different from the classical covalently cross-linked polymers. These systems could be seen as softly cross-linked polymers. The NMR spectroscopy is routinely used to characterize the formation of hydrogen-bonding networks, such as in supramolecular polymer networks based on ureido-pyrimidone subunits.[41] These subunits, when taken as molecular entities in chloroform solutions, dimerize, forming different isomers.[42] Rotational nuclear Overhauser enhancement spectroscopy (ROESY) experiments elucidated the structure in solution of one of these isomers: not obtained from x-ray crystallography. The mutual rates of exchange between the isomers could be determined from a combination of exchange spectroscopy (EXSY) experiments and of integration of the ^{1}H-NMR signals.[42] The ^{1}H-NMR is also invaluable in following the thermal reversibility of these systems. the formation and dissociation of H-bonds in the network, such as in the assemblies of polystyrene-bearing nucleic acid bases.[43]

Other forces than H-bonding can lead to supramolecular polymer associations. Polymers such as PEO and sodium poly(α,L-glutamate) (PCNA) form complexes by ion–dipole and hydrophobic interactions.[44] A quantitative analysis of the ^{23}Na-NMR spectra in D_2O showed that only 6% of the sodium cations was complexed by PEO, while the majority of Na^+ was in the solvated form. In nonaqueous media. a combination of ^{23}Na and 2D-nuclear Overhauser enhancement spectroscopy (NOESY) ^{1}H-NMR suggests that the sodium ions are completely complexed by PEO through ion–dipole interactions.[44]

Using conventional solid-state NMR and double-quantum (DQ) techniques, the helical structure of small linear peptides, composed of alternating leucine and lysine residues. was confirmed when they were adsorbed onto highly porous hydrophobic polystyrene surfaces.[45] Moreover, the absence of chemical shift anisotropy averaging led to the conclusion that there is no detectable

motion of the peptides in the timescale of the experiment (<1 kHz). The fact that 2D DQ experiments allow such high-resolution determination of secondary structures in heterogeneous environments is another illustration (see also Ref. [40]) of the power of the structural tools offered by solid-state NMR.

Host–Guest Associations and Inclusion Compounds

A large number of host molecular architectures with internal cavities adapted to the recognition of guest ionic or molecular entities were designed. The recognition properties of inacrocyclic hosts such as crown ethers or calixarenes, for example. depend largely upon their preorganization in solution. Consequently. it is essential to analyze the conformational structures and their dynamics as a prerequisite to the interpretation of the recognition mechanisms. This will be exemplified in the following case, illustrating bow EXSY spectroscopy can be applied to the analysis of the conformational dynamics of a calix[4]arene[46] and to the mechanism of its complexation of the sodium cation.[47]

Tetramethoxycalix[4]arene (1) interconverts between four conformers: cone; partial cone. 1.2-alternate. and 1.3-alternate. The rate constants for the various conformational exchanges were obtained from 2D ^{1}H-EXSY NMR spectra (Fig. 3) on the basis of the exchange scheme shown on Scheme 1. A complete thermodynamic and kinetic picture of the various conformational exchanges could be drawn.[46]

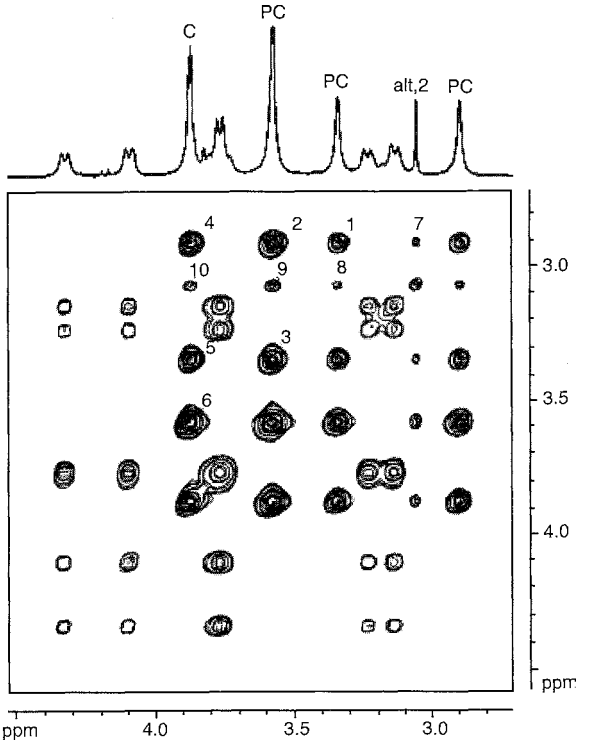

Fig. *3* The 1D ^{1}H- and 2D ^{1}H- EXSY NMR spectra of the methoxy and methylene regions of calixarene 1 at 280 K in a binary mixture of chloroform and acetonitrile. (From Ref. [46]. Reproduced with permission from the American Chemical Society.)

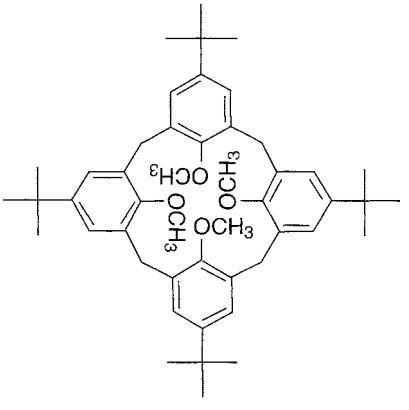
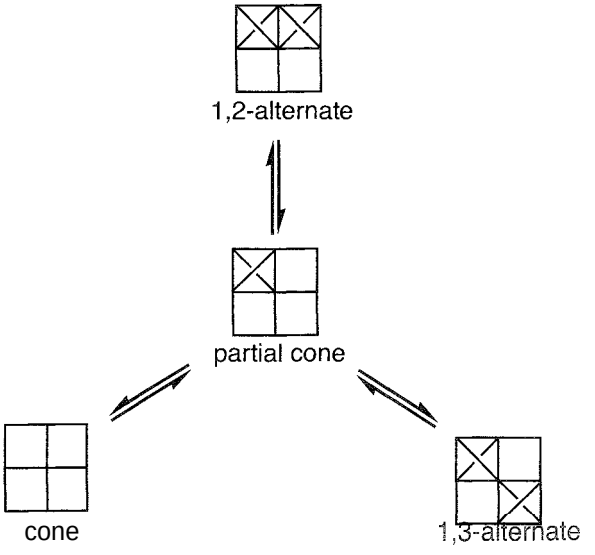


1

The main findings are the demonstration that the conformational exchanges proceed through one-step processes, as shown in Scheme 1, and the fact that the interconversion processes are kinetically controlled by the entropies of activation. This effect was tentativeiy attributed to a larger organization of the solvation cage



Scheme 1 (From Ref. [46]. Reproduced with permission from the American Chemical Society.)

in the transition state, in the case of the most kinetically stable 1,2 conformer.[46]

As sodium tetraphenylborate is added to a solution of (1), three new ^{1}H-NMR peaks appear in the range of 3–4.5 ppm.[47] As [Na^+]>, [I] only the peaks attributed to $(Na,1)^+$are present, with (I) exclusively in the cone conformation. demonstrating a slow exchange and a strong affinity of the sodium cation for the cone conformation. Similar studies using cesium triiodide showed the formation of 1:1 complexes of 1, with the cesium, cation in the 1,3 alternate and partial cone conformations.[48]

The calixarene cavity can also host neutral molecules. An example of co-complexation of the sodium cation and acetonitrile is provided by the *p-tert*-butylcalix[4]arene tetraacetamide receptor.[49] The p-tert-butyl calixarenes also show selectivity in the recognition of aromatic molecules, which can be attributed to weak attractive forces between the CH_3 groups and the π-system. A noticeable and interesting microdynamics experience, using NMR relaxometry measurements (T_1), was performed on *p-tert*-butyl-calix[4]arene (1:1) toluene systems in the solid state[50] to give information on the activation energy of the calixarene methyl group's reorientation in the presence of toluene in the cavity and to give information on CH_3–π interactions. The experimentally determined activation energy of reorientation of the methyl group pointing toward the interior of the cage is increased in the presence of a toluene guest, from 2.1 to 3.2 kcal/mol. This is not the case for the other two methyl

Aromatic ring electronic currents create large diamagnetic anisotropies resulting in chemical shift variations for the nuclei in the proximity of the aromatic ring. Given the relatively small chemical shift range of ^{1}H, the effect is particularly noticeable for this nucleus. Because of the spatial anisotropy of the effect. the observed chemical shifts can give indications of the relative positions of nuclei and aromatic rings. This property can be used as an indication of the inclusion of a guest in a cavity and of the resulting host–guest geometry.[15,16] The ^{1}H DQ techniques can now be applied to host–guest aromatic systems in the solid state. An example can be found in the application of rotor-synchronized ^{1}H DQ/MAS NMR to the complex formed by a molecular tweezer encaging 1, 4-dicyanobenzene.[51]

CONCLUSION

The spectacular development of NMR spectroscopy in the last decades provided invaluable, necessary tools for the precise determination of chemical structures not always accessible through x-ray single crystal analysis. It also provides the tools to reliably determine supramolecular levels of organization, in solution and in the solid state. It gives access to information on the dynamics and the kinetics of molecular assemblies, and, consequently, to the mechanisms by which they are created, they evolve, and they dissociate. Access to the new generation of ultrahigh-field NMR spectrometers will allow precise determination of faster exchange kinetics.

With the adaptation of NMR techniques for larger molecules, it becomes possible to analyze proteins with molecular weights reaching 50 kDa. These techniques include 'H-, ^{15}N-TROSY (transverse relaxation-optimized spectroscopy, with the mutual cancellation of ^{1}H-, ^{15}N-dipole–dipole coupling and the ^{15}N chemical shift anisotropy) and CRINEPT (Cross-correlated Relaxation-Enhanced Polarization Transfer, combining insensitive nuclei enhanced by polarization transfer (INEPT) transfer with cross-correlated relaxation-induced polarization transfer). They are used in conjunction with the ^{15}N-, ''c-labeling of the protein for increased sensitivity.

Consequently, the emerging field of proteomics will immensely benefit from the new; constantly developing multidimensional techniques and from increasing magnetic fields. Functional proteomics will rely on NMR tools to unravel supraproteinic interactions and dynamics and the structures of associating proteins in solution.

Access to ultrahigh fields will also allow the detection of quadrupolar nuclei bound on large structures. See, for example, the recent direct detection by ^{39}K solid-state NMR of potassium cations bound to G-quadruplex structures.[52] The ^{67}Zn or ^{25}Mg NMR, for example, will become more accessible in biological systems,[53] an achievement that was still a dream only 20 years ago. The main challenge in the development of new nanohybrid materials is their characterization, many being amorphous. The precise characterization of nanostructures will also strongly rely on the current developments of NMR spectroscopy.

Nuclear Quadrupole Resonance Spectroscopy

John A. S. Smith
King's College London, London, United Kingdom

INTRODUCTION

Nuclear quadrupole resonance (NQR) is a technique in radiofrequency (RF) spectroscopy in which the energy levels originate in an electric interaction between the nuclear electric quadrupole moment (Q), and the electric field gradient (q) at the nuclear site. The observed frequencies cover a wide range, from 100 kHz–1 GHz, depending on the nucleus; the nuclear spin quantum number, **I.** must satisfy the condition $I \geq 1$, but the frequencies and relaxation times are specific to a given compound and enable a study to be made of electronic structure and molecular motion in a wide range of materials, both crystalline and amorphous. Signals are usually seen only in solids. but in compensation. no static magnetic field is required, so portable instruments can be envisaged. and samples remote from the RF antenna can be studied.

PRINCIPLES

NQR is a branch of magnetic resonance spectroscopy concerned with the absorption of RF radiation by matter in a zero static magnetic field.[1] Like its close counterpart. nuclear magnetic resonance (NMR), the transitions are excited by interaction of the RF magnetic field B_1 with the magnetic moment of the nucleus, but the energy levels depend on electric rather than magnetic interactions. However. signals are only observed in the solid state, in single crystals and in polycrystalline or amorphous samples. Such signals may be observed when the nucleus possesses an electric quadrupole moment, a property of nonspherical charge distributions: the nuclear electric quadrupole moment. Q, may be defined as follows:

$$eQ = \int \rho_n (3z_n^2 - r_n^2) d\tau_n \quad (1)$$

in which ρ_n is the nuclear charge density in a volume element $d\tau_n$, e is the electronic charge, and the integration extends over the nuclear volume in the state in which the maximum component of the nuclear magnetic moment lies along the z axis, that is $I=I_z$. This integral and. hence. the nuclear electric quadrupole moment, can be positive or negative, depending on whether the nucleus has the shape of a prolate (elongated) spheroid or an oblate (flattened) spheroid. Approximately half of the elements in the Periodic Table have one or more isotopes with a quadrupolar nucleus, subject to the general condition that their spin quantum number $I \geq 1$. so that all quadrupolar nuclei also have a magnetic moment. Some of the more important of these are listed in Table 1. together with recent values of Q in units of mb (the unit of 10^{-28} m^2 is often referred to as a "barn"). Note that the reliability of these values is constantly improved by calculation and experiment; however. the accuracy of the isotopic ratios, that is the ratio of the electric quadrupole moments of two isotopic nuclei. is usually considerably higher.

In NQR spectroscopy, the energy of the quadrupole levels depends on the interaction between the nuclear electric quadrupole moment and the electric field gradient produced by neighboring charges. both electrons and nuclei. The electric field gradient behaves as a second-rank tensor: in its principal axis representation. it may be defined by its three principal components q_{xx}, q_{yy}, q_{zz}, where. for example.

$$q_{xx} = -\partial E/\partial x = \partial^2 V/\partial x^2 = V_{xx} \quad (2)$$

and V is the electric potential at the nuclear site (strictly speaking, the electric field gradient is $-q_{xx}$). Because Laplace's equation

$$V_{xx} + V_{yy} + V_{zz} = 0 \quad (3)$$

is assumed to hold, only two quantities are required to define the electric field gradient, in addition. of course. to the direction cosines of the principal axes with respect to some set of axes embedded in the molecule or crystal. By convention, these are taken to be the maximum principal component. defined to be $q=q_{zz}$ (where $|V_{zz}| > |V_{yy}| > |V_{xx}|$) and the so-called asymmetry parameter, η, defined by

$$\eta = (V_{xx} - V_{yy})/V_{zz} \quad (4)$$

a positive number lying in the range between zero and unity η may be regarded as measuring the departure of the electric field gradient at the nucleus from axial symmetry On the other hand. q. the maximum principal component, can be negative and positive, and is zero only at sites of high symmetry, e g . tetrahedral (T_d) or octahedra1 (O_h) It

[a]Values were taken from P. Pyykkö and J. Li, Report HUKI 1-92. Helsinki. 1992. and were updated to 2002 values.

will. therefore, be zero at the nuclei of the chlorine and sodium ions in crystalline NaCl. unless their immediate environments are perturbed by strains or defects in the crystal. In many solids, however, such ions will not be at sites of high symmetry, and nonzero values of q are to be expected.

It should be noted that the quadrupole interaction is only the first nonzero term in the mathematical expression governing the variation of the electric potential V over the nuclear volume: the second is the nuclear hexadecapole interaction.[''] which depends on the coupling between the nuclear electric hexadecapole moment H and the fourth derivative of the electric potential $V^{(4)}$. The nuclear hexadecapole coupling constant, $e^2HV^{(4)}/h$. is only observable when $\mathbf{I} \geq 5/2$, e.g., for ^{127}I in MI. In this example of a strain-free single crystal. the quadrupole interaction can be ignored. in which case a small hexadecapole coupling constant of 2.8 kHz is derived for ^{127}I. Its small value makes it difficult to measure experimentally. but it should be assumed to be present for all heavy high-spin quadrupolar nuclei.

Experimentally, it is the product of the nuclear electric quadrupole moment, Q, and the electric field gradient, q, that is usually measured. The quantity e^2qQ/h, where h is Planck's constant. is often referred to as the quadrupole coupling constant and has units of frequency. It is positive or negative, according to the product of the signs of q and (2. As an illustration, consider the H^{35}Cl molecule in the vapor phase; assume $r_e = 0.127_8$ nm, and $Q(^{35}\text{Cl}) = -81.6$ mb. The neighboring proton generates a positive electric field gradient at the chlorine nucleus given by $+0.862 \times 10^{40} e$ m^{-2}J C^{-2} (see Eq. 9). The electronic contribution is also expected to be positive; assuming a value of $+20.61 \times 10^{40} e$ gives a net value for eq of $21.47 \times 10^{40} e$, and from Table 1. the product (e^2qQ/h) is then negative with a value of −67.85 MHz. However, the actual value observed in the solid will normally differ significantly. first because of solid-state effects (presumably hydrogen bonding in this example) and the averaging effects of thermal vibrations, which render q and η dependent on temperature and, to a lesser extent. on pressure.

In "pure" or zero-field NQR, the energy levels are obtained by solution of the quadrupolar Hamiltonian.[3] which in the principal axis representation may be written as follows:

$$\hat{H}_Q = eQ/[4I(2I-1)] \cdot [3I_z^2 - I(I+1) + 1/2\eta(I_+^2 + I_-^2)] \quad (5)$$
